Use of dried blood spot (DBS) specimens eliminates the need for venipuncture and allows for greater flexibility in storage temperature and transport time. DBS samples have been used in NATs for diagnosis of and monitoring of perinatal response in HIV infection, HBV quantification and genotyping, diagnosis of neonatal HSV infection, and detection of congenital CMV infection. Antibodies to viruses such as hepatitis A virus, HBV, HCV, Epstein-Barr virus (EBV), measles virus, and rubella virus can be detected in DBSs, although the performance characteristics vary compared with serum testing depending on the virus. DBS card samples can be prepared from a few drops of blood, typically 15 to 200 μl, obtained from a capillary blood stab, i.e., a finger prick (81). A minimum of 2 h is needed for drying of the blood spot. Once dried, DBSs should be placed in hermetically sealed bags or containers with sufficient desiccant to minimize moisture exposure that could allow for growth of microorganisms (31). DBSs may be transported and stored at room temperature for relatively long periods (depending on the virus) or frozen at −20°C or lower for longer-term storage. Punch-out disks from DBS cards normally contain the equivalent of 3.1 to 12.4 μl of blood depending on the punch size (3 to 6 mm) (81). Once dried, HIV-1 RNA in a DBS is stable at ambient temperature or −70°C for at least 1 year and the virus is typically inactivated (82). Compared with plasma viral loads, >90% of finger-stick DBS samples from solid-organ transplant recipients showed <1 log₁₀ deviation in CMV viral load and the kinetics of CMV viral load during antiviral therapy were comparable (83). In this study, the 95% limit of detection of CMV in DBSs was estimated at 2,700 copies/ml (675 IU/ml).

Eye

Eye specimens include swabs or scrapings of the conjunctiva, corneal scrapings, and vitreous and aqueous fluids. The conjunctiva should be cleared of any exudate present with a swab before a specimen is collected. Using a second flexible, fine-shafted Dacron or rayon swab moistened with sterile saline, infected cells from the clean conjunctiva can be obtained and transferred to a vial of VTM or used to prepare a slide for immunofluorescent staining. The AdenoPlus test (Rapid Pathogen Screening, Inc., Sarasota, FL), a lateral-flow immunochromatographic cartridge test for the detection of ocular adenovirus infection, uses a built-in sampling pad to touch the eye and collect fluid from the conjunctiva. Test sensitivity for the AdenoPlus has been reported to be 85%, with a specificity of 98% compared to PCR (84). Corneal scrapings and swabs of the cornea are best collected and placed in VTM by a specially trained clinician. Thin smears may be made directly from scrapings or swab specimens for use in immunofluorescent staining. Retinal pathogens are detected in the aqueous and vitreous fluids by NA testing, as they are not easily cultivated from these samples. Direct testing of these surgically obtained fluids has resulted in PCR inhibition (85); therefore, the original specimen must be extracted.

Genital

The most common viral causes of genital lesions are HSV-1 and -2, which are easily detected by direct Ag (DFA) methods, NATs, or culture. Cells and fluid from genital ulcers are collected and processed as lesions from skin (discussed below).

Testing of HPV genotypes associated with a high risk of developing cervical cancer (16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 66, 68) is performed using molecular methods on cervical specimens collected with swabs or brushes (detailed in chapter 104). Specimens may be collected in manufacturer-specific systems or FDA-approved/cleared liquid-based cytology solutions used concomitantly for Papanicolaou smear preparation. Freshly collected cervical biopsy specimens, at least 2 to 5 mm in cross section, may be analyzed in some commercially available NATs. All specimens should be placed immediately into the specimen transport medium provided by the assay manufacturer and stored, transported, and processed according to their directions. Patient-collected cervicovaginal swab or lavage specimens (86–89) and swabs of penile lesions (90, 91) have also proven reliable.
for detection of high-risk HPV infection. Anal specimens for HPV testing can be collected using a saline-moistened Dacron swab and transported in liquid-based cytology media (92, 93).

Cervical brush specimens in standard transport medium for the hc2 High-Risk HPV DNA Test (Qiagen) may be stored for up to 2 weeks at room temperature, after which specimens can be stored for an additional week at 2 to 8°C for up to 3 months at −20°C. Specimens in PreservCyt liquid-based cytology medium may be held at 2 to 30°C for up to 3 months for hc2 testing, 20 to 30°C for up to 18 weeks for Cervista (Hologic, Bedford, MA) testing, and 2 to 30°C for up to 6 months for COBAS HPV (Roche Diagnostics, Indianapolis, IN) testing. For the Aptima HPV Assay (Gen-Probe), cervical specimens in ThinPrep Pap Test vials containing PreservCyt solution should be transported and stored at 2 to 30°C, with no more than 30 days at temperatures above 8°C, and, for longer storage, at −20°C for up to 24 months. PreservCyt specimens cannot be frozen prior to testing for high-risk HPV.

Oral
An oral specimen provides a noninvasive means of detecting infection, and for some viruses, the onset of salivary shedding can predict recent acquisition. The different types of oral specimens include oral mucosal cells (including lesions), whole saliva, glandular duct saliva (from parotid, sublingual, and submandibular glands), and oral mucosal transudates (OMTs). OMTs can be used for both culture and NAT methods (94). Oral mucosal cells are dislodged with a swab or plastic spatula; the collection device is then placed in VTM for transport to the laboratory. Saliva is collected by initially tilting the head forward and catching expectorated fluid after 5 min (94). Parotid gland saliva, useful for diagnosing infectious parotitis, is collected with a swab ~30 s after massaging the area between the cheek and teeth at the level of the ear (95).

Salivary gland fluid consists primarily of secretory IgA, whereas OMTs contain a mixture of secretory IgA, IgG, and IgM. OMTs (also called gingival crevicular fluid, crevicular fluid, or crevicular fluid) arise from the capillaries in the buccal mucosa and the base of the pocket between the teeth and gums (gingival crevice) and can be collected with commercially available devices and transported to the laboratory at 2 to 8°C (96). OMTs have been used for detection of both IgM and IgG antibodies to measles, mumps, rubella, HIV, and hepatitis viruses (97–99). The performance characteristics of oral fluid for the determination of antibodies to HIV and HCV approach those of blood-based specimens (100, 101). However, HIV antibody testing with oral fluid alone is not recommended for patients at high risk of infection, particularly in low-prevalence settings, and should be followed up by testing of a blood specimen (101).

Respiratory
Viruses causing upper and lower respiratory tract infections can be detected using Ag detection, culture, and NATs (Table 1). Ideally, diagnostic testing should be completed within a time frame (generally 24 h) that can affect patient management (102).

The primary site of replication for many respiratory viruses is the ciliated epithelial cells of the posterior nasopharynx and, to a lesser extent, the anterior nares and oropharynx. Therefore, nasal and throat specimens are traditionally not acceptable for virus detection because many viruses are present at low levels in these sites. However, these specimens may be suitable for use in highly sensitive NATs or when immunocompromised patients may be at risk of bleeding with harsher collection methods.

An NP aspirate is collected by inserting a narrow catheter or tube through the nostril into the posterior nasopharynx. A mucus trap or syringe is connected to the other end, and suction is applied while slowly withdrawing the tube back through the nostril. Any secretions remaining in the tubing should be flushed into the trap or syringe by aspirating VTM or sterile saline (28, 29). A nasal wash is collected by instilling several milliliters of sterile saline into the nasal cavity using a bulb or syringe with catheter tubing attached. The contents are immediately aspirated by releasing the bulb or pulling the syringe plunger and placed into a tube containing VTM or sterile container. Nasal washes can yield high rates of respiratory virus detection by NAT with minimal patient discomfort compared with swab, aspirate, and brush sampling (103).

Swabs for respiratory virus testing should be polyester, Dacron, or rayon with plastic or aluminum shafts. Wooden-shaft swabs may contain substances that are toxic to cultured cells. Calcium alginate swabs should not be used since they may impair recovery of enveloped viruses, may interfere with fluorescent-antibody tests, and are inhibitory to some NATs. Flocked swabs, made from nylon fiber using a proprietary spray-on technology, are designed for optimum specimen absorption and release and have been shown to collect more respiratory epithelial cells than conventional rayon swabs for DFA testing of respiratory viruses (104, 105). Midturbinate flocked swabs are designed with a tapered cone shape, a sampling depth indication gauge, and a greater length and diameter of flocked nylon in order to sample a larger surface area of respiratory mucosa, including the inferior and middle turbinate bones. These can be self-collected and yield comparable numbers of respiratory epithelial cells to nasal and NP swabs; in children, they compared favorably with NP aspirates for DFA detection of common respiratory viruses (106, 107). Polyurethane foam-tipped swabs provide an alternative to nylon or Dacron swabs for sampling of the anterior nares in patients who might be at risk for bleeding. Self-collected foam nasal swabs have been shown to be more sensitive than nasal washes for detection of several respiratory viruses by NAT in immunocompromised patients, and they performed better than nylon flocked swabs for rapid influenza Ag testing in children (108, 109).

A swab of the posterior nasopharynx typically yields more virus than a swab of the anterior nares or throat. Here, the flexible, fine-tipped swab is inserted through the nostril along the floor of the nose into the nasopharynx until resistance is felt, then rotated several times, removed, and placed in VTM (28). The swab should be pointed toward the ear rather than toward the top of the head and traverse the length and diameter of flocked nylon in order to sample a larger surface area of respiratory mucosa, including the inferior and middle turbinate bones. For DFA or NA testing, the sensitivity of flocked NP swabs for detection of respiratory viruses compares favorably to nasal wash or NP aspirate specimens (110, 111). Throat swabs alone are generally inferior specimens for diagnosis of upper respiratory tract infections. However, combined testing of throat swabs with either NP swabs or aspirates can improve the yield of diagnostic etiologies of respiratory infection, as can the testing or pooling of other types of respiratory specimens (111–113). Throat swabs are collected by depressing the tongue and swabbing the tonsillar area and posterior pharynx thoroughly.

Although the oropharynx and nasopharynx are common portals for the introduction of viruses into the respiratory tract, they are not typically the primary sites of replication for most respiratory viruses.
tract, the presence or absence of a virus in the upper respiratory tract may not be sufficient evidence of lower respiratory tract disease, as evidenced by cases of severe influenza infection in which upper respiratory tract samples tested negative for the presence of virus while those from the lower respiratory tract had detectable virus (114, 115). BAL specimens are collected by inserting a fiber-optic bronchoscope into the involved segment of the lung, instilling saline, and applying suction to remove the lavage specimen. BAL specimens for NA testing should be transported and tested within 24 h of collection, stored at 4°C for up to 72 h, or frozen at −70°C or lower for future testing (31). Although sputum is not a particularly worthwhile specimen for virus isolation, it is often submitted because of the ease of collection and need for other microbiologic analyses. Sputum can be a suitable specimen for respiratory virus detection using NATs (reviewed in reference 116) and has been shown to increase the diagnostic yield over combined nasal and throat specimens in adults with respiratory illness (117). However, viruses identified in sputum do not necessarily represent lower respiratory tract infection since they may originate in the oropharynx. Sputum for NATs should be fixed in acetone or fixed in a sterile container and transported to the laboratory at room temperature within 30 min or, if longer, transported at 4°C (31).

Respiratory fluids (e.g., NP aspirates and nasal washes) or swabs in VTM for culture should be vortexed to release cell-associated virus and centrifuged at 500 to 1,000 × g for 10 min unless there is a minimal amount of cellular debris. The supernatant can be used directly as inoculum or further clarified by filtration (0.45-μm pore size) to remove any additional bacterial, fungal, and/or cellular debris. The pelleted cells (washed two or three times in phosphate-buffered saline) may be used for immunofluorescent staining (28, 29). Application of the concentrated cell suspension to a slide by cytospin preparation can increase the sensitivity of immunofluorescent staining and reduce the number of infected cells (washed two or three times in phosphate-buffered saline) may be used for immunofluorescent staining (28, 29). Application of the concentrated cell suspension to a slide by cytospin preparation can increase the sensitivity of immunofluorescent staining and reduce the number of inadequate specimens (118). Centrifuged or filtered specimens are not suitable for Ag or NA detection since these assays should not be affected by microbial contamination. The loss of host cells may compromise Ag test sensitivity, and NATs have not been approved for use with acellular specimens.

Mucus in respiratory specimens can significantly affect Ag detection. In fluorescent-antibody tests, mucus can inhibit adherence of cells to slides and can cause nonspecific fluorescence. It also prevents penetration of the sample into filtration devices. To prevent these complications, mucus threads can be broken by repeated aspiration through a small-bore pipette.

**Skin**

Viruses can cause rashes with many different appearances, including maculopapular, petechial, and vesicular. Recovery of viruses from maculopapular and petechial rashes requires biopsy of skin, which is not routinely performed. Viral causes of disseminated diseases manifested by maculopapular and petechial rashes are usually identified by their clinical features and laboratory testing of specimen types other than skin; often blood is used for serologic or NA testing (Table 1) because the virions are not typically found in those lesions, resulting from the host immune response to infection (119).

Vesicular lesions are commonly caused by HSV, VZV, and enteroviruses. Cells and fluid from fresh vesicles are preferred over other lesion types such as pustules, ulcers, and crusts, which may not contain sufficient virus for Ag detection, NA testing, or culture. Vesicular fluid can be collected by use of capillary pipettes, syringes, or on swabs placed in VTM. Vesicles that have not been opened may have fluid contents withdrawn by means of a sterile tuberculin syringe fitted with a 26- or 27-gauge needle. Prior preparation of the area with disinfectants such as iodophors or alcohol may inactivate the viruses. Therefore, use local disinfection after the specimen has been collected. Promptly rinse fluids collected by syringe aspiration into VTM. Alternatively, vesicles may be uncapped using a sterile needle or scalpel and the vesicle fluids absorbed onto the tip of a sterile swab and placed in VTM. The margins and base of the lesion should be swabbed briskly to obtain infected epithelial cells (29). Cells from ulcers or crusted lesions (after removal of the crust) should be collected by rolling a swab over the same area. Specimens should be collected without causing bleeding, since the presence of neutralizing antibody in blood can impair recovery. Smears for immunofluorescent staining (e.g., HSV and VZV) can be prepared at bedside by spreading the material thinly onto a small area in the center of a clean slide. After air drying, slides should be fixed in acetone for 5 to 10 min prior to staining. Swabs or vesicle fluid in VTM can be tested by NATs, Ag detection, and/or culture. Specimens for viral culture can be inoculated directly after vortexing or first clarified by centrifugation and filtration if debris is present.

**Stool and Rectal Swabs**

Stool is the optimal specimen for identification of viruses causing gastroenteritis. Many gastroenteritis viruses (e.g., rotavirus) are noncultivable and require Ag or NA tests for detection. Ideally, specimens should be collected within the first 2 to 4 days of illness since detection rates are reduced in later stages of infection unless the patient’s underlying condition allows for prolonged shedding. However, most enteroviruses can be recovered in stool for several weeks after onset of symptomatic infection.

Approximately 2 to 5 ml of liquid stool or 2 to 5 g of formed stool should be collected in a clean, dry, leak-proof container or in VTM, depending on the type of testing to be performed. Fresh stool specimens can be stored at 4°C for 2 to 3 days if they are not tested immediately after collection. For prolonged storage, specimens should be kept frozen, preferably at −70°C or lower. Specially formulated paper strips have also been used for collection, transport, and storage of stool samples for NA testing of rotavirus, adenovirus types 40 and 41, and norovirus (49, 50, 120). The rectal swab is generally considered an inferior specimen to stool, as it usually collects an insufficient amount of visible stool collected. For collection, the swab is inserted several centimeters past the anal sphincter, rotated for several seconds, removed, and placed in VTM.

As bacteria comprise a significant proportion of the mass of stool, centrifugation, filtration, or both are often necessary to prevent microbial contamination of cell cultures. For virus isolation, prepare a 10 to 20% (wt/vol) stool suspension in VTM with antimicrobials and glass beads, vortex for 1 min, and centrifuge the suspension at 3,000 × g for 15 to 30 min. The clarified supernatant can be filtered through a 0.2- to 0.45-μm-pore-size filter prior to inoculation of cell cultures (28, 29).

**Tissue (Biopsy or Autopsy)**

Tissue specimens obtained during surgery or at autopsy can be assessed by several diagnostic methods. Lung, liver, lymph node, kidney, spleen, cardiac, and brain tissue can be used...
to identify the viral etiology of many clinical syndromes (Table 1). Due to the invasive nature of specimen collection, the laboratory should ensure that a sufficient quantity of tissue is available for all testing requested; otherwise, testing can be prioritized by the clinician. The tissue can be divided in the laboratory in consultation with the pathologist to determine which portions should be submitted for viral diagnostics (121). A small piece of tissue from the leading edge of the affected area should be excised and kept moist in a sterile container, typically with sterile saline if comprehensive microbiologic and histologic testing is requested. Formalin-fixed tissue is unsuitable for viral isolation and may affect the performance of NATs (31). Touch preparations of cells can be made by pressing tissue against the clean surface of a glass slide multiple times. Once air dried, the slide is fixed in acetone prior to application of staining reagents.

If NA is to be extracted, biopsies or large tissue specimens should be kept moist with sterile normal saline or placed in a suitable NA preservative. While the stability of NAs in tissue specimens varies with tissue type, it is recommended to transport tissues to the laboratory on wet ice or frozen (31). Fresh tissue specimens for NA detection are minced, treated with proteolytic enzymes, and extracted. Formalin-fixed, paraffin-embedded tissues for NA testing should be stored and transported at ambient temperatures, deparaffinized, and extracted. However, fresh tissue is superior for NA recovery since formalin treatment induces considerable NA degradation (31). For viral isolation from tissue, it is recommended to prepare a 10 to 20% (wt/vol) homogenate using VTM as a diluent from small or minced tissue fragments that have been aseptically ground in a tissue grinder (28). Fresh tissue specimens for NA detection are minced, and extracted. However, fresh tissue is superior for NA recovery since formalin treatment induces considerable NA degradation (31). For viral isolation from tissue, it is recommended to prepare a 10 to 20% (wt/vol) homogenate using VTM as a diluent from small or minced tissue fragments that have been aseptically ground in a tissue grinder (28, 29). The homogenate can be centrifuged (600 to 900 × g for 10 min) or allowed to settle by gravity and the supernatant used as inoculum.

Urine
Collect urine specimens as soon as possible after the onset of illness or when congenital or perinatal infection is first suspected. A volume of 5 to 10 ml of urine (midstream or catheter obtained) is collected in a sterile container; no VTM is required. The routine and timing of the collection is not known to have any effect on the reliability of testing methods. For NATs, ambient storage of fresh, unprocessed urine should be minimized since the low pH and high urea content rapidly denature DNA and RNA (31). NAs should be extracted before testing since urine contains substances that can inhibit PCR (122–124). NAs may be extracted from urine obtained on filter paper disks, or the disks may be used directly in the NAT as a template without additional purification or elution steps (125–127).

Prior to inoculating cell culture, urine can be filtered (0.45-μm pore size) or centrifuged (1,000 × g for 10 min) to remove bacteria and debris; the pH can be neutralized with sodium bicarbonate (7.5% solution) to reduce toxicity (28). Alternatively, antibiotics can be added directly to the urine or it can be diluted with VTM to neutralize pH and introduce antimicrobials (29). Allow the mixture to stand at room temperature for 15 min prior to inoculation of cell cultures.

TRANSPORTATION REGULATIONS
Shipment of specimens to reference or public health laboratories is common practice. All packages that contain infectious substances must meet the shipping regulations of various organizations or agencies. In the United States, the main source for regulations governing specimen and biological shipments is the U.S. Department of Transportation. The International Air Transport Association regulates all shipments on air carriers and provides its own Dangerous Goods Regulations (128). Since there is some harmonization between the national and international regulatory bodies, the International Air Transport Association requirements are usually acceptable under all regulations.

The Dangerous Goods Regulations include specific instructions for packaging and labeling of shipments containing biological or infectious substances such as patient specimens or cultured microorganisms (128). In the clinical laboratory, materials being shipped generally fall into one of three categories: exempt human specimen, category A, or category B. Category A infectious substances (UN2814 infectious substance, affecting humans) are those transported in a form that, when exposure to it occurs, can cause potentially life-threatening illness (e.g., Ebola virus). A list of category A microorganisms is available at www.phmsa.dot.gov. An infectious substance that does not meet the criteria for inclusion in category A is assigned to category B (UN3373 biological substance, category B) unless it is a patient specimen for which there is minimal likelihood that pathogens are present, in which case it would be labeled an exempt human specimen.

For transportation of any category A infectious substance, packaging must include an inner container, an itemized list of contents, and an outer packaging. The inner packaging must comprise one or more leak-proof primary receptacles and leak-proof secondary packaging capable of withstanding an internal pressure differential of at least 95 kPa. For liquid specimens, an absorbent material in sufficient quantity to absorb the entire contents must be placed between the primary and secondary packaging. Category B packing instructions are essentially identical to those for category A, although no packing list need be included. Exempt patient specimens are packaged with leak-proof primary and secondary receptacles within an outer container of adequate strength. Training of personnel for packaging and shipping dangerous goods must be documented, and recertification is required every 2 years. The Department of Transportation may inspect any shipper or receiver of dangerous goods unannounced at any time.

SUMMARY
The importance of appropriate specimen collection and handling to ensure accurate laboratory results cannot be overstated, and the laboratory must serve as a resource for clinicians. In some instances, proper collection, transport, and processing of specimens is determined by the manufacturer, whereas those laboratories that utilize in-house-developed tests need to verify these preanalytical factors themselves prior to routine, clinical testing (51).

The performance characteristics of viral diagnostic tests (sensitivity, specificity, positive predictive value, and negative predictive value) are, to a large extent, dependent on the integrity of viral or host components present in the specimen. For molecular methods, successful testing is based largely on the quality of the NA purified from the clinical specimen. That quality is directly related to how the specimen is stored and transported to the laboratory after it has been collected from the patient. Specimens for detection of viral Ags require that adequate amounts of intact cellular material from the site of infection be collected and maintained to prevent degradation. Serologic testing is affected by the timing of collection relative to disease progression.
Successful recovery of virus in culture requires maintenance of viability, which can be enhanced by (i) the timing and method of collection to incorporate high titers of virus, (ii) protection from thermal inactivation or drying, and (iii) use of an effective transport system.

REFERENCES

INTRODUCTION

In 1915, vaccinia virus was first propagated in cell culture for the purpose of vaccine production (1). However, the potential role of cell culture for clinical diagnostics was not highlighted until 1949, when Enders et al. (2) first described the use of cultivated mammalian cells and the observation of cytopathic effect (CPE) for the detection of polioviruses. Today, living cells are used to support the growth of a number of cell-dependent organisms, including viruses and certain bacteria such as Chlamydia spp. and, more rarely, Mycoplasma spp. In addition, cultured cells can be used to demonstrate the effects of bacterial toxins excreted from pathogens such as Shigella spp., toxigenic Escherichia coli, including O157:H7, and toxigenic Clostridium difficile, among others. Traditional tube cell culture and rapid cell culture methods (e.g., shell vial) are dependent on the interactions of viruses with a variety of animal, human, and/or insect cells and utilized within the laboratory setting as substrates for growth, identification, and enumeration of pathogenic viruses (3, 4).

In the era of molecular detection and quantification of viral pathogens, the applicability of viral isolation has been questioned. For many viruses, it is well documented that molecular detection methods are preferred (i) for their greater sensitivity; (ii) for their faster potential for detection and reporting (hours versus overnight or days to weeks); (iii) for their ability to quantify more accurately the amount of virus present in the sample; and (iv) in instances where viral culture may place the laboratory at risk due to the highly pathogenic nature of the virus (e.g., variola virus, Ebola virus, and avian influenza virus). However, cell culture methods have useful applications (i) when the potential viral agent is not known; (ii) when the cost of other methods of testing is greater than that of cell culture; (iii) for documentation of active infection; (iv) to perform antiviral susceptibility testing; (v) to assess response to antiviral treatment by the detection of viable virus; (vi) for serologic strain typing; (vii) for vaccine and therapeutic clinical trials; and (viii) for laboratories that do not have the ability to perform molecular detection methods. Some molecular assays, for practical reporting purposes, may take as long as overnight cell culture and may not lend themselves to single-specimen testing as well as cell culture does. For these reasons, cell cultures are still an indispensable research and clinical laboratory tool, particularly when combined with the use of highly specific monoclonal antibodies (MAbs) for the detection of common viruses and Chlamydia spp. or when cell lines are engineered to produce virus-induced enzymes (5), such as β-galactosidase for the detection of herpes simplex viruses (HSV) (6).

This chapter describes the cell lines, reagents, stains, and media used in association with traditional tube and rapid viral culture techniques. Included are examples of both well-characterized and emerging infectious viral agents that may be encountered while working with viral culture. Sample collection, specimen processing, and culture requirements for individual or classes of viruses are discussed in the appropriate chapters. The reader is referred to a comprehensive review of cell culture (7) and reference document M41-A from the Clinical and Laboratory Standards Institute (Wayne, PA), which provides guidance for viral culture methods, including the applicable biosafety measures required (8). The fourth edition of the Clinical Virology Manual lists the virology services offered by federal reference laboratories (9) and state public health laboratories (10). This chapter's appendix lists the manufacturers and suppliers of cell lines, media, and reagents referred to throughout the chapter.

REAGENTS

- Balanced salt solutions (Hanks’ and Earle’s)
  Hanks’ balanced salt solution and Earle’s balanced salt solution (EBSS) are the two most commonly used formulations. However, Hanks’ balanced salt solution has a better buffering capacity with CO₂ and EBSS has a better buffering capacity with air.

- Density gradient media
  Density gradient media or cell preparation tubes (BD, Franklin Lakes, NJ) are used for the isolation of peripheral blood mononuclear and polymorphonuclear leukocytes. Separated cells can be used for the direct detection of viruses, such as cytomegalovirus (CMV), using immunostaining methods. Detailed descriptions of the specific uses of the gradient media or tubes and commercial sources are listed in chapter 79.

- Dulbecco’s PBS
  Dulbecco’s phosphate-buffered saline (PBS) is a maintenance-type medium containing sodium pyruvate and glucose.
HEPES
HEPES is an organic chemical-buffering agent that maintains physiological pH despite changes in carbon dioxide concentration, in contrast to bicarbonate buffers. HEPES is used in culture media.

Formalin for cell culture preservation
Formalin can be used to preserve viral CPE in cell culture for both educational and research purposes.

Earle's minimal essential medium ......................... 81 ml
Formaldehyde (37 to 40% concentration) .......... 30 ml
Fill CPE-positive culture tubes with the solution, seal, and store at room temperature.

HAD test
Hemadsorption (HAD) refers to the attachment of red blood cells (RBCs) to infected cell culture monolayers. Influenza A and B; parainfluenza 1, 2, 3, and 4; and mumps viruses possess a surface hemagglutinin protein that is expressed on the cell surface of infected cells (11). The hemagglutinin protein binds RBCs and adsorbs them to the infected cell membrane. HAD may be performed when there is no visual CPE in culture or as a rapid screen for the presence of an orthomyxovirus or paramyxovirus in cell culture with a suspicious CPE. HAD testing is usually performed at 3 to 7 days of incubation or at the end of the incubation period (generally 10 to 14 days). MAb staining of the cell monolayer for infectious agents such as influenza and parainfluenza has largely replaced HAD procedures in most clinical laboratories because staining tends to be more specific and provide more rapid results, which can be critical to patient care.

Test procedure
Variations in HAD testing may occur from laboratory to laboratory. Positive- and negative-control tubes must be included when the test is performed.

1. Wash fresh guinea pig (GP) RBCs two or three times in PBS weekly, discarding the supernatant after each centrifugation. Prepare a final 4 to 10% GP-RBC stock suspension in PBS and store at 4°C. The GP-RBC suspension should be used within 7 days.
2. Using the 10% GP-RBC stock suspension, prepare a 0.4% suspension prior to testing (0.4 ml of the 10% suspension plus 9.6 ml of PBS).
3. Remove the cell culture tube media and replace with 1 ml of cold PBS. Add 0.2 ml of the 0.4% GP-RBC suspension to the tube cultures and incubate at 4°C for 30 min.
4. Shake each tube and examine the tubes at 40× and 100× lens objectives for HAD to the monolayer or hemagglutination in the supernatant. Place HAD-positive tubes in the incubator at 37°C for 1 h to release the adsorbed RBCs.
5. To detect parainfluenza virus type 4, place HAD-negative tubes at room temperature for 30 min and reexamine for HAD.

Saline
Normal or physiological saline (0.85%) is commonly used as a diluent.

10× Gentamicin-amphotericin B solution
Several different combinations of antibiotics and amphotericin B are added to transport media, particularly for pretreatment of specimens such as stool prior to culture inoculation, or are used in refeed medium to reduce both bacterial and fungal contamination. Commercial media containing the appropriate strength of antibiotics and amphotericin B can be purchased. Alternatively, a 10× gentamicin-amphotericin B solution can be added by the laboratory at a ratio of 1:10 (0.1 ml of 10× gentamicin-amphotericin B to every 1.0 ml of specimen). Following receipt by the laboratory of the transport medium containing a specimen, centrifugation may be helpful to reduce cellular artifact overlayers or bacterial or fungal contaminants; however, this is not always required. The specimen supernatant is inoculated onto the appropriate cell line(s).

Eagle’s minimal essential medium (EMEM) ...... 89 ml
Gentamicin (50 mg/ml) ................................. 1 ml
Amphotericin B (250 μg/ml) ......................... 10 ml
Combine all ingredients and store frozen at −20 to −70°C in working-size aliquots.

Tryptsin solutions
In lieu of scraping cells from tubes or wells, trypsin solutions are used to disburse cells from the monolayer for repassage and for immunostaining of cell-associated viruses such as adenovirus, CMV, and varicella-zoster virus (VZV). Tryptsin solutions made with 2.5% PBS or Versene EDTA solution are commercially available.

Tween 20-PBS
Tween 20-PBS may be used to wash cell monolayers prior to staining with fluorescent MAb, but is not always required. Follow manufacturers’ directions for specific staining protocols if using a commercially available product. Tween 20-PBS is stored at room temperature and should be discarded if the solution is turbid or a precipitate develops.

Virology Stains
Direct examination of clinical specimens using several methods, such as slide touch preps from unfixed tissue from an excision or biopsy, cytologic examination of tissue scrapings (e.g., Tzanck assay for HSV), smears from mucous membrane scrapings (e.g., HSV or VZV), or sample concentration by cytopsin or centrifugation (e.g., respiratory viruses), can provide relatively rapid results. Slides can be prepared at the bedside (e.g., skin scrapings for HSV or VZV) or in the laboratory (e.g., respiratory swabs in transport media) and fixed with 80 to 100% reagent-grade acetone, 95% alcohol, or a cytological fixative, depending on the method. Traditional staining with hematoxylin and eosin and Wright-Giemsa stains can demonstrate characteristic cell morphologies such as the “owl’s eye” nuclear inclusions indicative of CMV or the “smudge cells” that contain large basophilic inclusions consistent with adenovirus. Today, the definitive identification of certain viruses or Chlamydia spp., directly in clinical samples is mainly done using MAb labeled with fluorescein isothiocyanate (FITC), methylrhodamine isothiocyanate, or phycoerythrin (PE) with an Evans blue and/or propidium iodide counterstain. Results are available within 15 to 60 min. Additionally, direct fluorescent-antibody (DFA) or indirect fluorescent-antibody (IFA) testing is used for confirmation of viruses isolated in cell culture and for blind staining when using centrifugation-enhanced virus isolation methods (discussed in subsequent sections). Procedures require minimal equip-
ment (incubator, fluorescent microscope, pipettes, and centrifuge) and moderate technical expertise to perform and interpret the results (reviewed in reference 7). Commercial reagents, commonly provided at working strength and quality tested to ensure sensitive and specific reactions, cleared by the Food and Drug Administration for in vitro diagnostic testing are listed in Table 1. Reagents may be cleared for use with direct specimen testing or for culture confirmation, and in some instances for both applications. Various formats of MAb reagents are available for immunofluorescence testing methods that (i) detect Chlamydia spp. (Fig. 1) and Chlamydophila spp. but do not differentiate; (ii) target a single virus (Fig. 2); (iii) detect and differentiate two or more viruses (Fig. 3); (iv) target a single virus and contain a pool of MAbs that detect multiple additional viruses but do not differentiate (Fig. 4); and (v) detect a family of viruses or multiple viruses using a pool of MAbs but do not differentiate (Fig. 5). Both the location of the fluorescent staining (e.g., cytoplasmic versus nuclear) and the staining pattern (e.g., speckled versus homogenous) can aid in virus differentiation (Fig. 3).

### CELL CULTURES

Good manufacturing practices-regulated commercial vendors (see the appendix) provide tissue culture cells that are sterile, stabilized at the proper pH, thoroughly tested for susceptibility to common pathogens, and carefully screened to be free of potentially harmful endogenous agents, such as foamy viruses and mycoplasmas that will interfere with the detection of the intended pathogens. Monolayered, ready-to-use cells can be produced at the vendor facility within a day or two of order, allowing the laboratory flexibility in the quantity and delivery date. Culture cells are provided in a number of ready-to-use formats including traditional 16- by 125-mm glass round-bottom screw-cap tubes, 1-dram vials (shell vials), flasks, or cluster trays. Ready-to-use cell cultures have a shelf life that is defined by the manufacturer in days or weeks, depending on the cell line or intended pathogen to be recovered. Some cells are also supplied frozen in shell vials and may be stored for months or years at −70°C or below, ready to use with a simple thaw step and change of medium. Other frozen cells are supplied in cryovials and other containers at a stated density and require the laboratory to subculture them to obtain monolayers in a flask, multiwell plate, shell vial, or tube, depending on the end application (12). Frozen cells can be used as needed and for unexpected situations such as unanticipated increases in the volume of samples, sudden viral outbreaks, or delays in cell shipments.

For laboratories that require special cells not readily available from commercial sources, specific cell types can sometimes be obtained from research laboratories or the American Type Culture Collection (Manassas, VA) and then propagated within the user laboratory. Once the cells are received, the laboratory must confirm sterility, absence of mycoplasma contamination, and the appropriate passage or cell duplication number necessary to ensure sensitivity for viral or chlamydial isolation. Cell cultures must be maintained in an environment that allows appropriate cellular replication and proper utility for the tests desired (13). A number of references offer detailed procedures for growing cells from frozen or fresh flasks (4, 8); such procedures are not addressed in this chapter.

To ensure the safety of the technical staff and to prevent cell culture contamination, the laboratory must follow strict procedures for the handling of biohazardous materials throughout the testing process (8, 13). These include (i) the use of class II or higher biological safety cabinets with HEPA filters and, if possible, external venting, certified at least annually; (ii) facilities and procedures that are appropriate to the biohazard level of the viruses tested as defined by the Centers for Disease Control and Prevention (Atlanta, GA) (14); and (iii) training and annual competency assessment of the laboratory staff. Virology benches and safety cabinets should be disinfected at least daily with a high-level disinfectant, such as 10% sodium hypochlorite (bleach).

#### Traditional cell culture

The common culturable human viral pathogens causing significant infections are readily detected by using a variety of cell types, including the established cell lines listed in Table 2. Cell lines may be primary (e.g., rhesus monkey kidney and rabbit kidney), used for one or two passages; diploid (e.g., human embryonic lung), used for 20 to 50 passages; or heteroploid (e.g., human epidermoid lung carcinoma), which can be passaged indefinitely. The laboratory must maintain sufficient cell types and incubate cell cultures for an optimal length of time and under the appropriate conditions that permit the recovery of the potential range of detectable viruses for all specimen types processed by the laboratory (8, 13, 15). Cell culture systems can be variable and are susceptible to conditions that can adversely affect results, including cell culture source and lineage, age and condition of the monolayer, number of passages, shipping conditions, and the presence of contaminating agents. For example, in 2012, cultures of rhesus monkey kidney cells distributed to clinical laboratories throughout the United States were found to be contaminated with Coccidioides immitis that was endogenous to the harvested monkey kidney (16, 17). As a result of rapid communication of this information and adherence to laboratory safety procedures, there were no adverse effects in terms of personnel infection with this highly infectious fungus (16). Therefore, quality control procedures and specific testing guidelines must be followed (8, 13, 18). Shipments of cell culture material should be observed microscopically to confirm that the confluency of the monolayer is appropriate (75 to 90%); the cells are attached to the substratum; cell appearance is typical; and no evidence of contaminating viruses, bacteria, or fungi is present, usually signified by cytopathic appearance of the cells before use or turbidity of the cell medium. Cell culture media that will be added to newly shipped cells should also be free of contamination (clear) and near a neutral pH (salmon pink in color). If the laboratory introduces additives (e.g., l-glutamine or antibiotics) to commercial media, the final solution must be checked for sterility, pH, growth promotion, and the absence of toxicity to cells. The lot number and date of use for all media, buffers, reagents, and additives should also be recorded. Tubes of cell cultures should be stored in a slanted position with the cell monolayer covered by the medium. Tissue culture cells should ideally be inoculated within 7 days of receipt (8 to 10 days of seeding) for optimal propagation of cell-dependent organisms or demonstration of cytotoxicity. The laboratory should retain all documentation provided by the manufacturer, including cell culture records with cell types, source, passage number, and age of cells. Uninoculated lot-matched tubes, cluster plates, or shell vials that are incubated, maintained, and observed in the same manner as inoculated tissue cells serve as negative controls for CPE, toxicity, exogenous contamination, and procedures such as DFA, HAD, and hemagglutination. Daily inoculation of positive controls to monitor traditional tube culture performance.

*Refer to manufacturers’ websites for Food and Drug Administration and in vitro diagnostic status of reagents. Although uses for the reagents may be suggested on manufacturers’ websites, all suggested applications may not have been validated by the manufacturer. Abbreviations: adeno, adenovirus; CC, culture confirmation; DSD, direct specimen detection; dual, a 2-fluorophore stain; FluA, influenza virus A; ID, identification; IF, immunofluorescence; Para, parainfluenza virus. 

*Respiratory panel A: adenovirus, influenza virus A and B, parainfluenza viruses 1, 2, and 3, RSV; respiratory panel B: adenovirus, influenza virus A and B, parainfluenza viruses 1, 2, and 3, and differential identification of RSV; respiratory panel D: adenovirus, influenza virus B, parainfluenza viruses 1, 2, and 3, RSV, and differential detection of influenza virus A.*
is not routinely performed. However, commonly isolated viruses may be used to perform quality control on cell lines when new shipments are received in the laboratory, and they are a source of positive-control material for detection and confirmation methods such as HAD and DFA.

With the exception of a few slower-growing viruses such as CMV, or when viruses are present at very low titers, the time to detection by traditional tube culture methods is generally between 1 and 7 days of inoculation (4). The standard approach for detecting viral proliferation is the microscopic examination of the unstained cell culture monolayer for the presence of CPE. The presence of a virus is indicated by degenerative changes in monolayer cells, including shrinking, swelling, rounding of cells, clustering, and formation of syncytia, or by complete destruction of the monolayer. Identification of the virus is then based on the CPE characteristics, the cell line involved, the time to detection, specimen type, and confirmation, generally by staining with virus-specific MAbs. Alternatively, for the identification of viruses for which MAbs may not be available, molecular methods or ancillary traditional testing (e.g., acid resistance for rhinoviruses) must be performed. In addition, for certain viruses (influenza, parainfluenza, and mumps viruses) that do not always demonstrate CPE, HAD testing may be done (11).

**Centrifugation-enhanced rapid cell culture**

Centrifugation-enhanced inoculation using cells grown on coverslips in 1-dram shell vials and pre-CPE detection of viral antigen in the monolayer cells by use of MAbs was first described for the detection of *Chlamydia trachomatis* (19). This technique was adapted for the routine detection of CMV using MRC-5 shell vials and staining with MAbs directed against early CMV proteins (20). This pioneering method has reduced the time for virus detection from as long as 10 to 30 days to 16 to 72 h. The important factor in reducing the time to detection is the stressing of the monolayer during centrifugation (21). This process has been shown to increase cell proliferation, decrease cell generation times, alter cell metabolism, increase cell longevity, and activate specific genes.

Rapid cell culture is now commonly used for the detection of *Chlamydia* spp., CMV, enteroviruses, VZV, HSV, mumps viruses, and the main respiratory viruses (adenovirus; human metapneumovirus [HMPV]; influenza A and B viruses; parainfluenza viruses 1, 2, and 3; and respiratory syncytial virus [RSV]) (reviewed in reference 7). Centrifugation-enhanced rapid cell culture can be used with standard cell lines (Table 2; Fig. 1) and has been adapted for use with cocultivated cells (Table 3) for the detection of respiratory viruses (R-Mix and R-Mix Too; Quidel Corp./Diagnostic Hybrids, Inc., Athens, OH) (Fig. 2), for the detection of HSV and VZV (H&V-Mix; Quidel/Diagnostic Hybrids) (Fig. 6) (22–24), and with genetically engineered cells such as ELVIS (enzyme-linked virus-inducible system; Quidel/Diagnostic Hybrids) (Table 3) for the detection of HSV (Fig. 3) and Super E-Mix (Quidel/Diagnostic Hybrids) for the detection of enteroviruses (Fig. 5) (25, 26). Identifica-
tion of the viral pathogen when using centrifugation-enhanced rapid cell culture is not dependent on the visualization of CPE, allowing technologists not skilled in CPE recognition to perform viral testing. Instead, the virus is detected either by “blind staining” or staining “pre-CPE” with PE-, peroxidase-, or FITC-labeled virus-specific MAbs or a combination of PE- and FITC-labeled antibodies or by virus-specific induction of enzymes that are detected by the ELVIS HSV system using substrates such as β-galactosidase (6, 25, 26). A significant benefit of using cocultivated cells such as R-Mix, R-Mix Too, H&V-Mix, and Super E-Mix is that they allow the identification of multiple viruses from a single shell vial or cluster tray well, rather than having to use multiple shell vials to cover the range of viruses that the laboratory may wish to detect in a particular sample type. One shell vial can be substituted for up to four different tube cell cultures that require much longer (10 to 14 days) to identify fewer subspecies of the group.

Since rapid detection formats are not based on the detection of CPE but use blind staining for either single viruses or multiple viruses, positive- and negative-control slides are required for each day of patient testing. When a single-culture system detects multiple viruses, the detection reagents must be validated for all targets (including any pooled MAb reagents) upon receipt in the laboratory (13, 15). Virus isolate controls can be tested daily and virus types rotated so that during the course of 1 week, the lots of cells and reagents have been tested against all the routinely isolated viruses.

**ELVIS**

ELVIS uses a genetically engineered cell line (BHKIC-P6LacZ) that was first described by Stabell and Olivo (6). The promoter sequence of the HSV UL97 gene and the Escherichia coli lacZ gene were used to stably transform a baby hamster kidney cell line. When the cell line is infected with HSV, the virion-associated transactivator protein VP16 and other transactivating factors such as ICP0 strongly transactivate the UL97 promoter, which in turn activates the lacZ gene, resulting in high levels of β-galactosidase activity. Addition of 4-chloro-3-indol-β-d-galactopyranoside (X-Gal) turns a colorless substrate to blue, indicating the presence of HSV-infected cells (Fig. 3A). If HSV typing is required, a fluorescence-labeled MAb that specifically detects HSV-2 (Fig. 3D) and a nonlabeled MAb that specifically binds to HSV-1 are incorporated in the staining procedure. If the infected (blue) cells are not detected with the HSV-2 MAb, then the monolayers are stained with anti-mouse fluorescence-labeled antibody to detect the HSV-1 MAb (Fig. 3C). ELVIS is completed within 16 to 24 h for both positive and negative results (25, 26).

**Cell cytotoxicity assays**

Tissue culture assays using cell types such as human foreskin fibroblasts, MRC-5 cells, and Vero epithelioid cells are commonly used for the detection of toxin-producing strains of Clostridium difficile (27–29). Cell culture testing for the presence of C. difficile cytotoxin has demonstrated improved sensitivity compared to C. difficile toxin A/B enzyme immunoassays. Enteroviruses can cause a CPE similar to that caused by C. difficile toxin; therefore, the procedure includes the use of a C. difficile antitoxin to C. difficile toxin, which creates a more specific assay. Fecal filtrate is diluted, bacteria are removed by membrane filtration, and the tissue culture cells are exposed to the patient material, with and without C. difficile antitoxin. Test wells without C. difficile antitoxin demonstrating CPE within 12 to 48 h are presumed positive for C. difficile toxin if the control well with C. difficile antitoxin shows no evidence of CPE. As little as 1 pg of toxin can cause a visible change in cells over a period of hours up to 1 to 2 days.

**CELL CULTURE MEDIA**

**Transport Media and Collection Swabs**

An important consideration in using cell culture is ensuring collection of cellular material and maintaining the viability of the organisms from the time of sample collection to inoculation in cell culture. Therefore, time to processing, transport temperature, and the use of transport media need to be evaluated for each sample type. Cell culture media with additives, such as antibiotics and fungicidal agents to inhibit microbial growth, are used to maintain the viability of viruses during sample transport. Transport media may be specific for virus isolation (viral transport media) or also allow the isolation of Chlamydia, Mycoplasma, and Ure-

---

plasma (universal transport media). The types of transport media, uses and components, collection procedures, and swabs are detailed in chapter 79.

**Growth medium with 10% fetal bovine serum**

Cell culture media are an important part of the production and maintenance of cells. Cell culture stocks are generally grown in a richer medium than that which is used for the maintenance of the cells. The higher level of serum or protein in growth medium rapidly enhances cell growth and is used for a day or more before it is replaced by maintenance medium. Standard growth medium consists of EMEM with EBSS and supplemented with 10% heat-inactivated fetal bovine serum (FBS), one or more antimicrobials (gentamicin, penicillin, streptomycin, vancomycin, and/or amphotericin B), and HEPES buffer. Since simian viruses are endogenous to primary monkey kidney cell cultures, media that contain simian virus 5 (SV5) and SV40 antisera are available (Quidel/Diagnostic Hybrids).

**Maintenance medium**

Maintenance medium contains nutrients and buffers that protect the cells during the stage when rapid growth is not desired but healthy monolayers must be controlled for inoculation of specimens and recovery of the etiologic agent. Seeded flasks, tubes, trays, or shell vials may be fed with medium multiple times prior to release from the vendor to ensure that the cells are growing according to specifications and arrive at the user site ready to be used. At the user site, most cells remain stable for a period of a few days without needing changing of the medium with which they were shipped. However, before use, it is common to remove the shipping medium and add a maintenance medium such as 2% FBS EMEM or 0% FBS Hanks', minimal essential medium, or, for those viruses that would be inhibited by serum proteins (myxoviruses and paramyxoviruses), R-Mix refeed medium. Trypsin and antimicrobial agents can be added if indicated. Other refeeding media for viruses include E-Mix refeed medium (Quidel/Diagnostic Hybrids) and 5 or 10% FBS growth medium. Tube cell cultures may require refeeding on a weekly or twice-weekly basis; however, the use of shell vial or cluster plate technology usually reduces refeeding to one time just prior to inoculation. Commercial media with and without enrichments are available, such as PBS, l-glutamine, trypsin, and bactericidal and fungicidal agents.

**Chlamydia isolation medium**

Some cell-dependent bacteria such as C. trachomatis require the cell host to restrict protein synthesis, thus allowing the infecting microbe to replicate more easily. For this reason, media used for propagation of Chlamydia spp. in cell culture commonly contain cycloheximide, a protein synthesis inhibitor. Isolation media for Chlamydia spp. detection using shell vials generally contain EMEM with EBSS, supplemented with 10% FBS, HEPES, glucose, nonessential amino acids, antibiotics (cycloheximide, gentamicin, or streptomycin), and amphotericin B.

**EMEM pH 2–3**

Rhinoviruses require a lower temperature of incubation than many other pathogenic human viruses, and their characteristic CPE can be confused with enterovirus CPE, which has a similar appearance. At this time, MAbs are not available to identify rhinoviruses. For this reason, the ability of acid solutions to neutralize rhinoviruses, thus reducing viral titers, can be used to differentiate rhinoviruses from enteroviruses, which are not sensitive to low pH. EMEM pH 2–3 can be used to test for acid sensitivity.

**RPMI 1640 medium**

RPMI medium consists of glucose, essential amino acids, other amino acids, vitamins, HEPES buffer, antibiotics (such as penicillin and streptomycin), and phenol red as an indicator. This enriched medium is used for lymphocyte cell cultivation and culture of HIV.

**Proprietary Media**

**CMV TurboTreat medium**

CMV TurboTreat pretreatment medium (Quidel/Diagnostic Hybrids) consists of EMEM with EBSS without phenol red, 10% FBS, HEPES, and gentamicin. Pretreatment of Mv1Lu, R-Mix, and MRC-5 cultures overnight, prior to specimen addition, enhances the recovery of CMV (30).

**ELVIS replacement medium**

ELVIS replacement medium is used with the ELVIS test system and comprises EMEM, FBS, streptomycin, and amphotericin B.

**R-Mix refeed and rinse medium**

R-Mix refeed and rinse medium is used with R-Mix or R-Mix Too fresh and R-Mix or R-Mix Too Ready Cells (frozen shell vial) culture systems (Quidel/Diagnostic Hybrids) and is a defined serum-free medium with trypsin, penicillin, and streptomycin.

Algorithms for Detection and Identification of Viruses
MARIE LOUISE LANDRY, ANGELA M. CALIENDO, CHRISTINE C. GINOCCHIO, YI-WEI TANG, AND ALEXANDRA VALSAMAKIS

Virology is a dynamic field that in recent decades has moved from the periphery to the mainstream of clinical laboratory practice. When the first edition of the Manual of Clinical Microbiology was published in 1970, diagnostic virology was practiced in a limited number of laboratories, primarily in public health, research, and academic settings. Methods focused on conventional cell cultures, classical serologic techniques, and light and electron microscopy. Time to result was slow, and it was often said the patient was dead or better by the time the result was received.

Over the intervening years, diagnostic advances have transformed the field by allowing accurate results in a clinically useful time frame. These technology improvements include enzyme, chemiluminescence, and chromatographic immunoassays for antigen and antibody detection, IgM class capture assays, monoclonal antibodies for rapid identification of culture isolates, shell vial centrifugation cultures, and direct detection of viral proteins in clinical specimens by immunofluorescence. The most transformative, however, have been nucleic acid amplification techniques (NAATs), which are both rapid and sensitive; can be automated, high-throughput, or random access; and can detect and quantify viruses not amenable to routine culture.

Since the last edition of this Manual, the dramatic growth in the development and implementation of clinically useful molecular methods has accelerated. This trend has been facilitated by the increasing availability of commercial reagents and Food and Drug Administration (FDA)-cleared kits, some requiring minimal molecular expertise and no extraction step, and the greater variety of instruments for nucleic acid extraction and real-time amplification, including some integrated systems. Novel detection methods have permitted the diagnosis of multiple respiratory viruses in a single multiplex PCR test. One FDA-approved test, although low-throughput, is simple to perform, detects up to 21 respiratory pathogens, and provides "on demand" results within 1 h. A high-throughput but more complex test was also recently approved by the FDA for detection of common gastrointestinal viral, bacterial, and parasitic pathogens. Quantitative monitoring of viral load in blood has become more widely applied due to implementation of real-time PCR techniques and the availability of FDA-approved kits. Substantial effort has been and continues to be invested in the development of international quantitative standards (e.g., cytomegalovirus and Epstein-Barr virus) that will permit cross-institutional comparisons and interpretive guidelines. Thus, molecular assays have become the standard of care for the diagnosis of many viral infections, for predicting patient outcomes, and for monitoring response to antiviral therapies. Laboratories without classical virology expertise can now implement state-of-the-art molecular testing. The main obstacle for offering molecular testing in-house is no longer lack of technical expertise but cost, for both equipment and reagents.

In addition to the advantages of molecular testing, some pitfalls are also becoming apparent as the tests are more widely used. For example, the sensitivities and specificities of assays to detect the same virus can vary significantly between laboratories, especially for laboratory-developed tests. In addition, despite targeting conserved regions of the genome, strain variability and mutations can lead to underquantification of viral load, or even falsely negative results. Furthermore, as tests become more sensitive, low levels of clinically irrelevant or nonviable viruses may be detected and can be misleading to clinicians. Similarly, interpreting the clinical relevance of multiple viral pathogens in the same sample when relative quantification is not available is problematic. Requirements for staff training, test validation, and quality control can also be challenging.

At the other end of the spectrum are rapid tests requiring minimal or no equipment or reagent additions. These tests often employ immunochromatographic detection for viral antigen or antibody and can be used at the point of care for immediate impact on clinical decisions. However, the 2009 novel H1N1 influenza pandemic revealed the need to improve the sensitivity of point-of-care rapid tests. While newer tests with fluorescent labels and walk-away readers have improved accuracy, much work remains. Several integrated, rapid, and simple NAAT devices suitable for point-of-care testing are in the pipeline and may fill this niche.

Thus, with progress have come new challenges. Laboratories need to choose which tests to offer. Selecting the appropriate test will depend on the virus(es) sought, sample site, clinical presentation, clinical purpose (e.g., screening, confirmation, diagnosis, or monitoring), patient characteristics, and disease prevalence. Performance characteristics, staff expertise, and cost will also influence that choice. Laboratories must recognize the uses and also the limitations of each test in order to guide clinicians in test selection and in interpretation of results. This Manual should serve

NAAT is test of choice for B19-exposed fetuses and for immunocompromised hosts. Bocavirus NAAT included in some multiplex respiratory virus panels. | (Continued on next page)
as a key resource for accomplishing these tasks. The choices available for each virus differ and continue to evolve. Table 1 provides a concise overview for each virus group; however, the reader is referred to the specific chapters for more detailed discussions.

While it can be daunting for laboratories to acquire and maintain expertise in the variety of test methods and platforms now available, it is extremely gratifying to witness the impact of state-of-the-art testing on patient care. As we move forward, it is critical that laboratorians communicate with one another to address problems, including the optimization and standardization of methods, and, in addition, encourage input and feedback from clinicians. Due to the speed of methodological change and the continuing discovery of new viruses and new therapies, keeping abreast of the most recent literature is strongly recommended.

*Viral nucleic acids (DNA or RNA) can be detected and quantified by direct hybridization or by the performance of amplification methods such as PCR. Viral antigens can be detected by a variety of immunoassays, such as enzyme-linked immunosorbent assays, agglutination assays, immunofluorescence or immunoperoxidase techniques, and immunochromatography. Virus isolation includes conventional cell culture with detection of viral growth by cytopathic effects or hemadsorption, and shell vial centrifugation culture with detection of viral antigens by immunostaining. Antibody detection involves measurement of total or class-specific immunoglobulins directed at specific viral antigens. Electron microscopy involves the visualization of viral particles by negative staining or immunoelectron microscopy, or by thin-section techniques. Abbreviations: BSL, biosafety level; CNS, central nervous system; CoV, coronavirus; CRS, congenital rubella syndrome; EM, electron microscopy; IFA, immunofluorescence assay; IHC, immunohistochemistry; ISH, in situ hybridization; KS, Kaposi’s sarcoma; LCMV, lymphocytic choriomeningitis virus; MERS, Middle East respiratory syndrome; PML, progressive multifocal leukoencephalopathy; PrP, prion protein; PVAN, polyomavirus-associated nephropathy; SARS, severe acute respiratory syndrome. 

A test is generally useful for the indicated diagnosis, preferred method may vary with sample type; B, test is useful under certain circumstances or for the diagnosis of specific forms of infection, as delineated in the right-hand column and in the text of the individual chapters; C, test is seldom useful for general diagnostic purposes but may be useful for epidemiological studies or for the diagnosis of unusual conditions; D, test is not available or not used for laboratory diagnosis of infection.
RNA Viruses

Human Immunodeficiency Viruses*
BERNARD M. BRANSON AND S. MICHELE OWEN

TAXONOMY

Historical Perspective and Origin

The human immunodeficiency virus (HIV) is the etiologic agent of acquired immune deficiency syndrome (AIDS). The clinical manifestations of AIDS were first recognized in 1981 (1). Search for the cause of this severe cellular immune dysfunction led to isolation of lymphadenopathy-associated virus in 1983 (2). The following year, additional researchers isolated cytopathic retroviruses from persons with AIDS, which they termed human T-lymphotrophic virus type III (3, 4). These viruses were soon confirmed to be identical, and in 1986 the International Committee on the Taxonomy of Viruses designated human immunodeficiency virus (HIV) as the name for the virus causative of AIDS (5).

HIV exists as two major viral species. Both are members of the genus Lentivirus within the family Retroviridae. HIV type 1 (HIV-1), identified first, is the more virulent of the two and is responsible for the majority of AIDS cases worldwide. HIV-2, first isolated in 1986, has biological and morphological properties similar to those of HIV-1, but differs in some of its antigenic components (6). HIV-2 is less pathogenic and has a more limited geographic distribution than HIV-1. Both HIV-1 and HIV-2 are related to simian immunodeficiency viruses (SIV), which are found in 26 species of African primates but do not cause disease in their native hosts (7). Phylogenetic evidence indicates that HIV-1 arose as a consequence of at least three separate zoonotic transmissions of SIV from chimpanzees to humans; four interspecies SIV transmissions from sooty mangabeys are the origins of HIV-2 (7, 8). Genetic sequences of HIV have been identified retrospectively in human plasma specimens from as early as 1959 (9).

HIV Classification

HIVs are classified based on the phylogenetic relatedness of their nucleotide sequences. The current classification is hierarchical and consists of types, groups, subtypes, sub-subtypes, and recombinant forms (10). Subtypes are often referred to as clades. The most distantly related HIVs are categorized as types; HIV type 1 and HIV type 2. HIV-1 is further characterized into groups: the major (M) group; the more divergent outlier (O) group; the non-M, non-O (N) group; and group P, a new lineage closely related to a gorilla SIV (10–12). Most HIV infections occur with HIV-1 group M, which is differentiated into nine subtypes (A, B, C, D, F, G, H, J, and K). Subtypes A and F are further classified into sub-subtypes A1, A2, A3, F1, and F2. The sequences within any one subtype are more similar to each other than to sequences from other subtypes throughout their genomes and represent different lineages of HIV. Eight HIV-2 groups (A through H) have been defined; only two, A and B, have been recovered from more than a single individual. When viruses from two or more HIV-1 lineages infect one individual and exchange their genetic material, they are termed recombinant viruses (13). If transmission of the recombinant virus to three or more persons has been documented by whole-genome sequencing, it is referred to as a circulating recombinant form (CRF), and the CRF is given a numeric designation (13). As of December 2013, CRF01 to CRF55 are recognized (Los Alamos Laboratory National HIV Sequence Database, http://www.hiv.lanl.gov/content/sequence/HIV/mainpage.html). Recombinant viruses that have been identified but not documented to have been further transmitted are referred to as unique recombinant forms (URF). The variation in nucleotide sequences can have implications for the biology and transmission of the virus and for patient survival, and also helps to identify the geographic distribution and epidemiology of HIV infection. From the diagnostic perspective, sequence variation can have significant implications for the reactivity and cross-reactivity of diagnostic tests designed to detect specific viral proteins or peptides.

DESCRIPTION OF THE AGENTS

Structure and Genomic Organization

HIVs are enveloped single (positive)-stranded RNA viruses. The HIV genome is organized similarly to other retroviruses. HIVs are enveloped single-stranded RNA viruses.

Mature viral particles measure 100 to 150 nm in diameter and have a conical core surrounded by a lipid envelope.

*This chapter contains information presented by Brigitte P. Griffith, Sheldon Campbell, and Angela M. Caliendo in chapter 79 of the 10th edition of this Manual.
The core contains two copies of single-stranded RNA, approximately 10 kb in length, which are surrounded by structural proteins that form the nucleocapsid and the matrix shell as well as by-products of the pol gene. The lipid envelope is acquired as the virus buds from infected cells. The HIV-1 glycoprotein gp120/41 forms spikes that protrude from this envelope. The glycoprotein, a product of the env gene, is synthesized as a precursor, gp160, which is cleaved into the heavily glycosylated gp120, forming the majority of the external portion, and gp41, which contains the membrane-spanning domain. The major HIV-1 structural proteins encoded by the gag gene include p17, p24, p7, and p9. Products of the pol gene include protease, reverse transcriptase, RNase, and integrase.

HIV-2 is structurally analogous to HIV-1, but some of its protein components differ, most notably the outer envelope and transmembrane glycoproteins gp125 and gp36, and the core proteins p16 and p26. The major gene products that are of significance for the diagnosis of HIV-1 and HIV-2 are listed in Table 1.

### Replication Cycle

The replication cycle of HIV-1 is accomplished in vivo in approximately 24 hours (14). Replication begins with the attachment of virus to the target cell via the interaction of gp120 and the cellular receptor CD4. This binding results in gp120 conformational changes that allow the virus to interact with other cellular coreceptor sites, CXCR4 or CCR5. The interaction with CXCR4 occurs primarily with T-cell-tropic, syncytium-inducing viruses (15). In contrast, the β-chemokine receptor CCR5 is involved in attachment of macrophage-tropic non-syncytium-inducing HIVs and is thought to be the predominant mode of new infections (16).

After fusion with the host cells, HIV enters the cell and RNA is released. HIV particles contain reverse transcriptase (RT), an enzyme that plays a crucial role in the replication process. RT possesses three distinct functions: RNA-dependent DNA polymerase, which serves to synthesize complementary DNA (cDNA); ribonuclease H (RNase H), which degrades RNA from the cDNA–RNA complex; and a DNA-dependent DNA polymerase, which synthesizes a DNA strand complementary to the cDNA. The reverse-transcribed genome is associated with several viral proteins and is transported into the nucleus. The double-stranded DNA copy becomes integrated into the genome of the infected cell by the virally encoded integrase; this integrated retroviral DNA genome is called the provirus. The cDNA then serves as a template for viral RNA. Activation of HIV transcription and gene expression is modulated by cellular transcription factors and by viral regulatory proteins, including Tat, Rev, Nef, and Vpu. The regulatory genes tat and rev greatly influence the rate of viral replication. The Tat protein increases transcription from the long terminal repeat, and the Rev protein facilitates export of unspliced or partially spliced RNAs encoding the viral structural proteins. At the end of the replication cycle, the virion assembles and buds through the plasma membrane.
EPIDEMOLOGY AND TRANSMISSION

Epidemiology
Approximately 75 million people worldwide have become infected with HIV since the start of the pandemic. In 2012, 2.3 million people became newly infected, and an estimated 35 million people were living with HIV (UNAIDS 2013 Global Fact sheet). HIV-1 has been reported in virtually every country on earth. Group M viruses are responsible for most HIV-1 infections, with a predominance of subtype C. Subtype B is most prevalent in the United States, Europe, and Australia but is rarely found in Africa, where subtypes A, C, and D predominate. HIV-2 is found predominantly in West African nations, where it has infected an estimated 1 to 2 million people. In recent years, HIV-2 infections have been reported in countries with historical and socio-economic ties to West Africa, including Brazil, France, Portugal, and India, and in other countries among immigrants from countries where HIV-2 is endemic (17). In 2012, approximately 9.7 million people living with HIV had access to antiretroviral therapy in low- and middle-income countries; updates from 2013 indicate that globally, new HIV infections have fallen by 33% since 2001, and AIDS-related deaths have fallen by 30% since the peak in 2005 (18).

The CDC estimated that 1.1 million persons in the United States were living with HIV at the end of 2010, of whom 181,000 (15.8%) were unaware of their diagnosis (19). The demographic characteristics of HIV infection continue to evolve. The CDC now generates annual estimates of the number of new HIV infections, including both those that are diagnosed and undiagnosed. In contrast to new HIV diagnoses (which can occur at any point after HIV infection), HIV incidence (the number of new HIV infections in a single year) reflects the leading edge of HIV transmission and HIV infection trends. Approximately 50,000 persons acquired HIV-1 each year from 2007 to 2010 (20). From 2008 to 2010, the number of new HIV infections among adult females decreased 21%, from 12,000 in 2008 to 9,500 in 2010. In contrast, the number of new infections in males increased 7%, from 35,500 in 2008 to 38,000 in 2010. In 2010, blacks/African-Americans accounted for 44% of new HIV infections, followed by whites (31%) and Hispanics/Latinos (21%). Men who have sex with men continue to bear the heaviest burden of HIV: in 2010, 68% of new HIV infections overall, and 78% of new infections among males, were attributed to male-to-male sexual contact. Among females, 84% of new HIV infections were attributed to heterosexual contact (20). After rapidly increasing through the 1980s, deaths due to HIV infection peaked in 1994-1995, decreased rapidly through 1997 with the introduction of combination antiretroviral therapy, and continued to decrease steadily through 2010. However, HIV infection remains one of the leading causes of death among persons 25 to 44 years old. The age-adjusted death rate due to HIV infection has been highest among blacks/African-Americans and second highest among Hispanics/Latinos.

Transmission
HIV-1 and HIV-2 have the same modes of transmission. The most common mode of infection is sexual transmission at the genital mucosa through direct contact with infected body fluids, including blood, semen, and vaginal secretions (21). Infection may also occur through inoculation of infected blood, via transfusion of infected blood products, transplantation of infected tissues, from an infected mother to her infant during pregnancy, or by reuse of contaminated needles. The risk of HIV-1 infection from occupational percutaneous exposure to HIV-1-infected blood has been estimated to be 0.3% (22). Postexposure prophylaxis may reduce this risk by 81% (23). The U.S. Public Health Service currently recommends 4 weeks of postexposure prophylaxis with three or more antiretroviral drugs after an occupational exposure (24).

The majority of HIV transmissions from mother to child occur in resource-poor countries. The level of maternal HIV-1 RNA or DNA in blood and genital fluids has been documented to correlate strongly with mother-to-child transmission (25). HIV transmission can occur in utero, during labor and delivery, and during breast-feeding. In the absence of therapeutic intervention, the risk of mother-to-child transmission can range from 15 to 30% and is further increased with breast-feeding. However, the risk can be reduced to less than 2% if antiretroviral therapy is administered to women during pregnancy and labor (26). Antiretroviral treatment of the infant immediately after birth can also significantly decrease the risk of HIV-1 infection in the newborn.

CLINICAL SIGNIFICANCE

Virological Parameters during the Course of HIV Infection
The natural history of HIV-1 infection can be divided into three phases: a transient acute retroviral syndrome associated with primary infection, an asymptomatic period during which active viral replication continues and disease progresses, and finally, advanced disease resulting in severe immune dysfunction and AIDS. Each of these stages is associated with specific changes in virological and immunological parameters. After HIV-1 infection, HIV-1-specific markers appear in the blood in the following chronological order: HIV-1 RNA, p24 antigen, HIV-1 IgM antibody, and HIV-1 IgG antibody (Fig. 2). The exact time at which each of these markers can be detected depends on a number of factors including characteristics of the infecting virus, the type of test used, and individual host immune responses. Immediately after exposure and transmission, HIV-1 replicates in the mucosa, submucosa, and lymphoreticular tissues, and the virus cannot be detected in plasma. This so-called eclipse phase generally lasts 10 days (range, 7 to 21 days) (27, 28). Once HIV-1 RNA reaches a concentration of 1 to 5 copies/ml, it can be detected by sensitive qualitative methods of nucleic acid amplification; at concentrations of 50 copies/ml, it can be detected by quantitative assays used clinically to monitor viral load. HIV-1 p24 antigen is then expressed and quantities rise to detectable levels within 4 to 10 days after the initial detection of HIV-1 RNA (29). However, p24 antigen detection is transient, because as antibodies begin to develop, they bind to the p24 antigen and form immune complexes that interfere with p24 assay detection unless the assay includes steps to disrupt the antigen–antibody complexes. Next, immunoglobulin (Ig) M-class antibodies are expressed, which can be detected by 3 to 5 days after p24 antigen is first detectable and 10 to 13 days after the appearance of viral RNA (29). Finally, IgG-class antibodies emerge and persist throughout the course of HIV infection. The time period after infection when HIV antibody is not detectable is referred to as the window period. In most infected persons, HIV antibody becomes detectable within 1 to 2 months after infection.

Acute Retroviral Syndrome
An estimated 50 to 70% of individuals with HIV infection experience an acute clinical syndrome 3 to 6 weeks after
primary infection during which antibodies are often not detectable. Acute HIV-1 infection is a transient symptomatic illness that usually lasts 7 to 14 days and is associated with high levels of HIV-1 replication and a developing virus-specific immune response. Acute HIV-1 infection has been described as a mononucleosis-like syndrome. Clinical symptoms include fever, maculopapular rash, oral ulcers, lymphadenopathy, malaise, weight loss, arthralgia, pharyngitis, and night sweats (30–32). During acute HIV-1 infection, plasma viremia rises, reaching levels of up to 100 million copies of HIV-1 RNA per ml of plasma (33). Destruction of HIV-1-specific CD4+ T lymphocytes and widespread dissemination of the virus, with seeding of lymphoid organs and other tissue reservoirs, occurs. During resolution of primary infection, CD4+ T-cell counts rebound and viremia declines before reaching a steady level. This viral set point reflects ongoing viral replication and immune system damage and is an important prognostic indicator (34, 35). In prenatally infected infants, the HIV-1 RNA pattern differs from that in infected adults: high HIV-1 RNA levels may persist in HIV-infected children for prolonged time periods.

### Clinical Latency

In most patients, primary infection with or without the acute syndrome is followed by a prolonged period of clinical latency or smoldering low disease activity. In untreated patients, the length of time from initial infection to the development of clinical immunodeficiency disease varies greatly; the median interval is 10 years. HIV disease with active virus replication is ongoing and progressive during this asymptomatic period. The number of CD4+ lymphocytes declines slowly and the virus continues to replicate. During this asymptomatic period, high titer of virus can be found in lymphoid and other tissue compartments (36). In rapid progressors, AIDS can develop within 1 to 2 years. In contrast, 5 to 10% of HIV-1-infected individuals are long-term nonprogressors and remain symptom-free for longer than 20 years (37). Approximately 0.5% of persons with HIV infection, termed elite controllers, are able to spontaneously maintain undetectable levels of virus without antiretroviral therapy.

### Disease Progression to AIDS

In the absence of therapy, the continuous replication of HIV-1 in productively infected cells, together with the elimination of host cells and chronic immune activation, results in deterioration of the immune system. Studies of HIV-1 replication dynamics have shown that, in productively infected lymphocytes, the interval between infection, virus production, and cell death is very short. The half-life of HIV-1 in plasma is thought to be 6 hours, the length of the replication cycle in CD4+ lymphocytes has been estimated at 2.6 days, and 35 million CD4+ cells are thought to be lost daily (38). As the ability of the host to eliminate productively infected cells declines, CD4+ lymphocytes with integrated provirus accumulate. These resting memory CD4+ lymphocytes serve as a long-lived reservoir for HIV-1. This reservoir decays slowly (mean half-life of 44 months) even in treated patients who have had no detectable viremia for as long as 7 or more years (39). Clinical manifestations of HIV disease can affect nearly every organ system. Destruction of the immune system is clinically manifested by the occurrence of opportunistic infections and tumors. Central nervous system involvement also occurs, most commonly HIV-associated dementia (40). A decline of the CD4+ lymphocyte count to below 200 cells/μl marks the onset of immunologic AIDS and predisposition to opportunistic infections caused by viruses, bacteria, fungi, and protozoa, and to neoplastic disease, HIV encephalopathy, wasting

**FIGURE 2** Time course of appearance of laboratory markers for HIV-1 infection. Units for vertical axis not noted because their magnitude differs for RNA, p24 antigen, and antibody. Adapted data from reference 90 and updated with data from references 29, 97, and 107.

doi:10.1128/9781555817381.ch82.f2
syndrome, and progressive multifocal leukoencephalopathy, which are often the cause of death.

The course of HIV-1 infection and the clinical characteristics of AIDS in children differ from those in adults. The disease progresses rapidly in infants with vertically acquired HIV-1 infection. The most common AIDS-defining conditions in children include *Pneumocystis jirovecii* pneumonia and recurrent bacterial infections.

Public health organizations, including the CDC and the WHO, have published HIV disease classification systems for public health surveillance purposes. All case definitions of HIV infection now require laboratory-confirmed evidence of HIV infection. The current CDC classification system for adults and children categorizes HIV-1 infection into five stages (0, 1, 2, 3, and unknown). Stage 0, indicative of early infection, is defined by a negative or indeterminate HIV test result obtained within 180 days of a positive HIV test result. Stage 0 can be established either by testing history (a positive test result obtained after a previous negative or indeterminate test result) or by a laboratory testing algorithm that demonstrates the presence of HIV-specific viral markers, such as p24 antigen or nucleic acid (RNA or DNA), in conjunction with a negative or indeterminate antibody test result. Stages 1, 2, and 3 are categorized on the basis of age-specific CD4+ T-lymphocyte counts or percentages indicative of increasing severity (Table 2). Cases with no information on CD4+ T-lymphocyte count or percentage are classified as stage unknown (64).

**Therapy and Vaccination**

Significant scientific advances in the development of effective antiretroviral therapy have occurred in the past 25 years. The first effective drug against HIV-1, zidovudine, was approved by the FDA in March 1987. Currently, over 30 antiretroviral drugs or combinations of antiviral drugs have been approved by the FDA for the treatment of HIV infections (see [www.aidsinfo.nih.gov](http://www.aidsinfo.nih.gov) for a list of FDA-approved drugs). Approved antiviral agents used to treat HIV-1 fall into five classes: nucleoside RT inhibitors, nonnucleoside RT inhibitors, protease inhibitors, integrase inhibitors, and entry and fusion inhibitors. Guidelines for the use of antiretroviral agents in adults and in children evolve rapidly. These are updated on a regular basis, and the most recent guidelines can be obtained from the AIDSinfo website (http://aidsinfo.nih.gov).

Several obstacles have hindered the development of effective vaccines against HIV-1, including the inability of HIV-1 to induce neutralizing antibodies to contemporaneous virus particles, the lack of understanding of correlates of protective immunity, the genetic diversity of the virus, and the limitation of animal models (41, 42).

**COLLECTION, STORAGE, AND TRANSPORT OF SPECIMENS**

Serum and plasma are the most common specimen types used for routine HIV antibody and antigen determinations in the laboratory. The most common tubes for plasma collection are potassium EDTA, sodium citrate, sodium and lithium heparin, and plasma preparation tubes. Prompt separation of serum and plasma from the clot/cellular elements is important to decrease hemolysis and maintain the most viable specimen for testing. Serum or plasma specimens can be transported either at room temperature, refrigerated, or frozen (after removal from cellular components) in screw-cap plastic vials. For antibody immunoassays, serum or plasma specimens may be shipped refrigerated (2 to 8°C) or at ambient temperature (≤37°C) for up to 7 days. For HIV antigen/antibody combination assays, the time that specimens can remain at room temperature is more restrictive. It is necessary to minimize room-temperature storage for optimum preservation of p24 antigen. Specimens for the antigen/antibody combination assays available in the U.S. as of December 2013 can be stored at room temperature for a maximum of 48 to 72 hours, or refrigerated at 2 to 8°C for up 7 days. It is important to include specimen transport times as part of the maximum allowable storage times at any given temperature. For long-term storage, serum or plasma specimens should be frozen at −20°C or lower.

Some HIV antibody assays are approved for use with dried blood spots, oral fluid, and urine; and some rapid point-of-care HIV assays can be performed with finger-stick whole blood, venipuncture whole blood, or oral fluids. Collection devices, procedures, and storage requirements are specified by the test manufacturer for use with these alternative specimen types.

Quantitative HIV-1 RNA viral load assays are most commonly performed on plasma specimens. Plasma for viral load determination is generally collected in potassium EDTA or acid citrate dextrose (ACD) tubes. Heparin anticoagulants inhibit PCR and should not be used for any nucleic acid assay that involves PCR amplification. To ensure accurate HIV-1 RNA quantification in plasma, proper collection, processing, storage, and transport of plasma specimens are essential. For all assays, plasma must be separated from blood cells in a timely manner to prevent RNA degradation. Assay manufacturers specify that whole blood can be maintained at room temperature for 6 to 24 hours or stored at 2 to 8°C for up to 24 hours before centrifugation, depending on the specific assay used. HIV-1 RNA is generally stable in cell-free plasma refrigerated at 2 to 8°C for 5 to 7 days. For long-term storage, plasma samples should be frozen at −20 to −70°C. HIV-1 RNA remains stable for at least three freeze-thaw cycles (43).

*Note: The stage is based primarily on the CD4+ T-lymphocyte count; the percentage is considered only if the count is missing. Stage 0 is defined by a negative or indeterminate HIV test result obtained within 180 days of a positive HIV test result; cases with no information on CD4+ T-lymphocyte count or percentage are classified as stage unknown.*
To simplify the process of collecting and transporting plasma, plasma preparation tubes (PPT) (BD Vacutainer PPT; Becton Dickinson), which contain dried EDTA and a gel separator that forms a barrier between the plasma and cellular elements after centrifugation, are available. PPT provide a closed collection system for the preparation and transport of plasma specimens. Plasma samples do not need to be aspirated from a PPT after centrifugation, eliminating plasma transfer and relabeling steps. This improves convenience, decreases risks of error, and improves safety. Initial manufacturer recommendations allowed for either refrigerated or frozen transport of centrifuged PPT. However, discrepancies in viral loads have been reported to occur in plasma specimens that were frozen in situ (44, 45). The differences were noted only for samples with viral loads close to the assay limit of detection; a large proportion of samples with undetectable viral load in a standard EDTA aliquot were found to have detectable HIV-1 RNA in the corresponding PPT. As a result, the tube manufacturer has recommended that plasma in PPT be stored without freezing; plasma from PPT should be transferred to a secondary tube if plasma specimens need to be stored frozen. Each of the FDA-approved viral load kits has specific volume, collection tube, and storage requirements.

The same collection system and procedures should be used for subsequent patient monitoring because different systems may produce discrepant values. For example, specimens collected in ACD tubes have also been shown to yield results that are approximately 15% lower than results obtained with EDTA plasma (46, 47). If a change in collection system or technology is planned, new baseline HIV-1 viral load values should be determined.

Laboratories that test specimens from pediatric patients should investigate flexibility of specimen volume because it may be difficult to obtain the 1 ml of plasma needed for several of the assays. Viral load assays have also been used to measure HIV-1 RNA in specimens other than plasma, including serum, dried blood spots, cerebrospinal fluid, cervical secretions, and seminal plasma (43). The RNA quantity in serum has been found to be lower than that in paired plasma samples; applications with specimens other than plasma must be validated because they are not included as approved specimen types for the current FDA-approved viral load assays.

Qualitative HIV-1 RNA assays can be conducted with serum and plasma. For the FDA-approved qualitative diagnostic assay, APTIMA (Hologic Gen-Probe Incorporated), blood specimens can be collected in glass or plastic tubes. EDTA, ACD, sodium citrate, EDTA PPT, or serum tubes can be used. For this assay, whole blood can be stored at ≤ 25°C for up to 72 hours; temperatures not to exceed 30°C are acceptable for not more than 24 hours. Specimens can be stored for an additional five days at 2 to 8°C after centrifugation. Plasma separated from cells can be stored for longer periods of time at ≤ 20°C.

For HIV-1 antiretroviral drug resistance assays (genotypic and phenotypic), plasma collected from EDTA, ACD, or PPT EDTA tubes can be used. Plasma must be separated from the cellular elements within 6 hours of collection and frozen to prevent degradation of RNA. Higher integrity samples are achieved by minimizing the time before centrifugation and freezing of processed samples. Plasma specimens should be transported frozen and stored at ~70°C for optimal results. While there are no FDA-approved methods for HIV-1 DNA amplification or viral culture, there are instances where these procedures are used for clinical purposes after validations are completed that meet clinical regulatory guidelines or for research purposes. Whole blood is commonly used in these applications. Blood should be collected in EDTA, ACD, or cell preparation tubes. For preparation of the peripheral blood mononuclear cells required for HIV DNA amplification, the blood specimen should not be refrigerated or frozen but instead should be kept at ambient temperature for no longer than 4 days.

**DIRECT DETECTION**

**p24 Antigen Assays**

In the early days of the AIDS epidemic, p24 antigen testing played an important role as a tool for the diagnosis, prognosis, and evaluation of antiretroviral activity and for monitoring of HIV-1-infected cultures. In 1996, the FDA approved the Coulter HIV-1 p24 Ag assay (Coulter Co., Miami, FL) for screening blood products. This test was used for screening blood and plasma donors in the United States for a few years until it was replaced with more sensitive nucleic acid tests in 1999 (48). At present, use of individual p24 antigen assays is very limited in the United States. The presence of HIV p24 antigen can be detected in plasma or serum by antigen capture enzyme immunosorbent assay (EIA). Because p24 antigen tests can produce false-positive reactions due to interfering substances and immune complexes, positive samples need to be confirmed by a neutralization procedure (49). p24 antigen is usually not detectable during the first 2 weeks after infection, but during acute infection, it becomes detectable before HIV-1 antibody (Fig. 2). However, detection of p24 antigen is transient because as HIV-1 antibodies begin to develop, they bind to the p24 antigen and form immune complexes that interfere with p24 assay detection unless the assay includes steps to disrupt the antigen–antibody complexes (50, 51). Modifications to the HIV-1 antigen test have been made to boost the sensitivity of the assay, including acid or heat treatment for dissociation of antigen–antibody complexes (51–53), and increased sensitivity has been achieved by the addition of signal amplification (54). Heat denaturation combined with tyramide signal amplification has been reported to increase the sensitivity of p24 antigen detection to levels comparable to detection of viral RNA by PCR; this method can be effective for monitoring responses to antiretroviral therapy (55–57) and for pediatric diagnosis (58, 59) in resource-limited settings when nucleic acid testing is not feasible.

**HIV RNA and DNA Qualitative Assays**

The APTIMA HIV-1 qualitative RNA assay has clinical utility for identification of acute HIV-1 infection and neonatal HIV-1 infection, and for confirmation of HIV-1 infection in an individual whose specimen is repeatedly reactive for HIV antibodies. The test targets both the long terminal repeat and the pol gene of the HIV-1 genome, which allows detection of all HIV-1 group M, N, and O viruses. There are three general steps to the assay: target-specific capture of HIV-1 RNA from the clinical specimen, transcription-mediated amplification, and detection using a hybridization protection assay. The assay has a limit of detection of 30 copies/ml of plasma with a specificity of 99.8%.

Detection of HIV-1 DNA can also be used for HIV diagnosis in special situations such as during the acute phase of infection prior to appearance of antibody, in newborns of infected mothers, or in individuals with suppressed viral replication due to immunologic control or antiretroviral therapy. HIV-1 DNA qualitative assays use PCR to amplify conserved regions of the HIV-1 genome to detect proviral
HIV-1 DNA in peripheral blood mononuclear cells. Only one qualitative HIV-1 DNA PCR assay is commercially available (Roche Amplicor HIV DNA assay, version 1.5), but it is not approved by the FDA and may be phased out by the manufacturer (60). Laboratory-developed tests based on nested and real-time PCR procedures are also used. The limit of detection and ability to detect non-B subtypes vary among these assays. The sensitivity and specificity of standard HIV-1 DNA PCR assays for the diagnosis of neonatal HIV-1 infection have been reported to be 96% and 99%, respectively, at 1 month of age for HIV-1 subtype B (61). In the absence of antiretroviral therapy, comparisons of RNA versus DNA testing for infant diagnosis have shown little difference (62). It remains to be determined whether the more intensive combination antiretroviral regimens that women may receive during pregnancy for treatment of their own HIV infection will affect the sensitivity of RNA detection in their infants. The potential utility of qualitative DNA PCR assays in the diagnosis of vertical HIV-1 transmission has been greatly increased with the development of simple and sensitive procedures for dried blood spots. False-negative HIV-1 DNA results have been reported in infants with non-B subtypes (63), but the latest version 1.5 of the Roche Amplicor assay appears to have improved sensitivity for most HIV-1 subtypes.

### HIV RNA Viral Load Assays

Viral load assays, which measure the quantity of HIV-1 RNA present in plasma, are used as prognostic indicators, to monitor response to therapy, and to determine infectiousness (65). HIV-1 viral load assays have been used most commonly to guide treatment decisions, but because of the relationship between viral load and potential for virus transmission, they are also used as a tool for guiding treatment as prevention interventions (66). In the United States, five commercial assays are FDA-approved for the quantification of HIV-1 RNA in plasma. The two most recently approved assays utilize real-time RT-PCR technology. A comparison of the specimen requirements and characteristics of the assays is shown in Table 3. The RealTime HIV-1 assay (Abbott Molecular, Des Plaines, IL) and the Cobas TaqMan HIV-1 version 2.0 (Roche Diagnostics, Indianapolis, IN) have been optimized to detect all group M subtypes, including all circulating recombinant forms and group O. The other viral load assays have not been optimized for group O viruses and will likely underquantify HIV-1 RNA levels. None of the viral load assays detect HIV-2.

The two real-time RT-PCR assays offer several advantages over the conventional viral load assays, including a very broad linear range (40 to 10,000,000 copies/ml for the RealTime HIV-1 assay and 20 to 10,000,000 copies per/ml for Cobas TaqMan HIV-1 version 2.0 assay), extensive automation, and decreased risk of carryover contamination. The RealTime HIV-1 assay uses the automated m2000 system, which has two components: the m2000sp for nucleic acid extraction and loading of sample and master mix into the 96-well optical reaction plate, and the m2000rt for amplification and detection. The assay contains an internal control, which is an unrelated RNA sequence that is added to the sample lysis buffer prior to extraction. RNA is captured by magnetic particles, washed to remove unbound material, and eluted. After the master mix and sample are combined into the reaction plate, the reaction plate is covered and loaded into the m2000rt; these are the only manual steps of the assay. The amplification and detection utilize TaqMan technology. The HIV-1 oligonucleotide probe is a partially double-stranded complex; the long strand is complementary to the HIV-1 target (integrase) and is labeled at the 5′ end with a fluorophore. The shorter strand is complementary to the 5′ end of the long strand and is labeled with a quencher moiety at its 3′ end. When HIV-1 target is present, the HIV-1-specific strand preferentially hybridizes to the target, allowing emission of fluorescence (67, 68). For calculations of viral load values, two assay calibrators are run in replicates of three to generate a calibration curve; the slope and intercept of the curve are stored on the instrument and used to calculate viral load values. The limit of detection of the assay is 40 copies/ml for a 1.0-ml sample volume, 75 copies/ml for a 0.5-ml sample volume, and 150 copies/ml for a 0.2-ml sample volume. The RealTime assay has been designed to quantify all group M, N, and O viruses and CRFs (67, 69).

The Cobas AmpliPrep/Cobas TaqMan HIV-1 test version 2.0 is also based on real-time TaqMan technology, and targets two HIV-1 gene regions, LTR and gag. The extraction process is automated on the Cobas AmpliPrep instrument using a generic magnetic silica-based capture method and includes a quantitation standard (QS) that is

*For tests that use an automated extraction instrument (AmpliPrep and RealTime), the listed specimen volume is the volume of sample that is loaded on the instrument, which is greater than the actual volume of specimen used for the extraction.*
added to each specimen at a known concentration along with the lysis buffer. The extracted sample and the reaction mix are added to amplification tubes on the AmpliPrep instrument, and the amplification and detection are completed on either the Cobas TaqMan analyzer or the Cobas TaqMan 48 analyzer. Docking the Cobas TaqMan analyzer to the AmpliPrep instrument creates a fully automated system. Alternatively, the amplification tubes can be manually loaded into the Cobas TaqMan 48 analyzer. For calculation of viral load values, the fluorescent readings for the QS and target are checked by the instrument software to ensure they are valid, crossing threshold values are determined, and the viral load value is calculated from lot-specific calibration constants provided by the manufacturer. The amount of QS added to each sample is constant, so if the critical threshold for the QS has been affected, the HIV-1 target concentration is adjusted accordingly. The Cobas AmpliPrep/Cobas TaqMan HIV-1 test has been designed to quantify all group M viruses including CRFs and can also detect group O and N viruses (69–71).

The Amplicor HIV-1 Monitor assay (Roche Diagnostics, Indianapolis, IN) is based on reverse transcription of the target HIV-1 RNA and on PCR amplification of the resulting cDNA. The HIV-1 RNA copy number is calculated based on the input copy number of the QS RNA. One advantage of the assay is that there is minimal risk of amplification contamination because the kit includes UTP and uracil-N-glycosylase. One disadvantage of the Amplicor HIV-1 Monitor assay is that it has a limited dynamic range, requiring both the standard and ultrasensitive procedures to be performed for specimens that fall outside the dynamic range. The Cobas Amplicor HIV-1 Monitor assay captures amplions on magnetic beads, using the Cobas analyzer to automate the amplification and detection steps. The Cobas AmpliPrep/Cobas Amplicor assay automates the nucleic acid extraction, followed by amplification and detection on the Cobas instrument. Because of the popularity of the recently introduced real-time PCR format, the Amplicor assays are currently being phased out in the United States.

The Versant HIV-1 RNA 3.0 assay (Siemens Healthcare Diagnostics, Tarrytown, NY) is a branched DNA (bDNA) method that quantifies HIV-1 RNA by signal amplification instead of target (nucleic acid) amplification (72). The quantity of HIV-1 RNA is determined from an external standard curve run on the same plate; six kit standards of known viral concentration are used. Compared with other viral load assays, the reproducibility of the bDNA assay is superior, particularly at the low end of the dynamic range (73). The Versant HIV-1 RNA 3.0 bDNA assay offers the advantage of high throughput: in the current version, 84 specimens can be run on one plate. In addition, the assay can reliably quantify all subtypes of HIV-1. disadvantages of the bDNA assay include the requirement for a large volume of plasma, the absence of an internal QS for each sample tested, and lower specificity compared to target amplification methods (32).

The high cost and complex technical requirements of nucleic acid-based testing strategies have resulted in the development of other types of assays for measuring virus quantity in specimens collected in resource-limited settings. Two such assays are the heat-denatured signal-boosted p24 antigen assays (Perkin Elmer, Wellesley, MA) and RT assay (ExaVir Load assay; Cavidi AB, Uppsala, Sweden) (74, 75). Although both methods are less sensitive and reproducible than the nucleic acid-based assays, they are affordable alternatives to HIV RNA quantification. Numerous efforts are also underway to develop point-of-care quantitative assays for HIV-1 nucleic acids (76).

ISOlation PROCEDURES

Because HIV can be isolated from the blood of the majority of HIV-infected individuals, HIV culture was frequently utilized in the early years of the epidemic as a diagnostic or prognostic marker or for assessing the efficacy of antiviral therapy (35, 77). The procedure for HIV culture is elaborate and time-consuming (78). Although a positive culture provides direct evidence of HIV infection, HIV culture is utilized primarily in research laboratories and not for routine diagnosis. To isolate HIV, the patient specimen is first cultured by mixing patient cells with cells from healthy donors stimulated with phytohemagglutinin and interleukin-2; fresh stimulated donor cells must be added weekly because HIV-1 produces cell death. In the second step, the presence of RT or p24 antigen released in the culture supernatant is assayed periodically, generally every 3 to 7 days, for approximately 1 month of culture.

Viral culture assays have been used in phenotypic resistance assays and to determine the viral fitness of HIV-1 (79). However, phenotypic resistance assays based on recombinant DNA technology and amplification of plasma viral RNA have obviated the need for viral isolates (80). A commercially available fitness assay, also referred to as viral replication capacity (RC) assay, has been developed by Monogram BioSciences (South San Francisco, CA). The RC assay measures the ability of HIV-1 from a patient undergoing antiretroviral treatment to replicate in vitro compared to a wild-type reference virus. The patient RC value is expressed as a percentage of the RC of the wild-type reference standard. The assay uses a retroviral vector constructed from an infectious clone of HIV-1. The vector contains a luciferase expression cassette inserted within a deleted region of the envelope gene (52). HIV-1 protease and RT sequences are amplified from the patient plasma samples and inserted into the vector. The amount of luciferase produced by patient-derived viruses is then compared to the amount of luciferase produced by well-characterized wild-type reference virus. RC has been suggested as an additional parameter for making decisions regarding antiretroviral therapy. Patients who do not experience increases in viral loads despite the accumulation of multiple resistance mutations have been shown to harbor virus with decreased RC (81). In addition, certain drug resistance mutations have been shown to reduce RC (83, 84); lower RC has also been observed in persons who become HIV controllers (85).

SERoLOGIC TESTS

Diagnosis of HIV infection usually has been accomplished via detection of HIV antibody using a sensitive initial immunoassay validated by a subsequent supplemental test (86). Because HIV infection typically persists for the lifetime of the individual, and the initial infection may be minimally symptomatic, most patients who are identified by antibody detection are in the clinically latent or late phases of the illness. Immunoassays for HIV antibody are rapid and economical, but they have an important limitation because of the window period, the time between initial infection and the expression of detectable antibody (29). During the window period, active viral replication and high levels of viremia occur. Different types of antibody immunoassays have different window periods, but all tests based on detection of antibody miss patients during early infection. Recognition
that the risk of transmission from persons with acute infection is much higher than that from persons with established infection (87) and indications of the clinical benefits from antiretroviral treatment during acute HIV infection (88) have served as the impetus for adoption of techniques that detect HIV earlier after initial infection. Antigen-antibody combination immunoassays and an HIV-1 nucleic acid test (NAT) that allow earlier detection of HIV have received FDA approval and play an increasingly important role in HIV diagnosis.

Initial Screening Tests
Considerable progress in the development of HIV immunoassays has been made since the discovery of the virus in 1983. Current methods are summarized in Table 4. HIV immunoassays based on different design principles are generally grouped into generations. The earliest (first-generation) immunoassays are indirect EIAs that used coated (or immobilized) viral lysate antigens derived from cell culture on a solid phase for antibody capture and an indirect format that detected antibody using an anti-human IgG conjugate. To increase specificity, significant specimen dilution is required to overcome cross-reactivity with cellular protein contaminants. Second-generation immunoassays use synthetic peptide or recombinant protein antigens alone or combined with viral lysates to bind HIV antibodies, and they use an indirect immunoassay format that employs labeled anti-human IgG or protein A, which binds to IgG with high affinity (89), to detect IgG antibodies. Design of the specific antigenic epitopes in the second-generation assays improves sensitivity for HIV-1, HIV-1 group O, and HIV-2, allowing earlier detection of IgG antibodies (90). Eliminating cellular antigens that contaminate viral lysates improves specificity by eliminating cross reactivity with cellular proteins. Third-generation immunoassays also use synthetic peptide or recombinant antigens to bind HIV antibodies, but in an immunometric antigen sandwich format: HIV antibodies in the specimen bind to HIV antigens on the assay substrate and to antigens conjugated to indicator molecules. This allows detection of both IgM and IgG antibodies. Lower sample dilutions and the ability to detect IgM antibodies (which are expressed before IgG antibodies) further reduce the window period during early seroconversion (91, 92). Fourth-generation immunoassays use synthetic peptide or recombinant protein antigens in the same antigen sandwich format as third-generation assays to detect IgM and IgG antibodies, and also include monoclonal antibodies to detect p24 antigen. Inclusion of p24 antigen capture allows detection of HIV-1 infection before seroconversion (93–96). Most fourth-generation antigen/antibody immunoassays (termed "combo" assays) do not distinguish antibody reactivity from antigen reactivity. Analyses of specimens from seroconversion panels have established the approximate time of detection by the different generations of immunoassays. Estimates derived from several data sources are outlined schematically in Fig. 2 (29, 90, 94, 97).

Conventional Immunoassays
Conventional immunoassays for laboratory use consist of EIAs and chemiluminescent immunoassay (CIA) methods. Most of the commonly used assays incorporate specific antigens for the detection of HIV-1 groups M and O and HIV-2. HIV antigens (and anti-p24 antibodies in fourth-generation assays) are adsorbed to a solid phase (usually plates, beads, or tubes), which binds HIV antibodies (or p24 antigen) in the specimens. Antibodies (and p24 antigen with fourth-generation assays) are conjugated to enzymes (alkaline phosphatase or horseradish peroxidase) or to acridinium esters. The indirect EIA format uses an enzyme-labeled antiglobulin conjugate; the antigen-sandwich EIA and CIA formats use a conjugate with enzyme-labeled HIV antigens (or anti-p24 monoclonal antibodies). With an EIA, the end result is a color change, measured as optical density by a spectrophotometer, that is proportional to the amount of antibody (or antigen) in the specimen. CIA results are expressed in relative light units, also proportional to the amount of antibody (or antigen) in the specimen. Results are compared to those of a calibrator; a result with a signal-to-cutoff ratio of >1.0 is considered to be reactive. Both EIAs and CIAs are suitable for automation. CIAs, characterized by a shorter processing time and wider dynamic range than EIAs, have been developed for random-access immunochemistry platforms with the potential to make laboratory-based HIV testing simpler and faster.

Rapid Immunoassays
The logistics of conventional laboratory HIV immunoassays require phlebotomy and, typically, a follow-up visit for test results after the specimen has been processed. This complicates HIV testing for many hard-to-reach populations for which phlebotomy is impractical; many persons may also fail to return for their test results (98). In addition, an immediate HIV test result is medically desirable in certain circumstances when antiretroviral prophylaxis should be initiated promptly, for example, in assessment of the source patient after an occupational blood or body fluid exposure, and for pregnant women in labor whose HIV status is

unknown (24, 99). To meet these needs, rapid HIV tests have been developed that are suitable for use at the point of care as well as in clinical laboratories.

Rapid HIV immunoassays are single-use devices that use either immunoconcentration (flow-through) or immunochromatographic (lateral-flow) principles (100). Flow-through assays require the sequential addition of specimen, conjugate reagent, and a clarifying buffer through a membrane. Lateral-flow assays contain all necessary reagents and are extremely simple to perform because they require the addition of only specimen or specimen and buffer. Rapid tests differ in their required specimen volumes (range 3 μl to 50 μl for whole blood, serum, or plasma) and processing times (range 1 to 20 minutes). Rapid tests that can use direct, unprocessed specimens (whole blood or oral fluid) have been waived under the Clinical Laboratory Improvement Amendments (CLIA) and are especially well suited for testing outside of traditional laboratory settings. Nine rapid HIV antibody tests were FDA-approved in the United States as of December 2013 (Table 5). Disadvantages of rapid assays include their subjective interpretation, possible errors if the reader has vision problems such as color blindness, and potential for procedural errors when performed by less skilled personnel (101, 102). Accurate specimen volumes must be dispensed and tests read within specified times (range 1 to 20 minutes). Rapid tests are useful primarily for small-volume testing. Accurate timing of steps can be adversely affected when multiple specimens are tested simultaneously. Nevertheless, rapid HIV tests have become valuable tools for clinical situations in which rapid results are essential, and for outreach settings (103).

Published studies suggest that rapid HIV antibody immunoassays perform similarly to laboratory-based conventional immunoassays in established HIV infection (104). However, most use colloidal gold bound to protein A for detection of IgG antibodies; sensitivity with plasma seroconversion panels is similar to that of second-generation conventional immunoassays (94, 97). Comparative studies of rapid tests performed on oral fluid, whole blood, and serum demonstrate that rapid tests identified fewer HIV-1 infections than conventional laboratory immunoassays, and sensitivity with oral fluid specimens is lower than that with whole blood or serum in persons from populations with increased prevalence of early HIV infection (105, 106). One rapid HIV test that detects and distinguishes HIV antibodies and p24 antigen, the Alere Determine HIV Combo, has received FDA approval (Table 5). Its overall sensitivity is similar to that of third-generation assays; sensitivity of the antigen component is lower than that of laboratory-based fourth-generation assays (106–108).

Alternative Specimens for Antibody Testing

Alternative specimens to blood, serum, or plasma for HIV antibody testing include oral fluid, urine, and dried blood spots. These may be useful in testing of patients who are reluctant to undergo phlebotomy or who have poor vascular access, in mass-screening settings, in locations in which phlebotomy is impossible, in infants, and for seroprevalence studies. It is essential to employ only specimen collection systems and testing methods designed and validated for the specific specimen type. Oral fluid is a complex mixture of secretions from several different sets of glands, as well as transudated plasma from the capillaries of the gum and mucosa. Glandular secretions of saliva primarily contain secretory IgA, which is not a reliable target for diagnostic testing. Most IgG in the oral cavity derives from the crevicular space between the gums and the teeth, and not from salivary glands, or can be obtained by inducing an oral mucosal transudate. The OraSure specimen collection device is designed to collect oral mucosal transudate for conventional testing (109) with an FDA-approved oral fluid-based HIV-1 EIA and Western blot. Two rapid tests are FDA approved for use with oral fluid as well as whole blood and plasma specimens. However, false-negative and false-positive immunoassay results and indeterminate Western blot results occur more frequently with oral fluid than with serum specimens (105, 110–112). Dried blood spots, after

*Waived status applies only when tests are used with direct, unprocessed specimens (whole blood or oral fluid).
appropriate elution, can be tested for HIV antibody, p24 antigen, and HIV RNA. Results from HIV antibody and p24 antigen tests are comparable to those from matched serum or plasma specimens (58, 113, 114). Because of the lower specimen volume, sensitivity for RNA in dried blood spots is 78 to 100% compared with plasma at viral loads of <1,000 copies/ml, but increases to 100% at a threshold of 500 copies/ml (115, 116). Depending on the technology and the viral load distribution, the percent of dried blood-spot samples that are within 0.5 log_{10} of viral load in plasma ranges from 52 to 100%. HIV viral load tests performed on dried blood spots also measure cell-associated RNA and proviral DNA, potentially leading to false-positive results or elevated values compared with plasma, especially at low copy numbers (116). In urine, IgG is found in small quantities relative to serum. Sensitivity and specificity of the FDA-approved EIA and Western blot for urine specimens was lower than with matched serum specimens tested with conventional EIAs (117).

Screening for Atypical and HIV-2 Infections
The prevalence of HIV-1 group M subtypes and CRFs varies geographically. All subtypes and most CRFs are found in sub-Saharan Africa. Subtype B is the predominant strain in the United States, Europe, Canada, and Australia. However, the prevalence of non-B subtypes in these countries is increasing. In the United States, non-B infections account for approximately 3 to 5% of HIV infections (118, 119). Current HIV immunoassays reliably detect the overwhelming majority of HIV-1 group M, B, and non-B subtype infections (120, 121). Only three group O infections have been documented in the United States, all in individuals with a link to west central Africa. HIV-1 group O infections can be missed by immunoassays that do not contain specific reagents for the detection of antibody to group O (122).

Immunoassays specific for detection of HIV-1 antibodies can detect HIV-2 infections because of cross-reactivity to HIV-1 antigen present in the assay. However, detection of HIV-2 infection by HIV-1–only immunoassays is highly variable: different assays detect 51 to 100% of HIV-2 infections (97). The capability of HIV-1/2 and HIV-2 immunoassays to detect HIV-2 infections must be demonstrated for the assays to obtain approval by regulatory agencies, and most currently available FDA-approved HIV-1/2 assays incorporate gp36 antigen for reliable detection of HIV-2 (Tables 4 and 5).

Supplemental Assays for HIV
Initial screening immunoassays for HIV are optimized to provide very high sensitivity, often at the expense of specificity. HIV diagnostic testing therefore relies on a sequence of tests used in combination to improve the accuracy of HIV laboratory diagnosis. Specimens that are nonreactive on the initial immunoassay are generally considered HIV negative. If the initial immunoassay result is reactive, it must be followed by one or more supplemental tests. Four assay methods are FDA approved as supplemental tests: HIV-1 Western blot, indirect immunofluorescent assay (IFA), qualitative HIV-1 RNA assay, and HIV-1/HIV-2 antibody differentiation assay. Both the Western blot and IFA are highly specific, but because they rely on viral lysate antigens and anti-human IgG conjugates, they detect HIV-1 later during seroconversion than most currently available conventional initial immunoassays and thus may produce false-negative or indeterminate results (123, 124). In addition, because of cross-reactivity, the HIV-1 Western blot has been interpreted as positive for HIV-1 in 46 to 85% of specimens from persons infected with HIV-2 (125, 126). An HIV-1 qualitative RNA assay can be used for the diagnosis of acute HIV-1 infection in serum or plasma from patients without antibodies to HIV-1, and as a supplemental test, when it is reactive, for HIV-1 with specimens that are repeatedly reactive for HIV antibodies. However, HIV-1 RNA is undetectable in 2 to 5% of HIV-1 Western blot–positive specimens from infected persons. Therefore, a specimen with a nonreactive HIV-1 RNA qualitative assay result after repeatedly reactive HIV-1/HIV-2 antibody immunoassay results must undergo supplemental antibody testing to confirm whether HIV-1 or HIV-2 antibodies are present (92, 97). Two HIV-1/HIV-2 antibody differentiation assays have been approved by the FDA for use as supplemental tests and for differentiation of HIV-1 and HIV-2 antibodies. Because the differentiation assays use an indirect EIA format with an anti-human IgG conjugate, they also detect HIV antibodies later during seroconversion than most currently available conventional initial immunoassays (123, 124). Historically, the HIV-1 Western blot has been the gold standard for HIV diagnosis (86). The Western blot owes its specificity to separation and concentration of viral components (127). A viral lysate of HIV is applied in a gel under an electric field; the mixture of viral components is separated by their molecular weights into specific “bands.” Each viral component becomes relatively pure as it is separated. Components are blotted separately onto a membrane, which is cut into strips. The testing laboratory incubates the strips with patient serum, plasma, or dried blood-spot eluates and then develops the reaction with an enzyme-labeled anti-human antibody. Antibodies to the following HIV-1–associated antigens can be detected: gp160, gp120, p66, p55, p51, gp41, p31, p24, p17, and p15. Additional viral bands may be described by some manufacturers, and the molecular weight of some antigens might vary slightly between assays produced by different manufacturers. Because Western blot antigens are prepared from HIV grown in cell culture, nonviral cellular proteins may be present on the nitrocellulose strip and lead to nonspecific reactions. The interpretation of HIV-1 Western blots predominantly follows CDC guidelines. A positive result requires detection of at least two of three antigens: p24, gp41, or gp120/160 (86). The absence of all bands is a negative result. The presence of HIV-associated bands not meeting the criteria for positivity, or the presence of nonviral bands, is interpreted as an indeterminate result. After a reactive initial HIV-1/HIV-2 immunoassay, negative or indeterminate HIV-1 Western blot results should also be followed with additional testing specific for HIV-2 antibodies (128). Western blots that include HIV-2 antigens (e.g., gp36 or gp105) are available outside the United States, but none are FDA-approved. Line immunoassays employ a principle similar to that of the Western blot, but recombinant or synthetic antigens are placed on the strip instead of viral lysate antigens from an electrophoretic gel. This approach has the advantage of using only viral antigens in the reaction, eliminating the background from cross-reactivity with nonspecific cellular proteins. The manufacturer also has control over the quantity and type of antigens represented, and can include HIV-2 and group O antigens to confirm these infections with a single assay (129). The Inno-LIA HIV I/II Score test (Innogenetics, Ghent, Belgium) is a line immunoassay widely available outside the United States. The Fluorognost HIV-1 IFA (Sanochemia) has been used as both an initial screening test and as a supplemental test for HIV-1 infection with serum, plasma, and dried blood-spot eluates. HIV-infected and uninfected lymphocytes are fixed on a slide. The slide is incubated first with patient serum and then with a fluorescent-labeled anti-human antibody (130). For interpretation, patterns of fluo-
rescence in infected and uninfected cells are compared for each patient specimen; fluorescence on the infected lymphocytes that exceeds that from nonspecific antibody binding on the uninfected lymphocytes is interpreted as a positive result. Considerable skill is required, and indeterminate results can be produced in patients with autoantibodies and other conditions. In addition to its use as an independent supplemental test, IFA can be used to resolve indeterminate HIV-1 Western blots. An HIV-2-specific IFA has been described but it is not FDA approved.

The APTIMA HIV-1 Qualitative Assay is FDA approved for detection of HIV-1. HIV-1 RNA in the test specimen is hybridized to capture nucleotides homologous to highly conserved regions of HIV-1. The hybridized target is then captured onto magnetic microparticles and separated from plasma in a magnetic field. Target amplification occurs via a transcription-based nucleic acid amplification. Detection is achieved by chemiluminescent-labeled nucleic acid probes that hybridize specifically to the ampiclon. The chemiluminescent signal, measured in a luminometer, is reported as relative light units. Analytical sensitivity is 30 copies/mL of HIV-1 RNA. Quantitative viral load HIV-1 and HIV-2 RNA and DNA NAT are also available but are not FDA approved for HIV diagnosis.

The Multispot HIV-1/HIV-2 Rapid Test (Bio-Rad Laboratories, Redmond, WA) is a flow-through rapid EIA that differentiates HIV-1 and HIV-2 antibodies in a single-use cartridge. Microscopic particles are coated separately with a synthetic gp41 peptide and recombinant gp41 antigen for HIV-1, and with a synthetic gp36 peptide for HIV-2. The microparticles are immobilized separately on the reaction membrane in three separate test spots. Antibodies against HIV-1 or HIV-2 in the test specimen bind to the antigens in the spots on the membrane. Alkaline phosphatase-labeled goat anti-human IgG is added to the cartridge and binds to the antibody–antigen complexes immobilized in the spots. When development reagent is added to the cartridge, a purple color develops at the spots in proportion to the amount of antibodies present. The membrane is examined visually for the presence of purple color on the test spots. Reactivity at both gp41 spots is required for defining a positive supplemental HIV-1 test result; reactivity at only one HIV-1 spot is interpreted as indeterminate. Sensitivity of the Multispot antibody differentiation assay for established HIV-1 infection is comparable to that of the HIV-1 Western blot, but it produces fewer indeterminate results and accurately identifies HIV-2 antibodies, including those in specimens misclassified as HIV-1 by the HIV-1 Western blot (123, 124, 131, 132). Because of cross-reactivity, approximately 0.4% of reactive specimens remain dually reactive at the HIV-1 and HIV-2 spots after recommended dilution procedures (124). Although most dually reactive specimens represent HIV-1 infections with cross-reactivity to HIV-2 (133), one U.S. study of five dually reactive specimens found detectable HIV-2 RNA in the one specimen with strong HIV-2 reactivity, suggesting that strong reactivity at the HIV-2 spot indicated the need for further investigation with HIV-2 NAT (132).

The Geenius HIV-1/2 Supplemental Assay (Bio-Rad Laboratories, Redmond, WA) received FDA approval as a supplemental test in October 2014. The assay employs the dual path platform principle for rapid differentiation of HIV-1 from HIV-2 in serum, plasma, and whole blood specimens. The dual path principle appears to be more useful for multiplex testing for different antibodies on the same strip. Specimen is added to the cartridge device and flows from one direction across the test strip, onto which four separate HIV-1 antigens (p24, p31, gp41, and gp160) and two HIV-2 antigens (gp36 and gp140) have been adsorbed. The detection agent (colloidal gold conjugated to protein A) is added to flow from a perpendicular direction. The test uses an automated reader and software that provides interpretation of results based on the presence and intensity of the bands (163, 172).

**ANTIVIRAL SUSCEPTIBILITIES**

Resistance testing is an essential element in the management of antiretroviral therapy. It is important for the selection of initial regimens because of the prevalence of transmitted drug resistance in therapy-naive patients and for the selection of antiretroviral treatment for patients who are failing their current regimen due to the development of antiviral resistance (http://aidsinfo.nih.gov).

The clinical utility of HIV resistance testing has been evaluated in a number of prospective randomized clinical trials (79, 134, 135). Patients whose antiretroviral treatment was based on the results of resistance testing had greater decreases in viral load than did patients in whom the antiretroviral regimen was based on prior antiretroviral usage, and the use of resistance testing to guide treatment is cost-effective (136, 137). Two types of methods are available to assay for HIV resistance. Genotyping tests examine the population of viral genomes in the patient sample for the presence of mutations known to confer decreased susceptibility to antiretroviral drugs. Phenotypic assays measure viral replication of the patient’s virus in the presence of antiretroviral drugs. In addition, HIV tropism assays have become important for evaluating susceptibility to HIV entry inhibitors that target viruses that use CCR5 for cell entry. Table 6 provides a list of the currently available commercial HIV-1 resistance and tropism assays.

**Genotyping Assays**

The initial steps of genotypic assays include extraction of viral RNA from plasma and RT-PCR to amplify viral RNA sequences that code for portions of the viral genome that are targeted by antiretroviral drugs. These sequences include genes in the pol region of the virus for reverse transcriptase, protease, and integrase as well as envelope regions related to the entry and fusion inhibitors. The nucleotide sequence is determined and examined for the presence of known resistance mutations. This is accomplished most commonly by using automated sequencing technology. The nucleotide sequence of the gene of interest is obtained and compared to the sequence of wild-type virus to identify resistance mutations. The process requires alignment and editing of the sequence, comparison to the wild-type sequence, and final interpretation to identify mutations associated with resistance to specific antiretroviral drugs. FDA-approved kits containing sequencing reagents and the software programs required for sequence alignment and interpretation are commercially available. The Trugene HIV-1 genotyping kit and OpenGene DNA sequencing system (Siemens Healthcare Diagnostics), and the ViroSeq HIV-1 genotyping system (Abbott Molecular) perform in an equivalent manner (138). These tests detect mutations in the reverse transcriptase and protease genes but do not detect mutations associated with resistance to the integrase or entry inhibitors. Additional genotypic tests that detect mutations associated with other classes of drugs, such as integrase inhibitors (raltegravir, elvitegravir, dolutegravir) and entry inhibitors (enfuvirtide, maraviroc), are available in commercial laboratories but they are not sold as stand-alone kits. The databases used for interpretation of resistance mutations require regular updating as the number of new antiretroviral drugs continues to expand (173).

One limitation of genotypic assays is that they are only able to detect mutants that comprise major fractions of the
patient’s virus: resistant variants must constitute at least 25 to 30% of the virus population (139). Although the clinical significance of resistant mutations that are present at low levels remains to be fully elucidated, there is evidence that minor mutations that are missed by standard genotyping assays can lead to failure of subsequent treatments (140). Because standard genotyping assays lack sensitivity for low-frequency drug resistance mutations, efforts are underway to increase sensitivity by various methods including PCR-based assays (141), single-genome analysis (142), and deep sequencing (143, 144). These techniques are not FDA approved and the single-genome sequencing approach is not yet a practical clinical tool because the process is expensive and labor-intensive. However, next-generation deep-sequencing technologies offer the promise of reducing the cost of sequencing, and evaluations of this approach for clinical laboratories are underway (143).

### Phenotyping Assays

Phenotyping assays measure the ability of HIV-1 to grow in the presence of various concentrations of an antiretroviral agent. The amount of drug required to inhibit virus replication by 50% or by 90% is determined and given as a 50% or 90% inhibitory concentration (IC$_{50}$ or IC$_{90}$). The IC$_{50}$ or IC$_{90}$ obtained with the patient sample is compared to a control wild-type virus, and the result is reported as a relative difference. Early phenotypic resistance assays were labor-intensive because they necessitated the isolation and culture of HIV from the patient’s specimen. Currently, commercially available methods use HIV-1 RNA amplified from plasma and are based on recombinant DNA technology. These phenotypic assays are automated but remain labor-intensive and technically complex. They have not been developed into a kit format and are only performed at commercial laboratories such as Monogram Biosciences (South San Francisco, CA). The first step involves extraction of HIV-1 RNA from plasma. Reverse transcription and PCR amplification of the protease and RT genes follow. The amplified genes from the patient’s specimen are then inserted into vectors, and recombinants are used in culture to examine resistance. The PhenoSense assay (Monogram Biosciences) uses an HIV-1 vector with a luciferase reporter gene that replaces the viral envelope gene, allowing viral replication to be quantified by measuring luciferase reporter activity. PhenoSense tests are also available for measuring resistance to the entry inhibitor and integrase inhibitors. As with genotypic testing, the phenotypic assays can only detect mutant variants that comprise at least 25% of the viral population.

### Tropism Assays

An entry inhibitor, maraviroc, has brought about a need for viral tropism assays because the drug is only effective against virus that uses CCR5 as a coreceptor for entry. The drug is not active against CXCR4-tropic virus or dual/mixed tropic virus. The tropism assay must be performed prior to initiating maraviroc to determine whether the virus is CCR5 tropic. Like drug resistance assays, there are two general approaches in use, and two tropism assays are commercially available. The Trofile (Monogram Biosciences) uses the phenotypic approach, and SensiTrop II HIV coreceptor tropism assay (Pathway Diagnostics, Malibu, CA) uses the genotypic approach. For the Trofile assay, the env gene from the patient is amplified and used to construct pseudoviruses. Coreceptor tropism is then determined by measuring the ability of the pseudoviral population to infect CD41/U87 cells that express either CXCR4 or CCR5. Depending on which cells they infect, the viruses are then designated CXCR4 tropic, CCR5 tropic, or dual/mixed tropic (145). The SensiTrop assay uses a heteroduplex tracking assay combined with sequence analysis to identify minor viral populations that may be CXCR4 tropic. Only patients that are solely CCR5 tropic are candidates for a CCR5 inhibitor. Resistance to maraviroc has been reported, as have results

from the development of mutations that allow the virus to use CXCR4 coreceptors or mutations that lead to structural changes in the envelope that prevent the drug from being effective (146, 147). In addition to the commercially available tropism assays, laboratories are developing additional research tools for the prediction of virus tropism, including prediction of affinity for CCR5 binding (148) and next generation sequencing to predict viral quasi-species binding to CXCR4 (149).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Use and Interpretation of Serologic Tests

Currently available conventional immunoassays are exquisitely sensitive and specific. False-negative results may occur during early infection before the appearance of antigen or antibodies (105, 106). Delayed seroconversion has also been reported in persons taking antiretroviral therapy for pre- and postexposure prophylaxis (150, 151). False-positive results are rare, but have been reported to occur transiently after recent immunizations and may also occur in recipients of experimental HIV vaccines (152–154). As with any screening test, positive predictive value may be low in populations with low prevalence. The currently FDA-approved rapid methods have comparable sensitivity to conventional immunoassays for established HIV infection, but they produce more false-negative results during early infection (155). False-negative and false-positive results occur more frequently with oral fluid than with blood or serum specimens (105, 112).

No single supplemental assay is adequate to confirm the presence of HIV infection in all specimens after a reactive initial immunoassay. The Western blot and IFA are less sensitive than either third- or fourth-generation immunoassays during early infection and may give false-negative or indeterminate results (91, 123). HIV-1 RNA may be undetectable in 2 to 5% of infected persons who are antibody-positive (97, 156). Therefore, in September 2014 the CDC and Association of Public Health Laboratories recommended a new diagnostic algorithm for use with serum or plasma specimens that no longer relies on the Western blot (Fig. 3) (96). This algorithm maximizes the ability to detect acute HIV-1 infections and to correctly classify HIV-2 infections. Testing begins with an initial HIV-1/2 antigen/antibody combo immunoassay. If reactive, this is followed by an HIV-1/HIV-2 antibody differentiation assay. Reactive results on the initial immunoassay and the antibody differentiation assay confirm the presence of HIV-1 or HIV-2 antibodies, and no further testing is then necessary. Specimens that are nonreactive or indeterminate on the antibody differentiation assay undergo testing with HIV-1 NAT. A reactive fourth-generation immunoassay result, negative antibody differentiation assay result, and reactive HIV-1 NAT result is consistent with the presence of acute HIV-1 infection; a nonreactive NAT indicates false-positive results from the initial immunoassay. The same sequence of supplemental tests should be performed if a third-generation assay is used as the initial test. Reports of HIV test results should specify all assays that were used, the results of each assay, and an interpretation of the test results. Suggestions for reporting language are available from the New York State Health Department website (https://www.health.ny.gov/diseases/aids/providers/regulations/testing/docs/guidelines_diagnostic_testing.pdf) and the Clinical Laboratory Standards Institute (157).

Positive results from the testing algorithm indicate the need for HIV medical care and an initial evaluation that includes additional laboratory tests (such as HIV-1 viral load, CD4+ lymphocyte determination, and an antiretroviral resistance assay) to stage HIV disease and to assist in the selection of an initial antiretroviral drug regimen. Up-to-date recommendations for the initial evaluation are maintained at http://aidsinfo.nih.gov/guidelines. No diagnostic test or algorithm can be completely accurate in all cases of HIV infection. Inconsistent or conflicting test results obtained during the clinical evaluation, or results inconsistent with clinical findings, warrant additional testing of follow-up specimens with different assays.

Specimens submitted for testing after a reactive rapid HIV test result proceed through this same algorithm, beginning with an antigen/antibody combo immunoassay. Assays used in this algorithm are not suitable for use with oral fluid, dried blood spots, or urine. Testing of these alternative specimens is conducted with the specific immunoassays and HIV-1 Western blot approved for these types of specimens.

![Diagram of diagnostic HIV testing algorithm showing sequence of follow-up testing.](https://doi.org/10.1128/9781555817381.ch82.f3)
Use and Interpretation of Qualitative HIV RNA and DNA Assays

In adults, HIV-1 RNA tests are primarily used to diagnose acute infection, either as part of the diagnostic algorithm or as part of strategies that conduct pooled testing of specimens that are immunoassay-negative (158, 159). Nucleic acid tests are needed for infant diagnosis because serological tests are not useful for the detection of HIV infection in infants; maternal antibodies can persist in uninfected, HIV-exposed infants until 18 months of age. Both HIV-1 RNA and DNA tests can be used for the diagnosis of neonatal HIV-1 infection. DNA has often been the preferred method for determining an exposed infant’s HIV-1 infection status, but recent studies suggest that HIV-1 RNA is more sensitive at birth and at 4 weeks of age (160). The DNA or RNA assay can be performed on whole blood or dried blood spots, but the specimen collected at birth must be a neonatal and not a cord blood sample; cord blood samples yield a high rate of false-positive results (161). Current recommendations are to test HIV-exposed infants within 14 days of birth, at 1 to 2 months, and at 4 to 6 months after birth; some experts also recommend testing at birth for improved treatment outcomes (162, 164). HIV-1 infection in neonates is diagnosed by two positive RNA or DNA tests performed on separate blood samples regardless of age. Qualitative test characteristics vary, and the population tested may influence the choice of test to be used. The Aptima test may be more sensitive than some HIV-1 DNA tests for the detection of non-B subtypes, CRFs, and group O virus. An advantage of proviral DNA tests is that they generally remain positive even in individuals receiving effective antiretroviral therapy and individuals that naturally suppress virus replication. However, no proviral DNA assays are currently FDA approved.

Use and Interpretation of Viral Load Assays

The clinical utility of HIV-1 viral load testing has been well established. Viral load assays are used widely to monitor changes in plasma viremia during antiretroviral therapy, because they are useful for predicting time to progression to AIDS and for monitoring responses to therapy. The magnitude of the decrease in viral load is dependent on the effectiveness of the antiretroviral therapy. The goal of optimum therapy is to suppress viral loads below the detection limit of the assay. Baseline testing of HIV-1 RNA viral load should be obtained before initiating therapy, and determinations should be repeated before changing antiretroviral regimens. After initiation of therapy, patients should be tested within 2 to 8 weeks to assess drug efficacy and then every 3 to 4 months to assess durability of response. Updated guidelines on using viral load to guide antiretroviral treatment are maintained at http://www.hiv.lanl.gov/content/sequence/HIV/mainpage.html.

Biological variation of HIV-1 RNA levels among clinically stable patients has been estimated to be approximately 0.3 log₁₀ (165). Reproducibility of commercial assays ranges from 0.1 to 0.3 log₁₀, depending on the region of the assay’s dynamic range. Changes in viral load values must exceed 0.5 log₁₀ copies/ml to represent significant changes in viral replication. The clinical implications of HIV RNA levels near the lower limit of quantitation in patients on antiretroviral therapy are controversial. Persistent HIV RNA levels that are >200 copies/ml are often associated with evidence of viral evolution and accumulation of drug resistance mutations (166); persistent plasma HIV RNA levels in the 200 to 1,000 copies/ml range should therefore be considered as virologic failure. “Blips” of viremia (e.g., viral suppression followed by a detectable HIV RNA level and then subsequent return to undetectable levels) are usually not associated with subsequent virologic failure (167).

Numerous studies comparing the performance of the conventional FDA-approved viral load assays show high correlations between assays in terms of net changes in plasma RNA levels after antiretroviral therapy (168–170). Early assays showed larger variations in absolute values between assays with the same sample, but current-generation assays have been standardized so that the differences in values between assays are narrowing. The two real-time RT-PCR assays show improved correlation and agreement between viral load values. Although there is improved overall agreement between the different viral load assays, it is still considered optimal for patient care to monitor viral load values over time with the same assay. Specifically, some variability exists among platforms in immunologically stable patients with very low viral loads near the limits of detection (170).

HIV-1 RNA load testing is sometimes requested to resolve equivocal serological findings, to facilitate the diagnosis of HIV-1 infection during the acute phase of infection, or for pediatric diagnosis. Viral load tests can be performed for these purposes with a physician’s order, but they are not approved by the FDA for the diagnosis of HIV-1 infection and should be validated within the laboratory prior to routine use for these purposes. False-positive results can be obtained because of contamination during specimen processing, carryover of amplified products, or by selecting incorrect thresholds for defining positivity.

Use and Interpretation of Resistance Assays

Clinical guidelines for the use of HIV-1 resistance testing in adults are published and updated on a regular basis (171). In general, resistance testing is recommended for patients entering care even if therapy is not immediately initiated, when initiating antiretroviral therapy, for patients failing therapy, for pregnant women, and for patients with acute infection. Genotyping assays are generally more widely available, technically easier to perform, faster, and less expensive than phenotyping assays. In some cases, a resistance mutation may be detectable before a change in the phenotypic has occurred, and therefore, genotypic and phenotypic results are not always correlated. One limitation of genotyping assays originates from the complexity of data that these assays generate. In the face of the rapid development of new drugs and new information on HIV-1 resistance, it remains challenging to keep databases updated on which mutations are associated with specific drug combinations. Updated lists of drug-resistant mutations for all classes of drugs are available at the International AIDS Society-USA website (http://www.iassa.org) and the Stanford University website http://hivdb.stanford.edu/.

Interpretation of HIV-1 genotyping results is complex; it requires knowledge of the identity of mutations associated with each drug, the interactions of resistance mutations, and the genetics of cross-resistance. Most systems use a rule-based approach; a group of experts establishes interpretation algorithms based on the types or combinations of mutations that are associated with resistance to specific drugs. In the Trugene and ViroSeq assays, these algorithms are used to generate automated HIV-1 genotyping reports. Depending on the mutations detected, the report will indicate, for each drug and each of the antiviral categories, whether HIV in the patient sample shows no evidence of resistance, resistance, or possible resistance, or if evidence is insufficient to categorize the virus in one of the three other categories. These rule-based systems provide easy-to-interpret information for clinicians, but the databases require regular updating. The manufacturer’s database update may lag behind the published literature, so clinicians may find it necessary
to refer to one of the online databases for the most up-to-date information. For this reason, it is very helpful for laboratories to report both the specific mutations and the interpretation to clinicians so they can easily use online databases.

Phenotyping assays provide results in a format that is more familiar to clinicians. Results are reported as a relative change in IC50 compared to wild-type virus. In addition, there is less need for expert interpretation because susceptibility is measured directly. One problem with phenotypic resistance testing is that drugs are used—but are not tested—in combination. Thus, synergistic effects are not detectable. Cutoffs for a significant change in IC50 can also vary greatly depending on the drug. Initially, biological cutoffs were established based on the reproducibility of the assays; however, over time, clinical cutoffs correlated with outcome have been established for most drugs. A second disadvantage to phenotypic testing is a longer turnaround time for a result.

Both genotypic and phenotypic assays generally only yield results if the plasma used for testing contains at least 500 to 1000 HIV-1 RNA copies/ml. Depending on the extraction method used, it may be possible to obtain results for specimens with a lower viral load. Concentration of the virus in the plasma by high-speed centrifugation may allow sequencing of specimens with viral loads of <500 copies/ml, but this process may also concentrate inhibitors and interfering substances. Because of the labor and expense involved with genotyping assays, laboratories should establish the lower viral load limit for reliable sequencing results. Cross contamination can occur with both genotypic and phenotypic resistance assays because both procedures rely on an RT-PCR step to amplify HIV-1 gene sequences. Both methods have clinical utility in managing patients and are widely used in clinical practice. However, the commercially available genotypic assays listed in Table 6 rely on bulk sequencing methods. To be detected, the resistant viral strain must constitute at least 20 to 30% of the viral quasispecies. Because of this limitation, minority resistant strains might be present that could be missed, and new methods such as allele-specific PCR and next-generation sequencing techniques have been developed for detecting drug resistance mutations that exist at low levels (141, 143, 144). Given their wider availability, faster turnaround time, and lower cost, most clinicians use genotyping for the initial evaluation of resistance. Phenotypic assays, on the other hand, can help in defining the significance of newly recognized resistance mutations and in elucidating the effects of complex mutation interactions, and may be very helpful in determining salvage regimens.

The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the CDC. The use of product names in this manuscript does not imply their endorsement by the U.S. Department of Health and Human Services.

**Human T-Cell Lymphotropic Viruses**

WILLIAM M. SWITZER, WALID HENEINE, AND S. MICHELE OWEN

---

**TAXONOMY**

Human T-cell lymphotropic virus types 1 and 2 (HTLV-1 and HTLV-2) are members of the *Deltaretrovirus* genus in the *Retroviridae* family (1). HTLVs likely originated from cross-species transmission of simian T-cell lymphotropic viruses (STLVs); combined, this group of viruses is also referred to as primate T-lymphotropic viruses (PTLVs) (2, 3). While the close phylogenetic relationships of HTLV-1 and STLV-1 indicate a simian origin for HTLV-1, HTLV-2 and STLV-2 are only distantly related, so the exact simian origin of HTLV-2 is unknown. Recently, two novel HTLVs were identified in hunters in Cameroon and were called HTLV-3 and HTLV-4 (2, 4–6). HTLV-3 likely originated from monkeys infected with highly related STLV-3 viruses (2, 4, 5). HTLV-4 is equidistant from all other HTVs and was recently found to have a gorilla reservoir in Cameroon (7, 8). HTLVs and STLVs are distinct from the *Lentivirus* genus that includes human immunodeficiency virus types 1 and 2 (HIV-1 and HIV-2) and simian immunodeficiency viruses (SIVs) (1). Classification of HTLV groups using Roman numerals was replaced over a decade ago with Arabic numerals following the guidelines of the International Committee on Taxonomy of Viruses (1).

**DESCRIPTION OF THE AGENT**

HTLV-1 and HTLV-2 are enveloped viruses about 80 to 100 nm in diameter; they contain an electron-dense, centrally located nuclear core with less prominent envelope spikes and bud from the cell surface. Electron micrograph studies have not been performed on HTLV-3 and -4 but likely possess morphologies comparable to HTLV-1 and -2. Within the core are two positive-sense single-stranded RNA genomes. Once a cell is infected, the RNA genome is converted by reverse transcriptase to DNA and integrates into the host genome.

HTLVs are complex retroviruses with regulatory genes in addition to the structural and enzymatic gag, pol, and env genes found in all classical retroviruses. HTLV-1, HTLV-2, HTLV-3, and HTLV-4 all have similar genomic organization: group specific antigen (gag), protease/polymerase (pol), envelope (env), accessory gene region (pX), flanked by long terminal repeats (LTRs) (Fig. 1). Each HTLV group is highly divergent, sharing about 60% nucleotide identity (8–10). The gag gene encodes the structural proteins, matrix (p19), capsid (p24), and nucleocapsid (p15) (Fig. 2). The pro and pol genes encode the protease and the reverse transcriptase enzymes, respectively. The env gene encodes the transmembrane (TM) and external or surface (SU) envelope glycoproteins, gp21 and gp46, respectively.

HTLVs use alternative splicing and internal initiation codons to produce several regulatory and accessory proteins encoded by at least four open reading frames (ORFs) located in the pX region of the viral genome between env and the Y' LTR (11, 12). The pX region encodes the spliced, regulatory proteins Tax and Rex and several additional ORFs, some of which are also believed to be involved in viral replication and transport (Fig. 1). Unlike other retroviruses, HTLVs also encode a protein on the antisense strand, called antisense protein of HTLV or APH, that is a repressor of Tax-mediated viral transcription (Fig. 1) (13). APH was first discovered in HTLV-1; it contains a basic leucine zipper (bZIP) motif and was thus originally called HBZ (HTLV-1 bZIP protein) (14, 15). HBZ is also believed to control cellular replication and promote T-lymphocyte proliferation associated with leukemia as seen in some HTLV-1-infected persons (13, 16, 17). APH proteins have now been identified in all PTLV groups, suggesting the evolutionary and biological importance of these proteins (8, 10, 13).

HTLV-1 and HTLV-2 use a receptor complex with three different molecules, including glucose transporter type 1 (GLUT-1), VEGF-165 receptor Neuropilin 1 (NPR-1), and heparin sulfate proteoglycans (HSPG), for cellular entry (18–23). HTLV-1 preferentially infects CD4+ T cells, whereas CD8+ T cells are the primary target for HTLV-2 (18). *In vitro* studies have shown that HTLV-3 can infect both CD4+ and CD8+ T cells and also uses GLUT-1, but does not need HSPGs or NPR-1 for cellular entry, suggesting it may use a different complex of receptor molecules (19). Cell receptor studies for HTLV-4 have not been reported yet.

**EPIEMIOLOGY AND TRANSMISSION**

Recently, meta-analyses of reliable epidemiologic data from about 1,100 published papers since the discovery of HTLV in 1981 showed that 5 to 10 million people worldwide are estimated to be infected with HTLV-1, with endemic foci in southwestern Japan, the Caribbean and surrounding islands, large parts of sub-Saharan Africa and Central and South America, some rare areas in Melanesia, the Middle East (northern part of Iran), and Romania (24). The seroprevalence rate in adults ranges from 2 to 17% in the Caribbean.
islands and the highest rates (1.7 to 17.4%) are observed in southern Japan (24, 25). While similar meta-analysis estimates of global numbers of HTLV-2 infections have not been reported, it is endemic in Amerindian tribes throughout the Americas, as well as in a few Pygmy tribes in Central Africa with seroprevalences of about 3% in Pygmies, 1 to 5.8% in South America, 8 to 10% in Central America, and 2 to 13% in North America (26-29). HTLV-3 and HTLV-4 have only been found in a few primate hunters in Cameroon and do not appear to have spread locally or globally, though screening has been limited to only certain non-African populations (2, 4, 5, 30-32). In all areas of endemicity, HTLV-1 and -2 seroprevalence increases with age, especially in women (24, 25, 33). In the United States and Europe, the seroprevalence for both HTLV-1 and HTLV-2 among low-risk populations is less than 1% (34, 35). However, high-risk populations such as intravenous drug users (IDUs) in the U.S. and Europe, in whom HTLV-2 infection predominates over HTLV-1 infection, are reported to have seroprevalences from 0.4 to 20% (24, 25). African-American IDU populations, especially in New Orleans, are at increased risk for HTLV-2 infection (25). IDUs in South Vietnam showed a very high prevalence (>60%) of HTLV-2 infection, believed to have been introduced and spread by American military personnel during the Vietnam war (36).

HTLV-1 and HTLV-2 infections are transmitted sexually (mainly male to female), vertically (mother to child, mostly by prolonged breast-feeding), and parenterally (drug use and blood transfusion) (24, 25, 33). In nonendemic populations, intravenous drug use and sex with IDUs are the most important risk factors for HTLV-2 transmission (24, 25, 33). Both cross-sectional and prospective studies support sexual transmission, and there was a strong concordance of seropositivity between spouses in an area where HTLV-2 is endemic (24, 25, 33). One study showed that transmission mode can affect viral evolution rates, with HTLV-2 strains transmitted between IDUs evolving 150 to 350 times faster than in mother-to-infant transmission (37). The increase in viral transmission rate between IDUs, which can be many transmissions per year, was proposed to account for the increase in the HTLV-2 evolutionary rate, whereas vertical transmission would be expected to occur just once every 14 to 30 years for a given viral lineage and thus would evolve more slowly (51, 70). This increased rate of transmission and evolution among IDUs may increase the risk for the emergence of HTLV-2 strains with a higher virulence.

Over the past 20 years, highly effective screening programs for volunteer blood donors have been implemented in Japan, Australia, the U.S., Canada, and several Caribbean and European countries to reduce the risk of transfusion-related HTLV-1 and HTLV-2 transmission (25, 33-35). For example, in the U.S. between 1991 to 1996, the incidence rate of seroconversion associated with HTLV in blood donors was estimated to be 1.59 per 100,000 persons per year (34), and the residual risk of transmitting HTLV infection by transfusing screened blood was estimated to be 1 in 641,000 (34). From 1998 to 2001, the estimated incidence of new infections among repeat blood donors to the American Red Cross (ARC) was 0.239 per 100,000 person years and the estimated risk of collecting blood during the infectious window period was 1.293,000 (38). More recently, the ARC found that the HTLV incidence and residual risk of transfusion-transmissible HTLV infection among repeat donors during 2007-2008 decreased to 0.21 per 100,000 person years and 1:3,394,086, demonstrating further the success of universal blood screening (39).

Many molecular epidemiologic studies have shown HTLV proviruses to be remarkably stable genetically, which has allowed strong resolution of HTLV phylogenies and molecular dating of these viruses (8, 10, 40-42). The differing evolution rates for HTLV-1 and HIV-1 are due to clonal expansion of HTLV-infected cells versus active replication of HIV-1 (43, 44). While the overall genome of HTLV is highly conserved, nucleotide divergence in the LTR, tax, pol, and gp21 env genes has been exploited to genotype HTLV-1, HTLV-2, and more recently HTLV-3 and -4 (30, 45-47). The impact of diversity and emerging variants continues to challenge HTLV serology. An understanding of phylogenetic relationships is therefore useful. There are at least seven major geographic HTLV-1 subtypes which evolved from STLV-1 through several independent interspecies transmissions between simian and human hosts at different geographic locations (2, 3, 48). Subtype A (cosmopolitan), subtype B (Central African), subtype C (Australo-Melanesian), subtype D (Central African, mainly among Pygmy tribes), subtype E found in an Efe Pygmy from the Congo, subtype F from persons in the Democratic Republic of Congo (DRC), and subtype G from primate hunters in Central and West Africa (2, 3, 24, 48). HTLV-2 has three subtypes named 2a, 2b, and 2d (26, 29) whose primate origin has been linked to a single primate, since STLV-2 has only been found in bonobos (3, 49). Subtype 2a is commonly found among IDUs worldwide, whereas subtype 2b is found primarily among Amerindians and in some Pygmies from Cameroon. Subtype 2d has been found in only one Pygmy from DRC. Earlier studies proposed subtype 2c in one Amerindian tribe from Brazil; however, subsequent analysis of complete genomes confirmed this to be a subtype 2a variant (50). HTLV-3 most likely originated from recent cross-species transmissions in primates exposed to nonhuman primates in Cameroon (2, 4, 5, 28, 51). Phylogenetic analysis has identified HTLV-3 infection originating from at least four highly divergent STLV-3 subtypes such that there are also four HTLV-3 subtypes (2, 4, 5, 28, 51, 52). Subtypes A and C include the original STLV-3 identified in a baboon from East Africa and STLV-3 in spotted monkeys (Cercopithecus nictitans) from Cameroon, but human infection has not been reported with either.

![FIGURE 1 Genomic organization of HTLV. LTR, long terminal repeat; Gag, group-specific antigen; Env, envelope; Pol, polymerase (including reverse transcriptase and integrase); Pro, protease; Rex, regulator of viral expression; Tax, transcriptional activator; HBZ, HTLV-1 basic leucine zipper-like protein also known as the antisense protein of HTLV (APH). Miscellaneous accessory genes (not shown) are located in the pX region, located between the env gene and the 3’ LTR region of HTLV. The Gag and Env proteins are the most immunogenic, and antibodies to these proteins are commonly detected by serological tests (EIA and Western blotting). PCR assays are typically designed to detect regions within the LTR region and gag, pol, env, and/or tax genes. doi:10.1128/9781555817381.ch83.f1](image-url)
FIGURE 2  Serologic testing algorithm for the detection and confirmation of HTLV-1 and -2 infections. If the initial screening immunoassay (EIA or ChLIA) is reactive, a repeat assay with the same specimen is performed in duplicate. If one or both of the repeat tests are reactive, the specimen is classified as repeatedly reactive and supplemental testing is done for confirmation. WB criteria shown are those used by the manufacturer and not the U.S. Public Health Service working group. In some cases, further follow-up is done using HTLV generic and/or type-specific PCR. *, HTLV-3 and -4 PCR is suggested if patient is linked to Cameroon or West Central Africa. r21e, recombinant p21 envelope (Env) protein; rgp46I and rgp46II, recombinant glycoprotein in Env specific for HTLV-1 or HTLV-2, respectively; Gag, group specific antigen; PBMC, peripheral blood mononuclear cells. doi:10.1128/9781555817381.ch83.f2

subtype (53–55). Subtype B includes both STLV-3 and HTLV-3 from West-Central Africa, while subtype D occurs in both monkeys and a human from Cameroon (2–5, 28, 49, 51, 55). HTLV-4 has only been identified in a single hunter from Cameroon (2). These studies suggest that cross-species transmission of a wide range of STLV lineages to humans is ongoing and not limited to rare historical events. It is currently unknown whether HTLV-3 and -4 represent dead-end infections in humans or have the potential to spread regionally or globally. A new STLV group, STLV-5, has been proposed recently for a macaque STLV originally classified as STLV-1 since detailed phylogenetic analysis showed it is highly divergent from STLV-1 (56, 57). A human counterpart of STLV-5 has not yet been found. The genetic heterogeneity within HTLV has provided valuable information on geographic clustering, movement of ancient populations, and viral transmission (3, 8, 10, 24, 40, 41, 48, 58, 59).

CLINICAL SIGNIFICANCE
HTLV-1 has been associated with two major diseases: adult T-cell leukemia/lymphoma (ATLL) and HTLV-1-associated myelopathy/tropical spastic paraparesis (HAM/TSP). Disease occurs in less than 5% of infected individuals (24, 25, 33). ATLL exists in four forms: acute, chronic, smoldering, and T-cell non-Hodgkin's lymphoma. The acute form comprises about 75% of all ATLLs and can be rapidly fatal. ATLL is characterized by severe malignant proliferation of CD4+ CD25+ T-lymphocytes diagnosed biologically by seropositivity for HTLV-1, the presence of morphologically distinct CD3+/CD25+ lymphocytes with cleaved nuclei (flower cells), and clonal integration of HTLV-1 proviruses in the tumor cells, as detected by Southern blotting, inverse PCR, or newer technologies such as ultra-deep sequence analysis (17, 60, 61). Both Tax and HBZ are believed to be involved in ATLL development (13, 17, 62).

The clinical features of the chronic neuromyelopathy HAM/TSP are muscle weakness in the legs, hyperreflexia, clonus, extensor plantar responses, sensory disturbances, various urinary manifestations, impotence, and low-back pain (24, 25, 33, 62, 63). Spasticity of the lower legs is the main disability of HAM/TSP, with patients often requiring wheelchairs. The main biological diagnosis includes the presence of high titers of HTLV-specific antibodies in the serum and cerebrospinal fluid (CSF). Levels of HTLV-1-infected cells in the CSF are over twice those found in the peripheral blood for HAM/TSP patients compared to levels
in HTLV-1-infected persons with other neurological disorders, and PCR determination of proviral loads in these compartments thus has diagnostic value (62). The estimated lifetime risk of developing HAM/TSP among HTLV-1-infected persons is 0.2 to 4% but can vary according to the geographical area, and the disease occurs more frequently in persons over 40 years old (24, 25). Other uncommon inflammatory disease associations include infective dermatitis, uveitis, polyarthritis, thyroiditis, and pneumonitis and HTLV-associated arthropathy (24, 25, 33, 62, 63). There have also been case reports of increased opportunistic infections in HTLV-1-infected persons such as cytomegalovirus (CMV), Pneumocystis jiroveci, herpes zoster, Cryptococcus, and Mycobacterium avium (25). Increased viral load has been identified in both ATL and HAM/TSP patients, compared to asymptomatic infected persons, and is one of the best predictors for disease development, though patients with high proviral loads can remain asymptomatic for decades (24, 25, 33, 62).

HTLV-2 has not been definitively associated with malignancy; however, it has shown rare association with a neurological disease resembling HAM/TSP that progresses more slowly and with milder symptoms (25, 64). The estimated lifetime risk of disease development for HTLV-2-infected persons is unknown but appears to be less than that estimated for persons with HTLV-1 infection (25, 26). While the majority of HTLV-2-infected persons remain asymptomatic (>95%), recent studies report an increased incidence of infectious diseases (such as bronchitis, pneumonia, tuberculosis, and kidney and/or bladder infections) in HTLV-2-infected persons (25, 64). A recent study also found a higher association of all-cause cancer and cancer mortality in a cohort of HTLV-2-infected persons in the U.S., suggesting that more research is needed to understand the pathogenic potential of HTLV-2 (65).

HTLV coinfection with HIV can occur in high-risk groups, such as persons from endemic HTLV areas and IDUs. To date, a few studies evaluating the impact of HIV-1 coinfection with HTLV have shown that there is an increased frequency of HTLV-1-associated clinical outcomes (lymphoma and neurological disease), especially in persons with high CD4+ T cell counts. In contrast, a delayed progression to AIDS is seen in some HTLV-2/HIV-1-infected persons (66–68). Moreover, HIV therapy that includes highly active antiretroviral therapy in HTLV-2/HIV-1-coinfected persons does not affect HTLV-2 proviral burden but has been reported to provide a protective effect from AIDS progression (67, 69). These limited numbers of studies suggest that HIV-1 coinfection may increase the morbidity of the HTLV-1-infected patients. A recent study also showed that the Tax proteins of both HTLV-1 and HTLV-2 inhibited HIV-1 replication in vitro, suggesting a protective effect of HTLV in HIV-1 infection (66). However, additional studies are needed to determine if coinfection affects the mortality of HTLV-infected patients. The pathogenic potential of HTLV-3 and HTLV-4 is not known and is limited by the small number of infected persons identified in surveys of apparently healthy populations (2, 4, 5, 28). In addition, limited studies of persons receiving care at outpatient clinics in Europe or individuals with some cancers in the U.S. have not identified evidence of HTLV-3 and HTLV-4 infection (30–32, 70).

Treatment options for HTLV-associated diseases are limited (17, 25). Chemotherapy has not proven effective against aggressive ATL forms (71–73). Although zidovudine (AZT) and alpha interferon (IFN-α) yield some responses and improve ATL prognosis, alternative therapies are critically needed (71–73). New drugs such as arsenic trioxide, proteasome inhibitors, retinoids, and angiogenesis inhibitors, as well as cellular immunotherapy, are under investigation (71–73). Antiretroviral treatments such as lamivudine and high-dose IFN-α and IFN-β have been evaluated with HAM/TSP patients and resulted in decreases in proviral loads, alterations in T-cell phenotypes, and anti-tax cytotoxic T-cell frequency changes (74). However, results of further follow-up on immunomodulatory therapies have been disappointing, and combination antiretroviral therapies (zidovudine and lamivudine) have been discouraging because of only partial or temporary success in decreasing proviral loads (75, 76). One study using STLV-1-infected baboons treated with zidovudine and sodium valproate showed significant viral load reduction, but clinical trials in HTLV-1-infected humans using both therapeutic agents have not been reported (77). Symptomatic or targeted treatment is still the foundation of HAM/TSP therapy (74, 75). Recently, the integrase inhibitor raltegravir was shown to have potent in vitro anti-HTLV-1 activity (78). However, the clinical effects of raltegravir treatment are not clear. In a small study of two persons with HAM/TSP and three asymptomatic HTLV-1-infected persons, treatment with raltegravir for 12 months did not show any sustained reduction in proviral load (79). For uveitis, topical and systemic corticosteroids appear to improve sight, whereas infective dermatitis responds well to antibiotic treatment (25).

Although animal model studies of various HTLV vaccines have induced neutralizing antibodies (nAb) and strong cytotoxic T-lymphocyte responses using peptides, and synthetic inhibitory peptides and nAb have blocked envelope-mediated viral entry, these vaccines have not yet been used in clinical trials (25). Recently, a subunit vaccine composed of recombinant SU proteins was successful in robustly activating cell-mediated cytotoxic responses and neutralized viral infectivity in mouse models (80). While these studies are promising for development of potential HTLV vaccines, more research is needed to determine their antiviral and prophylactic efficacy.

**COLLECTION AND STORAGE OF SPECIMENS**

Serum or plasma is suitable for use in serologic assays for HTLV detection and can be drawn at the time of presentation. Samples should be redrawn at 3 months from seronegative patients who are suspected of having HTLV infection, or those with seroindeterminate Western blot patterns, and should be retested to capture potentially infected persons during the seroconversion window period (81). Alternatively, these persons can also be tested by PCR to investigate possible infection, though these assays are not yet FDA approved. Serum and plasma specimens can be stored at 4°C or frozen for later use. Package inserts should be consulted for storage limitations and limitations on the number of freeze-thaw cycles permitted. Fresh whole blood for the preparation of peripheral blood mononuclear cells (PBMCs), and not plasma or serum, is an appropriate specimen for nucleic acid testing (NAT) and virus isolation since HTLV-1 and HTLV-2 are cell-associated viruses. PBMCs are typically isolated from fresh whole blood on a Ficoll-Hypaque gradient (discussed in chapter 80). Heparin as a blood anticoagulant is not recommended for NAT as it interferes with the enzymatic used in PCR. DNA is prepared using standard methods and can be stored at −20°C until needed. For virus culture, whole blood is collected in sodium citrate, EDTA, or heparin tubes and PBMCs are isolated on a Ficoll-Hypaque gradient.
DIRECT EXAMINATION

PCR Detection of Nucleic Acids

Amplification of proviral DNA by PCR is the preferred method for determining infection status, testing the validity of serologic assay results, distinguishing among the four HTLV groups, and studying tissue distribution in vivo (81). Qualitative PCR procedures utilizing primers in the pol, env, or tax genes and the LTR have been used to confirm and differentiate between HTLV-1 and -2 (and more recently HTLV-3 and -4) infections (Table 1) (2, 45, 46, 70, 82). These assays utilize HTLV consensus primers that allow amplification of all four viruses, with typing achieved either by hybridizing the product to an HTLV-specific probe or by sequence analysis. A second approach employs type-specific primers and probes in separate amplifications. The PCR products can be detected with labeled internal probes by Southern blot hybridization and with sequencing (45, 82). Most of these assays are performed for research use only, but some are now offered by commercial laboratories.

Viral detection and quantification of proviral DNA can be performed simultaneously using real-time PCR; viral load estimation from plasma is not feasible in HTLV infection since these viruses are cell-associated (30, 47). Noncommercial real-time PCR assays have excellent sensitivity and specificity and a broad dynamic range, from 10^6 copies/reaction, and have been used to define the relationship between proviral load and both pathogenesis and person-to-person transmission risks (25, 83). For example, proviral load is higher among HAM/TSP and ATLL patients than among asymptomatic carriers, suggesting that proviral load may be a prognostic indicator for future disease development (25, 33, 62, 68, 84). Both sexual and mother-to-child transmission are associated with higher HTLV proviral load in the index case (25, 33, 62, 68, 84, 85). Thus, quantification of HTLV proviral load has provided a better understanding of correlates of transmission and disease progression (25, 33, 62, 68, 84).

VIRUS ISOLATION AND IDENTIFICATION

Isolation of HTLV has been difficult since these viruses are cell-associated (25, 86). Nevertheless, cocultivation of HTLV-infected PBMCs with activated, allogeneic HTLV-

| TABLE 1 | Summary of serological and supplemental confirmatory tests for HTLV infection |
|--------------------------|-------------------------------|------------------|--------------------------|
| Detection method         | Description                    | Reference(s)     | Availability in U.S.*   |
| Serological screening tests | EIA   | HTLV-1- and HTLV-2-infected cell lysates and/or recombinant antigens used to detect HTLV antibodies by colorimetric readout. Excellent sensitivity and specificity for HTLV-1 and -2. Sensitivity for HTLV-3 and -4 detection is unknown. | 25, 46, 81, 89 | One FDA-licensed test |
|                          | ChLIA | Similar to EIA but with chemiluminescent detection | 90 | One FDA-licensed test |
|                          | Particle agglutination | Viral lysate coats gelatin or latex particles. Antigen-specific antibodies bind, which results in agglutination of particles. Visual readout by operator. | Research use only |
| Serological supplementary tests | WB | HTLV-1 viral lysates ± recombinant antigens used to detect HTLV-1- and -2-specific antibodies. May contain recombinant antigens to differentiate antibodies to HTLV-1 and HTLV-2. HTLV-3 and -4 can give variable WB profiles. | 46, 89, 95 | Research use only |
|                          | LIA | Recombinant or peptide HTLV-1 and HTLV-2 antigens printed onto membrane. Antibodies to individual viral proteins are visualized. HTLV-3 and -4 can give variable results. | 46, 89, 96 | Research use only |
|                          | IFA | Antibodies bind to HTLV-1-, HTLV-2-, and STLV-3-infected cells. Detected by secondary anti-human antibody with fluorescent label. Differentiates between antibodies to HTLV-1, HTLV-2, and HTLV-3. | 25, 46 | Research use only |
| Nucleic acid detection tests | Qualitative PCR | Distinguishes between HTLV groups either by using HTLV consensus primers with typing done by HTLV-specific primers and probes in separate tests, or by sequence analysis | 45, 82 | Research use only |
|                          | Quantitative PCR | Determines proviral DNA copy number by limiting dilution, quantitative competitive PCR, or real-time PCR using HTLV degenerate and/or type-specific primers | 25, 30, 47, 83 | Research use only |

*FDA licensed; may be used for blood donor screening and as an aid in clinical diagnosis of HTLV-1 or HTLV-2 infection and related diseases. Research use only (not for clinical use).
negative PBMCs or cord blood cells is used to obtain viral isolates. Tissue culture supernatants are collected weekly for up to 4 to 6 weeks, and the presence of HTLV-1 or HTLV-2 p19 Gag antigen is tested using a research use only antigen capture assay (Zeptometrix Corp, Buffalo, NY). Alternatively, PCR methods can be used to monitor for infection in tissue culture cellular DNA. Because of the time required and labor-intensive nature of this method, virus isolation and tissue culture detection are generally not done for HTLV diagnosis but rather serve as research tools to further characterize the viruses. HTLV-3 and HTLV-4 have not yet been isolated in vitro.

**Typing Systems and Serologic Tests**

Testing for antibodies to HTLV-1 and HTLV-2 should be performed for all blood donors and patients presenting with relevant clinical signs and symptoms. In the U.S., since 1988 all blood donors have been screened for antibodies to both HTLV-1 and HTLV-2 using assays that include both HTLV-1 and HTLV-2 antigens (34, 81, 87). Testing for HTLV-1 and HTLV-2 should also be offered to persons who are from areas where HTLV is endemic, who engage in high-risk behaviors such as needle sharing, and who have had sexual contact with persons from either group. Currently, HTLV-1 and HTLV-2 testing is not routinely performed for fertility or pregnancy testing in the U.S. This is different from some European countries, as well as some islands in the West Indies, where recommendations have been made to test pregnant and breast-feeding women originating from areas of HTLV-1 endemicity like Japan (24, 25, 35). In addition, in the U.S. all donors of viable, leukocyte-rich cells or tissue (e.g., hematopoietic stem/progenitor cells and semen) are screened for HTLV-1 and -2 (88). However, since favorable outcomes for recipients of HTLV-1/2-positive organs in the U.S. have been reported, discussion is ongoing to eliminate pretransplant HTLV-1/2 screening if a proposed retrospective testing study shows a very low incidence of HTLV infection and an absence of clinical sequelae in donors and recipients (88).

The most common screening assays detect antibodies to HTLV in serum or plasma (25, 34, 81). The immunodominant regions of structural and regulatory proteins are well characterized and are used in diagnostic assays that detect and differentiate HTLV-1 and HTLV-2. The major tests for HTLV-1 and HTLV-2 are described in Table 1. The serologic testing algorithm consists of a primary screening assay followed by testing for confirmation and identification of HTLV type (Fig. 2). Assays for the specific detection and discrimination of HTLV-3 and -4 are not currently available (89).

Primary screening assays include enzyme immunoassays (EIA), chemiluminescent immunoassays (ChLIA), particle agglutination (Fujirebio America, Fairfield, NJ), and immunoassay fluorescence assays (IFAs) (Table 1). EIA are sensitive and simple colorimetric tests that use purified HTLV-infected cell lysates and/or recombinant antigens or synthetic peptides. ChLIA is similar to EIA, but uses chemiluminescence for the detection step. The addition of HTLV-2 antigens to screening tests significantly improved the detection of antibodies to HTLV-2, compared with results using tests that contained only HTLV-1 antigens (25, 90). The EIA and ChLIA can be automated and performed on a large scale (90). However, neither EIAs nor ChLIAs can differentiate between HTLV-1 and HTLV-2 infection because of significant sequence identity of the structural proteins between the two viruses; therefore, these screening assays are referred to as tests for HTLV-1/2.

Comparative analysis of various commercial screening assays containing both HTLV-1 and HTLV-2 antigens indicates that sensitivity ranges from 98.9 to 100% for confirmed HTLV-1-positive specimens and 91.5 to 100% for confirmed HTLV-2-positive specimens. Specificity ranges from 90.2 to 100% (25, 91, 92). Currently, one HTLV-1/2 EIA (Avioq HTLV-I/II Microelisa System, Avioq, Inc., Research Triangle Park, NC) and one HTLV-1/2 ChLIA (Abbott PRISM HTLV-I/HTLV-II, Abbott Laboratories, Abbott Park, IL) are licensed by the FDA and are available for use in the U.S. The Avioq assay was previously called the Vironostika HTLV-I/II Microelisa System and was manufactured by bioMérieux but was not commercially available in the U.S. for a period of time. Both FDA-approved assays have reported overall sensitivity point estimates of 100% (95% confidence interval [CI] of 99.97 to 100% for Avioq and 99.89 to 99.96% for Abbott), Specificities of 99.93% (95% CI, 99.89 to 99.96%) for Abbott PRISM HTLV-I/HTLV-II and 99.95% for Avioq (95% CI, 99.89 to 99.98%) were reported from clinical trial data that supported the licensure of these tests. Both assays can be used for blood donor screening and as an aid in clinical diagnosis of HTLV-1 and HTLV-2 infection and related diseases. Further attempts have been made to develop a dual EIA algorithm to increase the predictive values of HTLV tests (Fig. 2) (34, 93). Pooling of samples for seroepidemiologic studies has been proposed; however, pooled testing is not recommended for blood donor testing (94).

While most screening assays are highly sensitive, specimens containing low titers of antibodies to HTLV-1 and HTLV-2 from certain areas of HTLV endemicity, or specimens from early seroconverters, may be missed by EIA screening. NAT can be used to detect infected individuals either with low antibody titers or within their window period prior to the development of an antibody response (median window period, 51 days; range, 36 to 72 days) (34). However, while NAT assays may be commercially available, they are not licensed by the FDA, are used mainly for research, and are not in routine clinical use.

Supplemental confirmatory or differentiation tests for HTLV-1 and HTLV-2 infection include Western blots (WB) containing viral lysates supplemented with recombinant proteins, line immunoassays (LIAs; Innogenetics, Ghent, Belgium), and IFAs (Table 1). Although WB assays using purified viral lysates are highly sensitive for detecting p24 and p19 Gag antibodies, they do not always detect antibodies to native Env glycoproteins. An alternative approach used in a second-generation confirmatory assay is a modified WB that contains type-specific gp46 Env recombinant proteins from HTLV-1 and -2 and a truncated form of recombinant p21 Env (r21e) that reduces nonspecific reactivity, improves performance (specificity and sensitivity), and allows differentiation between HTLV-1 and HTLV-2 (MP Diagnostics WB 2.4; MP Biomedicals, Science Park, Singapore) (Fig. 3) (95).

LIA is another supplementary test consisting of recombinant and synthetic HTLV-1- and HTLV-2-specific antigens printed onto strips (INNO-LIA, Innogenetics) (96); this assay can differentiate between HTLV-1 and HTLV-2 infection. IFAs that detect binding of antibodies from a specimen to HTLV-1 or HTLV-2-infected cells can also be used to discriminate HTLV-1/2 infections and to determine antibody titer (24, 25). No confirmatory or supplementary assay has been approved or licensed for clinical use by the FDA; however, WB and LIA have been certified for use in Europe.
FIGURE 3 Western blot (WB) analysis of representative plasma or serum specimens from persons infected with (A) HTLV-1, (B) HTLV-2, (C) HTLV-1/2 untypeable, (D) indeterminate, and (E) HTLV-3 and HTLV-4. Representative seroreactivity patterns are shown for WBs from MP Biomedical (HTLV-2.4 version), which contain HTLV-1 antigens spiked with recombinant r21e (common to HTLV-1 and HTLV-2) and two external envelope recombinant proteins specific for HTLV-1 (rgp46) and HTLV-2 (rgp46). (A) Typical patterns for HTLV-1 reactivity (lanes 1 to 5), atypical reactivity lacking p24 Gag response (lane 6), and specimens with high antibody titers showing dual reactivity to both rgp46 proteins (lanes 7 and 8; titration of sera results in reactivity only to rgp46). (B) Typical patterns for HTLV-2 reactivity (lanes 1 to 6; note that reactivity to the p24 band is stronger than to the p19 band, which is usually absent from sera from HTLV-2-infected persons). (C) HTLV-1/2-positive but untypeable specimens, with reactivity to Gag (p24, with or without p19) and r21e but not rgp46 or gp46. Lanes 1 and 2: characteristic patterns of specimens that are usually found to contain HTLV-1 after additional testing; lanes 3 to 5: characteristic patterns of specimens that are usually found to contain HTLV-2 after additional testing. (D) Typical patterns from HTLV indeterminate specimens. Shown are typical HTLV Gag indeterminate profiles frequently found in plasma or sera from individuals originating from tropical regions (Central Africa, Papua New Guinea, etc.) (lanes 1 to 4) and those from low-risk populations (lanes 5 to 7). In the great majority of cases, neither HTLV-1 nor HTLV-2 infection could be demonstrated in samples with such seroreactivity using PCR testing. (E) Seroreactivity observed in HTLV-3-infected (lane 4) and HTLV-4-infected (lane 5) persons from Cameroon. Plasma from an HTLV-3-infected person (Cam2026ND) was weakly reactive to p24, p19, r21e, and rgp46. Plasma from the HTLV-4-infected person (Cam1863LE) was weakly reactive to p24, r21e, and gp46, but was strongly reactive to p19, similar to that seen in HTLV-1-infected specimens. Lanes 1 and 2 are from HTLV-1- and -2-infected persons, respectively, while lane 3 is reactive of negative control plasma. doi:10.1128/9781555817381.ch83.f3

and other areas of endemicity (Brazil, Argentina, West Indies, Iran, and Japan) to confirm any repeatedly EIA-reactive sample (35).

HTLV-3 and HTLV-4 were detected in research studies using commercially available EAs and WB assays or research-based IFAs that use HTLV-1 and -2 antigens (2, 46, 89). The sensitivity for detecting these new HTLVs with these assays is unknown, and a broad range of WB or LIA profiles is observed which can be confused with those of HTLV-1 or -2. Thus, PCR and sequence analysis are critical for resolving infection with the specific HTLV group.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

A typical algorithm for HTLV testing for diagnostic purposes is outlined in Fig. 2. If the initial screening immunoassay (EIA or ChLIA) is reactive, a repeat assay on the same specimen is performed in duplicate. If one or both of the repeat tests are reactive, the specimen is classified as repeatedly reactive (RR). The RR specimens are subjected to confirmatory supplemental testing that is typically done by WB when available (Fig. 3 and Table 1). Based on the data available in 1992, the U.S. Public Health Service (PHS) recommended that the diagnostic criteria for confirmation of HTLV-1 or HTLV-2 seropositivity by supplemental tests include demonstration of antibodies to p24 Gag and to native gp46 Env and/or r21e (81). Subsequent data with more sensitive assays suggest that alternative patterns of WB reactivity may be considered. The second-generation modified WB is the most commonly used research-use WB assay worldwide (MP Diagnostics WB 2.4). Specimens with reactivity to p19 Gag (with or without p24 Gag), r21e, and gp46 are referred to as HTLV-1-positive (Fig. 3A). Sera with reactivity to p24 Gag (with or without p19 Gag), r21e, and rgp46, and rgp46, are referred to as HTLV-2 positive (Fig. 3B). Specimens without immunoreactivity to any WB bands are considered negative for antibodies to HTLV-1 and HTLV-2 (false-positive EIA specimens). Specimens reacting with p24 Gag (with or without p19 Gag) and r21e, but with no reactivity to either rgp46 or gp46, are considered HTLV positive but untypeable (Fig. 3C) since PCR analysis of untypeable specimens has identified the presence of HTLV-specific sequences in some cases (2, 45, 82). This type of
reactivity could indicate the presence of divergent HTLV such as HTLV-3 and HTLV-4. However, to date HTLV-3 and -4 have only been found in Cameroonian (2, 12–14). Similar interpretive criteria are used for LIA (see manufacturer’s instructions).

Both the WB assays and LIA can give indeterminate results (immunoreactivity to a single HTLV gene product or multiple bands not defined as positive above, conditions that do not meet the criteria for seropositivity [Fig. 3D]). Antibody to only Gag proteins (p24, p19) is the most common indeterminate pattern that is observed in EIA-reactive specimens and is an area of intense investigation (97–99). Extensive PCR analyses using primers to detect multiple gene regions have failed to detect HTLV-1 or HTLV-2 proviral sequences in low-risk seroindeterminate persons, thus indicating that these individuals are not likely to be infected with HTLV-1 or HTLV-2 (45, 82, 97–99). The possibility that such indeterminate WB results may represent a novel retrovirus with partial homology to HTLV has been explored; however, no DNA amplification was observed using generic PCR primers that would detect HTLV-related viruses (45, 82) with the exception of HTLV-3 and HTLV-4 (2, 4–6, 51). Limited studies have established that individuals with indeterminate WB profiles generally do not have risk factors for HTLV infection (97–100). Indeterminate WB results among low-risk persons may represent antibodies to different viral, microbial, and cellular antigens that cross-react with HTLV proteins (97–99) (Fig. 3E). The predictive value of positive WB results is increased in patients with a history of any potential HTLV risk factor, including residence in endemic areas, history of a blood transfusion before 1988 or IDU, having multiple sexual partners without condom protection, or having sexual partners or parents from an endemic region (25, 81).

In rare instances, specimens with confirmed HTLV infection have an indeterminate WB pattern of reactivity to p19 Gag (in the absence of p24 Gag) and r21e (25, 100). Likewise, in some instances, antibody to r21e may represent an early antibody response during seroconversion (25, 81). Individuals with such reactivity should be retested in 3 months by EIA and/or PCR (81).

Recent data suggest that a very small number of U.S. patients with chronic progressive neurological disease with HTLV-indeterminate WB patterns may be infected with a defective HTLV or have HTLV-1 in low copy numbers (97). Persons who have clinical neurological symptoms or are from high-prevalence areas (e.g., African, Asian, South American, and Caribbean countries) with HTLV-1/2-indeterminate results should be further investigated to exclude HTLV-3 and HTLV-4.

In the U.S., decisions to accept blood donations and defer blood donors are currently based on screening test (ChLIA) results because of the lack of FDA-licensed supplemental tests. Persons who are ultimately confirmed to be antibody-positive to HTLV-1 or HTLV-2 (i.e., when licensed supplemental testing becomes available) will be permanently deferred from donating blood (34, 39). Blood donors with plasma specimens that are RR on screening but not confirmed as seropositive for HTLV-1 or HTLV-2 (individuals with false EIA-reactive and supplemental test indeterminate specimens and specimens for which supplemental testing was not performed) should be notified and deferred if the same test result is obtained on two separate donations (34, 39, 81). Screening tests are weighted toward better sensitivity than specificity because of the public health implications of false-negative results (101). Therefore, in the absence of known risk factors for a given blood donor, repeatedly reactive results from a single-test kit most likely represent false-positive reactions. However, in the absence of an FDA-approved confirmatory test it is difficult to understand the true specificity of a screening assay in finding RR results. The positive predictive value (PPV) of a test result is always a function of the prevalence of disease in the screened population, which for HTLV is extremely low in blood donors following implementation of screening in 1988 (48). The lower the prevalence, the lower the PPV, and the lower the specificity of a test. Thus, blood specimens are routinely tested using the dual-screening test algorithm (Fig. 2) to increase the probability of detecting actual infection (34, 39, 93). Since sensitivities are similar in each individual screening test and nonspecific reactivity is not, specimens reactive in both tests are likely true positives (34, 39). Nonetheless, WB-indeterminate results are seen in RR blood donors but have been shown by PCR to be HTLV negative in nearly all cases (82). Thus, additional testing by PCR or from specimens collected at a later time point is required to resolve infection in these persons. Many studies have reported high concordance between WB and PCR results of infected and uninfected U.S. blood donors (101–103).

Persons with HTLV-1- or HTLV-2-positive or indeterminate test results are counseled according to the guidelines established by the USPHS Working Group at CDC (81). These guidelines state that persons should be informed that HTLV is not HIV and that their risk of developing HTLV-related diseases is low. HTLV-1- or HTLV-2-infected persons are asked not to donate blood, semen, organs, or other tissues and not to share needles or syringes. To prevent transmission of HTLV, the infected person is counseled to use protective measures during sexual activity and women are counseled to refrain from breast-feeding. Persons who have indeterminate results on two separate occasions at least 3 months apart should be advised that their specimens were reactive in screening for HTLV-1/2, but that these results could not be confirmed by more specific tests. Further, they should be reassured that indeterminate results are very rarely caused by HTLV-1 or HTLV-2 infection. Repeat serologic and/or PCR testing should be offered to persons with indeterminate test results.

Use of trade names is for identification only and does not imply endorsement by the U.S. Department of Health and Human Services, the Public Health Service, or the Centers for Disease Control and Prevention. The findings and conclusions in this report are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

TAXONOMY

The influenza viruses are members of the family Orthomyxoviridae. Antigenic differences in two major structural proteins, the matrix protein (M) and the nucleoprotein (NP), are used to separate the influenza viruses into three genera within the family: Influenzavirus A, Influenzavirus B, and Influenzavirus C. Members of these three genera are also referred to as influenza type A, B, and C viruses, respectively. The influenza A viruses are further classified into subtypes based on characteristics of the two major surface glycoproteins, the hemagglutinin (HA) and neuraminidase (NA). Subtypes are recognized by the lack of cross-reactivity in double immunodiffusion assays with animal hyperimmune sera corresponding to each antigen (1). Eighteen HA subtypes and 11 NA subtypes are now recognized (2). Within a subtype, strains may be further subclassified into lineages, or clades, based on phylogenetic analysis of gene sequences. An example is the classification of the Eurasian lineage of highly pathogenic H5N1 strains into clades and the further subdivision of circulating strains into second-, third-, and fourth-order clades (3).

The following information is used in the naming of individual virus strains: type, species of origin (if nonhuman), geographic location of isolation strain, laboratory identification number, year of isolation, and subtype (influenza A viruses only). Thus, an example of a human strain of influenza is A/Texas/50/2012 (H3N2), while A/quail/Vietnam/36/2004 (H5N1) is an example of an avian strain isolated in an epizootic in Asia.

DESCRIPTION OF THE AGENTS

Orthomyxoviruses are enveloped, single-stranded, RNA viruses with segmented genomes of negative sense. Influenza A and B viruses have eight RNA segments, and influenza C viruses have only seven segments. Gene segments range from ~800 to ~2,500 nucleotides in length, and the entire genome ranges from 10 to 14.6 kb. The segmented genome of influenza viruses allows the exchange of one or more gene segments between two viruses when both infect a single cell. This exchange, called genetic reassortment, results in the generation of new strains containing a mix of genes from both parental viruses. Genetic reassortment between human and avian influenza virus strains led to the generation of the 1957 A(H2N2) and 1968 A(H3N2) pandemic strains, and it also played a role in the emergence of the pandemic A(H1N1)pdm09 virus in 2009 and in A(H7N9) avian strains from China that have caused infections in people (4).

Influenza viruses are spherical and pleomorphic, with diameters of 80 to 120 nm after serial passage in culture. Filamentous forms also occur and may be as large as several micrometers. The lipid envelope is derived from the host cell membrane, through which maturing virus particles bud, and HA and NA form characteristic rod-like spikes (HA) and spikes with globular heads (NA) on the virus surface. As its name implies, the HA can agglutinate red blood cells from both mammalian (e.g., human [type O], guinea pig, horse) and avian (e.g., chicken, turkey) species by binding to sialic acid residues. The HA protein, the major antigenic determinant, is used to identify viruses using immune sera. The lipid envelope surrounds the nucleocapsid, which has helical symmetry and consists of the genomic RNA segments, several copies of the polymerase proteins, and the NP. The matrix-1 (M1) protein is located between the nucleocapsid and the envelope, and the matrix-2 (M2) protein forms an ion channel across the envelope in influenza A viruses.

EPIDEMIOLOGY AND TRANSMISSION

Influenza viruses cause annual epidemics in areas with temperate climates, while in tropical climates, seasonality is less apparent and influenza viruses can be isolated throughout the year. In the temperate regions of the Northern Hemisphere, epidemics generally occur between December and March, and in the Southern Hemisphere, the epidemic period is usually between May and August. Epidemics are characterized by a sudden increase in febrile respiratory illnesses and absenteeism from school and work, and within a community, the epidemic period usually lasts 3 to 8 weeks. A single subtype (A) or type (B) of influenza virus usually predominates, but epidemics have occurred in which both A and B viruses or two influenza A virus subtypes were isolated. Global epidemics, or pandemics, occur less frequently and are seen only with influenza A viruses. Pandemics occur following the emergence of an influenza A virus that carries a novel HA and that can be readily transmitted from person to person. The pandemic strain may develop due to genetic reassortment following coinfection of a susceptible host with human and animal influenza viruses or through gradual adaptation of an avian strain to mammalian hosts.
Influenza viruses are transmitted from person to person primarily via droplets generated by sneezing, coughing, and speaking. Direct or indirect (fomite) contact with contaminated secretions and small-particle aerosols is another potential route of transmission. The relative importance of these different routes has not been determined for influenza virus infections. As for human infections caused by avian strains of influenza virus, direct contact with infected birds has been the most common factor of transmission, and direct inoculation into the pharynx or gastrointestinal tract may lead to infection (6).

There has been concern about the pandemic potential of avian strains of influenza since 1997, when several human cases of infection with A(H5N1) viruses occurred in Hong Kong in association with a large poultry outbreak. The outbreak was controlled by slaughtering all poultry in Hong Kong, but A(H5N1) viruses again caused outbreaks in poultry in China in 2003. By late 2005, the virus had spread to other parts of Asia, as well as to parts of Europe, Africa, and the Middle East. Human cases of A(H5N1) have been directly associated with outbreaks in poultry, and as of 2013, more than 600 human infections have been documented. Most cases have occurred in southeastern Asia, but several cases have also been documented in the Middle East and northern Africa. Most human cases have been due to direct contact with infected birds, but limited human-to-human transmission has also occurred (6). Several mutations in influenza virus genes are required for avian influenza viruses to replicate efficiently in mammalian cells and to transmit by droplet aerosol between ferrets, an animal model of human infection (7–9). A(H5N1) viruses continue to evolve and increase diversity, raising the possibility that they may acquire the ability to spread efficiently among humans.

Other avian influenza A virus subtypes are also of concern. An outbreak of A(H7N7) virus in commercial poultry farms in the Netherlands in 2003 was associated with respiratory illness in more than 400 persons, although only a single person died (10). In 2013, an A(H7N9) virus emerged in poultry markets in China, and more than 100 persons were infected (11). The greatest risk of infection has been exposure to infected poultry, similar to what has been observed with human cases of A(H5N1).

Swine are another source of novel influenza virus strains that infect people. In 2009, a novel influenza A(H1N1)pdm09 was initially identified as a cause of significant febrile respiratory illnesses in Mexico and the United States, and it rapidly spread to many countries around the world, prompting the World Health Organization (WHO) to declare an influenza pandemic. The new strain subsequently replaced previously circulating seasonal A(H1N1) strains. In recent years, a number of infections with another swine virus with an antigenically distinct HA (variant H3N2) were identified in several states (12). Fortunately, most cases are associated with direct or indirect contact with swine, and the A(H3N2)v strain has not spread among the population like the A(H1N1)pdm09 strain. The transmission of influenza viruses to people from avian and swine species highlights the need for vigilant surveillance for such events.

**CLINICAL SIGNIFICANCE**

Influenza A and B virus infections typically cause a febrile respiratory illness characterized by fever, cough, upper respiratory tract symptoms (e.g., sore throat, rhinorrhea, nasal congestion), and systemic symptoms (e.g., headache, myalgia, malaise). This constellation of symptoms is called influenza, although other clinical presentations, ranging from asymptomatic infection to viral pneumonia, also occur. Illness begins abruptly after a 1- to 5-day incubation period (average, 2 days). Fever generally lasts for 3 to 5 days, but dry cough and malaise may persist for several weeks. Complications include otitis media in children, sinusitis, viral pneumonia, secondary bacterial pneumonia, exacerbation of underlying cardiac or pulmonary disease, myositis (including rhabdomyolysis), neurologic problems (seizures, acute encephalitis, and postinfectious encephalopathy), Reye’s syndrome (associated with aspirin use), myocarditis, and death (13, 14). In contrast, influenza C viruses cause mild respiratory illnesses that are clinically indistinguishable from common colds.

Influenza A(H5N1) viruses also cause a febrile respiratory illness, although lower respiratory tract illness has been more prevalent. Upper respiratory tract symptoms may be absent, and gastrointestinal symptoms (watery diarrhea, vomiting, and abdominal pain) occur in some patients (6). Acute encephalitis may occur. Infection is associated with a high mortality rate (<60%), with most patients dying of progressive pneumonia. Viral replication is prolonged, and levels of several inflammatory mediators (e.g., interleukin-6, interleukin-8, interleukin-1β) in plasma have been higher in fatal than in nonfatal cases. Surviving patients develop measurable serum antibody responses 10 to 14 days after symptom onset (6). Influenza A(H7N9) virus infections also can cause severe respiratory illness and mortality, although overall, the severity has been less (<18% mortality) than that observed with A(H5N1) virus (15).

Influenza A and B virus infections spread rapidly through the community, with documented clinical attack rates as high as 70% after a common source exposure in an enclosed space. Epidemic disease is associated with an increase in hospitalization rates, especially in young children and elderly persons, and an increase in mortality rates in elderly persons. Mortality rates have been higher in epidemics caused by influenza A(H3N2) viruses than in those caused by A(H1N1) or B viruses in the past 20 years. Additional information on the clinical presentation, manifestations, and complications of the diseases can be found in clinical textbooks (13, 14).

Four licensed antiviral medications are available for the treatment of influenza virus infection. Amantadine and rimantadine are adamantanes that block the M2 ion channel. The adamantanes have no activity against influenza B viruses, and unfortunately, the currently circulating influenza A viruses have developed resistance so that the adamantanes are not clinically useful as monotherapy for these viruses either. Zanamivir and oseltamivir are NA inhibitors and are active against both influenza A and B viruses. Clinically significant resistance can occur following treatment of children or immunocompromised patients with oseltamivir. Treatment of outpatients with any of these medications should be initiated within 2 days of symptom onset to have demonstrable clinical benefit, although treatment of virus-positive hospitalized patients can be started at any time during the illness (16). These drugs have also been used for prophylaxis, but annual immunization with a trivalent influenza vaccine is the primary means of prevention of influenza.

Inactivated influenza vaccines (IIVs), live attenuated influenza virus (LAIV) vaccine, and a recombinant hemagglutinin vaccine (RIV) are licensed in the United States (17). The IIVs are derived from viruses grown in cell culture (cIIV4) or embryonated chicken eggs that are harvested and then inactivated. Viral proteins are partially purified
COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Influenza viruses infect the respiratory epithelium and can be found in respiratory secretions of all types. The level of virus shedding parallels the severity of clinical symptoms in uncomplicated influenza and is maximal in the first several days of illness. Samples should be collected during this time (first 2 or 3 days) to maximize the likelihood of virus detection. A variety of upper respiratory tract samples, alone or in combination, is routinely used for virus identification, including nasal aspirates, nasal wash fluids, nasal or nasopharyngeal swabs, throat swabs, and throat wash fluids. Virus titers tend to be lower in samples collected from the throat, so assays of these samples alone tend to be less sensitive (18, 19). However, reports of human infection caused by A(H5N1) strains suggest that the upper respiratory tract may have better diagnostic yields than samples collected from the nose (6). Lower respiratory tract samples, including sputa, tracheal aspirates, and bronchoalveolar lavage fluids, may yield virus and can be assayed when indicated. Viruses can occasionally be identified in nonrespiratory clinical samples (6).

Once collected, the clinical samples should be placed in viral transport medium. A number of transport media are suitable for influenza viruses, including veal infusion broth, Hanks’ balanced salt solution, tryptose phosphate broth, sucrose phosphate buffer, and commercially available cell culture medium. All of these media are supplemented with 0.5% bovine serum albumin or 0.1% gelatin to stabilize the virus and antimicrobials (antibiotics and antifungals) to inhibit the growth of other respiratory flora. However, the use of transport medium may interfere with the test performance for certain commercially available virus detection assays; the package inserts of these assays should be consulted if they are to be used for diagnosis (Tables 1 and 2). Influenza virus infectivity is maintained for up to 3 days when samples are placed in transport media and maintained at 4°C (20). Clinical samples should be transported to the diagnostic laboratory as rapidly as possible after collection under these conditions. If a sample cannot be cultured during this time frame, it should be stored immediately at -70°C; storage at higher temperatures (e.g., -20°C) leads to the loss of virus viability. Immediate transport and processing of samples after collection are necessary for immunofluorescence detection of virus antigen in exfoliated epithelial cells.

DIRECT DETECTION

Microscopy

Influenza viruses have been detected in clinical specimens by direct and indirect visualization of their typical morphological appearance by electron microscopy (EM). Immune EM has been the most sensitive EM method and allows differentiation of virus type and subtype when specific hyperimmune sera are used in the assay (21). However, large numbers of viruses (>10³ to 10⁶/ml) must be present in the clinical sample for successful detection using this diagnostic approach. Because of the need for an experienced microscopist and access to an electron microscope, the relatively high costs of assay performance, and the greater sensitivity of other diagnostic approaches, EM is not routinely used for diagnosis of influenza virus infection.

Antigen Detection

Antigen detection assays are used in a variety of formats to rapidly detect influenza viruses in clinical specimens and to confirm the identity of isolates grown in culture. These assays are based on detecting the interaction of viral proteins with specific antibodies. A variety of different formats are used, including direct and indirect fluorescent-antibody (FA) staining, radioimmunoassay, enzyme immunoassay, immunochromatographic assay, and fluoroimmunoassay.

FA assays identify viral antigens present on or in infected, exfoliated epithelial cells in respiratory secretions. Cells are collected on swabs or in aspirates or wash fluids and are washed in cold buffer to remove mucus before being applied and fixed to a microscope slide. Use of cytocentrifugation for application of the cells to slides can improve the number and morphology of cells for evaluation and enhance the accuracy of interpretation. Virus-specific antibodies are applied to the fixed cells; monoclonal antibodies directed against viral proteins that are conserved and expressed in large quantities (e.g., M, NP) are used because of their greater specificity compared with polyclonal sera and are available from a number of manufacturers. A fluorochrome is conjugated to the virus-specific antibody in direct FA (DFA) assays, and it is conjugated to a second antibody that reacts with the virus-specific antibody in indirect FA (IFA) assays. Antibody staining of cells is detected with a fluorescent microscope. Contaminating mucus can cause nonspecific fluorescence that can be reduced by treating the samples with N-acetylglucosamine or diethiothreitol and by centrifuging cells through Percoll. DFA and IFA assays take 2 to 4 hours to perform, although some diagnostic laboratories batch samples and do not perform tests as soon as the sample is received, delaying the availability of results. In theory, IFA assays should be more sensitive and less specific than DFA assays, but there is significant overlap in the sensitivities (50% to 90%) and specificities (generally >90%) of these assays noted in published reports (22). An advantage of FA assays is that sample quality can be determined by observing whether an adequate number of epithelial cells are present. In addition, kits are available to screen for other respiratory viruses (e.g., respiratory syncytial virus, parainfluenza viruses, adenovirus), as well as for influenza

and standardized to contain 15 μg of HA per dose. The IIVs may be trivalent (IIV3), containing influenza A(H1N1), A(H3N2), and B virus strains, or quadrivalent (IIV4), containing influenza B virus strains from two lineages (B/Victoria and B/Yamagata), as well as A(H1N1) and A(H3N2) strains. A high-dose IIV3 containing 60 μg of each HA is also licensed for adults 65 years and older. The RIV3 vaccine contains 45 μg of baculovirus-expressed, recombinant hemagglutinin for an A(H1N1) and A(H3N2), and B strain. The LAIV vaccine is quadrivalent and contains the same strains recommended for IIV4. A reassortant vaccine virus for each strain to be included is derived to contain six internal genes from a parental attenuated influenza (A or B) virus and the HA and NA from the WHO-recommended vaccine strain. The vaccine is licensed in the United States for use in persons 2 to 49 years old. It is given topically into the nose, and virus replicates in the upper respiratory tract. Due to constant virus evolution causing gradual antigenic changes in the HA protein, viruses included in the influenza vaccines must be updated periodically. The strains to be included in the vaccine are selected twice annually by WHO. Vaccine strains for northern hemisphere countries are selected in January and February to make vaccine for use in September. New vaccine alternatives, including those given by other routes and in combination with adjuvants, are undergoing clinical studies.
A and B viruses (Table 1). These multiplex assays allow efficient screening for other viral causes of febrile respiratory disease. Disadvantages include the need for specialized equipment (a fluorescent microscope) and the impact of technician expertise on assay performance characteristics (i.e., sensitivity and specificity). Each laboratory should establish its own performance characteristics compared to those of cell culture.

A number of immunoassays that use different reporter formats (isotopic, colorimetric, fluorometric, and chromatographic) have been developed for the detection of influenza virus antigen in clinical specimens. Many of these assays take at least 2 hours to perform and have 50 to 80% sensitivity compared with culture methods (23). Rapid influenza diagnostic test (RIDT) kits use the immunoassay formats for rapid (<30 min) detection of influenza A and B viruses in clinical specimens and are used much more commonly than other antigen detection immunoassay formats (Table 2). The kits use monoclonal antibodies to detect the presence of the influenza A or B nucleoprotein by enzyme immunoassay or chromatographic immunoassay. All of the kits provide results within 30 minutes, and some of them can be used as point-of-care tests (i.e., those classified by the Clinical Laboratory Improvement Amendments [CLIA] as waived). The types of specimens that are appropriate for testing vary among the kits, and specific instructions for sample collection and processing must be followed for optimal results. Assay performance characteristics in clinical settings are affected by the age of the patient (generally lower sensitivity in adults), the amount of virus in the clinical sample, and the type of specimen analyzed (16, 22). The sensitivity of RIDTs for identification of infection with influenza A virus strains containing novel hemagglutinins (e.g., H1pdm09, H5, H7) has frequently been lower than for previously circulating seasonal influenza A strains, so such tests should not be relied on when such infections are suspected (24, 25). In fact, a negative RIDT result should not prevent prescription of antiviral treatment of a patient with suspected influenza, especially when influenza is prevalent.

*Additional information on rapid tests can be found at the following website: [http://www.cdc.gov/flu/professionals/diagnosis/rapidlab.htm](http://www.cdc.gov/flu/professionals/diagnosis/rapidlab.htm). BAL, bronchoalveolar lavage; NA, nasal aspirate; NPS, nasopharyngeal swab; NS, nasal swab; TS, throat swab; NP, nucleoprotein.
*Test characteristics compiled from published literature on clinical samples.
*CLIA (Clinical Laboratory Improvement Amendments) waived laboratory assays employ methodologies that are so simple and accurate as to render the likelihood of erroneous results negligible. CLIA moderate-complexity assays require some knowledge, training, reagent preparation, processing, proficiency, ability to troubleshoot or interpret, and judgment in the performance of the test.
*Requires a reader for assay interpretation.
*Analysis of nasal aspirate/wash samples is classified as moderate complexity.
in the community, and follow-up testing with culture or RT-PCR should be considered (16, 26). The lower sensitivity of the rapid antigen tests for these viruses is not just due to using nucleic acid tests as a gold standard (24), and it varies depending on the kit used (27). The lower sensitivity associated with many of the RIDTs is leading to a reassessment of their status by the U.S. Food and Drug Administration (FDA) with a proposal to establish minimum sample sensitivity requirements using appropriate culture or molecular methods as the gold standard to monitor device performance over time to evaluate its ability to identify contemporary strains, and to have provisions for evaluating an RIDT’s ability to detect a novel re-assortant influenza virus when it emerges in the setting of a public health emergency (28).

A novel lateral flow immunochromatographic assay (AVantage; Arbor Vita, Sunnyvale, CA) has been cleared by the FDA for the identification in nasal or throat swabs of some influenza A(H5N1) strains. The NS1 protein of many clade 1 and 2 influenza A(H5N1) virus strains, but not clade 0 or seasonal influenza virus strains, contains a unique sequence that binds to PDZ domains (29). The test uses a recombinant protein containing a PDZ-binding domain and gold-labeled monoclonal antibody that recognizes a wide range of influenza A virus strains in a sandwich immunoassay. However, the performance of this assay with clinical samples has not yet been determined, and variability in the PDZ domain among H5N1 viruses has been reported that may affect the ability of this test to detect some A(H5N1) viruses.

**Nucleic Acid Analyses**

Molecular methods are increasingly being used both for the detection and for the characterization (see below) of influenza viruses. The most commonly used molecular method is RT-PCR. Viral nucleic acids are first extracted from clinical samples. The use of guanidinium thiocyanate with silica particles or commercial kits based on this approach reliably removes inhibitors of the enzymatic amplification that are often present in clinical specimens. Automated extraction instruments can be used in place of manual methods, decreasing the amount of time personnel must spend in sample preparation while increasing the reproducibility of the procedure. Reverse transcriptase is used to synthesize cDNA from viral RNA using random hexamers or virus-specific oligonucleotides as primers and a heat-stable DNA polymerase. Resulting amplicons are identified as virus-specific by using a variety of different methods (e.g., identification by size, hybridization, restriction enzyme mapping, sequencing).

A large number of different RT-PCR assays have been developed since the initial description in 1991 of an RT-PCR method to detect and distinguish influenza A, B, and C viruses (30). Assays that identify and distinguish different influenza virus types have targeted conserved genes, such as the matrix gene, and subtype-specific assays have amplified a portion of the HA gene. Nested PCR assays have been developed to improve assay sensitivity, but the inherent problem of carryover contamination associated with the use of this assay format limits its utility for most diagnostic laboratories. Real-time RT-PCR assays, which are less vulnerable to cross-contamination, can directly and rapidly detect influenza viruses in clinical specimens with a sensitivity approaching or exceeding that of culture (31). Multiplexed assays able to identify influenza viruses and other respiratory viruses have been developed and have performance characteristics that meet or exceed those of cell culture (32, 33). A variety of methodologies are used to detect amplified products, and different equipment is needed based on each assay’s characteristics. Multiplexed respiratory virus panels may be less sensitive than monoplex molecular assays that target a single virus (34, 35). The availability and FDA clearance of such assays (Table 3) are leading many diagnostic laboratories to these assays for respiratory virus diagnosis in place of the more time-consuming cell culture methods, and the improved sensitivity of molecular methods is replacing culture methods as the gold standard for influenza virus detection (34, 35).

A number of isothermal molecular amplification assays are undergoing evaluation for direct detection of influenza viruses in clinical samples. These include nucleic acid sequence-based amplification (NASBA), reverse transcription-loop mediated amplification (RT-LAMP), RT-helicase–dependent amplification (HDA), and RT-nickase enzyme amplification reaction (RT-NEAR) (36). Nucleic acid amplification occurs at a single temperature without requiring the cycling associated with PCR. All of these assays require initial synthesis of complementary DNA using a reverse transcriptase. NASBA uses T7 RNA polymerase to generate RNA amplicons, while the other listed methods use a DNA polymerase to produce DNA amplicons. For the DNA-based methods, separation of double-stranded DNA occurs enzymatically rather than as a result of the heat denaturation used in PCR reactions. Successful amplification is detected using a variety of different methods, including molecular beacon probes, turbidity assays (RT-LAMP), and probe hybridization using electrochemical readouts. As with RT-PCR assays, these isothermal amplification methods are more sensitive than culture or immunofluorescent antibody staining for the diagnosis of influenza virus infection, and they hold the promise for future use as potential point-of-care tests (37, 38).

**ISOLATION PROCEDURES**

Influenza virus isolation procedures should be performed under biosafety level 2 (BSL-2) conditions. When the clinical sample comes from a patient suspected to be infected with a highly pathogenic avian influenza (HPAI) virus strain, attempts at virus isolation should be performed under BSL-3 or higher conditions (39). Human clinical samples should be processed in separate laboratories and by staff members other than those handling clinical material from swine or birds (40).

**Cell Culture**

Influenza viruses can be grown in a number of different cell lines, including primary monkey kidney cells, Vero cells, human diploid lung fibroblasts, and Madin-Darby canine kidney (MDCK) cells (41, 42). Although some variability can be seen from season to season, MDCK and primary monkey kidney cell lines have similar isolation frequencies (41), and MDCK cells are more sensitive than Vero or diploid lung fibroblast cells (42). Thus, MDCK cells (CCL 34; American Type Culture Collection, Manassas, VA), a continuous polarized cell line, are the most common cell line used for isolation of influenza viruses and will support the growth of type A, B, and C strains. Continuous cell lines do not produce proteases that will cleave the viral HA, a step necessary to produce infectious viral progeny, so exogenous protease must be added to the maintenance medium. i-(Tosylamido-2-phenyl) ethyl chloromethyl ketone (TPCK)-treated trypsin at a concentration of 1 to 2 μg/ml provides the necessary proteolytic activity and is the

recommended protease for virus isolation. Chymotrypsin cleavage of the HA prevents the trypsin-mediated enhancement of viral infectivity, and TPCK treatment inactivates chymotrypsin activity, which may contaminate pancreatic extracts of trypsin.

MDCK cells are propagated in growth medium that contains 5 to 10% fetal calf serum (FCS). FCS contains inhibitors that prevent the production of infectious virus, so the FCS must be removed before inoculation of the clinical sample (43, 44). The inhibitory effects of FCS can be prevented by washing the cell sheet with Hank’s buffer or serum-free medium sufficiently to remove the protein-containing growth medium and then adding serum-free medium to cover the cell sheet. The clinical sample is then inoculated into the medium. After a 2-hour incubation, the inoculum-medium mixture is removed and replaced with serum-free medium supplemented with TPCK-treated trypsin. Alternatively, the sample can be inoculated directly onto cells with serum-free medium supplemented with TPCK-treated trypsin.

The replication of influenza viruses typically leads to cytopathic effects (CPE) and destruction of the cell sheet within a week following inoculation. CPE may be inapparent or absent in the presence of viral replication, but viral replication can be identified by the ability of the viral HA to bind to sialic residues on the erythrocytes of different animal species. Cultures should be screened every 2 or 3 days by hemadsorption (binding of erythrocytes to the viral HA of infected cells) or hemagglutination (cross-linking of erythrocytes by virus in the culture medium) for evidence of viral replication. To evaluate hemadsorption of cells grown in a tissue culture tube, the monolayer is first examined for CPE (Fig. 1A), and then the medium is removed and stored. The cell sheet is rinsed three times with 1 ml of 0.05% guinea pig red blood cells. One milliliter of 0.5% guinea pig red blood cells is then added, and the tube is stored at 4°C for 20 min, with the red blood cell suspension covering the cells. The tube is then shaken, and adherence of red blood cells to the cell sheet is determined microscopically (Fig. 1B). If cytopathic changes are scored as less than 4+ (i.e., less than 75% of cell sheet with CPE), the tissue culture tubes are rinsed with phosphate-buffered saline and re-fed with culture medium. The media collected initially from tubes with 4+ cytopathic changes can be used for further characterization. All procedures are performed in a BSL-2 safety cabinet, and care must be taken to prevent cross-contamination between cultures. Guinea pig red blood cells are more sensitive for detection of influenza virus than are avian cells, but influenza C virus does not agglutinate guinea pig red blood cells. Chicken red blood cells can be used in agglutination assays to identify influenza C viruses. Although most isolates will demonstrate growth within 1 week after inoculation, virus from samples with low infectious titers may require extended culture incubation for 10 to 14 days and additional blind passaging of negative cultures. Presumptive isolates are characterized further, as outlined below.

A disadvantage of traditional cell culture methods is the time needed to obtain a positive result (average, 4 to 5 days). More rapid methods have been developed by inoculating samples onto cell culture monolayers maintained in shell vials or multiwell plates. This approach can use either cell lines employed in traditional cell culture for identification of influenza virus (e.g., MDCK cells) or mixed-cell cultures (e.g., A549 cells plus mink lung cells) to screen for multiple respiratory viruses (R-Mix FreshCells; Diagnostic Hybrids, Athens, OH) that are reported to detect seasonal influenza virus strains as well as strains with novel hemagglutinins (24, 45). The cells are fixed after 24 to 72 hours, and type-specific monoclonal antibodies are used to detect viral antigen. Sensitivity can be lower than that achieved by using standard isolation methods, although R-mix cells have been reported to have 82 to 100% sensitivity for detection of influenza A and B viruses (24, 45). Shell vial assays have the disadvantage of not producing virus for additional studies (e.g., antigenic characterization). Screening for viral...
antigen by immunofluorescence also can be used at the end of the 10- to 14-day incubation period for standard culture before discarding of cells (46). This step is usually not necessary if screening by hemadsorption or hemagglutination is being performed, but it may detect virus in the absence of cytopathic changes if other strategies for virus detection are not used.

**Isolation from Embryonated Chicken Eggs**

The amniotic and allantoic cavities of 10- to 11-day-old embryonated chicken eggs are inoculated with the clinical sample for isolation of influenza A and B viruses. Seven- to 8-day-old eggs are used for isolation of influenza C viruses, although these viruses are also isolated using 10- to 11-day-old eggs. Embryonated eggs have endogenous proteases that are able to cleave the viral HA to yield infectious virus, so exogenous administration of proteases is not necessary. Inoculated eggs are incubated at 33 to 34°C for 2 or 3 days (5 days for influenza C viruses), then both amniotic and allantoic fluids are collected and assayed for hemagglutination activity. Influenza A and B viruses can grow both in cells lining the allantoic cavities and in those lining the amniotic cavities, whereas influenza C virus grows only in cells lining the amniotic cavities of embryonated eggs. If no hemagglutination activity is detected, influenza viruses may still be recovered by performing one or two blind passages. A pool containing equal volumes of the amniotic and allantoic fluids is inoculated into eggs as described earlier (46).

**IDENTIFICATION AND TYPING SYSTEMS**

A variety of methods are used to identify and characterize influenza virus isolates. The most common are based on immunologic or molecular approaches (Table 4). The initial step is to identify the isolate as an influenza virus and to distinguish it from other respiratory viruses that can agglutinate or adsorb red blood cells (e.g., parainfluenza viruses, mumps virus). In many instances, it is sufficient to identify the virus by type by using immunofluorescent or immunoperoxidase stains or an enzyme-linked immunosorbent assay (ELISA) using commercially available, type-specific antibodies targeting the viral NP or M proteins. These assays are particularly useful for working with cell culture isolates. The rapid immunochromatographic assays described in Table 2 may be able to identify isolates and type them, but data on the use of these assays for this purpose are limited, and these assays are not approved for this use. Importantly, the immunochromatographic assays may also give false-negative results when the quantity of virus in a cell culture harvest is low.

**Hemagglutination inhibition (HAI) assays** have been performed for more than 70 years and are still used for identification (40, 47). HAI assays can be type-, subtype-, or strain-specific, and they are particularly useful for examining antigenic relationships among strains of the same subtype. HAI is the WHO gold standard for antigenic characterization of influenza isolates and vaccine strain selection. Immune sera are usually produced in ferrets, sheep, or chickens. The hemagglutination activity of the virus is quantitated, and a standard amount of viral HA (4 HA units) is mixed with serial 2-fold dilutions of the immune serum and turkey or guinea pig red blood cells. A 4-fold or greater difference in HAI activities between the isolate and the reference strain is an indication that the isolate may be an antigenic variant. Because the HA undergoes antigenic change over time, subtype-specific antisera for interpandemic strains

must be prepared and standardized periodically. Thus, subtype identification by HAI is usually performed only as part of surveillance activities or investigation of a case in which there is a strong epidemiologic suspicion of infection with a nonhuman strain.

Molecular assays can be used for virus identification and characterization. The same RT-PCR assays used for detection of viruses in clinical samples can also be used to identify clinical isolates. An advantage of molecular assays over immunology-based assays is that the molecular assays can identify influenza virus subtypes even after significant antigenic variation has occurred because there are well-conserved regions of the HA gene that serve as targets for the primers and probes used for identification. Multiplex assays can also be used to distinguish influenza A and B viruses or to identify HA and NA subtypes (48, 49). Results are determined by identification of amplicon size, by hybridization to type- or subtype-specific probes, and by direct sequencing of the amplicons. If the sequences of different variants are known, it may be possible to identify unique differences by digesting amplified DNA with restriction endonucleases that generate restriction fragment-length polymorphisms (RFLP) unique to each strain. For example, this method was used to distinguish two A(H3N2) variants that cocirculated during a single season (50). Influenza A/ Wuxian/59/95 (H3N2) virus-like variants generated amplicons that could be digested with the BstF5I restriction enzyme, whereas amplicons from influenza A/Sydney/55/97 (H3N2) virus-like variants could not. Given the difficulty to design and perform RFLP analysis, together with the reduced cost and time required to perform DNA sequencing, direct sequencing of amplicons, or the entire HA gene, has become a more common way to track and characterize specific strains. Electrospray ionization/mass spectrometry is another method that can be used to analyze virus-specific PCR amplicons and identify novel variants and reassortants when the viral genome sequence is unknown, as was done with the initial identification of the A(H1N1)pdm09 virus as a likely swine-origin virus (51).

DNA microarrays are being used increasingly in diagnostics for identification of specific pathogens. Oligonucleotide probes are arrayed on a chip or membrane, and hybridization of the specific sequences is then detected. The viral sequences can be generated by cDNA synthesis from viral genomic RNA or by amplification of fragments of genomic RNA by RT-PCR. Microarray analysis strategies have been developed that distinguish influenza virus types (A versus B) and subtypes (H1, H3, H5, N1, and N2) (52–54) but currently are too costly for most individual laboratories to develop. Nevertheless, this technology has the promise of being able to more fully characterize strains in surveillance studies and to provide rapid and accurate identification of influenza virus strains.

SEROLOGIC TESTS

Influenza virus infections are also identified by using serologic methods. Most persons have been infected previously with influenza viruses, so detection of virus-specific immunoglobulin M or other immunoglobulin subclasses has not been particularly useful (55). An exception may be detection of immunoglobulin M responses to novel HAs from avian strains (56). Instead, paired acute- and convalescent-phase serum samples collected at least 10 days apart are needed to detect a significant (4-fold or greater) increase in serum antibody levels. The requirement for paired sera to identify infection makes serology an impractical method for identification of influenza virus infection in the acutely ill individual. Instead, serology is used primarily in surveillance and in epidemiologic studies. The most widely used assay formats include complement fixation, HAI, neutralization, and enzyme immunoassay. Complement fixation identifies type-specific antibodies to the NP, but it is not as sensitive as the other commonly used serologic assays in detecting significant rises in antibody levels. HAI and neutralization antibodies in serum are functionally significant in that higher serum antibody levels correlate with protection from infection and illness, and these antibody levels are used to measure responses to vaccination as well as to identify infection. HAI antibodies block the binding of the viral HA to sialic acid residues on red blood cells and thus inhibit hemagglutination. Each of the components in the HAI assay may affect the outcome of the test.

Human and animal sera may contain nonspecific inhibitors of hemagglutination, but methods to remove these inhibitors have been developed (43). The source of the viral antigen can affect results in that virus initially isolated in cell culture may detect a greater frequency of antibody rises than egg-grown virus (57). The species from which the red blood cells are derived can affect assay results. Chicken and turkey red blood cells are commonly used to measure HAI antibody to human strains of influenza viruses, but they may fail to detect HAI antibodies to avian strains such as A(H5N1). Substitution of horse red blood cells can improve HAI assay sensitivity for detection of antibodies to avian influenza virus strains (58). Neutralizing antibodies block viral infectivity and provide a more sensitive assay for detection of antibodies to influenza A and B viruses (59). Although neutralization assays have been available for several decades, they are less standardized than HAI antibody assays (40, 60). Nevertheless, neutralization assays are the preferred method for detection of antigen to highly pathogenic avian influenza (HPAI) virus strains (60). Because these assays require the use of live virus, their use with HPAI virus strains is restricted to laboratories with BSL-3 or higher facilities. Enzyme immunoassays are also used for detection of antibody responses to whole-virus antigen or specific viral proteins. The conjugate and antigen used in the assay are factors that affect the performance characteristics (sensitivity and specificity) of these assays. Enzyme immunoassays used to measure specific immunoglobulin responses in a variety of clinical specimens (serum samples and respiratory secretions).

ANTIVIRAL SUSCEPTIBILITIES

Plaque inhibition assays are the gold standard for measuring susceptibility to amantadine and rimantadine, but the assays are cumbersome and time-consuming to perform. ELISA methods have also been used to measure decreases in the expression of viral antigens in the presence of these drugs. These assays can be used in combination with genotypic characterization of the M2 gene since in vitro and in vivo resistance to these drugs is associated with specific M2 gene mutations (61). RT-PCR amplification followed by RFLP analysis or direct sequencing of amplicons is a genotypic method used to identify resistant viruses (62). Amplification of the influenza A M2 gene followed by pyrosequencing is a rapid, high-throughput method that allows the rapid and reliable identification of adamantane (amantadine and rimantadine) mutations (63).

Cell culture assays do not reliably identify antiviral susceptibility to the NA inhibitors, zanamivir and oseltamivir. Instead, NA enzyme inhibition assays with chemilumines-
cent or fluorescent substrates are used to identify resistance (64). A commercially available diagnostic assay (NA-Star, Applied Biosystems, Foster City, CA) is available for in vitro screening of influenza virus isolates (65). The results of these assays also correlate with mutations in the NA gene that can be identified by sequencing (65). Molecular approaches can be used to identify known NA gene mutations associated with NAi resistance (e.g., E119V and R292K in A(H3N2), H274Y in A(H1N1), R152K in influenza B) (64, 66). Both traditional terminal deoxynucleotide (Sanger) sequencing and pyrosequencing of the NA gene have been used successfully to identify these mutations (67, 68).

Another strategy to quickly screen a large number of isolates is application of a real-time RT-PCR assay that uses a probe that recognizes wild-type (susceptible) NA sequence. This approach identified all A(H1N1) strains with a H274Y NA gene mutation (67).

Mutations in the HA gene may also lead to a resistance phenotype through decreased binding affinity of HA to cell surface receptors and decreased reliance on NA function to release budding viruses from infected cells. No reliable cell culture system currently exists for identifying HA resistance mutations, so identification relies on sequencing of the receptor binding site of the HA gene.

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

The results of a diagnostic test must be considered in the context of the overall setting in which the test is ordered. Clinicians play a critical role in assessing the plausibility of a test result, but the laboratory also can contribute to this appraisal. Seasonal, epidemiologic, and clinical factors are elements that must be evaluated in addition to the type of assay used. Unexpected laboratory results can be recognized by the laboratory as well as by the clinician. For example, a positive influenza test result when influenza is not recognized to be circulating in the community should prompt an assessment as to whether epidemiologic (e.g., travel history) or clinical (e.g., immunocompromised host) factors support the diagnosis of influenza virus infection. Similarly, a negative result, especially with a less sensitive assay (e.g., an RIDT), should not preclude prescription of antiviral treatment to a patient with signs and symptoms of influenza. Close interactions between the laboratory and clinician are a vital component of a quality-control program.

No diagnostic assay has 100% sensitivity and specificity, so false-negative and false-positive results can be expected to occur. Many factors that contribute to lowered sensitivity and specificity are known and can be addressed in ongoing quality control programs. False-negative results may be due to poor quality or inappropriate clinical sample collection, delays in sample transportation or processing, inadequate sample storage (e.g., wrong temperature or transport medium), the time of sample collection during the clinical illness (e.g., later in the illness than recommended, when viral shedding has decreased), and the performance characteristics of the diagnostic assay (i.e., lower sensitivity). False-positive results may also be due to other characteristics of the diagnostic assay (i.e., nonspecific reactions), as well as to cross-contamination within the laboratory, mislabeling of specimens, and microbial contamination. Standard operating procedures in the collection, transportation, and processing of clinical samples should be established and followed to minimize the occurrence of the inaccurate test results. Reagents should be standardized, and periodic assessments of assay performance should be performed with known positive and negative controls. The timing of these assessments will be based on the type and number of tests being performed and the sources of reagents.

Each laboratory must decide on the goals of its influenza virus diagnostic program in selecting the diagnostic assays to be performed. Rapid and sensitive assays can favorably impact patient management by allowing the prescription of targeted antiviral therapy and the institution of appropriate infection-control isolation procedures. Positive test results may form the basis for offering prophylactic therapy to close contacts of infected patients, especially those with high-risk medical conditions. Early and rapid laboratory diagnosis also can be important for evaluating influenza-like illnesses in the setting of a nosocomial outbreak, at the beginning of the influenza season (before influenza is recognized to be circulating in the community), and in persons with a history of contact with pigs or birds or travel to an area where influenza virus is circulating. The laboratory’s expertise, staffing, and available equipment also will influence test selection. For example, a fluorescent microscope and an experienced technician are necessary for the performance of immunofluorescence assays, and a thermal cycler along with other equipment is needed for RT-PCR assays. If the clinical specimen being tested comes from a patient who may be infected with an HPAI virus strain (e.g., H5N1), non-culture-based assays are currently recommended for laboratories that do not meet the BSL-3 or higher conditions recommended for growth of these strains (39). Commercially available antigen-detection assays or the more sensitive H5-specific RT-PCR assays may be performed using BSL-2 work practices. In the United States, influenza A virus-positive samples from patients meeting the clinical (febrile >38°C respiratory illness (cough, sore throat, or dyspnea) and epidemiologic (contact with poultry or domestic birds or with a patient with known or suspected A(H5N1) virus infection in an A(H5N1)-affected country) parameters for suspected A(H5N1) virus infection are referred to the Centers for Disease Control and Prevention (CDC) for further evaluation. Selected negative samples may also be sent to the CDC for analysis in consultation with the local public health department (39).

As new strains of influenza virus emerge, the sensitivities of established methods to detect these strains may change. For example, cell lines may have diminished sensitivity to new strains, or the ability to detect influenza virus antigen in infected tissue culture cells (e.g., by hemadsorption) may decrease (46). Thus, it is prudent to reevaluate periodically the performance characteristics of established methods, especially if results do not correlate with those expected based on clinical and epidemiologic criteria.

Influenza diagnosis is also performed for reasons other than patient management. On the local level, knowledge that influenza is circulating in a community allows diagnosis of influenza based on clinical symptoms (febrile respiratory illness with cough) with a sensitivity (60 to 80%) similar to that of many rapid antigen tests (69). Influenza viruses isolated in national and global surveillance systems are characterized antigenically and genetically to identify variants. Information gained from these surveillance activities is used in the annual selection of strains for inclusion in updated trivalent influenza vaccines. Surveillance and characterization of isolates also allow the identification of infection with novel subtypes, as has occurred with influenza A(H5N1) viruses in southeast Asia and A(H7N7) strains in the Netherlands (70).

The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the CDC. The use of

TAXONOMY
The human parainfluenza viruses (HPIVs) and mumps virus are members of the Paramyxoviridae family. This family includes the Paramyxovirinae subfamily, to which both HPIV and mumps virus belong. However, within this subfamily, the Respirovirus genus is home for HPIV-1 and HPIV-3, and the Rubulavirus genus is home for HPIV-2, HPIV-4, and mumps virus. The Paramyxovirinae subfamily includes two additional genera: Morbillivirus, to which measles virus belongs, and Megavirus, to which Hendra and Nipah viruses belong. The Paramyxovirinae subfamily completes the Paramyxoviridae family. Within this subfamily are the Pneumovirus genus, which includes respiratory syncytial virus (RSV), and the Metapneumovirus genus, which includes human metapneumovirus. The Paramyxoviridae family of viruses produces significant human and veterinary diseases, with its effects noted among virus families as “one of the most costly in terms of disease burden and economic impact to our planet” (1).

DESCRIPTION OF THE AGENTS
Although some of the HPIV types and mumps virus are classified into different genera, they are all pleomorphic, enveloped, medium-sized helical viruses, usually ranging from 150 to 250 nm in diameter. All have single-stranded, nonsegmented RNA with negative polarity. The genome encodes six common structural proteins. The largest, L, is a polymerase. L, along with the phosphoprotein P and the nucleocapsid protein N (or NP), is associated with the viral RNA to make up the viral nucleocapsid. The surface glycoproteins, hemagglutinin-neuraminidase (HN) and fusion protein (F), project from the viral envelope and can be seen with an electron microscope. The sixth structural protein is a membrane (M) protein. In viral replication, N protein binds to viral RNA, L and P function in transcription and replication, and the HN and F surface glycoproteins interact with the M protein, which attracts completed nucleocapsids to areas of infected membrane that will become the envelopes of the new virions during budding. The HN surface glycoproteins also function in virus-host cell attachment via sialic acid receptors, and the F proteins function in virus-host cell membrane fusion that allows the viral nucleocapsid to enter and infect a host cell.

Four serotypes of HPIV, types 1, 2, 3, and 4, have been identified. HPIV-4 can be further subdivided into HPIV-4A and HPIV-4B; because these are so closely related, they are considered HPIV-4 for the remainder of this discussion. Only one antigenic type of mumps virus has been identified, although strains show differences in expression of the small hydrophobic (SH) gene; 12 genotypes have been identified and are designated A to L. HPIV and mumps virus are inactivated by temperatures above 50°C, organic solvents, UV irradiation, formalin treatment, low pH (3.0 to 3.4), drying, and desiccation. Preservation by freezing at −70°C or colder is effective, and the addition of 0.5% bovine serum albumin, skim milk, 5% dimethyl sulfoxide, or 2% chicken serum prior to freezing prolongs survival.

Although they are similar in structure and antigenic composition, HPIVs and mumps virus currently present very different pictures of disease production in the United States. The HPIVs are common agents of respiratory infections in children and adults in the United States, and virology laboratories routinely test for HPIV by direct antigen testing, virus isolation, and molecular methods. In contrast, mumps virus, which was considered one of the common diseases of childhood prior to the introduction of an effective vaccine in 1968, is now relatively uncommon. Although sporadic mumps outbreaks occur, most virology laboratories no longer focus on the isolation and identification of mumps virus. Because of these differences, the HPIVs and mumps virus are discussed separately below.

PARAINFLUENZA VIRUSES
Epidemiology and Transmission
HPIVs are thought to be transmitted by large-droplet aerosols and by contact with contaminated surfaces. The viruses have been shown to survive for up to 10 h on porous surfaces; however, HPIV-3 experimentally placed on fingers was shown to lose more than 90% of its infectivity in the first 10 min (2). Currently, HPIV-1, -2, -3, and -4 represent approximately 5% of all viruses isolated in routine hospital diagnostic laboratories (3) and 13% of viruses isolated from respiratory specimens (4). HPIV-1 occurs most often in the fall of the year and biennially. The incidence of HPIV-2 is generally lower than that of HPIV-1 and HPIV-3, occurring biennially with HPIV-1, in alternate years from HPIV-1, or yearly. HPIV-3 occurs yearly, in spring and summer, but can circulate year-long in temperate climates. HPIV-4 is rarely isolated, but diagnostic methods specifically targeting this virus are not as widely available.
**Clinical Significance**

HPIV-1, -2, and -3 are associated with upper respiratory tract infections in infants, children, and adults. The mean incubation period is estimated to be between 2 and 6 days for HPIV infection (5). These are typically fairly mild and self-limited (6) and mortality is rare in developed countries (7). Reinfection is common because natural infection does not induce lifelong immunity. HPIVs accounts for the majority of cases of viral croup, which is the most common cause of upper airway obstruction in children of 6 months to 6 years of age. Croup is characterized by inspiratory stridor, barking cough, and hoarseness (8).

HPIV-1 is associated with up to 50% of cases of croup reported in the United States, with the majority of cases occurring in children of 7 to 36 months of age. HPIV-2 is associated with croup in immunocompromised or chronically ill children. HPIV-2 also causes typical lower respiratory tract syndromes in otherwise healthy children, with about 60% of infections occurring in children younger than 5 years of age; peak incidence is in children between 1 and 2 years of age. HPIV-3 is more frequent in infants younger than 6 months of age, with 40% of infections occurring during the first year of life. Only RSV causes more lower respiratory tract infections in neonates and young infants than HPIV-3. Although HPIV-4 is less frequently isolated, it can cause all of the different respiratory syndromes (9). As many as 7% of all hospitalizations for viral acute respiratory illness in children younger than 5 years of age have been shown to be due to HPIV infection (10). HPIV-1, -2, and -3 have also been found in as many as one-third of lower respiratory tract infections in children younger than 5 years of age in the United States and are second only to RSV as a cause of hospitalization for viral lower respiratory tract infections (9).

Although associated with infections in children, HPIVs have the potential for serious pulmonary infections in adults, with HPIV-1 and HPIV-3 being among the four most commonly identified pathogens in adults requiring hospitalization for community-acquired pneumonia (11). HPIVs also cause lower respiratory tract infections in the elderly. Of nine common infections, HPIVs were significantly associated with mortality in those aged ≥75 years; this association was of lower magnitude than that of influenza A and RSV—which were significantly associated with mortality in all age groups—but of higher magnitude than that of the other pathogens (12).

HPIV is increasingly recognized as a source of severe morbidity and mortality in immunocompromised patients, especially in those with congenital immunodeficiencies, and is capable of infecting tissues in the gastrointestinal and urinary systems in these individuals (6). HPIVs replicate productively in respiratory epithelium and generally do not spread systemically unless the host is severely immunocompromised (13). HPIVs cause more than 50% of the respiratory infections in pediatric bone marrow transplant recipients and 19% in pediatric solid organ transplant recipients (14). HPIV infection, most commonly HPIV-3, was identified in 3.3% of 5178 pediatric and adult hematopoietic stem cell transplant recipients, causing both upper and lower respiratory tract infection and resulting in poor outcomes for those with lower respiratory infections (15). HPIVs were detected in 3% of pediatric patients with cystic fibrosis, second only to rhinovirus (16), and, similarly, in 5% of very low birth weight infants, next in frequency behind rhinovirus and RSV (17). In Korea, HPIVs were the most commonly isolated pathogen among 137 pediatric cancer patients with respiratory viral infections, with 80% of these acquired nosocomially (18).

There are currently no U.S. Food and Drug Administration (FDA)-cleared antivirals for treatment of HPIV infection. Ribavirin has been used to treat HPIV infections in immunocompromised patients, but results have varied. Elizaga et al. (19) reported no efficacy for this therapy. In contrast, successful HPIV treatment was reported for intravenous ribavirin therapy (20), oral ribavirin along with methylprednisolone (21), and high ribavirin doses used with early intervention (22). Management of symptoms through administration of corticosteroids has been recommended (8).

There are currently no FDA-cleared vaccines for the HPIVs. The search continues for an effective HPIV vaccine using live-attenuated recombinant HPIVs carrying various mutations and utilizing a bovine PIV-3 strain. However, these remain in clinical trials, and success has been only moderate (7).

The diagnosis of HPIV infection may be based primarily on clinical signs and symptoms, and laboratory diagnostic studies may not be needed for all patients. However, laboratory assays to confirm HPIV infection, thus differentiating it from the many other viral infections that present with similar respiratory tract signs and symptoms, are widely available, and confirmation of infection may improve patient management and decrease costs (1, 23).

**Collection, Transport, and Storage of Specimens**

Testing to confirm HPIV infection may include virus isolation, antigen or nucleic acid detection, or antibody detection (Table 1). Viral specimen collection, transport, and storage guidelines are provided in chapter 79 in this Manual. Because detection of HPIV often involves immunofluorescence assays performed directly on the clinical material, care should be taken to include cellular material in samples collected from respiratory sites. The nasopharynx and oropharynx are primary locations of initial HPIV replication, and children shed virus from 3 to 4 days prior to the onset of clinical symptoms until approximately 10 days past onset. Virus recovery from adults is much more difficult than that from children, although immunocompromised patients and adults with chronic diseases, especially lung disease, have been shown to persistently shed HPIV for many months (9). Throat swabs, nasopharyngeal swabs, nasal washes, and nasal aspirates have all been used successfully to recover HPIV, but specimens from the nasopharynx—which is the primary location of initial HPIV replication—are best. Specimens should be collected, placed in viral transport medium, and kept at 4°C until cell culture inoculation. Inoculation within 24 h of collection is recommended (9).

Peripheral blood samples for use in HPIV antibody assays should be collected in tubes without anticoagulant, and serum should be separated from the clot as soon as possible to ensure sample integrity. Serum samples may be stored at 4°C if testing will be performed within 24 to 48 h but should be frozen at −20°C or lower if testing is delayed.

**Direct Examination**

**Microscopy**

Electron microscopy can easily demonstrate the presence of HPIV, but HPIV and the other parainfluenzaviruses appear the same. Cellular material from the lung, other bronchial tissues, pancreas, kidney, and bladder exhibit the typical appearance of giant-cell formation under a light microscope when they are infected with HPIV (6).

Antigen Detection

HPIV-1, -2, and -3 antigens are routinely detected in clinical specimens through the use of immunofluorescence techniques that employ monoclonal antibodies (MAbs). Cells from nasopharyngeal washes, aspirates, and swabs are fixed on the microscope slide, usually in several cell spots or dots or by cytocentrifugation (24). At least 20 columnar epithelial cells must be present if the assay is to be valid. Many laboratories use pooled MAbs containing antibodies against seven common respiratory pathogens; these are adenovirus, influenza A and B viruses, HPIV-1, -2, and -3, and RSV. These MAbs are applied in either a direct (DFA) or indirect (IFA) fluorescent-antibody staining protocol that detects antigens of all seven viruses. When a positive result is seen, further testing must be done to determine which virus is present. The sensitivity of HPIV antigen detection compared to virus isolation in cell culture varies from laboratory to laboratory and with the various DFA and IFA staining methods and reagents but has been reported to range from 70% (3) to 83% (24). Specificity is very high.

Pooled and individual MAbs in DFA or IFA formats are commercially marketed in the United States and are FDA-cleared for use in detecting HPIV-1 to -3 antigens directly in clinical specimens and for culture confirmation. Distributors of these reagents include but are not limited to the following: DakoCytomation USA, Carpinteria, CA; Diagnostic Hybrids/Quidel (DHI), Athens, OH; Millipore Corporation Light Diagnostics, Temecula, CA; and Trinity Biotech, Carlsbad, CA. FDA-cleared MAbs in the DFA format are available from Millipore Corp. for HPIV-4 culture confirmation. HPIV-infected cells demonstrate bright fluorescence that is primarily cytoplasmic and often punctate, with irregular inclusions. A brief overview of the protocol for one HPIV DFA method can be found in reference 62. The principles of DFA and IFA are reviewed in chapter 7 of this Manual.

MAb pools that screen for common respiratory viruses are marketed in two DFA formats. In one format, a pool of labeled MAbs is used in initial staining to screen for seven viruses (influenza A, influenza B, RSV, adenovirus, and HPIV-1 through -3); fresh smears are then prepared and stained with individual MAbs to identify the infecting virus. A second DFA format allows definitive identification of more than one virus simultaneously through the use of two different fluorescent dyes with overlapping spectra (Light Diagnostics SimulFluor reagents, Millipore Corp.; Duet reagents, DHI). The reagents are cleared by the FDA for direct specimen testing and for culture confirmation. When stained preparations are examined with a fluorescence microscope with a fluorescein isothiocyanate (FITC) filter set, one antibody will produce apple-green fluorescence, and the second will appear gold or golden orange. The SimulFluor reagents have shown excellent sensitivities and specificities, comparable to those of individual stains, for the respiratory viruses (24).

A rapid format for staining cells in solution is also available (D3 FastPoint; DHI). This system features three dual-labeled (R-phycoerythrin versus FITC) MAb preparations also containing propidium iodide. HPIV-1, -2, and -3 are detected but not differentiated in this system. In FastPoint testing, after a short incubation of specimen material with the three MAAb preparations, the samples are placed on a microscope slide and examined in the wet state with a fluorescence microscope with an FITC filter set. False positive trials by the manufacturer showed 85 to 100% sensitivity and 98% to 100% specificity for HPIV-1, -2, and -3 detection by the FastPoint method compared to other HPIV antigen detection methods.

HPIV-4 is the least frequently encountered of the HPIV types. It is not detected by most respiratory virus immunofluorescence screening reagent pools, which screen for only HPIV-1, -2, and -3. Although MAbs are available for immunofluorescence staining of HPIV-4 cell culture isolates, these are not FDA cleared for direct HPIV-4 antigen detection in clinical specimens.

Nucleic Acid Detection Techniques

In the last decade a number of molecular assays have been used for HPIV detection. Initially these were lab-developed...
assays that detected individual HPIVs. More recently, multiplexed assays that detect HPIVs, either alone (Prodesse ProParflu+, Hologic GenProbe, San Diego, CA) or in combination with other respiratory viruses (Luminex xTAG RVPv1, Luminex Molecular Diagnostics, Austin, TX; eSensor RVP, GenMark DX, Carlsbad, CA; FilmArray RP, Biofire Diagnostics, Salt Lake City, UT), have received FDA clearance.

These involve various applications of molecular technology and have unique performance characteristics (Table 2). Of the four, only the FilmArray includes HPIV-4; the others detect only HPIV-1 through -3. These assays have been compared to antigen detection, virus isolation, and other individual and multiplexed molecular methods, and have shown excellent sensitivity and specificity (25–33).

Most method comparisons have included fewer than 20 samples positive for HPIV types 1 and 3 and fewer than 5 positive HPIV-2s. HPIV-4 was often not evaluated because it was not present in the samples tested or not detected by one or more of the comparator methods. Evaluations of HPIV detection consistently show improved sensitivity over traditional cell culture and antigen detection by immunofluorescence for molecular multiplex methods (25, 27, 31).

Although individual lab-developed PCRs were shown to detect slightly more HPIVs than the GenMark eSensor (28) and Biofire (30), all of the FDA-cleared multiplex methods showed sensitivities of 92 to 100% and specificities of nearly 100% for HPIV detection compared to each other and to individual PCRs (25–28, 30, 33). The Luminex xTag RVPv1 showed elevated HPIV-1 signal in the presence of a strongly positive HPIV-3 result, but this was not a substantial problem because the HPIV-3 signal was remarkably stronger (33).

The enhanced sensitivity of molecular methods over antigen detection and virus isolation is especially important for immunocompromised patients and older patients in whom the viral titer may not be high. Most large virology laboratories employ molecular technologies for detection of all of the common viral respiratory pathogens. As this technology is further refined and made more “user-friendly,”

<td>FilmArray RP (BioFire Diagnostics—formerly Idaho Technologies, Salt Lake City, UT)</td>
<td>Parainfluenza 1–4 (also adenovirus, coronaviruses [HKU1, NL63, OC43, and 229E], metapneumovirus, influenza A [H1, H3, and H1 2009] and B, RSV, rhinorrhino/entero). Includes bacterial targets of Chlamydophila pneumoniae, Mycoplasma pneumoniae, Bordetella pertussis</td>
<td>Fully automated closed system with extraction, amplification, and readout in self-contained plastic pouch. Pouch is placed in instrument-loading station, rehydrated, and injected with sample. The instrument mixes/moves reagents and heats/cools to perform cell lysis, magnetic bead-based nucleic acid isolation, reverse transcription, and multiple PCRs (1st stage multiplex and 2nd stage nested PCRs). Uses endpoint DNA melting-curve analysis to automatically generate a result for each target. Takes 3–5 min of hands-on time and 1.25 h for complete assay. One sample at a time, moderately complex</td>
</tr>
<tr>
<td>eSensor RVP (GenMark DX, Carlsbad, CA)</td>
<td>Parainfluenza 1–3 (also adenovirus [B/E, C, metapneumovirus, influenza A [H1, H3, and H1 2009] and B, RSV [A and B], rhinovirus).</td>
<td>Open system requires separate extraction (with addition of bacteriophage MS2 as internal control) and conventional endpoint PCR amplification. After amplification, ferrocene-labeled signal probes specific for the various targets are added, and target DNA hybridizes to the corresponding probe. Mixture is added to a detection cartridge that passes the solution across a single-file microarray of gold-plated electrodes coated with single-stranded oligonucleotide capture probes specific for individual targets. Hybridization brings ferrocene label close to the gold electrode. Electrical current is applied to electrodes, facilitating electrochemical detection using voltammetry. Batch testing, 6–7 h turnaround. Highly complex</td>
</tr>
<tr>
<td>Luminex xTag RVPv1 (Luminex Molecular Diagnostics, Austin, TX)</td>
<td>Parainfluenza 1–3 (also adenovirus, metapneumovirus, influenza A [H1 and H3] and B, RSV [A and B], rhinorrhino/entero)</td>
<td>Open system requires separate extraction, reverse transcriptase PCR, and steps to attach PCR product to Luminex beads. Amplicons are hybridized to target-specific primers possessing unique DNA tags. DNA polymerase extends perfectly formed complements, at the same time incorporating biotin-dCTP into the extension product. The extension products are added to microwells containing polystyrene microbeads, each of which contains an anti-tag sequence unique to a specific viral target and all of which are treated with colored dyes to distinguish each bead set. Each tagged primer hybridizes onto its unique anti-tag complement. Biotinylated extension products hybridizing onto the bead surface are detected with a streptavidin-phycocerythrin reporter molecule. Dual lasers identify bead sets and amount of bound target. Most hands-on time of methods shown, 6–8 h turnaround. Batch testing. Highly complex</td>

(i.e., less technical expertise required, faster turnaround time, less sophisticated specimen processing, instrumentation, and facilities due to closed systems), smaller laboratories will also be able to take advantage of this superior diagnostic approach. Experts in viral molecular diagnostics caution users that molecular panels are expensive and should be selected carefully to best fit the needs of the individual laboratory and the patient population it serves. Large multiplexed viral respiratory panels may not be the preferred assay for diagnosis when clinical symptoms are consistent with a particular viral infection already known to be circulating in the community (34).

**Isolation and Identification**

Many commonly used cell lines support the growth of HPIVs, but the best growth is seen in primary monkey kidney (PMK) cells, including rhesus, cynomolgus, and African green monkey cells (9). LLC-MK2 cells are also acceptable for primary isolation when 2 to 3 μg/ml of trypsin is added to the cell culture medium (9). Madin-Darby canine kidney (MDCK), HeLa, Vero, and HEP-2 cells may be used for transferring isolates but are not recommended for primary isolation (35). At this writing, commonly used cell lines are available commercially from DHI.

In preparing for cell culture inoculation of specimens collected on swabs and transported in a viral transport medium, the transport medium is mixed extensively on a vortex mixer, and excess fluid is expressed from the swab by pressing the swab against the side of the tube; the swab is then discarded. The transport medium is then centrifuged at 1,500 × g for 10 min. The medium is decanted from cell culture tubes that are to be inoculated, and the supernatant from the centrifuged transport medium, usually 0.2 ml for each tube, is applied to each cell culture monolayer. The inoculated tubes are incubated in a horizontal position in a 35 to 37°C incubator for 1 h before excess inoculum is discarded and fresh cell culture medium is added. Inoculated cell culture tubes are incubated in rotating racks at 35 to 37°C and examined microscopically on alternate days for 14 days.

In PMK cells, some HPIVs produce a cytopathic effect (CPE) of rounded cells and syncytium formation in 4 to 8 days. However, many HPIVs will produce little, if any, CPE in traditional cell culture tubes. Fortunately, HPIVs produce hemagglutinin proteins that are inserted into the membranes of infected cells. These proteins have an affinity for erythrocytes, a phenomenon called hemadsorption (HAD), and this property can be used as another approach for detecting HPIVs in cell cultures. For HAD testing, culture medium is replaced with a dilute suspension of guinea pig erythrocytes, and the cell culture tubes are refrigerated at 4°C for 30 min; the tubes are then examined microscopically (3). When a hemadsorbing virus is present, erythrocytes adhere to the infected cell monolayer. If hemadsorbing virus is absent, erythrocytes will not adhere and will float free when the tube is tilted or tapped. Uninfected and infected control tubes should be included in HAD testing. HAD testing may be performed at the end of the typical incubation period of 14 days, or earlier, after 3 to 7 days of incubation (36). HPIV-4 hemadsorbs weakly compared to HPIV-1, -2, and -3 at 4°C and more strongly at room temperature. Other members of the Paramyxoviridae family, including mumps virus, and other viruses, such as influenza virus, also give positive HAD test results. Whether the presence of HPIV is suspected based on the appearance of typical CPE or by a positive HAD test result, confirmatory testing must be done to definitively identify the virus.

Confirmatory testing is routinely completed by immunofluorescence techniques involving the use of HPIV MAbs in DFA or IFA assays, as described for HPIV antigen detection in clinical samples. MAbs against HPIV-1, -2, and -3 are readily available in the various respiratory virus antibody testing kits. However, HPIV-4 antibodies are not included in most testing kits and must be purchased separately. Infected cells are scraped from the cell culture monolayer, applied to a microscope slide, fixed, and stained. The presence of apple-green fluorescence when the smear is viewed with a fluorescence microscope confirms the identification of HPIV. Confirmatory testing may also be accomplished by many other methods, including hemagglutination inhibition, complement fixation, and neutralization tests. These techniques are laborious and time-consuming compared to immunofluorescence methods and are seldom used.

Cell cultures grown on coverslips in shell vials or in microwell plates provide an alternative to traditional tube cell cultures for isolation of HPIVs. Centrifugation of the inoculated vials and plates, usually at 700 × g for 1 h, is an important feature of the inoculation process. Inoculated vials or plates are incubated for 24 to 48 h or as long as 5 days. Detection of viral proliferation depends on pre-CPE detection of viral antigens by application of HPIV MAbs to the monolayers in a typical DFA or IFA staining assay. Use of shell vial cultures with centrifugation-enhanced inoculation and pre-CPE detection by immunofluorescence staining has been shown to be very useful in HPIV detection. Cocultivated mink lung (MLV) and A549 cells in shell vials, marketed as R-Mix (DHI), are used with centrifugation-enhanced inoculation and pre-CPE detection by a DFA staining technique. Staining involves pooled MAbs to seven respiratory viruses (adenovirus, influenza A and B viruses, HPIV-1, -2, and -3, and RSV). In a recent comparison of respiratory virus detection in 3,800 clinical samples in R-Mix and in shell vials of PMK, A459, and MRC-5 cells, 33 of 38 (87%) HPIVs were detected after overnight incubation in the R-Mix cells (37). This included 26 of 30 HPIV-1 isolates, 2 of 2 HPIV-2 isolates, and 5 of 6 HPIV-3 isolates. Cocultivated MDCK cells and A549 cells comprise R-Mix Too (DHI). This combination, which does not support the replication of severe acute respiratory syndrome coronavirus, was prepared as an alternative to R-Mix. The HPIVs proliferate very well in R-Mix Too (unpublished data) and are easily detected (Fig. 1).

An overview of the recommended protocol from the manufacturer of R-Mix and R-Mix Too (DHI) is shown here; however, this may be adjusted to meet the needs of the laboratory. Briefly, the processed clinical specimen for respiratory virus detection is inoculated into three vials containing R-Mix or R-Mix Too cells, and the vials are spun in a centrifuge (700 × g for 1 h). At 16 to 24 h, one vial is stained with respiratory virus screening reagent (tests for seven respiratory viruses). If fluorescence is observed, the cells are scraped from one of the remaining shell vials, rinsed in phosphate-buffered saline, and spotted onto an eight-well slide; seven of the wells are stained with individual MAbs against the seven respiratory viruses, and the eighth well is used as a control well. If no fluorescence is observed when the first vial is stained, the second vial is stained after an additional 16 to 24 h of incubation. If this vial is positive, the cells are scraped from the remaining vial and stained as described above. If the second vial is negative, the culture may be considered negative for the seven respiratory viruses (i.e., the remaining vial is discarded and the culture is terminated), or the third vial may be observed for CPE for up to 7 days.
Serologic Tests

Most children are born with HPIV-neutralizing antibodies of maternal origin, but these diminish by 6 months of age, allowing more than two-thirds of children to be infected by HPIV during the first year of life. Most children have early serologic evidence of HPIV-3 infection, with HPIV-1 and -2 antibodies developing later, at 2 to 3 years of age. Antibodies to HPIV-4 peak in school-age children (9). Immunoglobulin M (IgM) is produced in most primary HPIV infections of children, so IgM detection in a single sample supports diagnosis of current infection. Likewise, measurement of a significant increase in the IgG antibody level, which is an increase of 4-fold or more in assays that test serial 2-fold dilutions of serum samples collected 2 weeks apart, supports diagnosis of current infection. Cross-reactivity among the various HPIV types and other paramyxoviruses, such as mumps virus, makes serologic diagnosis more difficult. Serologic differentiation of the HPIV types is unreliable by all methods; this determination can be made only through virus isolation and antigen typing with MAbs or identification of the viral RNAs.

Antibodies to the HN protein may appear early, but both HN and F protein antibodies must be present for protection. Immune status determinations are not useful for HPIV. Serology in general is seldom used as a diagnostic approach for HPIV infection because of the wide availability and improved reliability of virus isolation and viral antigen and nucleic acid detection methods.

Principles of various immunoassays are described in detail in chapter 7 of this Manual. HPIV antibodies can be detected by many types of assays, including hemagglutination inhibition, complement fixation, and neutralization assays; all of these detect total antibody (IgG and IgM), and most laboratories do not offer these methods due to their cumbersome nature. A detailed procedure for hemagglutination inhibition testing for HPIV antibodies was published previously (35). HPIV antibody detection can be accomplished by enzyme immunoassay (ELISA), but commercial kits are not available. Complement fixation is the least sensitive method for antibody detection, and ELISA is the most sensitive.

Evaluation, Interpretation, and Reporting of Results

Isolation of HPIVs-1, -2, -3, and -4 in traditional or shell vial/microwell cell cultures and detection of HPIV RNA in clinical samples are the best evidence for current or very recent infection because HPIV is seldom present in the absence of infection. Rapid reporting of positive results is important (35). As molecular panels that include the HPIVs become more widely available in formats that produce rapid results, they will become the diagnostic method of choice due to their excellent sensitivity and specificity. Although the sensitivity of HPIV antigen detection by immunofluorescence is lower than that of virus isolation in cell culture or molecular detection, the rapid availability of results and high specificity make such testing useful in patient management. Confirmation of HPIV infection via the serologic route and HPIV immune status determinations are seldom employed due to the difficulties with cross-reactions among the paramyxoviruses.

MUMPS VIRUS

Epidemiology and Transmission

More than 150,000 cases of mumps were expected each year in the United States before the aggressive vaccination programs implemented in the late 1960s. The mumps vaccine was combined with the measles and rubella vaccines to make a trivalent vaccine (MMR). In the United States, the initial dose of MMR is administered to children between 12 and 15 months of age. Vaccination produced a dramatic decline in the incidence of mumps, resulting in fewer than 3,000 cases in the United States by 1985. There was a brief resurgence of mumps in 1986 and 1987 that peaked at 8,000 to 12,000 cases. Following the resurgence, a requirement for a second dose of the MMR vaccine was implemented. This dose is administered to children between ages 4 and 6 or 11 and 13 years (38) and has been expected to confer life-long immunity. The number of mumps cases continued to decline in the United States until the largest U.S. outbreak in 2 decades occurred in the Midwestern states in 2006 (39). More than 6,500 cases were involved in this outbreak. The highest incidence of mumps was in persons aged 18 to 24 years; 83% of these were college students, and 84% of this group, as well as 63% of all those infected in the outbreak, had received two doses of mumps vaccine. The cause of this outbreak is unclear. Potential explanations include waning immunity and incomplete vaccine-induced immunity to circulating wild-type virus (39). In addition, the overall estimate of mumps antibody seroprevalence in the U.S. in 1999–2004 was 90% (40). This is the lower end of the level of immunity (90–92%) needed to achieve herd immunity.

During 2009–2010, another mumps outbreak occurred in the U.S. The outbreak started at a New York summer camp for Orthodox Jewish boys and resulted in 3,502 cases of mumps, 97% of which were in Orthodox Jewish persons, most of whom lived in three neighborhoods in New York (41). As with the 2006 outbreaks, a high percentage of infected individuals had received either one (14%) or two...
(76%) doses of the MMR vaccine, so waning of vaccine-induced protection against mumps was again suggested as a contributing factor. In addition, it was concluded that the level of immunity required to protect against clinical mumps may depend on the size of the inoculum of virus involved in the exposure, indicating that a particular antibody titer versus protection from infection is not absolute (41). However, in a study of antibody in students prior to the 2006 Kansas outbreak, it was shown that pre-outbreak neutralizing titers were significantly lower among patients who developed mumps than in individuals neither exposed nor infected and in individuals exposed but not infected during the outbreak. However, although those who developed mumps had lower pre-outbreak mumps antibody levels than non-infected individuals, antibody titers overlapped, and no cutoff points clearly separated the groups (42).

At this writing, the incidence of mumps has returned to its pre-2006 outbreak levels. It remains unclear whether the virus itself or in vaccine administration schedules will be needed to prevent future outbreaks in the United States. Mumps remains common throughout much of the world, usually infecting 6- to 10-year-old children in the setting of unvaccinated populations. The virus is transmitted from person to person through respiratory droplets or contaminated fomites and is highly contagious, with approximately 85% of susceptible contacts becoming infected when first exposed. Humans are the only known host and reservoir for the virus. The virus replicates initially in epithelial cells in the upper respiratory tract and in regional lymph nodes. Initial replication is followed by viremia, which results in infection of the salivary glands and other sites. Mumps virus can be isolated from saliva 7 days before and up to 8 days after the onset of parotitis, but the isolation is more likely and the highest virus loads occur closest to parotitis onset and decrease rapidly thereafter. Disease transmission likely occurs before and within 5 days of parotitis onset. Transmission can also occur during the prodromal phase and with subclinical infection (43). The virus is excreted in the urine for as long as 14 days after the onset of illness.

Clinical Significance
The average incubation period for mumps is 16 to 18 days. Mumps virus infection is asymptomatic in 25 to 30% of cases and is associated with nonspecific or respiratory symptoms in 50% of cases. Symptoms are typically mild and characterized by slightly elevated temperature and enlargement of one or both parotid glands in 30 to 40% of cases. Complications of mumps include meningocerebral complications (up to 15% of cases) and, in postpubertal individuals, orchitis in males (20 to 30%) and oophoritis in females (7%). Polyarthritis and pancreatitis have also been associated with mumps.

When mumps was a common disease of childhood, the diagnosis was made largely on clinical grounds alone. With the decrease in incidence of mumps, many physicians no longer readily recognize the symptoms. In addition, typical clinical signs and symptoms may be absent in immunocompromised individuals. Parotitis, the hallmark of clinical diagnosis, is now known to be present in other viral and nonviral diseases or conditions. Mumps-like symptoms in acutely ill children who previously received the MMR vaccine have been associated with Epstein-Barr virus, HPV1, adenovirus, and human herpesvirus type 6 (44). Therefore, laboratory confirmation of mumps virus infection is now more important in making the diagnosis.

Collection, Transport, and Storage of Specimens
The accepted laboratory criteria for the diagnosis of mumps virus infection are isolation of the virus from clinical specimens, detection of mumps virus RNA via molecular methods, a significant rise between acute- and convalescent-phase antibody titers in serum, or a positive IgM result for mumps. Guidelines for specimen collection, transport, and storage of specimens are presented in chapter 79 in this Manual. Specimen collection guidelines differ for diagnosing mumps in unvaccinated and previously vaccinated individuals. Information on sample procurement in both hosts is provided below.

Specimens for mumps virus isolation in cell culture include the following: saliva, blood, urine, and cerebrospinal fluid (CSF). Virus can be isolated from saliva 7 days before and up to 8 days after the onset of parotitis, recovered from the urine for up to 2 weeks after onset of symptoms, isolated from CSF during meningitis, and detected rarely in peripheral blood. Throat swabs and urine samples have been shown to have similar efficacies as sources of mumps virus (45). It is always advisable to collect samples for virus isolation early in the course of the infection, when the viral load is the highest. Samples for virus isolation and molecular testing should be collected even sooner in previously vaccinated individuals. In these individuals neither virus isolation nor molecular methods are likely to yield positive results unless samples are collected within 3 days after onset of parotitis (46). The virus is stable for several days at 4°C, although inoculation of susceptible cell cultures within a few hours of specimen collection is recommended for optimal virus isolation. The virus may survive for months or longer when frozen at −70°C or lower. Information regarding materials and methods for specimen collection (samples for virus detection as well as blood samples for antibody testing), storage, and shipment is available online from the Centers for Disease Control and Prevention (CDC) at http://www.cdc.gov/mumps/lab/specimen-collect.html.

An alternative to serum collected by venipuncture is whole blood obtained by finger stick, heel prick, or venipuncture and then spotted on filter paper and dried. Following elution and dilution of the dried blood samples, commercial antibody assays may be used to test the sample for mumps virus antibody. Results of EIA in testing for mumps virus IgG and IgM by use of samples collected as blood spots have shown excellent correlation with those obtained in testing of fresh serum. The dried blood spots may be stored for 6 to 24 months without a significant change in antibody testing results (47).

In order to compare IgG or total antibody levels, two samples should be collected, the first (acute phase) as soon as possible after onset of symptoms and the second (convalescent phase) within 2 to 3 weeks following the acute-phase sample. A single serum sample collected within 4 to 10 days of onset is all that is required for IgM-specific antibody testing. If the purpose of the serologic testing is simply to determine the patient’s mumps immune status, a single serum sample collected at random is sufficient. Neither comparison of IgG levels in sequential samples nor detection of IgM in a single sample collected early in the infection has been shown to be an effective diagnostic approach for confirming mumps virus infection in previously vaccinated individuals.

Direct Examination
Microscopy
Diagnosis of mumps does not typically involve examination of biopsy samples. However, microscopic examination of
affected salivary glands reveals an edematous interstitium diffusely infiltrated by macrophages, lymphocytes, and plasma cells, which compress acini and ducts. Neutrophils and necrotic debris may fill the ductal lumen, causing focal damage to the ductal epithelium (48).

**Antigen Detection**

Mumps virus antigen detection by immunofluorescence in cells from CSF and salivary glands was described in the early 1970s (49, 50). More recent studies of immunofluorescence staining of throat swab specimens for mumps virus antigen have shown sensitivities as high as 98 to 100% compared to mumps virus isolation in cell culture (45). Although mumps virus MAbs are available commercially, most are not FDA cleared for use in direct detection of mumps virus antigens in tissues and other clinical samples, and most virology laboratories do not offer direct antigen analysis for mumps virus.

**Nucleic Acid Detection**

Various molecular approaches have been developed to aid in mumps diagnosis. Mumps virus RNA has been detected by reverse transcriptase (RT)-PCR in oral fluid, CSF (51, 52), saliva or throat, and urine (52) specimens and in mumps virus isolates from cell culture (51). Although there are currently no commercially available FDA-cleared molecular assays for mumps detection, two of these assays have been developed and standardized by the CDC, with information available online. Step-by-step procedures are provided and commercial sources of reagents are identified for one standard RT-PCR to detect the SH gene of mumps virus (http://www.cdc.gov/mumps/downloads/lab-rt-pcr.doc) and for one real-time RT-PCR assay (http://www.cdc.gov/mumps/downloads/lab-rt-pcr-assay-detector.doc). Molecular assays are more sensitive than virus isolation in culture and can provide sequence information for the coding region of the SH gene that is needed to determine the viral genotype. Laboratories with advanced molecular assay capabilities may be able to offer mumps detection by RT-PCR, but most routine virology laboratories rely on mumps virus isolation as the standard method for diagnosing mumps virus infection.

**Isolation and Identification**

Mumps virus proliferates in traditional cell cultures of several cell lines commonly used in viral diagnostic laboratories. These include PMK, human neonatal kidney, HeLa, and Vero cells. Recently, a mammoset lymphoblastic cell line, B95a, was shown to be as sensitive for mumps virus isolation as PMK cells (53). A hybridized Vero cell line transfected with a plasmid carrying the gene for human CDw150—a signaling-lymphocytic activation molecule (SLAM)—and called Vero/SLAM has been used for mumps virus isolation (54). Although used originally for isolation of measles virus, these cell lines have been shown to be effective for mumps virus isolation as well (46, 55). Directions for cell culture inoculation for swab samples in viral transport medium are the same as those described above in “Parainfluenza Viruses” under “Isolation and Identification.”

In cells infected with mumps virus, CPE characterized by rounded cells and multinucleated giant cells is typical, usually appearing after 6 to 8 days of incubation at 35 to 37°C. However, this characteristic CPE may be very subtle, may not appear at all, or may be confused with a similar CPE produced by endogenous contaminant viruses that sometimes infect PMK cells.

Mumps virus, like the HPIVs, inserts hemagglutinin proteins into the membranes of infected cells, so mumps virus-infected cells can be demonstrated through HAD testing. The HAD testing protocol is described above in “Parainfluenza Viruses” under “Isolation and Identification.” Whether mumps virus is detected by CPE production or by a positive HAD result, confirmatory testing must be performed. Confirmatory testing for mumps virus is routinely performed by IFA staining. FDA-cleared mumps MAbs in an IFA format for culture confirmation are available from Millipore Corp.

Many laboratories currently use centrifugation-enhanced inoculation and pre-CPE detection with MAbs to detect mumps virus within 24 to 48 h after inoculation. Various cell lines can be used in either shell vial or microwell plate formats for this purpose. The recommended centrifugation speeds and times may vary for inoculation, ranging from 700 × g for 45 min (45) to 3,000 × g for 20 min (37). Up to 66% of mumps virus-positive samples were identified within 2 days of inoculation in the shell vial system; after 5 days of incubation, the shell vial system was 98% sensitive compared to mumps virus isolation in traditional cell cultures (36). When various cell lines were compared for efficacy of mumps virus isolation in shell vials, Vero and LLC-MK2 were the most sensitive (100%), followed by MDCK (78%), MRC-5 (44%), and HEp-2 (22%) cells (57). Mumps virus can also be isolated in R-Mix cells (Fig. 1). An overview of the recommended protocol from the manufacturer of R-Mix (DH1) is shown above in “Parainfluenza Viruses” under “Isolation and Identification.”

Because mumps virus infections in previously vaccinated individuals result in decreased levels of virus shedding into the buccal cavity, virus isolation may be difficult (58). Specimens collected and cultured within 3 days of onset of parotitis may aid in confirming the presence of mumps virus, but negative results do not rule out the infection (39).

**Serologic Tests**

In mumps virus infection, IgM is detectable initially within 3 to 4 days of appearance of clinical symptoms and persists for 8 to 12 weeks. IgG is detectable within 7 to 10 days of the onset of symptoms, is maintained at high levels for years, and remains detectable for life. Traditional serologic diagnosis of mumps is based on the detection of virus-specific IgM in a single sample or measurement of a significant increase in the titer of IgG or total antibody, i.e., 4-fold or greater increase for methods that use serial 2-fold dilutions, between two specimens collected 2 weeks apart. Antibodies produced in mumps virus infection often cross-react with related viruses, which complicates the interpretation of results. Assays for mumps immune status indicate whether mumps virus IgG is present at detectable levels or is absent or undetectable. These qualitative results are sufficient, and reporting of titers is unnecessary given that there is no particular antibody level that correlates with protection (41, 42). With the rarity of mumps cases in the United States at present, most laboratories focus mumps virus serology on immune status testing.

In previously vaccinated persons, serologic diagnosis has very limited use. IgM may be produced weakly or not at all in a secondary immune response. In a recent outbreak, mumps virus IgM antibodies were detected in fewer than 15% of mumps virus-infected persons who were previously immunized, and 95% of these patients were positive for mumps virus IgG (46).

Basic principles of immunoassays are described in chapter 7 in this Manual. Mumps virus antibodies can be detected by many types of assays, including hemagglutination inhibi-
tion, complement fixation, and neutralization assays; all of these detect total antibody (IgG and IgM). These methods are usually laborious and are available only at reference or specialty laboratories. A detailed procedure for mumps virus antibody hemagglutination inhibition testing was published previously (59). The complement fixation technique can be used with two different mumps virus antigens, V and S. Antibodies against the S antigen appear earlier and rise quickly, in contrast to the antibodies to the V antigen, which appear later. The presence of both V and S antibodies is thought to signal a recent past infection, while V antibodies alone signal a long-past infection (35). An IgM-capture EIA was used recently for detection of mumps virus IgM (46).

Most diagnostic laboratories use commercially supplied mumps virus antibody EIA kits, in either manual or automated formats, or IFA testing systems for mumps virus antibody determinations. Most of these measure only mumps virus IgG. Antibodies are produced against various mumps virus proteins, but protection is most closely correlated with antibodies to the mumps virus HN protein. Most assays use whole virus or viral extract antigens that detect HN antibody effectively. Written protocols, along with the proper reagents and controls, are included with each commercial product, and each manufacturer’s guidelines must be followed if assays are to yield high-quality results. The procedural steps for performance of antibody testing are not published here due to the need for strict adherence to manufacturers’ guidelines. None of these mumps virus antibody assays has been shown to be superior in regard to sensitivity or specificity.

Standard diagnostic tests that detect virus or virus-specific antibody perform inconsistently for individuals with prior immune exposure via either immunization or natural infection. Detection of activated mumps-specific antibody-secreting memory B cells (ASCs/plasmablasts) by EIA has been shown to be a more reliable test (60). ASCs are detectable in circulation only following recent activation by antigen. In testing for ASCs, peripheral blood mononuclear cells are cultured in the presence of polyclonal mitogens, and the ASCs are detected by exposure to viral antigen. Trials with this method detected mumps ASCs in recently MMR-vaccinated individuals and in those with clinical mumps during a mumps outbreak. Detection of ASCs appears to be more sensitive for longer periods of time that RT-PCR or IgM EIA and may be useful for diagnosing mumps cases that cannot be confirmed with standard methods and for testing asymptomatic case contacts in an outbreak. Interestingly, mumps ASCs appear to be produced in lower numbers than measles or rubella ASCs, suggesting that mumps infection may not generate robust B-cell memory (60).

Evaluation, Interpretation, and Reporting of Results

Isolation of mumps virus in traditional or shell vial/microcell cultures is evidence of current or very recent infection. The same can be said for the detection of mumps virus RNA in clinical samples. Rapid antigen detection may also confirm the presence of mumps virus. However, neither molecular methods nor rapid antigen assays are routinely available in U.S. laboratories, so mumps virus isolation in culture remains the most sensitive approach. Confirmation of mumps virus infection via the serologic route is less straightforward. Mumps virus IgM may be detectable, along with significant increases in IgG, in patients infected with related viruses, including the other paramyxoviruses, such as HPV-1, -2, -3, and -4. In general, cross-reactivity with related viruses can be ruled out by testing for antibodies to the related viruses in parallel with mumps virus antibody testing. The greatest increase in antibody level should identify the true infection. Given the potential lack of serologic test specificity, virus isolation and RNA detection in clinical samples (preferably buccal swabs) remain the most effective ways to confirm infection in virus antigens, V and S.

Virus isolation and RNA detection have also been recommended for mumps diagnosis in individuals with a documented immunization history. Buccal swabs should be procured early (within 3 days of parotitis onset), as the duration of viral replication is likely to be shorter in these hosts. Despite these recommendations, it should be recognized that none of the traditional diagnostic approaches is highly effective for diagnosis of mumps in previously vaccinated individuals. IgM is not consistently observed, so is not a reliable indicator of recent infection. Virus detection can also be variable, presumably due to low viral loads. Alternative tests may have better diagnostic efficacy. Recent data from the 2009 outbreak suggest that the IgM capture assay used at the CDC has improved sensitivity compared to commercially available tests in previously vaccinated individuals (~50% for CDC capture versus 9–24% for commercial assays) (61). Additionally, use of nucleoprotein RNA as a target enhanced the sensitivity of real-time PCR compared to the historically used SH-based test. The CDC provides guidance online for mumps testing at http://www.cdc.gov/mumps/lab/qa-lab-test-infect.html.

N. ESTHER BABADY AND YI-WEI TANG

RESPIRATORY SYNCYTIAL VIRUS

Taxonomy

Respiratory syncytial virus (RSV) belongs to the Paramyxoviridae family, subfamily Pneumovirinae, genus Pneumovirus (1). Other members of the Pneumovirus genus include morphologically and biologically similar animal viruses, such as the pneumonia virus of mice, bovine RSV, ovine RSV, and caprine RSV (1). RSV and other Pneumoviruses differ from Paramyxoviridae viruses in the number and order of genes and the lack of hemagglutinin and neuraminidase activity (2). RSV was first isolated in chimpanzees with coryza in 1956 and subsequently recovered from children with pulmonary disease in 1957 by cell culture (3, 4). RSV derives its name from the characteristic formation of multinucleated giant cells (syncytia) in monolayer cell cultures of nonpolarized epithelial cells (5, 6). Only one serotype of RSV has been identified and further subdivided into two major antigenic groups designated RSV A and RSV B (1, 7). Additional variability, both genetic and antigenic, exists within each subgroup, with the RSV A subgroup being significantly more diverse than the RSV B subgroup (8). The prototypes RSV A and RSV B strains are the Long and A2 viruses and the CH-18537 and 8/60 viruses respectively (7).

Description of the Agent

Although mostly spherical, RSV virions are pleomorphic with spherical, filamentous, or both forms observed by electron cryotomography (Fig. 1) (9). The enveloped RSV virion consists of a single-stranded, negative-sense, nonsegmented RNA genome with 10 genes that are transcribed into 11 monocistronic polyadenylated mRNAs, each of which encodes a major polypeptide chain (1, 7). The virus lipid envelope is derived from the host plasma membrane and contains three structural proteins: the F (fusion) protein, the G (glycosylated) protein, and the SH (short hydrophobic) protein. The F protein initiates viral penetration by fusing viral and cellular membranes and promotes viral spread by fusing the infected cells to adjacent uninfected cells. The G protein mediates attachment of the virus to the host cells and the SH protein accumulates within lipid-raft structures of the Golgi complex during RSV infection (5, 6). The six other structural proteins include the nucleoprotein (N), the phosphoprotein (P), the polymerase or large protein (L), a matrix protein (M), and two proteins M2-1 and M2-2 (3, 8). The N protein serves as the major structural protein for the nucleocapsid, while the F and L (polymerase or large) are involved in transcription and replication (5, 6). The M protein is present in detergent-solubilized cores and inhibits viral replication in preparation for budding. The M2-1 protein is a transcription regulator that promotes the association of the M and N proteins while the function of the M2-2 protein is unclear (10). Two nonstructural proteins, NS1 and NS2, are unique to Pneumovirus and some studies have suggested that these proteins can inhibit apoptosis (11) and the host interferon-α/β response to viral infection (12).

Differences between RSV A and RSV B subgroups are primarily due to variability in the G protein with only one of six epitopes shared between the two subgroups (13). The variability in the G protein also accounts for the diversity of RSV strains within each subgroup. In contrast, the F protein is highly conserved, and antibodies against F cross-react with viruses from both subgroups A and B (5, 6). Studies have suggested that differences in the clinical presentation of RSV infections might be due to antigenic differences with RSV A being more virulent than subgroup B, resulting in greater disease severity among hospitalized infants (14, 15).

RSV is highly vulnerable to environmental changes. Only 10% of RSV remained infectious after exposure to 55°C for 3 minutes. At room temperature, 10% infectivity was present after 48 hours, and at 4°C, 1% of the infectivity remained after 7 days. The RSV infectivity titer fell by approximately 90% after each freezing and thawing cycle (6, 16). The virus is inactivated quickly by ether, chloroform, and a variety of detergents such as 0.1% sodium deoxycholate, sodium dodecyl sulfate, and Triton X-100. The survival of RSV in the environment depends in part on drying time as well as humidity (16). Long-term storage of RSV can be enhanced by flash freezing in an alcohol and dry ice bath and by adding stabilizing agents such as glycerin or sucrose.

Epidemiology and Transmission

Transmission of RSV occurs via droplets and direct or indirect contact with infected patients and/or contaminated...
86. Respiratory Syncytial Virus and Human Metapneumovirus

FIGURE 1 Tomography of A2 HRSV virions. Virion morphology ranges from completely filamentous (A) to completely spherical (C) with intermediate forms (B and D) that have some tubularly curved parts but are otherwise spherically curved. Spherical particles are highly deformable when in the proximity of other particles and the membrane proximal to the neighboring particle is free of glycoprotein spikes (E). (F) Virions in panels A through E are illustrated schematically in alphabetical order. Black arrows: side views of the RNP; white arrows: top views of the RNP; green arrows: secondary density layer under the membrane in a spherical particle (bar, 100 nm). Tomographic slices are 3.8 nm thick. Reprinted from reference 9 with permission.

surfaces (17, 18). Environmental factors including temperature, humidity, and precipitation can significantly impact the rate of transmission of RSV (19). Studies have shown that a combination of low temperature and high humidity can result in increased RSV activity in temperate climates while a high number of rainfall days correlates with an increase in activity in tropical climates.

RSV infections occur year round worldwide. In the temperate northern hemisphere, RSV infections occur in the winter with a peak between December and February (Fig. 2A). In the temperate southern hemisphere, RSV infections peak between May and July (Fig. 2C), and in a few tropical locations, including Taiwan, Hong Kong, Singapore, Malaysia, and Colombia, semiannual RSV peaks have been identified (Fig. 2B and 2D) (20). Epidemiology data have established that both RSV A and RSV B can circulate in the same region in a given respiratory season with one subtype, commonly RSV A, dominating. The pattern of dominance, however, can shift between seasons with RSV genotype strains evolving and new strains emerging (21–23).

A meta-analysis review of studies published between 1995 and 2009 estimated that in 2005, 33.8 million new episodes of acute lower respiratory tract infections were caused by RSV worldwide in children less than 5 years old with 66,000 to 199,000 associated deaths, mostly in developing countries (24). In the United States, early reports estimated that 100,000 hospitalizations and 4,500 deaths were related to RSV infection with excess expenses from $300 to $600 million for hospitalized infants with RSV in the United States (16).

RSV is associated with 20% of hospitalizations, 18% of emergency department visits, and 15% of office visits during
the peak season. Hospitalization rates from RSV were three times higher than those of influenza (25). The overall increased prevalence of RSV subgroup A over B viruses may be due to a more transient nature of subgroup A-specific immune protection (26). Virtually all children are infected by the time they reach 3 years of age and repeated infections with RSV are common throughout life. No age group appears completely protected against reinfection due to prior exposure (16).

RSV causes hazardous nosocomial infection and produces outbreaks each year with widespread infection in both children and adults, including medical personnel, who may have a mild enough illness as to not cause absences from work (27). In a classic experiment, volunteers in close physical contact with RSV-infected infants were more readily infected than volunteers who remained 6 feet away from the infected infant, suggesting that small-particle aerosol is less important in the spread of RSV than direct contact with infectious secretions via fomites or large-particle aerosols (6, 16). A targeted infection control intervention has been demonstrated to be cost-effective in reducing the rate of RSV nosocomial infections (27, 28). Contact isolation procedures are recommended for RSV-infected patients when they are hospitalized (16, 27).

**Clinical Significance**

**Children**

RSV is recognized as the most serious cause of severe acute lower respiratory tract illnesses in young children and infants (29). Clinical syndromes caused by RSV include upper respiratory tract infections characterized by cough, low-grade fever, and rhinorrhea (29). The incubation period ranges from 2 to 8 days with a median of 4.4 days based on a systematic review (30). Common lower respiratory tract infections include bronchiolitis, tracheobronchitis, and pneumonia (29). One study estimates that, each year in the United States, 2.1 million children younger than age 5 years required medical attention for RSV, which is far higher than previously thought (25). Crowding increases the attack rate of RSV. Schools or day-care centers provide ideal settings for the spread of RSV to susceptible individuals. Infants who have not breast-fed appear to be at greater risk for developing severe RSV infections in some studies, but a strong effect has not always been noted (28). Breastfeeding appears to have the strongest protective effect in female infants (31). Most children with RSV infection are previously healthy children with no underlying conditions and experience recovery from illness after 8 to 15 days (25). Risk factors for acquiring RSV include being younger than 2 years of age and residential crowding (25, 32). Development of severe disease has been associated with the following risk factors: male gender, premature birth, lack of breastfeeding, bronchopulmonary dysplasia, chronic and congenital heart disease, smoke exposure, immunodeficiency, sickle cell anemia, and high viral loads (33). While hospitalization is rarely required in healthy children (0.5 to 2%), up to 25% of high-risk children require hospitalization (16).

**Adults**

RSV infection in adults was first reported in the 1960s. Immunity to RSV is incomplete and adults are subject to reinfection (34). Adult populations at increased risk for severe RSV infections include nursing home or long-term care residents; adults with underlying heart and lung diseases, such as chronic obstructive pulmonary diseases, chronic cardiac diseases, and asthma; and immune-compromised patients, including cancer and transplant patients (35). In adults older than 50 years, RSV can cause significant
morbidity resulting in hospitalization rates of 6.1 to 11% (36, 37).

The incidence of RSV infection following hematopoietic stem cell transplantation (HSCT) and solid organ transplantation (SOT) ranges from 1 to 12% with 18 to 55% progressing to lower respiratory tract infection and death due to RSV in 7 to 33% of patients (38). Risk factors associated with acquisition of RSV infection in HSCT recipients include male gender, cytomegalovirus seropositivity, allogeneic transplant, and pre-engraftment status (39, 40). Due to the potential complications associated with RSV infections in HSCT recipients, a delay in transplantation of patients with upper respiratory tract infection due to RSV has been suggested (41).

Data on RSV disease in SOT recipients are limited. The incidence and risk of RSV infections in SOT recipients are lower than in the HSCT recipient group but higher than in immunocompetent individuals. The most common symptoms reported for RSV infections in SOT are fever, cough, and dyspnea, and complications, such as bronchiolitis obliterans, may occur in lung transplant recipients (42–45).

Treatment and Prevention

Treatment of RSV infections can be challenging. Current options that have been cleared by the FDA include ribavirin and palivizumab (PVZ) for RSV treatment and prophylaxis respectively (46). PVZ is FDA cleared for RSV prophylaxis of high-risk children. PVZ is a monoclonal antibody that functions by preventing RSV entry into host cells and is administered as a monthly injection in high-risk children during the respiratory season (46). PVZ prophylaxis reduces rate of hospitalization due to RSV in young children with chronic lung disease, extremely premature birth, and significant congenital heart disease (16, 47). A second-generation monoclonal antibody, motavizumab, has also been evaluated for prophylaxis in high-risk children including preterm infants and children with congenital heart disease (48, 49).

Ribavirin is a broad-spectrum nucleoside analogue that targets RNA viruses and can be administered orally, intravenously, or as an aerosol, with aerosolized ribavirin being the preferred method (46). Data from a large retrospective study in allo-HSCT recipients, including both children and adults, supported the early initiation of ribavirin therapy for RSV upper respiratory tract infections to prevent progression to lower respiratory tract infection and subsequent mortality from RSV lower respiratory tract infections (50). Ribavirin has been used alone or in combination with PVZ, total intravenous Ig, or corticosteroids in both SOT and HSCT recipients (46). Although there is a worldwide need for a preventative vaccine in the pediatric population, an effective and safe RSV vaccine is not yet licensed. Experimental live attenuated, vectored, and subunit vaccines are in development.

Collection, Transport, and Storage of Specimens

Most general viral specimen collection principles also apply to specimen collection for RSV detection and culture, including collecting specimens during the acute phase of illness, maintaining recovered cells in intact form, delivering specimens promptly to the diagnostic laboratory, refrigerating specimens if stored temporarily, and sealing well in an O-ring sealed cryovial if stored on dry ice. Heating or freezing the specimen will result in a decreased number of infectious virions in the sample. If a delay of longer than 2 hours is expected between collection and receipt of the sample, specimen containers should be kept at 4°C, including during transport to the laboratory, to effectively isolate RSV. RSV is labile and should ideally be transported to the laboratory and processed for culture within 4 hours of collection as viral titers can significantly decrease with prolonged storage at 4°C. Alternatively, specimens may be snap frozen to prevent viral degradation (51). However, differences in recovery of RSV from various specimen types and transport or storage temperatures are less pronounced with the use of sensitive nucleic acid testing (52–54).

Appropriate respiratory specimens for RSV detection should reflect the site of infection. RSV infects respiratory epithelial cells and can spread to the lower respiratory tract following 1 to 3 days of incubation (29). For upper respiratory tract infections, the ideal specimens include nasal or nasopharyngeal washes, aspirates, and swabs (55). Nasopharyngeal aspirates have traditionally been considered the best specimen for recovery of respiratory viruses, but insertion of the catheter through the nostril and aspiration are invasive and painful. Hence, swab samples are commonly obtained, as they provide adequate sensitivity without the discomfort associated with collection of washes or aspirates or the requirement for suction devices (56). Similarly, nasopharyngeal swabs collect a greater number of epithelial cells, but nasal swabs are associated with the least discomfort (57, 58). Studies comparing nasopharyngeal aspirates to nasal swabs for the detection of RSV by culture and/or immuno-fluorescence showed a lower recovery rate for nasal swabs (97% versus 67–79%) (58).

Washes and aspirates should be collected in sterile containers and transported directly to the laboratory. Swabs should be placed in tubes containing viral transport medium. Any synthetic (Dacron or rayon) tipped swabs without calcium alginate are acceptable (59), although nylon flocked swabs collected significantly more epithelial cells than rayon swabs as observed by direct fluorescent antibody (DFA) assays and therefore would provide the greatest number of cell-associated RSV (56, 57). Throat swab and saliva specimens are inferior but might be acceptable when it is impractical to obtain nasal or nasopharyngeal specimens (60).

For lower respiratory tract infections, bronchoalveolar lavage (BAL) fluids, bronchial washings, sputa and endotracheal aspirates can be used, with BAL having the best recovery when compared to nasal washes or nose and throat swabs (51, 53). Endotracheal tube aspirate or bronchoalveolar lavage fluid collection is preferred in immune-compromised adults who are being mechanically ventilated (51).

The likelihood of identifying RSV as the etiology of a patient’s infection is greatest when a specimen is obtained within the first several days of illness. Viral cultures or antigens usually become negative 1 week after onset of illness in about 50% of patients. However, shedding of live virus in immune-compromised infants has been documented up to 3 weeks after onset of illness (16, 61, 62). The quantity of virus in the upper respiratory tract (nasal aspirates) is nearly equivalent to that found in the lower respiratory tract when tested by quantitative culture or real-time PCR methods (63, 64). In healthy adult volunteers experimentally inoculated with RSV, the mean duration of RSV shedding was 7.4 (±2.5) days while naturally infected older adults could shed the virus on average for 10 days to 13 days but for as long as ≥20 days (65, 66).

Direct Examination

Microscopy

Although RSV can be visualized by electron microscopy, its application has been limited to research laboratories.
However, characteristic syncytial cytopathic effects (CPE) in lung biopsy facilitate the diagnosis.

Antigen Detection

Rapid Antigen Detection Tests

Rapid RSV antigen tests are commercially available in a variety of platforms or test formats including immunofluorescent assay (IFA) (Table 1), enzyme immunoassay (EIA), dipstick immunoassay (DIA) and chromatographic immunoassay (CIA) (Table 2). Rapid antigen tests can be performed in less than 30 minutes and do not require experienced technologists to perform and interpret test results. Results are visualized as a color change or the appearance of a line or sign on a solid membrane as a result of antigen-antibody complex binding. Most rapid antigen tests have waived status and can be performed as point-of-care tests (67). However, the sensitivity of these assays is highly variable (44 to 95%) and highly dependent on the prevalence of RSV in the community (68–70). Hence, false-positive and false-negative results are a concern depending on the time of the year and the performance of these tests is much reduced during the RSV off season (71, 72). In addition, the accuracy of these rapid tests can be influenced by the type of specimen obtained and the age of the patient. Rapid antigen tests tend to perform better in children than in adults because children generally have higher RSV titers. In contrast, these tests have limited value in the diagnosis of RSV respiratory illness in adults (36, 72). Several studies performed on RSV-infected older adults showed antigen detection in nasal specimens to be very insensitive (69). The extremely low sensitivity in adults is due to low magnitude detection in nasal specimens to be very insensitive (69). The sensitivity and specificity (95% confidence intervals) of the mariPOC test were 89% (78 to 99%) and 100% for RSV detection, respectively (85). Sensitivity and specificity of DFA detection are comparable to that of cell culture (84); however, test turnaround time is longer than for other rapid antigen tests. DFA tests offer the advantage of evaluating the specimen quality by visualizing cells on the slide, but they are fairly labor intensive and require experienced technologists (67, 86).

Nucleic Acid Detection

Compared with conventional diagnostic tests, NAATs have increased diagnostic yields for RSV detection with sensitivities ranging from 93.5 to 100% and specificity approaching 100% (Table 3). The RSV N gene has been used as the principal target for developing NAA-based assays because (i) nucleotide sequences in the N gene are highly conserved and (ii) the N gene is preferentially transcribed because it is located nearer the 3′ end of the genome where transcription and replication initiate. Different technical platforms have been described to detect RSV nucleic acids. PCR-based procedures incorporating one-step, nested, random-access, monoplex, or multiplex RT-PCR have been developed and are used for RSV nucleic acid amplification (68, 87–93). Other non-PCR amplification procedures have been described, including nucleic acid sequence-based amplification (NASBA) (94, 95), loop-mediated isothermal amplification (LAMP) (77, 96), and multiplex ligation-dependent probe amplification (MLPA) (97).

Several diagnostic commercial multiplex molecular diagnostic assays have been cleared by the U.S. FDA for detection of RSV nucleic acids. Although the only specimen type that is currently cleared by the FDA for most of these NAATs is nasopharyngeal swabs, most published reports have included analysis of other respiratory specimen types, including nasal swabs and bronchoalveolar lavage fluids, with sensitivity and specificity similar to that of nasopharyngeal swabs (98–102). In addition, a wide range of research-use-only tests and analyte-specific reagents (ASRs) are available. These assays range from moderate to high complexity with turnaround time as short as 1 hour, allowing implementation of sensitive and rapid molecular assays in a wide range of diagnostic settings (101, 102).

Isolation Procedures

Isolation of the virus from respiratory secretions by cell culture remains the gold standard method for RSV diagnosis due to its excellent specificity. Furthermore, unlike NAAT, viral culture is not affected by mutations in amplification targets, which may result in false-negative results (103), and most specimen types are amenable to culture (74). However, due to the labile nature of RSV, viral culture is not longer the most sensitive and reliable method for diagnosis of RSV infections. Diagnostic samples for culture should be kept cold and inoculated as quickly as possible. Inadequate specimen collection or delays in processing may result in lower sensitivity by culture than antigen tests.

For primary isolation, human heteroploid cells, such as HEP-2, HeLa, and A549 cells, are usually preferred. Other cell lines that may be used but are usually less sensitive include human kidney, amnion, and diploid fibroblastic cells.

and monkey kidney cells (5, 6, 16). Cell line cultures show characteristic syncytial CPE after 3 to 7 days of incubation (Fig. 3). However, the degree of syncytia formation depends on the type of cell culture, the confluence of the cell monolayer, the medium, the strain of virus, the multiplicity of infection, and whether the RSV strain is laboratory adapted. The reported sensitivities of conventional tube cell culture have ranged from 57 to 90%, in part due to compromise of virus viability, the technical expertise required, and the cell lines used in the laboratory (74).

The shell vial assay has significantly shortened the length of time needed for detection of the virus to about 16 hours. This method combines centrifugation and immunofluorescence to detect expression of viral antigens on infected cells before development of CPE (74). The use of R-Mix cultures (Diagnostic Hybrids/Quidel Corp., Inc., Athens, OH), which contain a mixture of human lung carcinoma A549 and mink lung Mv1Lu cells, has been shown to be a rapid and sensitive method for the detection and identification of respiratory viruses (104, 105). With significantly decreased costs compared to conventional culture, the use of R-Mix was slightly more sensitive than RMK, HEp-2 and MRC-5 cell lines used in conventional cultures, and it was several days faster (104). Screening of R-Mix cells after overnight incubation was more sensitive and produced more timely results for RSV and other respiratory viruses, and was more reliable than direct antigen testing (105, 106). In addition, R-Mix cell cultures have the major advantage of identifying viruses not detected by direct staining. A cryopreserved R-Mix ReadyCells preparation can be stored frozen, thawed, and used as needed with minimal addition of re-feeding media (107). A second cell line, R-Mix Too (Diagnostic Hybrids, Inc./Quidel Corp., Athens, OH), which contains a mixture of human lung carcinoma A549 and Madin-Darby canine kidney cells, is also used for rapid growth of respiratory viruses including RSV and shows comparable detection rate to R-Mix cells (74).

**Identification**

The appearance of characteristic syncytial CPE in cell culture, together with a negative hemadsorption test, may be adequate to establish the presence of RSV during the epidemic season. However, since other respiratory viruses (e.g., parainfluenza virus 3 and measles virus) can produce similar CPE in certain cell lines, clinical virology laboratories confirm RSV detection by performing subgroup-specific IFA on infected cells from cell culture vials as a standard practice (74).

**Typing Systems**

Infections with RSV of subgroup A or B may result in differing clinical manifestations and outcomes; therefore, RSV subtype information may become useful in clinical patient management if type-specific vaccines or treatments are developed (16). More commonly, RSV subgroup information has been used widely to facilitate epidemiological investigations (26). Several of the molecular commercial assays include concomitant detection and subtyping of RSV into RSV A and RSV B (Table 3).

Methods commonly used for RSV genotyping include restriction fragment length polymorphisms (RFLP), DNA sequencing, and heteroduplex mobility assays (HMA) of the G protein (108, 109). More than 100 genotypes of RSV group A (i.e., GA2, GA5, GA7) and group B (i.e., GB3 and GB4) have been identified (15, 110–112). Genotyping studies have shown an association between RSV subgroups and clinical severity, with RSV subtype A generally associated with more severe disease (14, 15). Furthermore, molecular epidemiology studies confirmed that multiple subgroups circulate each year and that the predominant genotype may shift with the season (15). These highly discriminatory typing techniques have been useful in monitoring possible nosocomial RSV infections and facilitating the interruption of RSV outbreaks (26).

**Serologic Tests**

Serology is generally not used for clinical diagnosis of RSV infections. Most children have serologic evidence of RSV infection by 2 years of age. A significant proportion (10% to 30%) of young patients with documented RSV infections remain serologically negative, probably due to the immaturity of the infant immune response (16). Secretory antibodies to RSV in nasopharyngeal secretions may also be detected (113, 114), and low RSV-specific nasal IgA is an independently significant risk factor for RSV infection (114). Repeated infections with viruses of the same subgroup of RSV occur frequently; therefore, it is usually necessary to test acute and convalescent sera and observe an increase in titers to confirm the diagnosis.

Serologic diagnosis of RSV infection has been more useful for analysis of vaccine take, defined by 4-fold rise in titers, and for epidemiologic monitoring of infections in the community (116). Current means of serologic diagnosis for RSV infections include IFA, EIA, complement fixation.

Not all targets are FDA cleared.
(CF), and neutralization assays (16, 113, 115). EIA is analytically more sensitive than CF and has the feature of eliminating false IgM-positive results (115). Oral-fluid samples have been used in the place of serum for RSV IgG and IgA antibody detection and surveillance by EIA (113). Virus neutralization tests have been developed only for research and epidemiologic studies as plaque reduction assays or in a microneutralization format.

Antiviral Susceptibilities

Resistance to ribavirin and palivizumab has not been recognized in the clinical setting. Several RSV escape mutants derived in the laboratory have been shown to be resistant to palivizumab prophylaxis in cell culture and cotton rats (117). A total of 435 RSV isolates from treated subjects were recovered during 1998 to 2002 and were tested for resistance. The evidence to date suggests that development of palivizumab-resistant mutants does not appear to play a significant role in hospitalizations for breakthrough RSV disease occurring in infants receiving palivizumab prophylaxis. The nucleotide and amino acid sequence of the F protein epitope to which palivizumab binds appears to be highly conserved among clinical isolates, even in children receiving palivizumab prophylaxis (118).

Evaluation, Interpretation, and Reporting of Results

Test results should be interpreted with knowledge of the natural history of RSV infections in the context of the patient’s clinical presentation and medical history. Serologic results have little clinical value, and rapid antigen, DFA, and NAAT-based molecular assays are the tests of choice for laboratory diagnosis. Culture for RSV detection has lower sensitivity than DFA or NAAT and is mainly used as a backup test, especially for specimens yielding negative antigen results, or when further characterization has been requested. The availability of rapid antigen assays with a turnaround time as short as 15 minutes makes it possible for clinicians to receive results in a timely fashion. However, due to their relatively low sensitivity, false-negative results can be expected and should not be interpreted as excluding the possibility of RSV infection. To improve detection, DFA or RT-PCR assays should be used as backup tests. Additionally, several of the rapid antigen assays are only cleared and/or recommended for use in infants and children and negative results in other age groups should be interpreted with caution.

Cell culture is considered to have the highest specificity, followed by antigen tests or NAAT. NAATs, which are the most sensitive tests for RSV detection, are particularly useful for testing of respiratory specimens collected from adults and in the off-season. With the increased number of multiplex molecular FDA-approved assays, simultaneous detection and identification of common viral pathogens, including RSV, is becoming the main tool for detection and subtyping of RSV. Special attention should be paid to potential carryover contamination and cross-reaction between tested viruses when evaluating and implementing these tests. Whereas multiplex NAATs are currently qualitative, real-time NAATs can provide an estimate of viral load. Additionally, when more than one virus is detected, the viral load can be helpful in identifying the predominant pathogen. Viral load estimates might also be helpful in determining the rate of RSV clearance, as the increased sensitivity of NAAT often results in persistent detection of RSV RNA even after symptoms have resolved. This is especially crucial in immunocompromised patients or pre-transplant patients, where a positive RSV test result could result in further therapy or a delay in transplant procedures, respectively. Nevertheless, the clinical relevance of quantitative respiratory virus PCR awaits further investigation and standardization.

The positive and negative predictive values of these tests vary according to the prevalence of the disease in a particular population during certain seasons. The diagnosis of RSV infection is often made with reasonable accuracy in combination with clinical and epidemiologic findings in infants with lower respiratory tract disease during the epidemic season. However, due to the significant overlap in symptoms and seasonality, diagnostic testing is recommended to accurately identify the infecting virus. Effective exchanges of relevant information between clinicians and the laboratory are essential to good patient care. RSV is extremely labile and improper specimen collection, transport and processing, even when sensitive methods such as RT-PCR are used, can lead to false-negative results. The importance of correct specimen collection and prompt specimen transport cannot be overemphasized. Prompt reporting of test results may assist clinicians in discontinuing unnecessary forms of therapy or in implementing infection control precautions, thereby preventing nosocomial spread of infection.

HUMAN METAPNEUMOVIRUS

Taxonomy

Human metapneumovirus (HMPV) virus was not discovered until 2001, a half century later than its closest cousin RSV (119). HMPV was classified as the first human member of the Metapneumovirus genus, in the subfamily Pneumovirinae, the family Paramyxoviridae, and the order Mononegavirales. The avian pneumoviruses (APV) are highly related to HMPV. APV and HMPV were separated by taxonomists into the separate genus because they can be distinguished from members of the Pneumovirus genus by their lack of genes encoding the nonstructural proteins NS1 and NS2, and by a different gene order in the RNA genome (120).

Description of the Agent

HMPV is an enveloped respiratory virus with a single-stranded nonsegmented negative-sense RNA genome revealing pleomorphic particles measuring 150 to 600 nm (120). Although APV and HMPV are related to RSV viruses, they differ in that the gene order in the nonsegmented genome is slightly altered and APV/HMPV are lacking the two nonstructural proteins NS1 and NS2, which are located at the 3′ end of RSV genomes. The HMPV genome, ranging in length from 13,280 to 13,278 nucleotides, encodes nine proteins in the order 3′-N-P-M-F-M2-SH-G-L-5′ (the M2 gene is predicted to encode two proteins M2-1 and M2-2 using overlapping open reading frames, as in RSV). HMPV nucleoprotein (N) and phosphoprotein (P) proteins interact and are recruited to cytoplasmic viral inclusion bodies in HMPV-infected cells that can be detected easily by immunofluorescent staining. Similar to RSV, nucleotide sequences in the N gene are highly conserved. HMPV fusion protein (F) induces virus-cell fusion by binding to heparin sulfate and uses multiple Arg-Gly-Asp-binding integrins as attachment and entry receptors (121). The glycosylated protein (G), which is the most variable protein among HMPV isolates, binds to the host cell via cellular glycosaminoglycans, including heparin sulfate-like molecules (122).
Epidemiology and Transmission

Nearly all children have evidence of prior infection by the age of 5 years, when they are tested by serology (119). A prospective, population-based surveillance for acute respiratory illness or fever among inpatient and outpatient children in three U.S. counties from 2003 through 2009 revealed that HMPV infection is associated with a substantial burden of hospitalizations and outpatient visits among children throughout the first 5 years of life, especially during the first year (123). The burden of HMPV illness on the intensive care unit in terms of resource utilization may be considerable (124). Approximately 12% of outpatient lower respiratory tract illness was associated with HMPV infection, and 3.9% of hospitalizations in children due to acute respiratory illness or fever were associated with HMPV. HMPV has been found in association with respiratory tract disease in every environment; dozens of country-specific case series have been reported (122).

HMPV has a seasonal distribution in temperate countries with most cases occurring in winter and spring (Fig. 4), often overlapping in part or in whole with the annual RSV epidemic (123). Long-term studies have shown that sporadic infection does occur year round. HMPV strains vary genetically and antigenically and have been classified into two broad groups: group A and group B, with each group divided into genetic subgroups 1 and 2 (119, 120). The A2 sublineage shows the greatest diversity; phylogenetic analysis showed a further bipartition of A2 into two new genetic clusters designated A2a and A2b (125–127). Both antigenic group A and group B were noted to cocirculate in the same location during the epidemic periods and had various patterns of predominance. Antigenic variability is thought to contribute to reinflection throughout the life of the patient and may pose a challenge to vaccine development (125–127).

The incubation period is thought to be about 3 to 5 days. Humans are the only source of infection. The usual period of viral shedding has not been defined, but is likely to be weeks following primary infection in infants. Formal transmission studies have not been reported, but experts believe that transmission occurs by close or direct contact with contaminated secretions involving large particle aerosols, droplets or contaminated surfaces (120). HMPV, as a nosocomial pathogen, has been underestimated until recently. Several health care–associated HMPV infections have been reported in hospitalized children and adults, and contact isolation with excellent hand washing for health care providers is necessary to prevent spread (122, 128–131). There should be increased awareness of HMPV infection within health care settings, particularly when the population at risk has a high prevalence of underlying co-morbidities (129).

Clinical Significance

HMPV is associated with the common cold and with lower respiratory tract illnesses such as bronchiolitis, pneumonia, group, and exacerbation of reactive airways disease. The signs and symptoms caused by HMPV are very similar to those caused by RSV; providers cannot distinguish between the two infections based on clinical assessment alone. Like RSV, HMPV infection leads to significant morbidity in infants and other special populations, including patients who are immunocompromised, high-risk, or elderly. Most children with HMPV infection were previously healthy. Female gender, hospital acquisition of HMPV infection, and presence of chronic medical conditions each independently increase mortality (123). The virus causes upper and lower respiratory tract illnesses. About half of the cases of lower respiratory tract illness in children occur in the first 6 months of life, suggesting that young age is a major risk factor for severe disease (123). Both young adults and the elderly can suffer HMPV infection that leads to medically attended illnesses including hospitalization, but severe disease occurs at lower frequencies in adults than in young children (132). RSV and HMPV coinfections have been reported, which is not surprising given the overlapping seasons. Coinfection with bacteria is not common, except for the complication of otitis media, which occurs frequently (123).

Immunocompromised patients are particularly susceptible with resultant morbidity and mortality. A large proportion of respiratory tract samples submitted to diagnostic virology laboratories are obtained from immunocompromised patients. HMPV infection is associated with wheezing more commonly in patients with underlying pulmonary disease, especially asthma (123). HMPV causes severe lower respiratory tract disease in pre- and post-HSCT recipients, with mortality rates at 100 days of 43%. Steroid therapy, oxygen requirement of >2 liters or mechanical ventilation, and bone marrow as cell source were significant risk factors for overall and virus-related mortality in multivariable models, whereas the virus type was not (133).

The majority of immunocompetent children infected with HMPV can be managed with supportive care. Both ribavirin and polyclonal human immunoglobulin have been used for HMPV infections in immunocompromised patients. In a case report of a 2-year-old girl undergoing intensive chemotherapy for Burkitt lymphoma who developed severe HMPV pneumonia, rapid and complete recovery was observed after treatment with oral ribavirin and intravenous Ig (134). Ribavirin has been used in conjunction with Ig in severely immunocompromised patients with some evidence of efficacy (135). In a series of nine immunocompromised patients who were diagnosed with pneumonia secondary to HMPV, two treated with aerosolized and oral ribavirin along with intravenous immunoglobulin recovered (136). Oral ribavirin therapy alone did not improve clinical outcomes in hematologic disease patients infected with HMPV (137). HMPV vaccine is not available. Recently, it was reported that a HMPV-like particle vaccine induced cross-protection against HMPV infections in mice (138).

Collection, Transport, and Storage of Specimens

Reports in the literature suggest that HMPV can be recovered or detected by antigen detection, culture, and RTPCR from nasal washes, nasopharyngeal aspirates, nasopharyngeal swabs, and bronchoalveolar lavage specimens. Typically, nasopharyngeal aspirates are collected from infants by using a 10F catheter. Washing the catheter after dispensing, in addition to collection of material in the collection trap, may enhance yield over use of the trap material alone (139). Nasopharyngeal flocked swabs have been gradually used to replace aspirate specimens without significantly decreasing diagnostic yield (140). Transport is generally performed using standard viral transport media. Specimens should be processed as soon as possible after collection and stored at 4°C for less than 72 hours before processing. Incubation at 37°C has been shown to lead to a rapid decrease in HMPV titer (141). For long-term storage of specimens or laboratory stocks, a temperature of ~70°C is preferred with specimens in O-ring sealed cryovials.
Direct Examination

Microscopy
The virus can be seen by electron microscopy (119). This method was used to study host binding domain to the HMPV F protein; however, it is not sufficiently sensitive or reproducible for clinical diagnosis use.

Antigen Detection
Several rapid antigen tests using different platforms have been reported for use on nasopharyngeal aspirate and swab samples using HMPV-specific monoclonal antibodies (120, 142, 143). An antigen detection EIA kit is commercially available from Biotrin (Dublin, Ireland). The initial studies reported a sensitivity of 81% and a specificity of 100% in comparison to viral culture and RT-PCR (144) and an agreement of 94% with the Pro HMPV Real Time Assay from Prodesse (Gen-Probe) (145). Another antigen detection kit using immunochromatography (the Check HMPV assay previously known as the SAS HMPV test; SA Scientific, San Antonio, TX) was evaluated on nasal swab specimens with overall sensitivity and specificity of 82.3% and 93.8%, respectively, when RT-PCR was used as standard (146). This assay was used to rapidly identify index patients during an HMPV outbreak in a long-term-care facility (130).

In addition to rapid EIA format, DFA staining has been widely implemented for HMPV detection in the clinical setting (Table 1). Mouse monoclonal antibodies specific for HMPV have been developed and used for DFA staining of
Nucleic Acid Detection

The most sensitive test for identification of HMPV in clinical samples to date is RT-PCR. Numerous real-time RT-PCR tests targeting the N and F genes have been reported to detect HMPV from the four known genetic lineages (71, 91, 150–152). Although the copy number of the N gene transcript should be higher than that of the F gene because of its more proximal position relative to the virus’s 3’ leader region where transcription begins, both F and N primers sets have been shown to be positive in RT-PCR tests. Quantitative RT-PCR tests have been employed to define viral load in patient samples (152). A NASBA test also has been described; however, the sensitivity of this assay (limit of detection of 100 copies) appears to be lower than that of quantitative RT-PCR (153). Several molecular devices, including NucliSens EasyQ-HMPV (bioMérieux, Durham, NC), MGB Alert HMPV Detection Reagent ASR (Nanogen, San Diego, CA), Quidel Molecular RSV+ HMPV Assay (Quidel Corp., San Diego, CA), and Pro HMPV Assay (GenProbe Inc, San Diego, CA), are commercially available specifically for detection of HMPV; their performance characteristics are contrasted in Table 3.

Recent advances in nucleic acid amplification and identification techniques have allowed for the development of molecular systems that can simultaneously detect and differentiate multiple respiratory viruses, including HMPV in clinical laboratories with varied sizes, resources, or capacities. Several commercial devices, with different amplification and detection platforms, have been reported including RespiFinder (PathoFinder BV, Maastricht, The Netherlands) (97), ResPlex II assay (Qiagen, Valencia, CA) (91), FilmArray Respiratory Pathogen Panel (BioFire Inc., Salt Lake City, UT) (100, 154), Infiniti Respiratory Viral Panel (AutoGenomics, Inc., Carlsbad, CA) (93), Seeplex Respiratory Virus Detection Assay (Seegene, Inc., Seoul, Korea) (155), PLEX-ID RVP Panel (Abbott Molecular Inc., Des Plaines, IL) (156), xTAG Respiratory Viral Panel (Luminex Molecular Diagnostics, Toronto, Canada) (92, 177), and eSensor XT-8 Respiratory Viral Panel (GenMark Diagnostics, Inc., Pasadena, CA) (157) (Table 3). Among them, the xTAG RVP, the FilmArray Respiratory Pathogen Panel, and the eSensor XT-8 Respiratory Viral Panel have received FDA-approval for HMPV to date (92, 157). Most of these devices targeted highly conserved HMPV N or F genes. Some of these systems have potential for high-throughput testing, and others allow rapid near-patient testing (92, 158, 159). The multiplex testing reveals positive tests for more than one agent in a significant proportion of cases (88, 160); however, the potential coinfections should be interpreted with caution for several reasons. First, PCR is susceptible to false-positive tests due to cross-contamination in some laboratories that perform frequent amplifications. Second, viral genome can be detected by RT-PCR in respiratory secretions for several weeks or more, even after live virus shedding has ceased. It is difficult to know in this situation if the presence of positive virus-specific nucleic acids signifies active infection or simply a recent acute infection. Potential future applications of quantitative molecular tests would be to differentiate acute and resolved infections as well as to determine the significance of positive findings (152, 160–162).

Identification

The characteristics of the CPE are not distinct enough that the virus could be identified on this basis, even by trained observers (119, 163). HMPV is suspected when a virus is isolated during the epidemic season in Vero or LLC-MK2 cells in monolayer culture (141, 142). HMPV grown in LLC-MK2 cell or Vero cell monolayer cultures is slow and often requires several blind passages before CPE appears, especially following primary isolation. The CPE in cell lines is not particularly striking, often appearing only as focal areas of rounding of cells and minor patches of cell-cell fusion (119, 163). A shell vial culture method using R-Mix cells with mixed monolayer of human adenocarcinoma cells (A549 cells) and mink lung cells (Mv1Lu cells) (Diagnostic Hybrids Inc./Quidel Corp), and an HMPV-specific monoclonal antibody had a sensitivity of 100% compared with tube culture in one study (164).

Typing Systems

The typing of strains of HMPV is mainly of interest to epidemiologists at this time and does not currently provide guidance in clinical care or therapy. The nomenclature and classification of genotypes, subgroups, strains, variants, and isolates of HMPV are still being developed. The HMPV G glycoprotein genes exhibit the greatest diversity with nucleotide and amino acid sequence identities ranging from 52 to 58% and 31 to 35%, respectively, between subgroups A and B (120, 165). Within the A subgroup, the A2 sublineage shows the greatest diversity and has been further divided into two new genetic clusters designated A2a and A2b (125–127). Studies using experimental infection of animals and reciprocal cross-neutralization studies suggest for the most part that the viruses of varying subgroups all fall within one serotype (120).

Serologic Tests

Serology is generally not used for clinical diagnosis of acute infections, because diagnosis requires a comparison
of acute- and convalescent-phase titers. Several serology methods using both virus-infected cell lysates and recombinant viral proteins in enzyme-linked immunosorbent assay (ELISA) have been reported (119, 166–168). Serum neutralizing antibody assays have been used to demonstrate the induction of functional antibodies in both humans and experimentally infected animals. Most of these tests have used reduction of virus plaques or CPE as the readout; however, a more objective microneutralization test using a recombinant HMPV expressing green fluorescent protein has been reported (169). The use of molecular diagnostics may have exaggerated the HMPV infection prevalence determined by serology methods (170). In contrast, additional HMPV diagnostic yield by adding serology to PCR was revealed in Kenyan patients (171).

Antiviral Susceptibilities

Both ribavirin and polyclonal human Ig have been used for HMPV infections in immunocompromised patients (134–137, 172). No controlled trials have been conducted and antiviral effect remains determined. Resistance to ribavirin and immunoglobulin has not been recognized in the clinical setting.

Evaluation, Interpretation, and Reporting of Results

Several FDA-approved rapid antigen (DFA) and molecular tests are commercially available for detection of HMPV. Therefore, the laboratory diagnosis of HMPV should be based on the detection of HMPV genomes by NAAT or antigen tests by DFA in nasopharyngeal aspirates or swabs. Currently, the diagnosis is best made when an HMPV-specific RT-PCR test is found to be positive. Multiplex PCR assays are available to detect and differentiate a panel of respiratory viruses, which helps distinguish the infection from RSV and other viral respiratory tract infections. Although CLIA waived, point-of-care tests are not commercially available for HMPV, some of the molecular assays allow rapid near-patient testing that helps prompt patient care and control nosocomial transmission. Serology and typing are mostly of utility in studies of epidemiology at this time.

Because the average duration of shedding during infection is not defined, and the role of coinfection in disease expression is not well understood, the clinical interpretation of a positive HMPV molecular test must be made with caution, especially when RNA from another virus is detected simultaneously in the same sample. In general, the diagnosis of HMPV infection is most likely when a positive nucleic acid test for HMPV infection occurs when testing a respiratory secretion during late winter or early spring in temperate climates from a patient with acute respiratory illness and negative tests for other respiratory viruses. Real-time PCR-based quantitative molecular test results including threshold cycle (Ct) values may be useful to determine the significance of positive findings as well as to differentiate acute and resolved infections. Inversely correlated to the HMPV loads in clinical specimens, higher Ct values would be more consistent with a resolved infection.

Measles and Rubella Viruses

WILLIAM J. BELLINI AND JOSEPH P. ICENOGLE

MEASLES VIRUS

Taxonomy

Measles is the prototypic member of the genus Morbillivirus in the family Paramyxoviridae, and it is the only member of the genus that causes human disease (1). With rare exception, the members of this genus have restricted host ranges, indicative of long-term association with, and adaptation to, their respective zoonotic hosts. Other genus members include rinderpest virus, canine distemper virus, peste des petits ruminants virus, and cetacean and phocine distemper viruses.

Description of the Agent

Measles virus is an enveloped, nonsegmented, single-stranded, negative-sense RNA virus with a diameter of 120 to 250 nm. The measles virus genome is 15,894 nucleotides in length and contains six structural genes organized on the single strand of RNA in a gene order consistent with most of the paramyxoviruses, i.e., 3′-N, P, M, F, H, and L-5′. The genome encodes at least eight proteins; three gene products are coded for by the phosphoprotein (P) cistron. The nucleoprotein (N) gene encodes the N protein, which encapsulates both full-length minus-strand (genome) and full-length plus-strand (antigenome) RNAs. The protein products of the P and the polymerase (L) genes interact with the full-length viral RNA and form the ribonucleoprotein complex. Viral nucleocapsid structures are surrounded by a membrane, derived from the plasma membrane, which includes the gene products from the M, F, and H genes (matrix, fusion, and hemagglutinin proteins, respectively). The F and H envelope proteins are N-linked transmembrane glycoproteins, and are responsible for fusion of virus with host cell membranes (1). The H glycoprotein is the major target for neutralizing antibody, and interacts with the two cellular receptors for measles virus, CD46 (2) and human signaling lymphocyte activation marker (hSLAM) (3). Recently, an epithelial cell protein, nectin-4, was identified as a third measles receptor. This receptor also interacts with the H glycoprotein and is present in adherens junctions of tracheal airway epithelial cells (4, 5).

Although measles virus has only a single serotype (monotypic), antigenic and genetic variability has been detected between and among wild-type viruses and vaccine viruses. The nucleotide sequence variability among wild-type viruses is most evident in the genes encoding the N and H proteins (7 to 10%), and the maximum sequence variability has been determined to reside in the last 450 nucleotides of the coding region of the N gene (∼12%) (6). Based on this sequence region, a standard nomenclature has been established. For molecular epidemiologic purposes, the genotype designations are considered the operational taxonomic unit, while related genotypes are grouped by clades. The World Health Organization (WHO) currently recognizes 8 clades designated A, B, C, D, E, F, G, and H. Within these clades, there are 24 recognized genotypes (7). A recent report by Rota and others (8) provides an excellent overview of the current status of the molecular epidemiology of measles and the global distribution of the various genotypes.

Epidemiology and Transmission

Measles virus infections are transmitted via aerosols, droplets, or contaminated fomites. Measles is a highly contagious disease, and susceptible individuals who come into close contact with measles patients have a 99% probability of acquiring the disease. In the prevaccine era, greater than 90% of individuals would acquire measles infections before 10 years of age.

In unvaccinated populations, measles causes periodic epidemics, with interepidemic periods of 2 to 5 years. These periods decrease as population size and density increase and are directly related to the availability of susceptible individuals for sustained disease transmission.

In vaccinated populations, the interval between measles outbreaks increases, and sufficiently high levels of vaccination can interrupt endemic transmission. With vaccination, the age distribution of cases is determined by which groups are likely to lack vaccine- or measles-induced immunity. In the United States, an extensive effort to achieve high levels of first-dose measles vaccination at 12 to 15 months of age and the addition of a recommended second dose of vaccine in school-age children has resulted in a decrease in reported measles cases from 400,000 to 500,000 per year in the 1960s to record lows of approximately 63 cases from 2000 to 2007, and increasing somewhat due to importations in recent years (9–11). Endemic transmission of measles in the United States was interrupted in 1994 (12), and measles was declared eliminated from the U.S. in 2000 (13). Recently, a panel of experts was convened to certify the maintenance of elimination of measles and of rubella (14).

The decade or more absence of circulating measles virus and, therefore, natural “boosting” of the antibody response,
has led some investigators to question whether endemic measles transmission might be reestablished if population antibody immunity were to wane below theoretical protective levels (15). Investigation of outbreaks associated with importations of measles into the U.S. or similar measles-eliminated settings have resulted in the majority of spread cases occurring among unvaccinated individuals. However, limited spread was occasionally observed among one- and two-dose recipients of measles-containing vaccine. These suspect measles cases often presented with modified symptoms, such as reduced fever and modified rash illness in terms of appearance and duration, and were reminiscent of suspect measles cases often presented with modified symptoms, such as reduced fever and modified rash illness in terms of appearance and duration, and were reminiscent of cases referred to as “secondary vaccine failure” cases. In fact, laboratory testing indicated that these individuals had a heightened memory response, manifested as a high-avidity IgG and an unusually high neutralizing-antibody response (>50,000 mIU) within the first few days of rash (16, 17).

Confirmed measles infections in health care workers with numerous pediatric contacts resulted in no additional cases, indicating that these modified infections pose a low transmission risk (18) and little threat to the eradication effort. Nevertheless, good public health practice would dictate that these modified measles cases be monitored to assure that contacts remain uninfected, particularly unvaccinated contacts.

Although measles remains a formidable disease of children in many areas of the world, tremendous strides have been made in global measles control and mortality reduction between 2000 and 2010, with recent estimates suggesting infections and deaths declined by approximately 75% during this period (18). Effective use of available live-attenuated measles vaccines and a variety of multidose vaccination strategies (second opportunities for vaccination) have combined to eliminate measles in many large geographic regions, including the Americas, Australia, the Scandinavian countries, and the United Kingdom (19, 20). Unfortunately, large measles outbreaks in Africa and delays in implementing vaccination campaigns and other control measures in India have slowed the global march toward the mortality-reduction goal. Successful achievement of this goal will require redoubling of political and especially financial commitments at a time when such resources are very difficult to secure. Nevertheless, the World Health Assembly recommended proceeding to the eventual global eradication of measles, if measurable progress towards reaching the regional measles elimination goals can be achieved (21).

Clinical Significance

Uncomplicated Clinical Course

Approaching 1 week to 10 days following exposure, the clinical presentation begins with cough, coryza, conjunctivitis, and fever. The prodromal stage then progresses over the next 3 to 4 days, with all symptoms intensifying and the associated fever reaching as high as 105°F. Koplik’s spots, pathognomonic for measles, appear on the buccal mucosa in 50 to 90% of cases 2 to 3 days before rash onset, and may persist for 1 to 2 days following rash onset. These lesions are small, irregular red spots with a bluish white speck in the center. The erythematous rash appears approximately 2 weeks following exposure and is first evident on the forehead or behind the ears. The rash presents as red macules 1 to 2 mm in diameter, becoming maculopapules over the next 3 days. The exanthem is usually most confluent on the face and upper body and initially blanches on pressure. By the end of the second day the trunk and upper extremities are covered with rash, and by the third day the lower extremities are affected. The rash resolves in the same sequence, first disappearing from the face and neck. The lesions turn brown and persist for 7 to 10 days and then are followed by a fine desquamation. In most cases, recovery is rapid and complete.

Death resulting from respiratory and neurological causes (see below) occurs in 1 of every 1,000 measles cases, but estimates during the 1989 to 1991 outbreaks were three to four times higher (22). The risk of death is greater for infants and adults than for children and adolescents. However, rates of acute measles virus infections of infants and children in developing countries, particularly malnourished populations, can approach 10%, with rates of morbidity being much higher.

Complications

The most common complications associated with measles virus infection are otitis media (7 to 9%), pneumonia (1 to 6%), and diarrhea (6%). Pneumonia may occur as a primary viral pneumonia (Hecht pneumonia) or as a bacterial superinfection. Measles commonly involves the central nervous system (CNS), with as many as 50% of cases reported to have electroencephalogram abnormalities during the acute or convalescent phase of the illness (23).

Notable CNS complications include acute disseminated encephalomyelitis and subacute sclerosing panencephalitis (SSPE). Acute disseminated encephalomyelitis occurs approximately 1 week after rash onset in 1 per 1,000 cases and is manifested clinically by seizures, lethargy, irritability, and/or coma. It results in the death of 5 to 30% of patients, causes residual deficits in about 30% of survivors (24, 25), and is presently considered an autoimmune disease since an immune response to myelin basic protein has been reported and measles virus has not been isolated from these patients (26).

SSPE is a progressive, inevitably fatal, late neurological complication caused by persistent measles virus infection of the CNS that occurs in approximately 1 per 100,000 measles cases (27), although recent studies estimate the rate to be 1 per 11,000 cases (28). Only wild-type measles virus nucleic acid sequences have been found in association with this disease. The average time from natural measles virus infection to manifestations of SSPE is 7 years. The disease characteristically involves personality changes, decreased motor and intellectual capabilities, involuntary movements, and muscular rigidity and ultimately leads to death. The virus is difficult to recover from brain specimens, requiring cocultivation or brain tissue explant techniques, yet measles virus proteins and RNA can readily be detected in brain tissue (29, 30). Patients with SSPE usually have high titers of measles virus-specific IgG antibodies in their sera and cerebrospinal fluid.

Infection during pregnancy is associated with an increased risk of miscarriage and prematurity, although there is no convincing evidence that maternal infection with measles virus is associated with congenital malformations. Clinical illness in the newborn after intrauterine exposure follows a shortened incubation period and may vary from mild to severe.

Atypical measles syndrome occurred in children who had been vaccinated with multiple doses of formalin-killed measles vaccine and subsequently exposed to wild-type measles virus. The syndrome was believed to occur as a result of immunopathological responses due to a combination of the Arthus reaction and delayed hypersensitivity (31). The syndrome has little relevance today, but the experience serves to emphasize the safety concerns that should be...
addressed by those wishing to develop alternative measles vaccines or to explore alternate routes of vaccine delivery.

The use of combined, live-attenuated measles-mumps-rubella (MMR) vaccines has been the subject of controversy particularly as their use might be associated with immune-mediated bowel disorders, ileal lymphonodular hyperplasia, and a regressive form of autism (32, 33). Reviews conducted by expert panels assembled by the Institute of Medicine, as well as numerous carefully controlled epidemiological and laboratory studies in many countries including the United States and United Kingdom, have failed to confirm those reports (34, 35). Most recently, the Office of Special Masters of the US Court of Federal Claims rejected test cases claiming compensation for injuries due, in part, to MMR playing a causal role in autism-spectral disorders. A portion of the ruling was based on exhaustive review of the current literature regarding any causal relationship between MMR vaccine and autism spectral disorders. On January 28, 2010, a full retraction from the published record of the original paper by Wakefield and coworkers (33) was made by The Lancet (published online February 2, 2010).

Other described complications include thrombocytopenia, purpura, encephalitis, meningitis, myocarditis, and Stevens-Johnson syndrome.

In immunocompromised patients, syndromes such as giant-cell pneumonia and measles inclusion-body encephalitis (MIBE) have been observed (36, 37). Measles-induced giant-cell pneumonia is usually unrecognized due to the absence of rash. It usually occurs in patients with deficits in cell-mediated immunity, and several cases have been diagnosed following vaccination of children with severe combined-immunodeficiency syndrome (38). MIBE is generally fatal and is best described as the unchecked replication of measles virus in the CNS in the face of an impaired or absent cell-mediated immune response. There are anecdotal reports of more severe and even fatal measles in patients with AIDS (39). However, vaccination is considered safe unless patients are severely immunocompromised.

**Collection, Transport, and Storage of Specimens**

In general, specimens for successful virus isolation should be collected early in the acute phase of the infection, when the virus is present in high concentrations, and transported to a laboratory under conditions that maintain the infectivity of labile viruses. Suitable samples for isolation of measles virus or for detection of viral antigen can be whole blood, serum, throat and nasopharyngeal secretions, urine, and, in special circumstances, brain and skin biopsy samples. Specimens should be processed as soon as possible after collection and are best kept at 4°C rather than frozen, since freezing causes significant loss of recoverable virus. Specimens should be frozen and shipped with dry ice only if the time between specimen collection and delivery to the laboratory is expected to exceed 48 h.

Transport medium should be used to maintain measles virus until isolation of virus from clinical specimens can be performed. Samples requiring viral transport medium and commercial sources of viral transport medium are reviewed in chapter 79. Measles virus is lymphotropic, and macrophages are a known source of infectious virus during natural infection (40). Thus, peripheral blood mononuclear cells (PBMCs) are an excellent source for the isolation of measles virus. PBMCs are obtained from heparinized blood (diluted 1:3 in saline) by sedimentation through density gradients.

Serum specimens from patients with suspected measles should be assayed in an IgM enzyme-linked immunosorbent assay (ELISA) within 7 to 10 days of rash onset, if possible. A single serum specimen is sufficient in most cases (41). To assess seroconversion following measles vaccination, serum specimens can be tested with IgG enzyme immunosassays (ElsAs) or plaque reduction neutralization (PRN) tests (see below). Ideally, paired specimens should be obtained: the first prior to vaccination and the second approximately 3 to 4 weeks later, so that a rise in measles virus-specific IgG can be measured. Serum samples should ideally be stored at −20°C, but antibody is stable for extended periods at 4°C. Samples for IgM determinations should not be frozen and thawed more than five times. Spinal fluid samples should also be obtained if neurological complications are present or suspected.

Respiratory specimens are appropriate for testing. Nasal aspirates or bronchial lavage samples yield virus more frequently than throat swabs, because of the greater likelihood of obtaining infected cells. For immunofluorescence assays (IFAs), slides of respiratory specimens should be fixed in cold acetone for 2 min and stored at 4°C.

For isolation of virus from urine, a large volume of midstream (clean-catch), preferably morning urine should be collected into a sterile container. Measles virus is very cell associated; thus, the urine is centrifuged at 800 × g for 30 min. The pelleted cells and sediment are resuspended in 1 to 2 ml of Hanks’ balanced salt solution in preparation for cell culture, PCR, or other diagnostic methods (42). Two approaches show promise in terms of alternatives to serum specimen collection for the diagnosis of measles: the use of oral mucosal transudates (OMT) (see chapter 79) and the use of blood spots on filter paper. OMT samples have been used both for detection of measles virus-specific IgM and IgG and for detection of hepatitis, rubella, mumps, and other infections (43–45). This specimen collection method has been used successfully for many years for routine measles surveillance in the United Kingdom (46). The use of OMT samples has appeal because the collection method is noninvasive. The specimens can be used for rubella testing, do not require processing in the field, and offer the opportunity to detect measles virus-specific IgM for case confirmation and nucleic acids for molecular characterization (47, 48). Commercial serological assays performed on OMT samples can result in heightened background reactivity and decreased sensitivity; cold chain issues remain a problem with OMT specimens in warmer climates. Devices (such as OraSure) containing compounds that stabilize IgM should be avoided if molecular testing is to be performed as these additives inhibit nucleic acid amplification enzymes.

Like OMT samples, blood spots collected onto filter paper do not require processing in the field, but a cold chain does not appear necessary. They can be used to test for rubella as well as for measles (49–52) and they can be used for molecular characterization of the measles virus genome (53), although virus isolation would not be possible. In addition, the eluted serum from blood spots can likely be tested in commercially available measles ELISAs without the loss of sensitivity and specificity (49, 53, 54), making this technology very attractive for widespread use. Although still considered an invasive technique, fingerstick as a method for sample collection is often more acceptable to parents than phlebotomy (55).

In June 2007, WHO convened a special meeting of the Laboratory Network collaborators to review the available data on use of OMT and dried blood spots (DBS). Among the recommendations that emerged, the committee en-
dorsed the use of both methods as viable options for measles and rubella surveillance in all regions, especially where patients might resist venipuncture, or where special challenges exist with specimen storage or transportation (47).

Direct Examination
Cytologic Examination
Characteristic cytopathic effects (CPE) of measles virus infection include multinucleated cells and cellular inclusions (intracytoplasmic and intranuclear). Cytologic examination of various lymphoid tissue specimens and secretions frequently reveals the presence of giant cells with multiple overlapping nuclei, Warthin-Finkeldey giant cells. Slides can be stained with either Wright stain or hematoxylin and eosin. Tissue samples may be fixed in 10% formalin, embedded in paraffin, sectioned, and then stained with hematoxylin and eosin (36). Staining of tissue specimens with monoclonal antibodies (see below) to the measles virus N protein has been used for the diagnosis of giant-cell pneumonia and MIPE (57).

Immunofluorescence Assay
Detection of measles virus can be achieved using an immunofluorescent antibody (IFA) to examine clinical specimens as well as cell cultures infected with clinical material. The standard assay uses a commercially available monoclonal antibody to the N protein of measles virus and fluorescein-conjugated goat anti-mouse antiserum (see “Confirmation of Measles Virus Isolation” below). Naphospharyngeal aspirates or swabs from the posterior nasopharynx are the specimens of choice and can be diluted in sterile saline solution and centrifuged at 800 × g to pellet the cells. The cell pellets are then washed several times with sterile saline before being applied to a glass slide and fixed in cold 80% acetone for 10 min at −20°C (58, 59). Using the N monoclonal antibody, specific granular or punctate fluorescent staining restricted to the cytoplasm is often observed in multinucleated giant cells.

Nucleic Acid Detection Techniques
Standard and real-time reverse-transcriptase quantitative PCR (RT-PCR and RT-qPCR) assays have been used in research settings to detect measles virus RNA in a variety of clinical specimens and infected cells (60–63). While measles IgM serology remains the recommended routine diagnostic test for acute measles infections, molecular detection methods can be more advantageous in certain circumstances. Recently real-time RT-qPCR was included as an acceptable method for measles case confirmation along with IgM serology, IgG seroconversion, and 4-fold rises in antibody titer using a quantitative IgG method (64). The measles RT-qPCR assay is used in conjunction with IgM serology in elimination settings to provide the best opportunity of confirming suspect measles cases. Collection of both blood and respiratory specimens when the patient first presents with symptoms is now strongly recommended.

RT-PCR should be considered for measles case confirmation where IgM testing is compromised by the concurrent or recent use of measles-containing vaccine as part of outbreak response or in settings of recent vaccine distribution, such as supplemental immunization activities (65). Likewise, molecular detection methods can be used when cell culture isolation is not a practical alternative, and/or when genetic characterization of the virus is required. RT-PCR amplification and nucleotide sequencing of the last 450 nucleotides of the coding region of the N protein gene permit genotype analysis and delineation between vaccine and wild virus (see “Genotyping” below). The use of molecular techniques to detect and track diseases like measles and rubella has expanded tremendously, particularly within the WHO LabNet. However, these tests are performed primarily in Regional Reference Laboratories (RRL) and in some cases National Laboratories where measles has been largely controlled or is near elimination. In contrast, molecular methods have not been implemented beyond the RRL level in places where case-based surveillance is less of a priority, such as areas challenged by uncontrolled measles or large measles outbreaks (8, 66).

Isolation and Identification of Measles Virus
Measles virus can be isolated from the conjunctiva, nasopharynx, and blood during the latter part of the prodromal period and during the early stages of rash development. Although virus has been isolated from the urine as late as 4 to 7 days after rash onset, viremia generally clears 2 to 3 days after rash onset in parallel with the appearance of antibody. Thus, virus can be most readily isolated within a period from 2 to 4 days prior to rash onset to about 4 days after rash onset.

Though other cell cultures and lines, such as primary monkey kidney and Vero cells, have traditionally been used, an Epstein-Barr virus-transformed B lymphoblastoid cell line derived from marmoset lymphocytes until recently has been the preferred cell line for primary isolation of measles virus (67). These cells (B95a cells) were found to be as much as 10,000 times more sensitive for isolation of measles virus from clinical specimens than other cell lines, such as Vero cells and primary monkey kidney cells. Laboratories should note that this cell line does produce Epstein-Barr virus and should be handled as infectious material at all times. B95a cells can no longer be obtained from commercial sources, thus dramatically restricting the widespread use of this cell line.

Recently, a Vero cell line transfected with a plasmid encoding the protein for the hSLAM molecule has been constructed (68). The hSLAM molecule has been shown to be a cell surface receptor for both wild-type and laboratory-adapted strains of measles. Testing conducted to date indicates that the sensitivity of Vero/hSLAM cells for isolation of measles virus is equivalent to that of B95a cells. Vero/hSLAM cells also express the simian CD46 molecule. The cell line has been recommended for use in the WHO Laboratory Network as a replacement for the B95a cell line. The CPE that results following measles infection is essentially that observed in measles-infected Vero cells (Fig. 1). The advantage to the Vero/hSLAM cells is that they are not persistently infected with Epstein-Barr virus, and therefore, are not considered as hazardous material like B95a cells. This provides a significant safety advantage for laboratorians and greatly facilitates international shipments. The disadvantage of the Vero/hSLAM cells is that they must be cultured in medium containing Geneticin to retain hSLAM expression. This increases the cost of the cell culture medium. Laboratories (U.S. public health and WHO LabNet laboratories) should only accept Vero/hSLAM cells from a WHO-approved source (RRL or Global Specialized Laboratory). Upon receipt, the cells should be passaged in medium containing 400 μg of Geneticin/ml as described in the protocol distributed with the cell line. Laboratories should passage the cells two to four times in the presence of Geneticin to expand the number of cell culture vessels sufficient for preparation of 20 to 50 vials of seed stock for liquid-nitrogen storage.
To prepare cells for virus isolation procedures, Vero/hSLAM cells can be recovered from liquid nitrogen and passaged up to 15 times in medium without the addition of Geneticin. These cells should be used for virus isolation attempts only and should be discarded after 15 passages. Even with addition of Geneticin to the medium, the cells should not be passaged forward beyond about 20 to 30 passages, as with the standard Vero cell line. Cells that have been passaged without Geneticin in the medium should never be used to prepare cell stocks for liquid-nitrogen storage or shipped to another network laboratory for use in virus isolation.

Confirmation of Measles Virus Isolation

Confirmation of isolation is most often achieved by IFA detection and uses a monoclonal antibody to detect the N protein or other internal antigen of measles virus in infected cells. The infected cells are fixed onto a microscope slide. Binding of the measles virus-specific antibody is detected using a goat anti-mouse antibody that is conjugated to fluorescein isothiocyanate. IFA test kits are available from Milli- pore Corporation, Billerica, MA (Light Diagnostics, catalog no. 3187). It is also possible to configure an indirect IFA using a goat anti-mouse antibody that is conjugated to fluorescein isothiocyanate-labeled conjugate have to be determined by experimental titration.

Genotyping

Amplification sequencing and phylogenetic analysis (genotyping) of the last 450 nucleotides of the measles N gene has proven useful in suggesting the possible source of virus involved in outbreaks, tracking transmission pathways during outbreaks, and differentiating between vaccine and wild-type strains of measles (8, 66, 69). The latter application is the most pertinent to measles diagnostics, but until recently, rarely performed at the state or local public health laboratory level. In general, these laboratories are asked to collect appropriate viral specimens from suspected cases, and send them to the Centers for Disease Control and Prevention (CDC) if the results of IgM serology are positive.

In 2012, the CDC, in collaboration with the Association of Public Health Laboratories (APHL), established four Vaccine Preventable Disease Reference Centers (VPD RCs) at four state public health laboratories. The VPD RCs were established to provide an efficient means of measles (rubella and other viral and bacterial VPDs) testing based on CDC-developed and -evaluated protocols to state and local health departments that have limited budgets for testing for diseases of low incidence or low-volume testing. To date, 32 state and nine local health departments submit specimens for testing to the VPD RCs. The RCs have provided surge capacity for three major measles outbreaks in 2013–2014. In addition, the RCs provide serological and molecular confirmatory testing and genetic characterization for other VPDs, surveillance support, and confirmation of vaccine adverse events in a shared-service model to 32 state and 9 local-submitter public health laboratories. Results are contemporaneously transmitted to the submitting public health departments and CDC (70).

Genetic characterization of wild-type measles viruses provides a means to study the transmission pathways of the virus; molecular epidemiology in conjunction with conventional case investigation and epidemiology has permitted the linking of imported cases to their foreign sources. Genotyping is also an essential indicator for establishing and maintaining the elimination status of the U.S. and the region of the Americas (14). Laboratory-based surveillance for measles and rubella, including genetic characterization of wild-type viruses, is performed throughout the world by the WHO LabNet, which serves 160 of 193 member countries in all WHO regions. In particular, the genetic data can help confirm the sources of virus or suggest a source for unknown-source cases as well as to establish links, or lack thereof, between various cases and outbreaks. Virologic surveillance has helped to document the interruption of transmission of endemic measles in some regions. Thus, molecular characterization of measles viruses has provided a valuable tool for measuring the effectiveness of measles control programs, and virologic surveillance needs to be expanded in all areas of the world and conducted during all phases of measles control (6, 14, 71, 72). It must be emphasized, however, that conventional epidemiology and case investigation must be done hand in hand with the molecular studies to achieve the optimal outcome of this approach. Drawing conclusions from genotype determinations without proper epidemiologic investigation can lead
to false assumptions regarding geographic origin or source of infections.

**Serologic Diagnosis**

The recommended laboratory method for the confirmation of clinically diagnosed measles is a serum-based IgM ELISA. Several of these tests are commercially available and are used worldwide by public health, clinical, and commercial laboratories. These assays have been used as the primary confirmatory test by the laboratory network of the Pan American Health Organization throughout the Americas. The WHO LibNet has also recommended use of the IgM ELISA for laboratory confirmation of measles (73). As regions enter the elimination phase, measles cases become more difficult to diagnose and ELISA results become less reliable. As mentioned above, many RRLs have already implemented additional testing such as molecular methods, as well as IgG, and in some cases IgG avidity testing to supplement surveillance and case classification (66, 72, 74). However, the ELISA still remains the mainstay of confirmatory measles testing. The ELISAs can be done using a single serum specimen, which are relatively rapid (2 to 6 h), are simple to perform, and can be used to diagnose acute measles virus infection from the time of rash onset until at least 4 weeks after rash onset. Thus, the IgM ELISAs fulfill all of the basic criteria for the accurate, effective, and efficient diagnosis of measles. Both indirect and IgM capture formats have been used (75–77). Though the IgM capture assay format is often regarded as more sensitive than the indirect format, comparative studies of some commercial indirect formatted ELISA kits have demonstrated that the two formats have equivalent sensitivities and specificities (78, 79).

Traditional antibody tests such as hemagglutination inhibition (HI), PRN, and ELISA have been used extensively in the serologic confirmation of the clinical diagnosis of measles. However, because of the availability of sensitive and specific commercial kits, ELISA has become the most widely used test format. Commercial ELISAs also have the ability to measure measles virus-specific IgM as well as IgG responses and, therefore, have particular importance in confirming clinical diagnosis as well as monitoring measles-control programs. Although limited in number, a few available IgG assay kits were found to have sensitivities and specificities that compared favorably with PRN (80–82). In general, IgM measurements by ELISA or similar assay have been used for surveillance (antibody prevalence) studies, while PRN has been reserved for those studies interested in questions regarding immunity. Most laboratories have trained personnel and are already equipped to run ELISAs.

Commercial laboratories and some large clinical centers performing large-volume testing of measles (and rubella) specimens require high throughput automated platforms in combination with ELISA, chemiluminescent, and Luminex immunoassays. Although the formats for some of the assays may differ from the traditional ELISAs, their performance characteristics and rapid turnaround times make them viable alternatives for large surveillance, seroprevalence, and seroconversion studies (83, 84).

**Standard ELISAs**

Currently, only one commercial assay includes a measles virus antigen produced by a yeast recombinant DNA expression system rather than antigen produced by infected cell cultures. ELISAs using recombinant-expressed N protein in both capture and indirect formats have high sensitivity and specificity compared to those of other commercial ELISAs (76, 77).

Though the configurations of the commercial measles virus IgM kits vary, the tests are simple and straightforward to perform by following the manufacturers’ protocols. Indirect ELISA has been successful in the detection of IgG (76). For this indirect test, either whole virus antigen diluted in 0.05 M bicarbonate buffer (pH 9.5) or recombinant antigen diluted in phosphate-buffered saline is distributed into polystyrene microwell plates. Serum specimens are diluted in phosphate-buffered saline containing 4% normal goat serum (plus 4% Sf9 cell lysate for recombinant antigen) and 0.05% EDTA and then added to the washed plates. Bound antibody can be detected with standard commercial reagents such as goat anti-human IgG conjugated to either alkaline phosphatase or biotin. Assays are developed with the appropriate substrate, and the plates can be read either by eye or spectrophotometer.

**Plaque-Reduction Neutralization (PRN)**

The PRN assay, which measures neutralizing antibodies that are directed against the surface glycoproteins of measles virus, is more sensitive and specific than hemagglutination inhibition (HI) or ELISA (85). Since functional antibodies are detected, the PRN provides the best serologic correlate for the assessment of immune protection (86, 87). However, the PRN test is not practical for routine serologic diagnosis because it is very labor-intensive, requires paired serum samples, and takes 5 to 7 days to complete. Recently, a fluorescent-based plaque-reduction microneutralization assay for measles virus immunity (88) has been developed that permits higher-throughput processing of small quantities of serum specimens and is more amenable for use in large serosurveys for assessing immune status. This assay has been standardized against the conventional PRN assay (80) using the WHO 2nd International Standard for antimeasles serum and awaits further validation.

In the PRN assay, measles virus-specific antibody in serum combines with and neutralizes measles virus, preventing it from infecting a cell monolayer and forming a plaque under the overlay. The endpoint for the test is the highest dilution of serum that reduces the number of plaques by 50%. Serum dilutions are made in 96-well microtiter trays, making either 2- or 4-fold dilutions (depending on the expected titer of the serum). On day 4 of culture, a plaque-forming unit (PFU) is added to each well and incubated for 2.5 h at 36°C. After incubation, 100 μl of the serum-virus mixture is added to each of two 16-mm diameter wells on a tissue culture plate(s) containing Vero cell monolayers. These plates are then incubated for 1 h at 36°C. Following incubation, the inoculum is removed by aspiration, and the monolayers are covered with overlay medium consisting of either 2% carboxymethyl cellulose in Leibovitz-15 medium or 1% agarose in Eagle’s medium. The plates are then incubated for 4 days at 36°C, and the monolayers are stained with a solution of neutral red in cell culture medium. On day 5, the overlay is removed and the plaques are counted. The numbers of PFU in duplicate wells representing a given serum dilution are averaged.

**New ELISAs**

A new and potentially promising development has been the use of ELISAs to measure the avidity of IgG antibodies to measles virus (89, 90). As the immune response matures, low-avidity antibodies are replaced with high-avidity antibodies. These avidity differences can be detected by using protein denaturants, 6 to 8 M urea or diethylamine (91) in the washing step of the indirect ELISA for measles virus
IgG. An avidity index is then calculated by comparing the optical densities obtained with and without the denaturing agent in the wash buffer. These tests show promise in differentiating between primary and secondary responses to vaccination and to natural infection (92). Measles avidity assays are limited in their use and can only be used to rule in a case of measles. Nevertheless, this can be very useful in elimination settings where IgM assays yield indeterminate or questionable results that appear to conflict with clinical presentation and patient history. Although there are several commercial products available, these assays remain investigational tools due to the lack of appropriate guidelines for use and the availability of well-characterized standardized controls.

**Evaluation, Interpretation, and Reporting of Results**

The interpretation of negative culture results should be made with caution, since many factors influence the outcome. Some of the most important considerations include the timing of sample collection, transportation to the laboratory, preparation for culture, and, finally, and probably most importantly, the cell culture system used for virus isolation.

In a recent survey of public health laboratories that performed cell culture for measles virus, most were not using engineered cell lines that are required for optimal isolation of wild-type measles (93). This report was the basis for the establishment of VFD RCs that in turn has led to greater availability of RT-qPCR among state public health laboratories. Proper interpretation of results is therefore increasingly important given the improved availability of molecular tests. Negative RT-qPCR results cannot be used to rule out a case of measles, for many of the same reasons that negative culture results may not be definitive. Moreover, genomic regions selected for amplification for measles virus RT-qPCR assays do not distinguish between wild-type and vaccine viruses, and therefore, would not be useful in many outbreak settings where vaccine is in use to control the outbreak. The utilization of conventional RT-PCR coupled with nucleotide sequencing and genotyping as confirmatory testing is strongly advised when considering implementing RT-qPCR. Alternatively, access to these methods should be arranged.

The serum-based IgM assay is the recommended test for the confirmation of acute measles infection. False-negative results can occur when serum specimens taken too early with respect to rash onset are tested. For example, the CDC capture IgM assay, which has a sensitivity and specificity equivalent to those of commercial ELISAs, has been shown to detect IgM in only 77% of true measles cases within the first day of rash onset (94). In the case of indirect IgM assays, false-negative values can be the result of insufficient removal of high levels of measles virus-specific IgG from a test specimen. The residual IgG competes with IgM for viral antigen placed on the solid-phase support, thereby blocking IgM binding to the antigen and interfering with IgM detection. Present-day immune-absorbent reagents are much improved over earlier reagents; thus, fewer problems of this nature occur.

False-positive tests due to the presence of rheumatoid factor (RF) appear to be more frequently encountered when using the indirect IgM assay. RF is an IgM class immunoglobulin that reacts with IgG and is produced as a result of some viral and autoimmune diseases. Immune complexes may form that contain test antigen-specific IgG and RF IgM. By virtue of the IgG binding to the viral antigen, the IgM component of the RF immune complex is recognized by the detector system, thus rendering a falsely positive result. Similar false-positive results can occur in capture assays but appear to be enhanced by the presence of high levels of both antigen-specific antibody and RF (75).

The inherent sensitivities and specificities of the ELISAs in times of low disease prevalence become a factor in interpretation. This situation occurs in countries that have eliminated endemic measles but remain vigilant in performing case-based surveillance of rash illnesses. In these geographic regions, both measles IgM and IgG ELISAs are performed on serum specimens from suspected cases due to high vaccine-induced seroprevalence. In this setting, if the IgG test is positive and the IgM test is negative, the case is usually discarded (depending upon the timing of serum collection). Recall as well the rare instances of “modified measles,” although many of these do have an IgM response (16, 17).

Unfortunately, ELISA specificity is not 100%. Serum specimens from patients with parvovirus B19 and rubella have inherent rates of false-positive reactions (overall rate of about 4%) when tested in measles IgM ELISAs and vice versa (95, 96). The reason(s) for these false-positive reactions are not understood, and attempts to remove immune complexes using anti-RF have proven unsuccessful.

There is also evidence that case contacts that have a resident IgG response, due either to a history of natural infection or to vaccination, may develop a secondary IgG or an IgM response to currently circulating virus (97, 98). The IgM is generally fleeting and weakly positive and, except for rare instances, should not be a source of diagnostic confusion (65).

Table 1 summarizes the possible interpretations of ELISA results. Despite the vagaries associated with the ELISAs, they are the best assays available for laboratory confirmation of clinically diagnosed measles. It should be emphasized that the vast majority of serum specimens submitted for serology will yield a test result that will be easily interpretable. However, as mentioned earlier, the current CDC Surveillance Manual for Vaccine Preventable Diseases (64) strongly encourages the collection of both blood and respiratory specimens when suspect measles cases first visit the health care provider. Additionally, laboratories should be provided with as much clinical and epidemiological information as possible to aid in the final interpretation of the test result(s).

**RUBELLA VIRUS**

**Taxonomy**

A number of small, enveloped viruses having the same overall genetic organization and replication strategy as rubella virus exist, and they are grouped into the Togaviridae family. The *Togavirus* family consists of the *Rubivirus* genus, containing only rubella virus, and the *Alphavirus* genus, containing about 25 other viruses, all of which are transmitted by arthropods (e.g., western equine encephalitis virus). Rubella virus has a restricted host range and humans appear to be the only species in which rubella circulates.

**Description of the Agent**

Rubella virus virions are particles about 70 nm in diameter that are composed of a core surrounded by a lipid envelope. The core consists of the positive-strand RNA genome (~9,760 nucleotides) and the virus protein C. The viral envelope contains two viral glycoproteins, E1 and E2 (99).

The viral RNA replicates in the cytoplasm of infected cells, with nonstructural proteins being translated from the 5′ two-thirds of the genomic RNA and the structural proteins being translated from a subgenomic RNA that is a copy of
Rubella viruses currently circulating in the world contain RNAs that differ sufficiently that two clades of rubella viruses, differing by about 10% in the nucleotide sequence, have so far been identified (102, 103). Groups of related viruses, differing by about 10% in the nucleotide sequence, have so far been identified (102, 103). Groups of related viruses, differing by about 10% in the nucleotide sequence, have so far been identified (102, 103). Groups of related viruses, differing by about 10% in the nucleotide sequence, have so far been identified (102, 103). Groups of related viruses, differing by about 10% in the nucleotide sequence, have so far been identified (102, 103). Groups of related viruses, differing by about 10% in the nucleotide sequence, have so far been identified (102, 103).

Rubella virus was not isolated until 1962, largely because infected cells are difficult to identify in tissue culture (105, 106). Introduction of rubella vaccine in the United States (licensed in 1969), mostly through childhood immunization, immediately broke the 6- to 9-year epidemic cycle of rubella. The last major U.S. rubella epidemic was in 1964 to 1965, when approximately 20,000 congenital rubella syndrome (CRS) cases occurred (107). The combined MMR vaccine was recommended for the United States in 1972. Rubella and CRS have been eliminated in the United States; from 2004–2012, only 79 cases of rubella and six cases of CRS were reported in the U.S. (14, 108). Most mothers of CRS children were born in countries without rubella-susceptible mothers who were inadvertently vaccinated after conception (109). Recent summary indicated only 1 of 833 infants born to rubella-susceptible mothers who were inadvertently vaccinated after conception was born with abnormalities consistent with CRS (117). However, a small theoretical risk remains. Thus, the Advisory Committee on Immunization Practices recommends avoiding pregnancy after receipt of rubella-containing vaccine for 28 days (118).

Clinical Significance
Rubella (German measles or 3-day measles) was first described in the 18th century and was accepted as a disease independent of measles and scarlet fever in 1881 (119). Postnatal rubella is characterized by an acute onset and generalized maculopapular rash with mild fever (greater than 99°F) and may include arthritis or arthralgia (mostly in postpubertal females), lymphadenopathy (specifically postauricular and suboccipital nodes), and conjunctivitis. Because disease caused by rubella virus is mild, about 50% of postnatal rubella cases are not diagnosed clinically. Although rubella had been largely ignored for 60 years, in 1941 N. McAlister Gregg first recognized that cataracts in children followed maternal rubella during gestation (120). The association between congenital rubella and a spectrum of significant birth defects including sensorineural hearing loss, cardiovascular abnormalities, cataracts, congenital glaucoma, and meningoencephalitis is now accepted. Rubella virus is now recognized as the most potent infectious teratogenic agent yet identified (121, 122).

When rubella occurs in a pregnant woman in the first 11 weeks of gestation, there is a high likelihood of defect(s) in the infant (about 90%). After 18 weeks, the likelihood of birth defect is much lower, although the infant may still be born infected with rubella virus. Congenital rubella infection (CRI) refers to infants born with rubella virus infection with or without birth defects. The pathogenesis of CRI leading to congenital rubella syndrome is not well understood, but rubella virus infection early in gestation results in an altered immune response to the virus and altered organogenesis. The significant effect on the fetus of rubella virus infection during the first trimester is likely related to the facts that the fetus cannot synthesize IgM until about 20 weeks of gestation and cell-mediated immunity does not develop until until late in gestation. Congenitally

infected infants shed virus for long periods, have a slowly developing immune response to rubella virus, and respond to particular rubella virus proteins differently than individuals with postnatal rubella. These three characteristics of congenital infection are all consistent with selective immune tolerance to rubella virus proteins in such infants (180). Infection during the first 11 weeks of gestation often results in multiple organ involvement and necrosis in many tissues (121). Organogenesis is affected in CRS cases, since specific organs are abnormal and other apparently normal organs have a reduced number of cells. Reinfection with rubella virus can occur, but viremia is rare; reinfection of a pregnant woman poses low risk to the fetus (121, 123).

CRI results in both shedding of virus and IgM antibodies in the neonate. Diagnosis is based on detection of rubella virus (RT-PCR or virus culture) or rubella virus-specific IgM in such patients. If congenital defects characteristic of CRS are not present, the infant is diagnosed as having CRI only. The clinical definition of CRS is standardized, but laboratory confirmation of rubella virus infection in the newborn by either serologic or virus detection techniques is critical, especially when only a single defect presents, since the defects characteristic of CRS can occur for other reasons (124).

Collection, Transport, and Storage of Specimens

Clinical specimens for culture of rubella virus are usually throat swabs or nasopharyngeal secretions diluted into transport medium (e.g., Culturette collection and transport devices). The virus can also be isolated from a number of other specimens, including cataract tissue and urine (provided that pH is controlled) (113). Urine is often a source of infectious virus from CRS patients. Specimens for virus detection should be stored at 4°C for short periods (days) or at −70°C for longer periods (weeks); virions lose infectivity at higher temperatures (e.g., 37°C). Virions are rapidly inactivated by mild heat (56°C), detergents, or lipid solvents. Rubella virus-specific IgG can be detected in urine (125). Specimens for serology or culture can be transported by standard methods (e.g., overnight carrier) at 4°C since virions are relatively stable at that temperature. Alternative specimens such as DBS and OMT (see chapter 79) have been shown to be adequate for surveillance of rubella using IgM detection (DBS and OMT) and virus detection (OMT) (47, 49, 126–129). Two caveats should be considered if these alternative specimens are used. First, diagnostic kits are usually not approved by FDA for use with DBS; second, low IgM levels in OMT necessitate the use of highly sensitive detection assays.

The timing of specimen collection is especially important in postnatal rubella. Rubella virus-specific IgM is the laboratory diagnostic criterion typically used for rubella, but about 50% of rubella cases are IgM negative on the day of rash (see Table 2 and related text below). Since postnatal rubella is a mild disease of short duration, special effort may be required to obtain a serum sample 5 to 7 days after rash, when most rubella patients are strongly IgM positive. Patients with CRS are IgM and virus positive for months; therefore, timing is less critical for these patients.

Direct Examination

Nucleic Acid Detection Techniques

Amplification of rubella virus RNA directly from a clinical specimen using RT-PCR can be used to determine if a patient is infected with rubella virus. Not all RT-PCR protocols are sufficiently sensitive to be used directly with clinical specimens. Assays that can reliably detect 3 to 10 copies of rubella virus RNA are sufficiently sensitive. Real-time and nested RT-PCR protocols, although difficult to maintain, usually meet this criterion (126, 131, 132).

Many postnatal rubella cases are IgM negative before 4 to 5 days post-rash and direct detection of viral RNA is the most sensitive test during this time period (126). For example, on the day of rash onset, direct detection of rubella virus RNA by real-time assay will confirm about twice as many suspected rubella cases as commercial IgM ELISAs. No standard real-time or RT-PCR protocol for detection of viral RNA has been established and there are currently a number of such tests being used. At present, real-time and RT-PCR are mostly used in national or reference laboratories.

Isolation and Identification of the Virus

Growth of rubella virus from clinical specimens can be used to diagnose postnatal rubella, CRS, and CRI (Table 2). Throat swabs taken on the day of rash, typically a convenient time for sample collection, are usually positive for rubella virus, even though a slightly higher percentage of cases are positive 2 days before rash onset. Virus shedding in the throat declines rapidly, and by 4 days after rash onset, only about 50% of cases

| TABLE 2 | Timing of biological markers of rubella virus infectiona |
|-----------------|--------------------------|--------------------------|--------------------------|
| Postnatal rubella | Convenient time when many cases are positive (%) | An example of a time when >90% of cases are positive | Approx time for 50% decline |
| Virus in throatb | Day of rash (90%) | 2 days before rash | 4 days after rash |
| lgM in serum by ELISAe | Day of rash (50%) | 5 days after rash | 6 wk after rash |
| lgG in serum by ELISAe | 3 days after rash (50%) | 8 days after rash | Lifetime |
| Virus in blood by cultured | Day of rash (50%) | 5 days before rash | 1 day after rash |
| CRSf | At birth (almost all) | 2 wk after birth | 3 mo of age |
| lgM in serum by ELISAf | At birth (80%) | 1 mo of age | 6 mo of age |

a Times and percentages given are approximate and are meant to guide typical specimen collection. Percentages vary depending on the sensitivity of the assay used. Note that the times listed in the third column were chosen to help guide specimen collection and may not be the earliest time when >90% of cases are positive.
b After maximum number of cases are positive for a given criterion, the approximate time for 50% of cases are negative.
c “Alternative” specimens, oral mucosal transudate (OMT) and dried blood spot (DBS), have been evaluated for detection of virus (OMT) and IgM (OMT, DBS). See references 47 and 126–128.
d Data are from reference 130.
e Information given is for fetal infection in the first trimester.
f Declining maternal IgG and developing IgG response in a CRS patient lead to high (steady) or increasing IgG levels in the CRS patient through the first year of life.
are positive. In addition, viral culture is used to monitor virus in CRS and CRI patients for the purpose of determining when isolation of these patients from susceptible contacts can be stopped. The virus will grow in a variety of cell types, including Vero, BHK21, AGMK, and RK-13 cells. The primary problem encountered with tissue culture is the lack of a cell type that produces CPE in a single passage of wild-type viruses. Historically, this problem was overcome by clever assays exploiting the fact that rubella virus growth interferes with the replication of lytic enteroviruses such as coxsackievirus A9. However, interference assays are quite difficult to maintain (133). Virus growth can now be identified in the absence of CPE using methods such as RT-PCR, IFA, and immunocolorimetric assays (ICA) to detect viral RNA or proteins (132, 134).

The sensitivity of the RT-PCR system used to detect viral RNA from infected tissue culture cells is not critical, since the amount of rubella viral RNA has been amplified by passage in tissue culture (about 10^9-fold) (102, 132). Detection of rubella virus-infected cell monolayers can also be accomplished by IFA or ICA. It is crucial that IFA and ICA reagents have low background, since rubella virus culture does not produce high levels of progeny virus (about 10^7 PFU/ml for laboratory strains such as f-Therien). Infected cells are easily identified when stained with high-quality reagents (Fig. 2). Dilution of specimens may be desirable since it is useful to have both infected and uninfected cells in the same field. Monoclonal antibodies to the E1, E2, and C proteins, which react with both reduced and non-reduced antigens on Western blots, often work well in the IFA and ICA.

Utility of Sequences Derived from Viral RNA

Sequencing of the nucleic acid amplified directly from specimens or from tissue culture material can provide useful information. Vaccine virus can be differentiated from wild-type viruses (135). Useful information on the origin of imported cases of rubella and CRS can be obtained (108, 136). Documentation of the elimination of rubella can be supported by analysis of sequences obtained over time (137).

Serologic Tests

ELISA

Detection of rubella virus-specific IgM by either IgM-capture ELISA or indirect-IgM ELISA is the fastest and most cost-effective diagnostic test for recent postnatal infection. Unfortunately, only about 50% of postnatal rubella cases are IgM positive on the day of symptom onset (Table 2) (126). Most postnatal rubella cases have virus-specific IgM detectable by capture ELISA from 5 until 40 days after symptom onset and IgG by indirect ELISA ≥8 days after symptom onset (Fig. 3) (138). A negative IgM serologic result 4 to 5 days after onset should be followed with testing of a serum sample taken as soon as possible thereafter to avoid false-negative results (110). If acute- and convalescent-phase sera are available, a 4-
FIGURE 3 Time course of rubella virus-specific IgM and IgG detection by ELISA in sera of rubella patients. Commercial IgM capture ELISA (A) and IgG indirect ELISA (B) were used to detect rubella virus-specific antibodies at the indicated number of days after onset of symptoms (usually rash); antibody index and ISR are the commercial test designations for the ratio of the optical density obtained for the test serum to the optical density obtained for a standard (cutoff) serum. The minimum signal considered positive in each test is indicated by a dashed line. Only results from patients who tested positive for IgM to rubella virus at some time after the onset of symptoms are shown. doi:10.1128/9781555817381.ch87.f3

fold rise in rubella virus-specific IgG is diagnostic for postnatal rubella infection; such sera should be taken as early as possible after disease onset and about 2 to 3 weeks after disease onset. When IgG titers are used for diagnostic purposes, a dilution series of each serum sample should be made and ELISA results for each dilution series compared, since optical density values at a single dilution are an unreliable measure of the amount of IgG.

The same ELISAs may be used to confirm CRS. Most congenitally infected infants have IgM detectable from birth to 1 month of age (Table 2). The percentage of infants who are IgM positive declines over the first year of life. At 1 year, most infants are negative. In CRS patients, the IgG response increases gradually over the first 9 months, while maternal IgG declines. Thus, high or increasing IgG levels in the first year of life, in the absence of vaccination or any rubella virus-specific antibodies are then detected with fluorescent dye-labeled goat anti-human IgG (or IgM) and fluorescence microscopy. Negative human sera and uninfected control cells are useful for detecting nonspecific signal. Fluorescence should be cell associated. Staining restricted to the periphery of the cell monolayer is artifactual and not indicative of a true-positive result.

Immunofluorescence Assay
IFA has been used for detection of IgG and IgM antibodies to rubella virus. Typically cells expressing rubella-virus proteins and control cells are reacted with patient serum and any rubella virus-specific antibodies are then detected with fluorescent dye-labeled goat anti-human IgG (or IgM) and fluorescence microscopy. Negative human sera and uninfected control cells are useful for detecting nonspecific signal. Fluorescence should be cell associated. Staining restricted to the periphery of the cell monolayer is artifactual and not indicative of a true-positive result.

Plaque-Reduction Neutralization
PRN is performed when a quantitative assessment of the neutralizing capacity of an antiserum is necessary. A laboratory strain (e.g., f-Therien) should be used since viruses from clinical specimens do not exhibit CPE. The assay follows a format common to many viruses. The initial step is incubation of 2- or 10-fold dilutions of antiserum and a standard amount of rubella virus (usually about 100 to 200 PFU) in medium- or buffer-containing protein to inhibit losses on surfaces (e.g., 0.1% bovine serum albumin) for 1 h at 35 to 37°C followed by overnight in a refrigerator. A control consisting of virus alone must be included in the assay, since some reduction in the number of plaques is observed during the 1 h incubation. Virus-antiserum specimens are then allowed to attach to confluent Vero cell monolayers for 1 h at 35°C and then overlaid with diethylaminoethyl (DEAE) dextran (100 μg/ml)-containing medium with 0.5% agar (e.g., Oxoid). Medium in the agar overlay is typically Dulbecco's modified Eagle's medium; 1% fetal calf serum may also be included to maintain the monolayer. After 6 days, agar is removed and plates are stained with neutral red. Crystal violet can also be used; however, a wash step to remove dead cells should be used prior to crystal violet staining. The ICA for rubella virus

Latex Agglutination
Commercial rapid latex particle agglutination tests consist of latex spheres coated with rubella virus antigen. These particles aggregate in the presence of either rubella virus-specific IgG or IgM. Because high throughput is possible with these assays, they are often used in immunity-screening programs (e.g., prenatal screening).

Hemagglutination Inhibition
The HI test was once the standard test for antibodies to rubella virus, and many current tests are calibrated using HI assays. However, indicator erythrocytes are not readily available and the assay is difficult to perform as a diagnostic test since removal of nonspecific inhibitors and internal standardization are required.
can also be used for virus detection (134). The neutralizing capacity of the antiserum is typically reported as the inverse of the antiserum dilution giving a standard reduction in plaques, typically 90% reduction. In both vaccination of non-immune individuals and postnatal rubella cases the neutralizing capacity rises at least 100-fold, allowing the easy use of PRN data to confirm past exposure to rubella. However, information on the precise assay used is required to quantitatively compare neutralization capacities of antisera when assays are done in different laboratories (e.g., rubella virus-plaquing efficiency may vary between laboratories).

Other Serologic Tests

Avidity tests have been used when IgM detection does not reliably indicate recent infection (e.g., first serum sample was collected months after clinical symptoms). Low-avidity anti-rubella IgG suggests recent infection (96, 139, 140). This test compares the ability of detergents or chaotropic agents to dissociate case IgG and control IgGs from rubella virus proteins. Both high- and low-avidity control sera should be used in each assay. Avidity tests are not widely available and vary in performance (141).

Since the clinical symptoms of postnatal rubella and CRS are dramatically different, it is not surprising that there are significant differences in the immune responses of patients with these diseases. These differences can be observed on Western blots, in which antibodies in sera from CRS patients often demonstrate different reactivity to rubella glycoproteins than those from postnatal rubella patients (142). These tests are not widely used, but have been developed in some diagnostic laboratories (109).

Prenatal Screening

The present description of laboratory testing for rubella emphasizes identification of postnatal and congenital rubella cases. However, in the United States much of the testing is for immunity to rubella, since health care providers should test for immunity by a serum IgG test in all pregnant women at the earliest prenatal visit. There are slightly different criteria for rubella immunity that are recommended by various groups (range is about 10 to 15 IU/ml) (116). Commonly used tests, e.g., ELISA, are standardized to give positive results for 10 IU/ml, the breakpoint defining immunity to rubella in the United States (143). Much of the screening for immunity to rubella virus in the United States is done by automated random-access systems using microparticle immunoassays.

Evaluation, Interpretation, and Reporting of Results

IgM and IgG testing should be done with most sera for both suspected postnatal rubella and CRS cases, since results from both immunoglobulin classes often provide additional information useful for diagnosis. For example, results from a serum sample taken at 8 days post-rash which are positive for IgM but negative for IgG to rubella virus would be inconsistent with the immune response to rubella; usually the IgM result would be most suspect in this situation (e.g., cross-reaction with antibodies to parvovirus). A serum that tests rubella IgG antibody positive and IgM negative is inconsistent with recent postnatal rubella infection in the patient, since the IgM response should precede the IgG response and persist for weeks after rash onset.

A positive result for rubella virus culture is obtained when a positive real-time assay or RT-PCR result is obtained from the culture or at least one cluster of cells are infected as determined by IFA or ICA. Control cultures must be negative. When an IFA or ICA is used, the expected distribution of viral proteins should be obtained (e.g., E1 glycoprotein distribution when using an E1 monoclonal) (134).

Direct detection of rubella virus RNA by PCR-based protocols requires the laboratory to evaluate the significance of results from such tests. Multiple negative controls and amplified product in more than one specimen from a given patient will increase confidence of a positive diagnosis based on direct RT-PCR. The significance of negative results is usually difficult to determine since false-negativity rates are usually not available. Sequence variation in wild-type viruses, which can lead to poor primer binding and poor amplification, must be considered when evaluating the significance of negative results. Nevertheless, when serum from a patient cannot be obtained, or when confirmation of serologic results is desired, direct detection of rubella virus RNA by RT-PCR may be necessary since it is more rapid than viral culture.

There is often a considerable burden on the laboratory in the diagnosis of rubella. For example, when primary rubella virus infection is suspected for a pregnant woman, false positives and false negatives may lead to incorrect clinical decisions (144). Thus, the laboratorian may be asked to go beyond just communicating false-positivity and false-negativity rates. Testing for recent infection with other viruses that cause clinically similar diseases (e.g., human parvovirus B19) is often prudent. Positive rubella results may be more believable if no other infection is found. Specimen retesting and testing of different specimen types with alternative methods (e.g., serology and viral culture [Table 2]) often yield consistent results and reduce the likelihood of false-positive results. False positives can occur even with IgM-capture ELISA. For example, in one study, 1 of 87 sera testing positive for rubella virus-specific IgM by IgM capture ELISA was from a patient whose final diagnosis was primary human parvovirus B19 (96). False negatives can often be identified by testing multiple specimens from a patient (e.g., sera taken 1 week apart). If only a single specimen is available, it may be tested by multiple assays. For example, IgG avidity may resolve the diagnosis from a single serum sample that is IgM positive for both rubella virus and human parvovirus B19 (96).

Postnatal rubella can be clinically similar to other diseases, or it can be asymptomatic. Additionally, birth defects characteristic of CRS occur for other reasons. Thus, correct classification of suspected postnatal rubella and CRS is based on laboratory results rather than clinical presentation. Classification of a postnatal rubella case results in its categorization as suspected, probable, confirmed, or asymptomatic confirmed; for a case of congenital rubella, categories are suspected CRS, probable CRS, confirmed CRS, or infection only. Positive laboratory results are required to correctly classify asymptomatic confirmed or confirmed cases of postnatal rubella and CRS. Clinical, laboratory, and epidemiological information (e.g., international travel) all may enter into the final clinical decision(s). A full description of classification criteria and recommendations should be consulted (110). One specific diagnostic situation should be noted. A series of tests including a rubella virus IgM test should not be used to determine immunity in a pregnant woman because of the possibility of a false-positive result; immunity should be determined by IgG testing alone. Since standard TORCH (toxoplasmosis, other, rubella, cytomegalovirus, and herpes simplex virus) panels include testing for rubella virus IgM, they should not be used to determine immunity.

TAXONOMY
Enteroviruses (EV) are members of the Picornaviridae family, with “pico” meaning very small, “ribo” indicating an RNA genome, and “viridae” signifying viruses. Traditional criteria for taxonomy and identification of EV to subgroups were based on patterns of replication in cell cultures, clinical syndromes, or disease, and on disease manifestations in suckling mice. The subgroups were poliovirus (PV), coxsackievirus A (CVA), coxsackievirus B (CVB), and echovirus (E). Echoviruses were initially named as the acronym “echo,” meaning enteric cytopathic human orphan, since they were first isolated from the stool of asymptomatic children and caused a cytopathic effect in cell culture. The criteria classified 67 different human EV serotypes until the designation was dropped in the 1960s, with all subsequent serotypes designated enterovirus (EV) followed by a number beginning with 68 (1).

With the development of molecular sequencing and the limited availability of antisera for characterizing newly identified strains and variant strains, the traditional methods of taxonomy have become challenging. The EV taxonomy was effectively redefined through phylogenetic analysis (2). Currently, human EVs are divided into seven species: EV A through D and rhinoviruses (RVs) A to C (Table 1)(3).

The genus Parechovirus (HPeV) comprises 16 different types (http://www.Picornaviridae.com/parechovirus/hpev.htm). Originally identified in 1956 as members of the EV genus based on growth characteristics, echoviruses 22 and 23 are genetically distinct from other EVs and were renamed HPeV1 and HPeV2 (6–8). HPeV3 was identified decades later by molecular methods (9). Analogous to the genotyping of EVs, the use of the VP1 gene sequence to determine the HPeV genotype is standard (10, 11). As with EVs, molecular techniques have led to the identification of a number of additional types based on the VP1 gene sequence, designated HPeV3 to 16. With new HPeV genotypes being identified by sequence analysis of the VP1 gene, whole-genome sequence analysis will elucidate the genetic relatedness to other HPeVs. As more data become available, a better understanding of the new types, and of any evolutionary relationship with the origin, will be established.

Similar to other members of the family Picornaviridae, EVs are small (30-nm diameter in the hydrated state), non-enveloped viruses that possess a single-stranded positive (message)-sense RNA genome. Their buoyant density in cesium chloride is 1.30 to 1.34 g/cm³ (12). The majority of the EVs, from group A to group D, are stable in acid, ether, and chloroform and are insensitive to non-ionic detergent. They are inactivated by heat (>56°C), UV light, chlorination, and formaldehyde. In cell culture, most EVs replicate optimally at 36 to 37°C, with the exception of RVs A and B, which replicate optimally at 33°C. RVs are covered more extensively in chapter 89.

The EVs are stable in liquid environments and can survive for many weeks in water, body fluids, and sewage. This is due to a number of viral properties, including thermostability in the presence of divalent cations, acid stability, and the absence of a lipid envelope.

The EV RNA genome serves as a template for both viral protein translation and RNA replication (Fig. 1) (13). The genome contains a long (approximately 750 bases) 5′ non-translated region (5′ NTR), which immediately precedes a single open reading frame (ORF) (Fig. 1). The ORF is translated into a single polyprotein that is posttranslationally cleaved into several functional intermediates and the final 11 proteins by virus-encoded proteases. Immediately downstream of the ORF is a short non-coding region of approximately 70 to 100 bases (3′ NTR) and a terminal polyadenylated tail.

The EV 5′ and 3′ NTRs play critical roles in the EV life cycle. The 5′ NTR contains multiple regions of predicted higher-order structure (i.e., stem loops or domains). A domain located at the extreme 5′ terminus of the 5′ NTR is essential for viral RNA replication. Cap-independent translation of the EV genome is regulated by the internal ribosome entry site (IRES), which spans a discontinuous region within the 5′ NTR. For PV and several non-polio enteroviruses (NPEVs), the 5′ NTR has been documented to be a determinant of virulence phenotype and cell type specificity (14, 15). Given the crucial nature of the functions controlled by the 5′ NTR, it is not surprising that nucleotide sequences, with near absolute conservation among the EVs, exist within this region. These regions of high nucleotide identity have been exploited for the design of primers and probes used for the detection of the EVs. The 3′ NTR has also been demonstrated to play a role in viral RNA replication.

The EV capsid is arranged in 60 repeating protomeric units that confer an icosahedral shape to the virion (Fig. 2) (13). VP1, VP2, and VP3 comprise the surface of the virion and possess an eight-stranded "beta barrel" core structure. The external loops that connect the beta strands are responsible for the differences in surface topography and antigenic diversity among the EVs. Neutralization sites, typically three or four per protomer, are most densely clustered on VP1. VP4 is located internally within the capsid and has no surface-exposed regions.

The resolution of the near-atomic structures of multiple human picornaviruses revealed that the EVs (and RVs) share a number of conserved structural motifs. Surrounding a conserved protrusion at the 5-fold axis of each pentameric unit (i.e., five protomers) is a narrow deep cleft (25 Å) or canyon. It is into this site that the specific receptors for the EVs bind when the virus encounters a susceptible host cell.

The genomic organization of HPeVs is similar to that of EVs. However, unlike the EVs, HPeVs possess only three capsid proteins, VP0, VP3, and VP1, as a result of the lack of cleavage of VP0. In addition, the HPeV IRES is more similar to those of the cardioviruses and aphthoviruses than those of the enteroviruses (16). Recently published images, obtained using cryo-electron microscopy, revealed a 28-nm-diameter HPeV particle similar to other known picornaviruses but with a somewhat smoother surface (17). Sequence similarities between HPeVs and the other picornaviruses suggest that the major capsid proteins share the typical beta-barrel core structure. Relative to the EVs, the HPeVs are predicted to have flatter surface topography (as shown with cryo-electron microscopy), with antigenic variants determined by the external loops, as for EVs.

EPIDEMIOLOGY AND TRANSMISSION

The EVs and HPeVs are ubiquitous agents found worldwide. In regions with temperate climates, the majority of EV infections (70 to 80%) occur in summer and fall. In tropical
FIGURE 2  Schematic representation of the three-dimensional structure of a PV particle and the four neutralizing antigenic (N-Ag) sites. The icosahedral capsid structure typical of EVs is composed of 60 protomers, each consisting of the capsid proteins VP1, VP2, and VP3 (black areas). Each of the 12 5-fold symmetry axes is surrounded by five protomers, forming a pentamer (surrounded by a bold black line). The attachment site for the virus-specific receptor is a depression around the 5-fold symmetry axis, also called the canyon (dark gray circles). Each of the three surface-exposed capsid proteins contains immunodominant antigenic sites at which neutralizing antibodies bind. Four N-Ag sites (white ellipses) have been mapped to surface loop extensions. Reprinted from reference 13. doi:10.1128/9781555817381.ch88.f2
hence, leads to unnecessary treatment. During summer and
fall, the EVs are responsible for 50 to 60% of hospital
admissions for the evaluation of acute febrile illness in
children and infants (25).

By far the most vexing clinical EV/HPEV syndrome
that the physician encounters is aseptic meningitis. The EVs are
the most common cause of meningitis in the United States
and account for over 80% of all viral meningitides (32,33).

More recently, HPEV3 has been recognized to cause a signifi-
cant number of cases of neonatal sepsis and aseptic meningi-
tis in children <2 years of age (16, 34). The onset of symp-
toms is usually sudden and generally includes a biphasic
fever, headache, occasionally photophobia, vomiting, rash,
and myalgias. In young children, symptoms include fever,
lethargy, and anorexia (35), again mimicking bacterial in-
fection. Currently, treatment is supportive with illness gen-
erally resolving after a week with no long-term sequelae.
An estimated 30,000 to 50,000 hospitalizations for NPEV
meningitis occur each year. The echoviruses and CVBs,
particularly E4, E6, E9, E11, E16, and E30, and CVB2 and
CVB5, constitute the principal EVs associated with this
syndrome.

The term poliomyelitis refers to the inflammatory dam-
age due to infection of the anterior horn cells of the spinal
cord. Recognized clinically as acute-onset lower motor neu-
ron paralysis of one or more muscles, the case fatality rate
in the prevaccine era ranged from 5 to 10% (36), and in
recent epidemics, as high as 48% (37). Historically, this
disease was most commonly associated with the PVs; how-
ever, in most countries, this is no longer the case. In regions
of the world where the polioviruses have been eradicated,
the NPEVs and circulating vaccine-derived PVs (cVDPVs)
are now the principal causes of acute flaccid paralysis.cVDPVs are circulating strains derived from the vaccine
(Sabin) strains of PV that have regained the capacity to cause paralytic poliomyelitis. Multiple NPEV serotypes are known to cause acute flaccid paralysis, and at least six polioviruses outbreaks have been caused by cVDPV (1). It is also important to point out that despite efforts towards polio eradication, these viruses are still endemic in some countries and have served as reservoirs for the reintroduction of polio to other areas.

Studies conducted in the United States prior to the development of molecular diagnostic techniques identified the EV as the cause of 11 to 20% of viral encephalitides (38). Larger, more recent studies of the etiology of encephalitis have identified EVs in approximately 3 to 5% of all cases, accounting for 27 to 37% of identified viral etiologies (39, 40). Serotypes from the HEV-B and HEV-A species are the predominant EV subgroup associated with this syndrome (25, 38–40). HPeV has also been shown to cause acausal agent (31). Rhombencephalitis, a severe and often fatal form of brainstem encephalitis, has been associated with EV71 infections in small children from several countries in the Asia-Pacific region (41–43); however, cases in the United States have also been reported (44, 45). Chronic EV meningencephalitis in agammaglobulinemia occurs and is caused most frequently by the echoviruses, particularly E11. Myocarditis was once an often fatal disease associated with EV; however, mortality rates are lower (~10%) with current medical care. Symptoms range from nonspecific (fever, myalgias, palpitations, or exertional dyspnea) to fulminating hemodynamic collapse and sudden death. Myocarditis has been implicated in 8.6 to 12% of cases of sudden cardiac death of young adults (46, 47). CVBs are responsible for one-third to one-half of all cases of acute myocarditis and pericarditis (48), with CVB2 and CVB5 being the most predominant serotypes identified in clinical studies. The echoviruses and PV have also been associated with myopericarditis, but significantly less so than CVB.

Neonatal systemic EV disease is associated with EV and HPeV acquisition in utero, perinatally or within the first 2 weeks of life (16, 22). This syndrome is characterized by multi-organ involvement with symptoms including lethargy, feeding difficulty, vomiting, tachycardia, dyspnea, cyanosis, jaundice, and diarrhea, with or without fever. Typically, neonatal systemic EV disease is associated with two severe clinical presentations (although infants may present with combinations or organ system involvement): encephalomyocarditis, often with heart failure; and hemorrhage-hepatitis syndrome with hepatic failure and disseminated intravascular coagulation (16, 22, 50). The morbidity and mortality associated with this syndrome are significant, with death occurring rapidly. Recently, three distinct clusters of severe EV illness due to CVB1, including six neonatal deaths, were reported in the United States from 2007 to 2008 (49, 50). However, other CVB and echoviruses, particularly serotype 11, are also frequently associated with this syndrome.

Although originally described for agammaglobulinemic patients, persistent, life-threatening EV infections can also occur in patients with combined variable immunodeficiency, severe combined immunodeficiency, hypogammaglobulinemia, or hyper-immunoglobulin M (hyper-IgM) syndrome, and in those undergoing bone marrow and solid organ transplant. Manifestations almost always include meningencephalitis.

Hand-foot-and-mouth disease (HFMD) has historically been associated with CVA16. However, EV71, which is closely related to polioviruses and CVA16, has been the cause of large outbreaks of HFMD with neurological and systemic complications in the Asia-Pacific region (51). The neurological manifestations range from aseptic meningitis to acute flaccid paralysis and brainstem encephalitis, which is associated with systemic features, such as severe pulmonary edema and shock. Although serious disease due to EV71 has been described worldwide, high rates are observed in Asia; the reason for the geographic disparity in presentations is largely unknown but may be related to viral strain differences or to host HLA antigens (51). CVA6, which has been associated with herpangina, has now been linked to outbreaks of HFMD in the United States (52).

Upper respiratory tract signs and symptoms may accompany many of the enteroviral syndromes. The enteroviruses may be causal agents of upper and lower respiratory tract syndromes (e.g., summer cold, pharyngitis, tonsillitis, laryngotracheobronchitis, bronchitis, and pneumonia) (53, 54). Enteroviruses have been etiologically linked in up to 15% of cases of upper respiratory tract syndromes (54).

The use of nucleic acid amplification methodologies has demonstrated that, depending on the country, the enteroviruses are responsible for up to approximately 19% of lower respiratory tract infections in hospitalized children (55, 56). Several of the EV C types (CI04, CI09, CI17) have been isolated from individuals with pneumonia or respiratory tract disease (57–60).

In recent years, EV-D68 has become recognized as a cause of significant respiratory disease. Originally isolated from four children with pneumonia and bronchiolitis in 1962 (61), the overwhelming majority of reports of its isolation since then (and recently) have been from the respiratory tract as sporadic isolations or as clusters of infections or epidemics (60, 62–67). EV-D68 is phenotypically anomalous among the enteroviruses in that it is acid-labile and replicates poorly at 37°C, characteristics commonly found among the RVs (21, 68, 69). Furthermore, EV-D68 has been uncommonly encountered until recently (60, 65, 67), a 36-year review of nonpolio EV isolates reported to the CDC revealed that only 26 out of 52,812 isolates were EV-D68 (23).

Phylogenetic analysis of EV-D68 isolates from around the world has indicated that, over the past 20 years, multiple clades have emerged and spread rapidly (70), possibly accounting for the increase in reported clusters and epidemics worldwide (62–66, 71).

Clinically significant lower respiratory tract disease occurs primarily in young children and infants (62–67, 71) but has been reported in adolescents and adults (60, 62, 65). Underlying conditions such as asthma or wheezing have been reported in approximately 70% to 80% of cases (62, 71). Reported clinical syndromes associated with EV-D68 include pneumonia, bronchiolitis, laryngotracheobronchitis, asthma exacerbation, and wheezing (63, 64, 66, 67). Pulmonary signs and symptoms include cough, wheezing, dyspnea, tachycardia, and inter- and subcostal retractions (62, 63, 66, 71). Surprisingly, approximately one-half to three-quarters of children are afebrile. Hypoxia requiring supplemental oxygen is very common and can be severe enough to require admission to intensive care. Some children require bilevel positive airway pressure ventilation, mechanical ventilation, or even extracorporeal membrane oxygenation. Deaths are uncommon but have been reported. Chest radiographs may show infiltrates and atelectasis.

Other acute, clinical EV syndromes of significance include acute hemorrhagic conjunctivitis (predominantly caused by EV70 and a variant CVA24), herpangina, and pleurodynia (Bornholm disease). Over the past several years, data have been presented suggesting a link between EV...
infections and several chronic illnesses, including amyotrophic lateral sclerosis, chronic fatigue syndrome, polymyositis, congenital hydrocephalus, and attention-deficit/hyperactivity disorder, but definitive proof of causation is lacking (72). However, recent reports strengthen the possible association between enteroviruses and type 1 insulin-dependent diabetes mellitus, although human genetic factors also play an important role (73–75).

In general, the spectrum of diseases caused by HPeV is similar to that of EV (16). Diarrhea or respiratory symptoms have been described alone or in combination with other syndromes. Evidence linking HPeVs as the etiologic cause of epidemic diarrheal disease is lacking, but they may be associated with endemic cases of diarrhea (16). Outbreaks of respiratory disease have been reported, but data for the role of HPeV in endemic community respiratory disease are scant. In a cohort of 2,200 persons with respiratory symptoms, HPeV was detected in respiratory samples of only 1.2% (76). As with the EV neonatal sepsis, acute flaccid paralysis, aseptic meningitis, encephalitis, and myocarditis have been reported as a result of HPeV infection (particularly type 3). Interestingly, Ljungan virus, a parechovirus previously believed to infect rodents exclusively, has more recently been linked to intrauterine fetal death in humans (77).

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

Specimen selection is important for making a diagnosis of EV infection, as asymptomatic shedding, especially in stool, is common. The specimen collected should correlate with the clinical syndrome (Table 3). Typically, EV infection begins with viral replication in the epithelial cells of the respiratory or gastrointestinal tract and in the lymphoid follicles of the small intestine, followed by viremia, leading to secondary sites of tissue infection. Hence, for patients with aseptic meningitis, cerebrospinal fluid (CSF) is generally the specimen of choice; however, testing serum can yield better results early in the disease process. Likewise, if CSF is obtained >2 days after the onset of symptoms, the diagnostic yield may be lower. Prescreening of CSF for pleocytosis (lymphocytosis) is not recommended, as lack of pleocytosis, particularly in infants, is common (78–80). Furthermore, in the early stage of the disease, neutrophils may predominate for a few hours. On the other hand, patients with EV encephalitis often have negative CSF PCR results even when they have CSF pleocytosis; in these patients, throat and/or rectal swabs may be the specimen of choice. However, since EVs and HPeVs are excreted from the throat and gastrointestinal tract for prolonged periods (81, 82), their presence from these sites is not necessarily proof of cause. Furthermore, viruses detected from sterile sites can differ by 10 to 20% from viruses detected in throat and rectal swabs, as a result of dual infection (83). In cases of myocarditis and pericarditis, myocardial tissue is recommended over fluid (84). Analyses of blood samples by PCR have been almost uniformly negative (85). However, one report suggests that, at least in pediatric patients, testing of tracheal aspirates may be an alternative to myocardial biopsy (86). For cases of herpangina and HFMD, vesicle fluid is an efficient sample for diagnostic testing, with greater yields observed when multiple vesicles are swabbed.

The EVs are quite stable in liquid environments and are able to survive for many weeks in water, body fluids, and sewage; hence, rapid transport of specimens to the laboratory is generally not necessary. CSF and serum may be submitted to the laboratory in their original containers. Optimal specimens for virus isolation include stool, throat swabs, or throat washings, and swab specimens are best transported and stored in viral transport media. Stool is preferred over rectal swabs because of significantly higher virus yield. Viral infectivity for cell culture is preserved for long periods (years) at −70°C.

Specimen-processing procedures for nucleic acid amplification methods should preserve viral capsid integrity so that the EV RNA genome is protected from nucleases that are ubiquitous in body fluids and the environment. Excessive freeze-thaw cycles should be avoided. Residual samples found in clinical laboratory refrigerators may be suitable for nucleic acid-based detection of the EVs because of the inherent environmental stability of the EVs. Specimens that have been handled by automated chemistry or hematology analyzers should be considered compromised because of the potential for cross-contamination with other specimens. EVs are highly stable; they can survive at room temperature for several days, and at 4 to −20°C for up to a year (87). However, at least for contrived specimens, room temperature storage for more than seven days negatively impacts reverse transcription (RT-PCR) detection of EVs (87). Long-term storage at −70°C or colder is recommended to prevent degradation of viral RNA.

Certain clinical specimens require processing prior to inoculation of cell cultures. Feces (1 ml if liquid, and approximately pea-sized samples if solid) are added to viral transport medium, vortexed, and centrifuged (1,000 × g, 30 min, 4°C). One milliliter of supernatant is removed and added to more viral transport media. Monolayers are inoculated with 0.2 to 0.3 ml of diluted supernatant. Nasopharyngeal aspirates and wash specimens are centrifuged (400 × g, 15

min, 4°C), and cell cultures are inoculated with 0.2 to 0.3 ml of supernatant. Serum, CSF, and urine need no pretreatment and may be inoculated directly onto the cell cultures. However, serum and urine can be toxic to monolayers. Cell death can often be prevented by replacing the culture medium within 24 hours of inoculation. Acid dissociation of antibodies bound to virus may improve detection when attempting to isolate EVs from serum and CSF (88).

Sera for antibody testing are best collected 2 to 4 weeks apart at both acute and convalescent stages. The sera should be frozen at −20°C and tested simultaneously.

### DIRECT EXAMINATION

#### Antigen Detection

Historically, immunofluorescent techniques have not been used for the detection of respiratory infections caused by EVs because these viruses were believed to be associated with self-limited upper respiratory tract infection only.

#### Nucleic Acid Detection

Currently, nucleic acid amplification tests (NAATs) are preferred for the detection of EV and HPeV. The time required for viral isolation by traditional cell culture (up to 10 days for EV and 21 days for HPeV) is too prolonged to provide clinical utility. Some serotypes within the EV group C (i.e., CVA1, CVA19, and CVA22), as well as HPeV7-16, fail to grow in cell culture. Finally, some specimen types (i.e., 25 to 35% of CSF specimens) have titers that are too low to be detected by cell culture (89). Furthermore, studies have demonstrated that the use of EV NAAT testing has a favorable impact on patient care. Outcomes studies have demonstrated a correlation between time to result and length of stay (80). Antibiotic usage was reduced, fewer ancillary tests were performed, and hospitalization was shortened and less costly when positive EV results were reported within 24 h (79, 90, 91).

NAATs (RT-PCR or nucleic acid sequence-based amplification [NASBA]) are sensitive, specific, rapid, versatile, and clinically useful methods for the detection of EVs (92–94). NAAT of CSF is more sensitive than cell culture, which has a sensitivity of 65 to 75% (94–96). Interestingly, the sensitivity of NAAT for the detection of EV in cases of aseptic meningitis ranges from 70 to 100% despite indications that EVs are the primary causative agent (94, 97–100). One partial reason for this discrepancy is the fact that HPeV, which can account for approximately 5% of cases of neonatal sepsis and aseptic meningitis in the U.S., is not detected by universal EV RT-PCR assays (6).

A limited number of studies have evaluated the sensitivity and specificity of NAAT with other sample types. For serum, the sensitivity and specificity of RT-PCR range from 81 to 92% and from 98 to 100%, respectively, for the diagnosis of EV infection (95, 101). In contrast, 100- to 1,000-fold greater sensitivity of RT-PCR over culture has been reported for detection of EV and HPeV from throat swabs or stool specimens (102, 103). In addition to the enhanced sensitivity of NAAT testing, this technology has the added benefit of rapid turnaround times, with results available in as little as 2.5 hours including extraction (104).

Prior to being tested by NAAT, EV RNA must be extracted from specimens to eliminate ubiquitous RNases and to remove potential amplification inhibitors. Only a small sample size, generally 100 to 200 μl of fluid or 1 mg of tissue, is required. The most common methods for RNA extraction are gel membrane or silica binding. Multiple automated extraction methods have been utilized, including MagNA Pure LC and Compact (Roche Diagnostics System); easyMAG (bioMérieux); and M48, QIAcube, EZ One and QIAasympHony (Qiagen). An EV RT-PCR assay on the GeneXpert system includes extraction, amplification, and detection all in one cartridge (104). All aspects of NAAT testing, from extraction to detection, are discussed in more detail in chapter 6, Molecular Microbiology.

Currently, two Food and Drug Administration (FDA)-approved real-time assays are available for the detection of EV from CSF: Xpert EV and NucliSENS EasyQ Enterovirus (Table 4). In a multicenter analysis, the Xpert EV had

*IVD, in vitro diagnostic (FDA-approved test).

*ASR, analyte-specific reagent.

*ELISA, enzyme-linked immunosorbent assay.

*LDA, laboratory-developed assay.
a sensitivity of 95% and specificity of 100% (105). The sensitivity of the NucliSSENS assay ranges from 89 to 93% (106–108); however, a limited head-to-head comparison suggests that the sensitivities of the two assays are similar (109). Additionally, 50K-cleared highly multiplexed respiratory virus assays that include the detection of EV and RV are currently available from Lumiplex Corporation (XTAG Respiratory Viral Panel) and BioFire Diagnostics (FilmArray Respiratory Panel). The Lumiplex and BioFire kits are only FDA-approved (as in vitro diagnostic tests) for nasopharyngeal specimens, and they do not differentiate EV from RV. Limited data have been reported on direct comparisons of EV in these assays, but comparisons have been performed on the overall sensitivity and specificity of all the targets, showing varying results (110).

Analyte-specific reagents (ASR) and laboratory-developed tests (LDT) for EV real-time RT-PCR are also widely used (111). LDTs routinely target conserved sequences within the 5′ NTR or VP2, for nearly universal amplification of EVs (112), with the most frequent 5′ NTR target reported by Roher (113) and Chapman et al. (114). Additionally, recent reports have separated the real-time RT-PCR into a two-step assay with cDNA being made with random priming. This modification has improved the sensitivity of the overall detection 10-fold compared with other commercially available kits (115). While these primers do not detect HPeV (discussed below), they do amplify the genomes of several RVs (106, 114, 115) and may miss some strains of EV (116). As with all ASR and LDT, laboratories must develop and validate the assays for themselves.

Despite the increased availability and benefits of real-time PCR, conventional RT-PCR is primarily used for viral typing (117, 118). There is a wide array of detection systems for conventional PCR, including agarose gel electrophoresis, reverse transcription loop-mediated isothermal amplification (119, 120) and colorimetric assays using enzyme-linked immunosorbent assay-type formats (102, 121, 122).

With regards to quality control, EV NAATs should include internal controls to detect amplification inhibitors and to assess nucleic acid recovery, as do the FDA-approved EV detection kits. EV RNA assay-verification experiments and quality-assurance performance demonstrate the need for a universal, nominal EV standard; however, none exists. Instead, most laboratories use either quantified EV isolates or transcripts from clones of target regions, both of which have to be created and validated in the laboratory. As an alternative, some companies offer EV and HPeV viruses for validation and control material. Unfortunately, these viruses are not quantified.

Multiplex PCR testing programs for LDT EV NAATs indicate that properly designed tests can be equally effective in the detection of EV, regardless of the format used (123). However, other studies have reported marked variation in testing proficiency between centers. In one survey, one-third of participating laboratories were non-profit in the detection of EV by RT-PCR (87). In another report, 6.8% of participating laboratories recorded false-positive results, pointing to the need for fastidious attention to methods for preventing cross-contamination (123). Overall, these findings underscore the importance of rigorous quality control and periodic proficiency reassessment to ensure uniformly high-quality testing.

Reports detailing the detection of HPeVs by RT-PCR have been published (10, 114, 124). Although the original methods were limited to the detection of HPeV1 and/or 2 (124–126), more recent reports detect at least types 1 to 6 (Table 4) (127–130) and some will detect all 16 (129). To date, an FDA-approved assay for the detection of HPeV has not been released, but LDTs and successful multiplexing of HPeV and EV PCR targets have been reported (131, 132).

**ISOLATION PROCEDURES**

A combination of human and primate cell lines are typically used for EV and HPeV isolation since no single cell line supports the growth of all types. The general susceptibilities of commonly used cell lines are summarized in Table 5. Isolation times for EVs from CSF using traditional cell culture techniques range from 4 to 8 days, but are shorter (1 to 3 days) from sites with higher viral titers. Recovery time for HPeV is variable and dependent upon type (HPeV1 and 2, 1 to 8 days; HPeV3, 14 to 17 days). Infections of susceptible cell monolayers with EVs result in a characteristic cytopathic effect (CPE), consisting of shrinkage and rounding of individual cells within the monolayers. The nuclei of infected cells exhibit pyknosis. As infection progresses, the cells degenerate and separate from the monolayer. Often, the CPE is so characteristic that a presumptive diagnosis of EV infection can be made (Fig. 4). However, experience is necessary, as toxic effects from primary specimens, such as Clostridium difficile toxin, can mimic CPE (133). Although the CPEs for EV and HPeV are very similar, differences have long been noted. The CPE for HPeV can appear as larger, regularly shaped spheres compared to small irregular shapes caused by EVs (Fig. 4) (134).

The relatively low sensitivity of viral culture from CSF (65 to 75%; reviewed in reference 135) is likely due to the presence of neutralizing antibody, inadequate CSF volume for a comprehensive culture (i.e., inoculate 3 to 5 cell types), low viral load, and resistance of some serotypes to culture. In particular, many serotypes within the EV group C (i.e., CV1A, CV1A9, and CV1A22) and HPeV7-14 are nonculturable. Historically, stool cultures have been thought to have greater sensitivity for EV/HPeV detection than CSF culture (136); however, in comparison with PCR testing of stool specimens, the sensitivity of stool culture is lacking (105).

Shell vial culture (SVC), in which virus is detected with monoclonal antibodies in the absence of CPE, reduces the time to detection to 2 to 3 days. The sensitivity of SVC may or may not be higher than that of traditional cell culture (137–139), and is probably laboratory- and cell-line dependent (140). SVC using a mixture of cell lines in a single vial (Super E-Mix containing decay-accelerating-factor-expressing BGMK cells and A549 cells, Diagnostic Hybrids Inc. [DHI], Athens, OH) improves sensitivity (139, 140). Evaluation of the capacity of Super E-Mix to isolate HPeV has not been performed; however, it is presumed that at least HPeV1 and 2 would grow in this cell mix because A549 cells are susceptible to infection. The greatest limitation of SVC is the monoclonal antibody used in the detection steps (discussed below).

**IDENTIFICATION**

Broadly reactive and serotype-specific EV monoclonal antibodies have been developed (88) and applied to cell culture confirmation by immunofluorescence. While preliminary studies suggest that these reagents, used singly and in blends (DAKO-Enterovirus 5-D/81 [DAKO, Glostrup, Denmark] and Pan-Enterovirus blend [Chemicon International Inc.]), demonstrated an important role in serotype identifications.

Further studies have identified several limitations (137, 138, 141). The most notable limitations are cross-reactivity with the Chemicon blend (137) and the lack of EV71 detection with the Dako blend. A pool of anti-EV antibodies has been developed (D3 IFA Enterovirus Identification, DHI) which reportedly has good sensitivity, including the detection of EV71 with little or no cross-reactivity. However, no peer-reviewed data on this product has been reported. The concordance of results for identification of clinical EV isolates to the species level using monoclonal blends versus the neutralization assay has demonstrated the latter may be significantly superior for the identification of the EVs (141). These studies appeared to indicate that monoclonal antibodies for EV identification should be used as a preliminary screen for species or serotype identification. With regards to HPeV, typing reagents are only available for types 1 and 2, and not all HPeV-2 isolates are neutralized by specific antisera (142).

**Typing Systems**

This virus family exhibits a considerable amount of genetic variability driven by both mutation and recombination (143, 144). However, serotype determination is usually unnecessary for clinical purposes because the diseases caused by the EVs are not serotype specific. Currently, the identification of EV type is most useful for distinguishing between VDPV and NPEVs to facilitate the interpretation of viral culture results in areas where the Sabin PV strains are used for vaccination, as the live vaccine can be shed for 1 to 2 weeks from the throat and can remain in the feces for several...
weeks to months (145). Identification of NPEV serotypes is useful for epidemiological purposes and for the determination of serotypes associated with unusual or novel clinical manifestations, such as flaccid paralysis (1).

Historically, EV serotype determination involved neutralization with the Lim and Benyesh-Melnick (LBM) pools of antisera; however, several limitations exist for these methodologies. The pools identify only 40 of the 64 originally described EV serotypes, and genetic drift of the EVs over time has given rise to antigenic variants. Furthermore, the procedure is labor-intensive and the supply of LBM pools available from the World Health Organization is limited (distribution is restricted to reference laboratories).

Sequence of the VPI gene is now the primary method used for typing. Specifically, a 340-bp region that encodes the serotype-specific neutralization epitopes of VPI is amplified, sequenced, and analyzed against a sequence database for known EVs (118, 146). A threshold of 25% nucleotide and 12% amino acid divergence generally corresponds to the previous serological division of EVs into members of the same or different serotypes (4). A pyrosequencing method based on the assay reported by Nix et al. (118) has also been developed (147). Molecular typing methods reduce the testing time by weeks (146) over classical serotyping. In addition, these methods of "molecular serotyping" have been extremely useful in typing the isolates that could not be neutralized by traditional LBM pools and were therefore classified as "nontypeable" EVs and in identifying multiple new EV serotypes and novel HPeVs. Various other molecular methods have been described for either species-specific typing (i.e., PV) or for the detection of multiple EV types. PV-specific typing includes PCR restriction fragment length polymorphism analysis (148), probe hybridization (149), reverse transcription-loop-mediated isothermal amplification (120), and PV type-specific PCR assays (150). Line blot hybridization (151) and microwell oligonucleotide array (152) have been reported for rapid typing of multiple EV types.

**SEROLOGIC TESTS**

In the clinical setting, situations may arise where EV serology is requested; such is the case for myocarditis and determination of congenital infection in pregnant women. A recent study by Mahfoud et al. (153) showed that endomyocardial biopsy should be used instead of EV serology for patients with myocarditis. Complement fixation testing is available from a few commercial laboratories in the United States but is generally not considered a relevant test for the diagnosis of EV infection as these assays lack specificity (24). Classically, serologic diagnosis of EV infection involved comparing antibody titers in acute- and convalescent-phase serum in a neutralization assay, with a 4-fold or greater rise in type-specific antibody titer considered as diagnostic of recent infection. However, acute-phase sera are often not obtained because of nonspecific presentations early in EV disease.

Type-specific enzyme-linked immunosorbent assays for the detection of EV serotype-specific IgM antibodies (i.e., CVB- and EV71-specific IgM), as well as heterotypic assays for the detection of IgA, IgM, and IgG antibodies against EVs in general, have been developed (154, 155). Homotypic assays are more relevant to epidemiological studies than to clinical diagnosis as they appear to be less sensitive than PCR for the diagnosis of EV infection but they have been successfully applied in such research settings (1, 156). Furthermore, the IgM response to EVs can be nonspecific and can lead to false-positive results (157, 158). Although cross-reactivity with non-EV pathogens has not been studied thoroughly, sera from patients infected with acute hepatitis A virus (a member of the Picornaviridae family) have been reported to produce a significant number of false-positive results in an enzyme-linked immunosorbent assay for detection of enterovirus IgM antibodies (155). Recently, PCR-enhanced immunoassays for the detection of EV-specific IgM have been evaluated (159). Such systems improve the sensitivity and specificity of immunoassays because the ligand is further amplified by PCR after immune capture (160). However, these methods are technically challenging to establish in the laboratory and are clearly investigational.

**ANTIVIRAL SUSCEPTIBILITIES**

There is no FDA-approved antiviral agent available for the treatment of EV or HPeV infections. However, several compounds targeting viral capsid proteins, proteases, polymerase, and other proteins are being developed, including some agents in phase-III clinical trials (161). A promising investigational drug, the WIN compound pleconaril, underwent extensive in vitro susceptibility testing against EVs, and clinical trials, but was not licensed for use by the FDA (162, 163). An antiviral compound with potent activity against the polioviruses is currently undergoing evaluation (164, 165).

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

An understanding of the sites where asymptomatic shedding and disease-induced replication occur is critical to the interpretation of EV and HPeV test results. Detection of these viruses in the CNS, bloodstream, lower respiratory tract, and genitourinary tract implies a true invasive infection and a high-level likelihood of association with current illness. In contrast, they can be shed asymptomatically from the nasopharynx and the gastrointestinal tract for weeks to months. Detection of EVs by virus isolation or NAAT at these sites must be interpreted cautiously because their presence alone does not establish a diagnosis. EV in the feces or nasopharynx of a patient with meningitis may represent residual shedding from an infection weeks from before and may not be unrelated to the current illness.

In young children, an additional factor potentially complicating the evaluation of results from these body sites is the administration of live attenuated oral PV in the first years of life. While the vaccine is no longer used in the United States (145), the majority of countries worldwide, including some in Europe, still employ oral PV as part of their vaccination regimens. Reporting an EV isolate in a setting where oral PV is used without specifying whether it is a PV or an NPEV can lead the physician to wrongly discontinue antibiotic or anti-herpes therapy in the belief that an EV etiology has been established. The distinction between PVs and NPEVs from the CNS, bloodstream, lower respiratory tract, and genitourinary tract is less important because VDPVs have rarely been isolated from such specimens, and may actually be causing the illness in question in those rare instances (166, 167).

A further cautionary note is warranted with regard to coinfections of the central nervous system with EVs and bacteria (142). In these rare instances, illness was clinically compatible with bacterial meningitis and EV was later isolated incidentally. Because of the severity of disease, antibiotics would have been used regardless of the sequence of pathogen detection. When the clinical presentation is
typical of viral meningitis, coinfection with a clinically "silent" bacterium would be extraordinarily unlikely. Hence, identification of an EV from a sterile site in a patient with a clinically compatible illness is sufficient evidence for establishment of EV causality. HPeV NAAT testing should be considered if negative results are obtained for EVs in the setting of clinically compatible disease.

TAXONOMY
Human rhinoviruses (HRVs) are members of the family Picornaviridae. Previously a separate genus, HRVs have been reclassified into three separate species (A, B, C) within the Enterovirus genus (1). Other Picornaviridae genera that are pathogenic for humans include Parechovirus, members of which have been associated with respiratory disease, and Hepatovirus. Recently, the Cardiovirus genus has been found to contain human pathogens as well (2).

HRVs derive their name from the predominant site of their replication and symptomatology, the nose. HRV isolates were originally classified into 99 serotypes (HRV1 through 99) based on neutralization with type-specific antisera; subsequent direct sequencing studies have shown that there are in fact many more types that have not been cultured and typed serologically (see below). While some cross-neutralization occurs, there is no group antigen (3, 4). HRV serotypes were further classified into two species—HRV-A, containing 74 serotypes, and HRV-B, containing 25 serotypes—based on sequence relatedness. The original 99 HRV prototype strains isolated in the 1960s and 1970s have been propagated and maintained by the American Type Culture Collection. One former HRV serotype, HRV87, has been shown by sequence analysis to be an acid-sensitive virus. HRV prototype strains have been reclassified into three separate species (A, B, C) within the Enterovirus genus (1).

HRV-A and 25 HRV-B serotypes can be further divided into two groups based on receptor binding (7, 8): (i) a major group (63 HRV-A and 25 HRV-B serotypes) that binds intercellular adhesion molecule 1 (ICAM-1), a member of the immunoglobulin supergene family that is expressed on the surface of many different cells (9); and (ii) a minor group (11 HRV-A serotypes) that binds to members of the low-density lipoprotein receptor family (8). Two different drug-reactivity groups of HRVs have also been identified based on composite sensitivities across a panel of antiviral compounds (10).

The wider use of molecular methods in viral diagnostics has led to the discovery of a novel group of HRVs identified in patients with lower respiratory tract disease. Classified as a new species, “C,” these viruses are not new or recently emerging viruses (11) but have been circulating unnoticed due to their lack of growth in standard cell culture systems used for HRV isolation. Recently, HRV-C viruses were grown in human sinus epithelium organ cultures, where they were shown to utilize an as-yet-unknown cellular receptor other than ICAM-1 or low-density lipoprotein receptor (LDLR) (12).

Sequencing of the complete genomes of the 99 HRV-A and -B serotypes and available HRV-C strains confirmed clustering of all strains into three distinct phylogenetic groups (13). Because serotyping HRV-C was not possible due to its refractoriness to growth in cell culture, a genetically based classification system was developed for assigning HRV genotypes while retaining the serotype numbering system (14). To date, 51 HRV-C genotypes have been assigned using a threshold of 13% nucleotide differences in the VP1 coding region from all HRV prototype strains or a 10% nucleotide difference in the VP4/VP2 region if the VP1 sequence is unavailable; thresholds of 13% and 12% nucleotide differences in VP1 for HRV-A and HRV-B type assignments, respectively, were also proposed (15). Designation of an additional six HRV-A and three HRV-B genotypes using the above thresholds brings the total number of currently recognized HRV types to 159.

DESCRIPTION OF THE AGENT
The HRV genome is a single-stranded, positive-sense RNA about 7,200 nucleotides in length. The genome is composed of a 5′ untranslated region (5′ UTR) coupled with a short peptide (VPg) that serves as a primer for genome replication (16), followed by a single open reading frame that terminates in a 3′ poly (A) tail (Fig. 1). Secondary structures within the 5′ UTR, a cloverleaf domain and an internal ribosomal entry site (IRES), are necessary for protein translation. The single polypeptide product of the open reading frame is subsequently cleaved into 11 viral proteins: 4 structural proteins that form the viral capsid (1A-1D or VP4-VP1) and 7 nonstructural proteins that are involved with virus replication or polyprotein processing (2A-2C and 3A-3D). The 3C protease participates in cleavage of polypeptide and is a target for antiviral drugs.

The HRV virion is a small (20 to 27 nm in diameter), nonenveloped icosahedron composed of 60 protomeric units, each consisting of the four structural protein subunits (VP1-VP4). VP1, VP2, and VP3 reside on the exterior of the virion and make up its protein coat. VP1 is the largest, most external and immunodominant protein of the virus capsid (17). A number of major neutralization sites reside in the VP1 proteins. Located within VP1 is a hydrophobic pocket into which antiviral compounds such as plecanaril bind (18). VP4 resides inside the protein shell. X-ray crystallography and cryoelectron microscopy studies have identified large depressions or “canyons” on each of the 60
protomeric units, which appear to be sites for cell receptor binding and also play a critical role in conformational changes that follow attachment (19). Conformational changes in the canyon floor can also be induced by certain antiviral agents, thus inhibiting virus attachment to cells or virus uncoating (18).

HRVs replicate in the cytoplasm of infected cells, producing infectious virions that sediment at a buoyant density of 1.40 g/liter in cesium chloride. Empty capsids and particles lacking one or more structural polypeptides are also produced.

Mutation and recombination are two mechanisms that drive the extensive genetic diversity of HRVs and serve as the basis for HRV evolution. The RNA-dependent RNA polymerase, designated 3D polymerase, which facilitates synthesis of new viral genome, has no proofreading capacity and frequently generates mutations. Evidence of recombination between HRV-A and HRV-C within the 5′ UTR has also been shown: on phylogenetic analysis, the 5′ UTR sequences of some HRV-C genotypes cluster within the HRV-A clade (20, 21). Although HRV-B and HRV-C show little evidence of recombination within the genome coding region, recent studies have shown that HRV-A sequences have undergone extensive recombination during the early stage of diversification into types, and several contemporary HRV-A strains have been formed by recombination (22, 23).

As they have no lipid envelope, HRVs are fairly resistant to inactivation by organic solvents such as ether, chloroform, ethanol, and 5% phenol. Although HRVs are relatively thermostable, heating at 50 to 56°C progressively reduces infectivity. HRVs are traditionally differentiated from HEVs by their loss of infectivity on exposure to pH 3 for 3 hours at room temperature, though this may not be the case with all serotypes and strains.

**Epidemiology and Transmission**

HRV infections are widespread and occur year-round. In temperate zones, transmission typically peaks in autumn and late spring (24). Some recent studies using molecular methods have also found substantial infections in summer and winter (24–26).

Seasonal fluctuations have been attributed to improved survival of HRV in conditions of high relative indoor humidity and herding together of children when school opens in the fall (27). HRV-A and HRV-C may cocirculate in equal proportions or may alternate as the predominant species (28–30). HRV-B is consistently detected less often (30). As the disease burden and diversity of HRV infections have become evident, the interest in HRV genotyping, molecular epidemiology, and virulence has intensified (11).

Studies in volunteers have shown that inoculation of virus into the nose or conjunctivae is the most efficient way to initiate infection, although virus can also be transmitted by aerosol (31, 32). HRV is present in highest titers in the noses of infected persons and commonly contaminates their hands. Consequently, investigators have found that HRV can be transmitted via hand-to-hand contact (33) or by contaminated fomites, followed by self-inoculation of virus into the nose or conjunctivae (34). Furthermore, transmission can be interrupted by using tissues impregnated with virucidal agents for nose blowing, by treating surfaces with disinfectant, or by applying iodine to the fingers (35). Recent studies have found ethanol hand sanitizers to be more effective than soap and water, and virucidal activity of the sanitizer can be enhanced and prolonged by the addition of organic acids (36). However, a reduction in transmission in a natural setting has not been established (154).

HRVs replicate primarily in airway epithelium, but also in the middle ear and sinuses, with an incubation period of 1 to 4 days (37). Peak of virus shedding coincides with the acute rhinitis. Symptoms last 7 days, on average, but can persist for 12 to 14 days or more (38, 39) and typically include profuse watery discharge, nasal congestion, sneezing, headache, mild sore throat, cough, and little or no fever. By culture, virus may become undetectable at 4 to 5 days or may be present in low titers for up to 2 to 3 weeks (40). Asymptomatic HRV infections are also common, occurring in 20 to 30% of infected persons (24, 41–43). Using reverse transcription PCR (RT-PCR), HRV RNA has been detected by some investigators 4 or 5 weeks after the onset of symptoms and, surprisingly, for 2 to 3 weeks prior to onset of symptoms (42, 44). However, genotyping has revealed that such prolonged shedding represents a series of sequential HRV infections with different HRV types, some asymptomatic (45). As many as 74 distinct HRV types have been found to be cocirculating, including multiple types in the same household (45, 46). Chronic shedding of a single HRV type has been documented only in immunocompromised hosts (47).

HRV causes minimal pathology in the nasal epithelium, and the symptoms of HRV infection parallel the rise
and fall of chemical mediators of inflammation (34, 35). Psychological stress and inadequate sleep appear to increase susceptibility and the development of clinical symptoms (48–50), whereas exposure to a cold environment does not (51). Early studies concluded that immunity is type specific and correlates best with local production of IgA (52, 53).

CLINICAL SIGNIFICANCE

HRVs cause approximately two-thirds of cases of the upper respiratory syndrome known as the common cold and thus are responsible for more episodes of human illness than any other infectious agent (24, 35). Although considered a trivial illness, the common cold is acutely disabling and its cost, in days lost from work, cold remedies, and analgesics, is estimated at $40 billion annually in the United States (54).

With the use of molecular methods, more severe consequences of HRV infections have been increasingly recognized. HRVs can be the sole etiology of sinusitis and otitis media, as well as facilitating secondary bacterial infections (55, 56). HRVs have been implicated as the major viral cause of exacerbations of asthma, cystic fibrosis, and chronic obstructive pulmonary disease (COPD) (57–59). Indeed, HRV wheezing illness in infancy has been linked to childhood-onset asthma in genetically susceptible children (60). The impact of disease in the elderly is also substantial. In a Canadian study, 59% of outbreaks of respiratory disease in long-term care facilities were found to be due to HRVs, and some disease was severe (61).

HRV has been increasingly detected in patients with lower respiratory tract infections (62, 63); in patients hospitalized with wheezing or pneumonia (64–66), including school-age children (67); the elderly (27, 68); and those with chronic illnesses, cancer, immunosuppressive illness, transplants (69–74), or underlying pulmonary disease (75). The clinical manifestations of HRV in hospitalized infants are similar to those caused by respiratory syncytial virus (RSV); however, the mean age of HRV-affected infants tends to be slightly older (66). HRVs are commonly found either singly or in combination with other viruses. HRVs have been shown to impair the innate immune response (76, 77) and may predispose to invasive pneumococcal disease in children and bacterial superinfections in COPD (77, 78).

HRV-C viruses have been implicated in some studies as the predominant HRV species linked to hospitalizations for fever, wheezing, and lower respiratory tract disease, especially in young infants and asthmatic children (28, 79–84). In contrast with classic HRV-A and HRV-B, HRV-C replicates equally well at 37 and 34°C, facilitating infection in the lower respiratory tract (85). However, additional population-based studies are needed before definitive conclusions can be made about the prevalence and virulence of HRV species (37).

Although HRV viremia has rarely been identified by culture, HRV RNA has been detected using sensitive molecular methods in the blood of HRV-infected young children with severe respiratory illness (37), including 25% of those with HRV-associated asthma exacerbations (43). HRVs have also been detected in fecal specimens of children with meningitis, pericarditis, and gastroenteritis and even in a healthy child (86–89).

Because HRVs have historically been difficult to culture and serotype, little information is available on the relationships between serotype, clinical manifestations, and virulence (90). With the development of genotyping methods and increased awareness of the disease burden of HRV, this currently is an area of intense study (24, 37, 89).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

In natural infections, HRV can generally be isolated in culture from 1 day before to 6 days after onset of cold symptoms but is shed in highest concentration on day 1 or 2 of illness. In upper airway disease, HRV is excreted in highest titers from the nose; thus nasal rather than throat specimens should be obtained for diagnosis.

Early comparisons of nasal wash, nose swab, throat gargle, and throat swab specimens for the isolation of HRV from clinical specimens revealed nasal washes to be the best (53, 91), which are obtained as follows. Tilt the patient’s head backwards and instill 1 ml of sterile phosphate-buffered saline (PBS) into one nostril. Then ask the patient to lean forward and allow the washing to drip into a sterile petri dish or other collection container. Repeat with the other nostril until each nostril has been washed with 5 ml of PBS. The washings are then transferred into a sterile container. However, nasal wash samples are cumbersome to obtain in most clinical settings.

For many years, nasopharyngeal (NP) aspirates have been the standard for infants and young children, but the most convenient and commonly collected sample at present is an NP swab placed in viral transport medium (VTM). Well-collected NP swabs can provide detection rates comparable to aspirates and are simpler to obtain (92, 93). A recent study found that, while nasal wash detected more HRV positives than NP swabs, the difference was not statistically significant when flocked swabs were used (94). Flocked swabs have been shown in some but not all studies to provide superior samples to cotton and some other swab types. However, due to the small, flexible shaft, flocked NP swabs are consistently rated as more comfortable for the patient than rigid-shaft, large-tipped collection swabs (94). Mid-turbinate flocked swabs provided a yield similar to NP swabs results in one report and are amenable to both self-collection and parents’ collection of samples from young children (95, 96). Sputum has been reported to be comparable in yield to NP aspirates for respiratory viruses (97).

To diagnose lower respiratory tract infection, endotracheal aspirate, bronchoalveolar lavage, bronchial wash, or lung biopsy samples should be collected. Sputum, including induced sputum in children, has been recently found to be useful for diagnosing viral lower respiratory tract disease (93, 98).

All specimens should be transported promptly to the laboratory. For isolation, best results are obtained with prompt inoculation of cell cultures; however, specimens can be held up to 24 hours at 4°C in VTM with neutral pH. If longer delays are necessary, specimens should be frozen at −70°C and thawed just before inoculation. Freezing does not appear to be detrimental to virus recovery (91). Similar sample handling is recommended for molecular analysis; however, the compatibility of various VTMs with different extraction reagents must be confirmed in each laboratory, and manufacturers’ instructions should be followed for all commercial kits.

DIRECT EXAMINATION

Antigen Detection

Due to the large number of serotypes and the lack of a common group antigen, antigen detection assays are not used in clinical practice.
Nucleic Acid Detection

Conventional RT-PCR Assays

Wider use of molecular diagnostics has dramatically increased HRV detection and greatly enhanced our appreciation of the role of these viruses in respiratory disease. RT-PCR assays have proven more sensitive than culture methods, doubling or even tripling the number of HRV infections detected (41, 99–102), and are clearly superior for detection of noncultivable HRV strains. Nevertheless, culture can occasionally recover some HRVs missed by RT-PCR due to variability in techniques and primer or probe mismatches (100, 102, 103).

The first RT-PCR diagnostic assay described for HRVs was reported by Gama et al. in 1988 (104). Since then, numerous molecular assays have been described. These assays typically target the 5′ UTR of the viral genome that contains highly conserved sequences suitable for molecular assay development. However, most of these assays also detected HEVs because the primer sets used could not effectively distinguish between these two virus groups. Earlier strategies to distinguish between HRVs and HEVs included differential amplicon sizing (105, 106), restriction enzyme digestion of a common-sized amplicon (107), internal probe hybridization (103, 108), and nested PCR using HRV-specific primers (84) or annealing and extension times optimized for HRV detection (101). Most of these reported methods failed to detect or accurately differentiate all viruses tested, and none evaluated all HRV and HEV types. RT-PCR and sequencing of amplicons to differentiate HRVs from HEVs and identify virus types (see below) are now commonly used by specialized reference laboratories but are still not easily implemented for routine clinical diagnosis (109).

At present, molecular methods are not standardized, and those published have differed in types of samples tested, methods of RNA extraction used, primer selection, and amplification and detection conditions. A comparison of the relative sensitivity of 11 published HRV primer pairs using clinical specimens positive for the three recognized HRV species demonstrated an overall discordance in performance, especially for specimens with lower virus loads (110).

Real-time RT-PCR Assays

More recently, real-time RT-PCR (rRT-PCR) assays for HRVs using SYBR Green, TaqMan hydrolysis probes, or molecular beacons have been developed (39, 72, 87, 109, 111–113). Real-time amplification methods have the advantages of simplicity, reduced risk of amplicon contamination, ability to estimate viral load, and a shortened time to result because detection occurs concurrent with amplification. Although SYBR Green and melt-curve analysis are less expensive than probe-based methods, results obtained using these techniques can be difficult to interpret (39).

A recently developed rRT-PCR assay (39) targeting the 5′ UTR was shown to detect all recognized HRV prototype strains as well as the novel species C viruses; it has been used successfully in studies to determine the epidemiology and clinical features of HRV infections in different populations (28, 114, 115). Although much effort has been devoted to improving the specificity of this assay, it still reacts with some HEVs when present at high titer in the clinical specimen.

Several HRV studies have demonstrated a positive correlation between viral load and disease severity, suggesting that virus quantitation may help clarify the clinical relevance of a positive test result (88, 116–119). Although a recent study has shown that rRT-PCR assays can be used to semiquantify HRV RNA in clinical material, accurate absolute HRV RNA quantification in respiratory specimens is complicated by (i) the lack of an accurately quantified international reference RNA standard, (ii) sequence variation among HRV strains that may differentially affect rRT-PCR amplification efficiency, and (iii) variability in sample collection procedures (120).

Multiplexed RT-PCR Assays

Numerous laboratory-developed and commercial multiplex RT-PCR assays based on different amplification platforms and combining multiple respiratory pathogens, including HRV, have been described in recent years. There are currently four commercial multiplex tests that include HRV that have been cleared for in vitro diagnostic use in the United States by the U.S. Food and Drug Administration (FDA): the Luminex xTAG RVP and Luminex xTAG RVP Fast (Luminex Molecular Diagnostics, Austin, TX); the FilmArray Respiratory Panel (RP) (BioFire Diagnostics, Salt Lake City, UT); and the eSensor Respiratory Viral Panel (RVP) (GenMark Dx, Carlsbad, CA) (Table 1).

The Luminex xTAG RVPv1 and xTAG RVP Fast utilize multiplex RT-PCR followed by amplicon identification using a fluid-microsphere-based array flow cytometry (121, 122) for detection of 12 and 8 viruses and subtypes, respectively. The FilmArray RP integrates sample preparation, amplification, and detection into one simple system using a preloaded blister pouch solid array and endpoint melting curve analysis to detect and identify 20 different respiratory pathogens in about 1 hour. The eSensor RVP uses competitive DNA hybridization and electrochemical detection to identify 14 different respiratory virus types and subtypes. Neither the FilmArray RP nor the LuminexTAG assays distinguish between HRV and HEV, while the eSensor RVP claims to be specific for HRV only (123, 124). Most commercial molecular assays require purchase of a dedicated instrument to perform. In contrast, the FTD respiratory pathogens multiplex assay (Fast-track Diagnostics, Luxembourg) uses standard real-time hydrolysis probe chemistries and common real-time PCR instrumentation for detection of 21 respiratory pathogens, allowing easy integration into the workflow of laboratories already using standard real-time PCR platforms (125).

At present, few clinical laboratories are either interested in or able to set up homewebased RT-PCR assays for HRV; even if available commercially, these assays may not be used unless they are part of a more comprehensive panel of respiratory pathogens.

These comprehensive multiplex assays have confirmed the frequent detection of HRVs in culture-negative clinical samples and have revealed many mixed pathogen infections. However, most are not quantitative, and all are costly to implement and maintain. Each commercially available system has its unique advantages and disadvantages, and each user should determine which system is appropriate for his or her specific diagnostic needs.

Although much effort has been devoted to distinguishing HRVs from HEVs in the clinical setting, a single assay that detects both virus groups could ultimately prove to be advantageous since some antivirals may be effective against both virus groups (38). Moreover, some HEVs (e.g., HEV-68, CoxA21) can also cause respiratory diseases (126–130). Thus, some multiplexed assays have not attempted to separate the 2 genera but instead target both (Table 1).

ISOLATION PROCEDURES

Cell Culture
Rhinovirus groups A and B grow only in cells of human or monkey origin. HRV group C has not yet been grown in cell culture. Although the original isolation of rhinoviruses was in primary monkey kidney cells, these cells have not been consistent in yielding a broad range of isolates. The most commonly used cells in clinical laboratories are the human embryonic lung fibroblast strains WI-38 and MRC-5. WI-38 cells are significantly more sensitive than MRC-5 (91), but MRC-5 cells are more commonly available. Human embryonic kidney (HEK) can also support rhinovirus replication. Unfortunately, different lots of normally sensitive cell lines have been found to vary over 100-fold in sensitivity to rhinovirus (10); the reasons for this variation are not known. Therefore, for optimal results, simultaneous use of at least two sensitive systems is recommended.

In the research setting, several HeLa cell clones, such as HeLa M or Ohio HeLa cells, HeLa H, HeLa R-19, and HeLa I cells, have been shown to support the replication of rhinoviruses to high titers (91). HeLa I cells were found to be more sensitive than WI38, MRC-5, fetal tonsil, or HeLa H or M cells for recovery of rhinovirus from clinical specimens (131). These specialized cell lines can be obtained only from research laboratories.

After inoculation, cultures are incubated in standard cell culture medium such as Eagle minimum essential medium (MEM) with 2% fetal calf serum and antibiotics at a neutral pH. To mimic conditions of the nose, cultures should be incubated at 33 to 35°C with continuous rotation in a roller drum to provide aeration of the monolayer. Rhinovirus cytopathic effects (CPE) can be observed as early as 24 to 48 hours after inoculation and are often detected by day 4.

Passage of infected HeLa cell cultures may be necessary for some isolates before CPE is apparent. In fibroblasts, cellular changes are easier to read and are often detected earlier than in epithelial cell lines. Both large and small rounded, refractile cells with pyknotic nuclei are observed in foci that also contain cellular debris (Fig. 2). Rhinovirus CPE are similar to HEV CPE but may sometimes be confused with nonspecific changes. The CPE progresses over a 2- or 3-day period, with the degree of cellular change depending on the serotype and the inoculum dose. It should be noted that rhinovirus CPE can regress, or virus may inactivate if left too long. Therefore, cultures should be promptly passaged. Passage is also necessary to increase viral titers prior to the performance of identification tests.

Human embryonic lung fibroblast cell cultures should be observed for 14 days, with refeeding at 7 days to increase recovery of virus. HeLa cell cultures can be observed for only up to 7 to 8 days, when passage becomes necessary due to nonspecific cell degeneration and rounding.

Rapid centrifugation cultures using the HuH7 hepatocellular carcinoma cell line have been reported to detect respiratory viruses including HRV. After 4 days of incubation, HRV can be detected in the amplified culture by RT-PCR. While results were faster, HuH7 cells were not as sensitive as MRC5 conventional cultures incubated for 14 days (99).

Organ Culture
Organ cultures of human fetal nasal epithelium or trachea were used in the past to isolate rhinoviruses not grown in standard cell cultures but are no longer used for this purpose. Recently, however, cultures of nasal, sinus, and tracheal mucosa obtained from biopsy material have been used for research studies of rhinovirus pathogenesis (12, 85, 132, 133).

doi:10.1128/9781555817381.ch89.f2
IDENTIFICATION

A presumptive diagnosis of HRV isolation in cell culture is made by the appearance and progression of characteristic CPE in the appropriate cell lines. In clinical laboratories, further identification of a presumed HRV isolate is usually limited to determining it from HEVs by determining sensitivity to acid pH, although this practice has declined in recent years. Virus neutralization testing with type-specific antisera is time-consuming, costly, and not routinely available. In addition, the recently recognized HRV-C strains do not grow in culture, and no neutralizing sera are available.

Acid pH Stability

HRVs are sensitive to low pH and are inactivated, whereas HEVs remain viable. Thus, a reduction in virus titer of 2 to 3 log_{10} 50% tissue culture infective dose (TCID_{50}) can be expected upon exposure of HRV to low pH. To perform the test, first passage the isolate to obtain a minimum titer of 10^5 TCID_{50}/ml. Then prepare two solutions of a buffer, such as HEPES, one at pH 3.0 and one at pH 7.0. Add 0.2 ml of unknown virus suspension to 1.8 ml of HEPES pH 3.0 and 0.2 ml of virus to 1.8 ml of HEPES pH 7.0. Keep these virus suspensions at room temperature for 3 hours, adjust the pH to 7.0, make serial dilutions of the mixtures, and inoculate into cell culture. If the unknown virus is an HRV, a minimum 2 log_{10} reduction in viral titer should be evident in the acid-treated sample. As a control, a known HRV and a known HEV should be treated in a similar fashion.

As an alternative to the acid lability test, staining of isolates in parallel with both a pan-enterovirus immunofluorescence reagent that detects both HEV and HRV and an HEV-specific reagent that detects only enterovirus has been shown to rapidly and correctly identify 11 HRV isolates in a clinical setting (134).

Temperature Sensitivity

Since HRVs often grow best at 33°C, they may be distinguished from HEVs by inoculation of parallel serial dilutions of the unknown virus and incubation at 33 and 37°C. The onset of CPE should be more rapid and the titer of virus obtained should be higher at the lower temperature. Some HRV isolates may not show this temperature sensitivity, so this test is no longer used clinically (63).

Virus Identification by RT-PCR

RT-PCR targeting highly conserved regions of the 5' UTR can be used for confirmation of HRV isolates in cell culture. However, cross-reactions with HEV can occur, especially with high-titered culture isolates (39, 135).

TYPING SYSTEMS

Serotyping HRVs by Virus Neutralization

Serotyping of HRV isolates by neutralization with type-specific antisera used to be the gold standard for HRV identification. However, the neutralization test is expensive and labor-intensive, results can be delayed for weeks, and few laboratories have the antisera necessary to perform the procedure. Moreover, HRV-C strains cannot grow in standard cell culture, and interpreting assay results can be difficult given cross-reactions between some serotypes. Serotyping requires the neutralization of 30 to 100 TCID_{50} of virus-induced CPE by 20 units of antiserum. Hyperimmune antisera for HRVs are available through the ATCC. Intersecting serum pools similar to those used for HEV identification have been prepared to help narrow the identity of the virus isolate. Identification of the specific serotype is then performed using monospecific antisera. Detailed procedures are described elsewhere (136).

Genotyping HRVs by Sequencing

Molecular typing based on RT-PCR and amplicon sequencing has essentially replaced serotyping for type-specific identification of HRVs. Because the HRV VP1 capsid protein contains a number of neutralization domains that correlate with serotype, genotypic identification of HRVs based on complete VP1 sequencing has been proposed using type assignment nucleotide differences thresholds of 13, 12, and 13% for HRV-A, -B, and -C, respectively (23). This change has led to only minor revisions of existing serotyping designations (such as reclassification of serotype pairs A8/A95 and A29/A44 as single serotypes). However, because of the high degree of sequence variation in the VP1 gene and surrounding regions, it has been difficult to design universal primers that will successfully amplify all HRV strains, often requiring new primer designs and assay optimization when new HRVs are recognized (137). In contrast, genotyping based on sequencing the capsid VP4/VP2 protein genes has been widely used for HRV genotyping in large epidemiological studies (64, 84) due to the availability of conserved regions for primer design that bracket the VP4/VP2 region. Overall, HRV species and type identification based on nucleotide sequences of VP4/VP2 correlate well with VP1 genotyping (137).

The HRV 5' UTR contains both highly conserved and variable sequences and has been reported as the most sensitive target for detection and typing of HRVs directly from clinical specimens (81, 90). However, sequence from the 5' UTR cannot unequivocally determine HRV species or genotype due to the tendency of some HRV-A and HRV-C strains to recombine in this region, resulting in incongruent phylogenetic clustering compared with the capsid coding regions (20, 117).

In a study to determine the relative contribution of the different HRV species to hospitalization among young children with acute respiratory infection (114), typing was first performed on all HRV RT-PCR–positive specimens using primers targeting a partial region of the VP1 gene (137). VP1 RT-PCR and sequencing identified a HRV genotype in 74% of the specimens. Specimens that were negative by VP1 RT-PCR were then tested with primers targeting VP4/VP2, and an additional 18% were genotyped. The remaining specimens were then tested with primers targeting the 5' UTR, and an additional 3% were genotyped. The remaining 5% of RT-PCR–positive specimens did not yield interpretable sequence data by any method. The presence of multiple HRV types in clinical specimens may complicate obtaining unambiguous sequence data when using classical Sanger sequencing methods. Next-generation sequencing methods may prove useful for discriminating among mixed HRV infections and studying HRV recombination and quasispecies.

SEROLOGIC TESTS

Determination of antibody response is impractical for the diagnosis of rhinoviruses in the clinical setting. The number of HRV serotypes and the lack of a common antigen make blind serologic testing impractical. Diagnosis by serology is also retrospective because antibody is usually not detectable until 1 to 3 weeks after onset of illness, with IgA predominant in nasal secretions and IgG predominant in serum (136). In research studies, antibody determination
by neutralization test is the gold standard for serology (138). Enzyme-linked immunosorbent assay (ELISA) using specific serotype antigens has been used to detect serum and nasal IgG and IgA in volunteers inoculated with known HRV serotypes, and it was 100 to 10,000 times more sensitive than neutralization (52). Detailed procedures can be found elsewhere (136).

**ANTIVIRAL SUSCEPTIBILITIES**

Many antivirals show activity against HRVs in the laboratory (139). However, inadequate drug delivery to the site of infection has reduced clinical benefit, and treatment remains experimental. Studies have included intranasal administration of soluble ICAM-1 in HRV-infected volunteers; use of intranasal ipratropium bromide, an anticholinergic agent; intranasal imiquimod; or administration of antivirals and antimediators in combination (34, 140–142). Efficacy studies in humans of echinacea, an herbal remedy, and zinc tablets have been mixed (143). Although the Picornavirus capsid binding agent, pleconaril, showed some benefit in clinical trials of natural colds (38), it was not approved for clinical use. A more recent phase II trial of a pleconaril nasal spray remains unpublished (139). Another capsid-binding agent, BTA-798 or vapendavir, has had a successful phase II clinical trial in 2010–2011 (89). Although inhibitors of HRV 3C protease have shown potent antiviral activity, trials of rupintrivir and compound 1 have been halted (139). Due to numerous HRV types and apparent lack of cross-protective immunity, prospects for a vaccine have been considered negligible. However, it is hoped that full-genome sequencing will usher in a new era of antiviral and vaccine design (13).

**EVALUATION, INTERPRETATION AND REPORTING OF RESULTS**

A comparison of HRV diagnostic methods is shown in Table 2. Nucleic acid amplification assays have revolutionized HRV detection, revealed both the ubiquity of HRV infections and the association of HRV with serious disease, fas-

b CMV, cytomegalovirus; VZV, varicella-zoster virus; HSV, herpes simplex virus; RSV, respiratory syncytial virus.
tered clinical research, and led to the discovery of HRV-C viruses.

In the clinical laboratory, screening for HRVs is rarely specifically requested. Historically, HRVs were isolated in conventional culture when the suspected virus was influenza or RSV. Following the 2009 influenza pandemic, demand for user-friendly, FDA-approved respiratory virus molecular assays greatly increased, and many of the commercial highly multiplexed respiratory viral panels (RVPs) target HRV. In clinical laboratories that utilize one of these RVPs, HRV is often the most commonly identified virus. The frequency of detection can even lead to the impression that HRVs are “normal flora” and can be ignored.

Thus, the interpretation of a positive HRV PCR result can be problematic. HRVs are extremely common, occur in asymptomatic persons, are prone to cause serial infections, can be shed for weeks after symptoms resolve, and can occur as coinfections with other viruses or bacteria. Interpretation of a positive HRV result in an individual patient often relies on risk factors and recovery of other pathogens. While viral load quantification by rRT-PCR may help determine its role in the acute illness, quantitative standards and guidelines are not available and may not correlate in an individual patient (88, 117–120, 144). Furthermore, the RVPs that include HRV detection do not generally provide quantitative results.

Molecular tests may also not accurately distinguish HRV from HEV (Table 1), and several HEVs have been recognized as common respiratory pathogens (126, 128, 130). Although therapy may not differ, more information is needed to determine whether differences in transmission, infection control measures, virus dissemination within the host, samples for diagnostic testing, and presence of extrarespiratory disease merit distinguishing HRV from HEV.

For laboratories relying on culture methods, isolation of HRV-A and -B, although insensitive, can be accomplished using commonly available conventional cell systems such as WI-38, MRC-5, or HEK. Incubation at 33 to 35°C and rotation of cultures provide optimal conditions for virus replication. Differentiation of HRV from HEV, with which their cPE can be confused, is based on acid-stability testing of isolates or confirmation by RT-PCR.

Specific identification of HRV serotypes by neutralization tests or genotypes by sequence-based molecular methods is reserved for epidemiologic research studies. Serologic testing is also not available outside the research setting.

Molecular techniques are essential for detection of HRV-C and to elucidate the role of HRV as lower respiratory tract pathogens and as significant causes of asthma and COPD exacerbation. However, HRV detection may not become a high priority for clinical laboratories until the cost effectiveness and impact of diagnosis on the management of hospitalized patients can be demonstrated, or effective therapy becomes available.

Coronaviruses*
NAOMI J. GADSBY AND KATE E. TEMPLETON

90

TAXONOMY
Coronaviruses (CoVs) are so called due to their striking crown of surface projections, reminiscent of the solar corona, which can be seen by electron microscopy (Fig. 1). The Coronaviridae is one of four families within the order Nidovirales and is divided into two subfamilies, Coronavirinae and Torovirinae. Within the Coronavirinae, there are four genera, Alphacoronavirus, Betacoronavirus, Gammacoronavirus, and Deltacoronavirus (1, 2). Species within the Betacoronavirus genus are further differentiated into lineages A, B, C, and D, although these lineages do not have formal taxonomic status. Previously, CoVs were separated into three serologically distinct groups: groups 1 and 2 contained human and animal CoVs and group 3 contained only avian CoVs. However, many new CoVs have recently been described and categorized genetically, and several hundred CoV genome sequences are now available (2). This has led to a reorganization of the taxonomic structure and the current phylogenetic relationship of the 20 recognized species within the Coronavirinae is illustrated in Fig. 2 (3). To date, six human CoVs (HCoVs) have been described. The Alphacoronavirus genus (previously CoV group 1) contains two HCoVs, HCoV-229E and HCoV-NL63, along with a number of other CoVs including those from bats, pigs, dogs and cats. The Betacoronavirus genus (previously CoV group 2) contains the remaining HCoVs and many other mammalian CoVs. HCoV-OC43 and HCoV-HKU1 are in Betacoronavirus lineage A, the causative agent of severe acute respiratory syndrome (SARS-CoV) is in lineage B, and the newly described Middle East respiratory syndrome CoV (MERS-CoV) is found in lineage C (4). The Gammacoronavirus genus (previously CoV group 3) and the newly proposed Deltacoronavirus genus predominantly comprise avian CoV species, with some CoVs found in mammalian species, but none thus far in humans (2, 5, 6).

DESCRIPTION OF THE AGENT

Structure
CoVs have very large, linear, positive-stranded RNA genomes, ranging from approximately 25 to 32 kb in size (6). The 5’ two-thirds of the genome is a replicase gene encoding 15 to 16 nonstructural proteins in two overlapping open reading frames, ORF1a and ORF1b. The remaining third of the genome encodes four to five structural proteins, translated from a nested set of subgenomic mRNAs, and additional accessory genes specific to particular CoVs. The spherical or pleomorphic virions are enveloped and contain a helical nucleocapsid of nucleoprotein (N) associated with the RNA genome. Embedded in the envelope are 20-nm-long trimers of spike glycoprotein (S), also called peplomers, which have a club-shaped morphology and facilitate attachment to cells. The envelope also contains integral membrane (M) and envelope (E) proteins. CoVs of Betacoronavirus lineage A also have 5- to 7-nm spikes of an additional membrane glycoprotein, hemagglutinin-esterase (HE). The molecular biology of CoVs has recently been reviewed (7). MERS-CoV is distinct from SARS-CoV in its use of a different cellular receptor for entry (8).

Origin
CoVs have been found in a wide range of domestic and wild mammals and birds; however, the particular diversity of strains found in birds and bats suggests that these animals are the natural reservoirs of CoVs, although this may also be the result of current sampling bias (2, 6). HCoV-229E and HCoV-NL63 were initially considered more closely related to each other than to the other alphacoronaviruses (9, 10). However, more recent genetic analysis of CoV from bats suggests zoonotic origins for both viruses (11–13). HCoV-OC43 is a subspecies of Betacoronavirus 1 closely related to other domestic animal CoVs, particularly bovine CoV, and it is postulated that zoonotic transmission may have occurred from cattle to humans (14). HCoV-HKU1 is distinct from HCoV-OC43 within Betacoronavirus lineage A and its origin is unknown at present (15). SARS-CoV is the sole species in Betacoronavirus lineage B, comprising only SARS-CoV from humans and related CoVs from civets, ferrets, badgers, and bats (2, 16). The zoonotic origins of SARS-CoV are still unclear; however, it is likely that it emerged from a natural reservoir in bats and that zoonotic transmission occurred via animals such as civets in the exotic animal markets of southern China. The existence of other intermediate animal hosts is still debated due to the relative divergence of human and civet SARS-like CoVs from the bat CoVs found to date (17). The origin of MERS-CoV is still obscure but is also likely to be zoonotic; closely related CoV sequences have been found in bats (18, 19), raising the possibility of direct transmission to humans or indirect transmission via an unknown intermediate host or

doi:10.1128/9781555817381.ch90
hosts, potentially camels (3, 20, 21). Recent genomic analyses suggest multiple sporadic introductions of MERS-CoV into the human population have occurred in Saudi Arabia, as well as human-to-human transmission (22).

Discovery
In the 1960s, a number of virus strains that had a cytopathic effect, morphology, and biology unlike those of known respiratory viruses were isolated in culture from individuals with respiratory illness in the United States and United Kingdom (23–25). Isolation of these viruses was difficult and generally required the use of primary organ cultures. They were morphologically and biologically similar and appeared most closely related to infectious bronchitis virus and mouse hepatitis virus. Together, they formed a new group of viruses recognized as coronavirus in 1968. From this group, HCoV-229E and HCoV-OC43 were subsequently well characterized, owing in part to their existing ability (HCoV-229E) or subsequent adaptation (HCoV-OC43) to propagate in vitro (23, 24, 26). In 2003, SARS-CoV was isolated from cell cultures inoculated with respiratory specimens from affected patients; it had CoV-like morphology on electron microscopy and was identified as a novel CoV by sequence analysis (27–32). Experimental infection of cynomolgus macaques demonstrated it was the etiological agent of SARS (33). Shortly after the SARS epidemic, two further HCoVs were identified, HCoV-NL63 in 2004 (10) and HCoV-HKU1 in 2005 (34). HCoV-NL63 was isolated using a novel cDNA-AFLP-based technique to identify an unknown virus from culture (10) (Fig. 3). HCoV-HKU1 was identified solely using nucleic acid-based methods because it was refractory to growth in conventional cell lines (34). Retrospective analysis using stored samples has shown that both these “newly discovered” HCoVs have been circulating

in the human population for many years (35). MERS-CoV was identified in 2012 by pan-CoV reverse transcription (RT)-PCR and genetic analysis (36). Rhesus macaques experimentally infected with MERS-CoV developed pneumonia, thus establishing a causal relationship between virus and disease (37).

**EPIDEMIOLOGY AND TRANSMISSION**

HCoV-229E, HCoV-OC43, HCoV-NL63, and HCoV-HKU1 are endemic in humans. In contrast, SARS-CoV has not been reported since early 2004 and MERS-CoV appears to have only recently emerged. The four endemic HCoVs have a worldwide distribution (38-42). Serological surveys carried out several decades ago showed that HCoV infection fluctuated between years, with a higher frequency of serological responses in the winter compared to summer months. With the advent of RT-PCR detection, the substantial temporal and geographical variation in HCoV detection, and in the predominance of individual HCoVs, has been confirmed. This variability makes it hard to draw conclusions about the burden and periodicity of infection from studies describing HCoV epidemiology over only 1 or 2 years. Furthermore, due to their relatively recent discovery, few studies have looked for all four HCoVs simultaneously over long periods of time. From multiregional molecular studies in children and adults, detection by RT-PCR of all four endemic HCoVs typically peaks in the winter and spring months in temperate countries, and HCoV-OC43 and HCoV-NL63 appear to be the most commonly detected (35, 38, 39, 43-48) (Fig. 4). A 2- to 3-year periodicity has been described for HCoV-NL63, HCoV-229E and HCoV-OC43 in some RT-PCR and serological studies (49-51) but not in others (35, 38, 46). The combined HCoV detection rate in individuals with acute respiratory illness (ARI) in multiregional studies varies from 1 to 18% and co-infections with other respiratory viruses are common (38, 39, 44-46, 48). The highest HCoV detection rates are typically seen in children less than 2 years of age (Fig. 4).

Historical serological surveys demonstrated that infection with HCoV-229E and HCoV-OC43 could occur on a background of preexisting neutralizing antibody and that apparent reinfection with the same virus species was common (49, 50, 52, 53). Reinfection could also be achieved in experimental inoculations of healthy adults, although it generated subclinical infections under these conditions (54). In longitudinal studies in children, approximately half of the serological responses to HCoV-229E and HCoV-OC43 occurred in the absence of symptoms, suggesting the occurrence of natural subclinical infection (49, 50). Contemporary serological studies have shown that infection with HCoVs is a common event in early childhood, with seropositivity to all four HCoVs generally increasing with age. Seroconversion to at least one HCoV was observed in 24 out of 25 healthy infants by the age of approximately 20 months (44). However, seroconversion was more frequent with HCoV-OC43 and HCoV-NL63 than HCoV-229E and HCoV-HKU1, in line with individual detection frequencies determined by RT-PCR (44). The sequence of HCoV infection in infancy appears to be important, as prior HCoV-OC43 or HCoV-NL63 infection may elicit immunity that protects from subsequent HCoV-HKU1 or HCoV-229E infection, respectively, but not vice versa (44). In two independent cross-sectional seroepidemiologic studies in different populations, the proportion of infants with antibodies to both HCoV-229E and HCoV-NL63 decreased significantly from 0 to 6 months of age, but then increased rapidly, so that by the age of 4 years, more than 50% of children were seropositive for both viruses (55, 56). It is likely that this pattern illustrates the waning of maternal antibody and the development of new antibody in response to infection in early childhood. Some studies in adults have reported seroprevalences as high as 90 to 100% for HCoV-229E, HCoV-NL63, and HCoV-OC43, with a lower seroprevalence for HCoV-HKU1 of 59 to 91% (57). However, other studies have found much lower seroprevalences for all four HCoVs (56, 58-60). Differences in study population and geographic location as well as in assay sensitivity and specificity may account for the variation.

The major transmission route of HCoV is likely to be respiratory, although many animal CoVs also have a fecal-oral route of transmission and can replicate in epithelial cells in both the respiratory and gastrointestinal tracts. The isolation of HCoVs from fecal specimens has been described, but it is unclear to what extent HCoVs are transmitted feco-orally. In addition, a pilot study identified potential maternal-fetal transmissions of HCoV-229E, but further studies are awaited. HCoV can be detected by RT-PCR in respiratory secretions for over 3 weeks after the onset of illness, particularly in immunocompromised patients and neonates; however, it is not known if this represents viable virus (61, 62). HCoVs may survive on inanimate surfaces (63), in suspension (64), or as aerosols (65). Therefore, contact-mediated and aerosol-mediated transmission from the environment is a possibility. Nosocomial outbreaks of HCoVs have been associated with severe illness in elderly-care facilities and neonatal and pediatric intensive care units (66). The typical incubation period of HCoV-229E, HCoV-OC43, and related strains was shown to be 2 to 5 days in intranasal inoculation experiments in healthy adults; however, it has not been well described for other common HCoVs or in different populations, such as children.

SARS-CoV emerged as a zoonosis in Guangdong province, China, in 2002 and then spread globally via human-to-human transmission to cause the SARS pandemic. Mutation in the receptor-binding domain of the S protein may have contributed to adaptation of the virus for human-to-human transmission (67). Global transmission appeared to be largely related to super-spreading events involving symptomatic individuals in places such as hospitals, hotels, and residential complexes, and asymptomatic seropositivity in the community was low (17, 30). Initial epidemiological investigations suggested that respiratory droplet secretion and direct or indirect contact were the most likely routes of transmission (31). The generation of aerosols, particularly in hospitals, was also important. SARS-CoV was shed in respiratory specimens, stool, urine, and other bodily fluids but, unusually for a respiratory virus, shedding peaked in
FIGURE 4. HCoV detection frequencies by month and age band over a 3-year period between 2006 and 2009 in Edinburgh, United Kingdom, using multiplex real-time RT-PCR. During this time, 11,661 specimens were tested, with 61 specimens positive for HCoV-HKU1, 99 for HCoV-OC43, 35 for HCoV-229E, and 75 for HCoV-NL63 (adapted from reference 39). doi:10.1128/9781555817381.ch90.f4
the second week of illness (68). This meant the peak of infectivity occurred at the time when the patient was already likely to be symptomatic and in hospital. Public health measures, including rapid identification and quarantine of cases and improved infection control, brought transmission to a halt in mid-2003. SARS-CoV briefly re-emerged in Guangdong province in late 2003 from a probable nosocomial transmission event and there were also later incidences of laboratory transmission. The incubation period of SARS was typically 2 to 14 days, with a mean of 4 to 5 days, although occasional cases with longer incubation periods were reported (30, 31).

MERS-CoV was first isolated from a patient with severe pneumonia hospitalized in the Kingdom of Saudi Arabia (KSA) in June 2012 (36). Further cases have since been reported from the Arabian Peninsula, particularly KSA, or linked to travel or residence in the region, or to close contacts of cases. MERS-CoV was found retrospectively in samples associated with a nosocomial outbreak of severe pneumonia in Jordan in April 2012 (69), but tests on stored sera have not shown evidence of infection in the general population (36). Cases have occurred sporadically or in clusters, but sustained human-to-human transmission has not been observed to date. Limited person-to-person transmission has been identified among close contacts and in health care facilities in a number of clusters; however, the vast majority of contacts have tested negative (70–72). The mode of transmission is currently unknown, and contact and droplet-based precautions are recommended, with airborne precautions for aerosol-generating procedures. The incubation period for MERS-CoV is estimated at a median of 5 days. Although 9 to 12 days has been reported, in most cases the incubation period appears to be less than one week (70, 71).

**CLINICAL SIGNIFICANCE**

The endemic HCoVs, HCoV-229E, HCoV-OC43, HCoV-NL63, and HCoV-HKU1, are associated with upper respiratory tract infection (URTI) in individuals of all ages and occasionally with lower respiratory tract infection (LRTI). HCoV-229E and HCoV-OC43 were originally isolated from adults with mild URTI and were demonstrated to cause the symptomatic presentation of “common cold” in human experiments (23, 24, 73, 74). Such experiments have not been carried out with HCoV-NL63 and HCoV-HKU1, so a causal relationship cannot be formally demonstrated. The four different endemic HCoVs are associated with similar URT symptoms such as fever, cough, sore throat, nasal obstruction, and rhinorrhea (40). HCoV-NL63 has been particularly associated with croup in children (42, 51, 75–77). Numerous epidemiological studies have indicated a temporal association with all four of the endemic HCoVs and ARI, and some studies have shown higher rates of HCoV detection in patients symptomatic with ARI compared to asymptomatic individuals (38). However, other studies have found similar detection rates in hospitalized cases compared to controls, typically 2 to 10% (42, 78). Drawing firm conclusions is difficult because in the majority of case-control studies, detection rates for HCoV are relatively low, and coinfection with other respiratory viruses is common. However, significant LRTI, such as community-acquired pneumonia and bronchiolitis, has been described in hospitalized adults and children from whom an endemic HCoV was the sole etiologic agent detected (76, 79, 80). HCoV has also been associated with significant morbidity due to LRTI in immunocompromised patients, patients with other underlying conditions, and those at the extremes of age (35, 39, 45, 79, 81). Overall, however, it is likely that the burden of severe illness due to endemic HCoVs is relatively minor in comparison to other respiratory viruses such as adenovirus, influenza virus, and respiratory syncytial virus (82, 83).

Several animal CoVs are known to cause diarrheal disease in animals, but the link between HCoV infection and enteric infection is unclear. At present, HCoVs are thought to play a minor role, if any, in gastrointestinal disease. CoV-like particles have been seen in fecal specimens by electron microscopy, and human “enteric” CoVs, some apparently closely related to the betacoronaviruses bovine CoV and HCoV-OC43, were also isolated from patients with gastrointestinal disease (62, 84, 85). In recent years, work has focused mainly on RT-PCR detection of the four endemic HCoVs; although these have been found occasionally in cases of acute gastroenteritis, they have been equally rarely detected in controls (86–88). Some animal CoVs are also neurotrophic, and both HCoV-OC43 and HCoV-229E RNA has been detected in brain tissue, with HCoV-OC43 found significantly more frequently in patients with multiple sclerosis than controls (89). However, the clinical significance of these findings is currently unknown.

SARS-CoV and MERS-CoV cause severe respiratory illness with high mortality rates. During the SARS epidemic, the virus spread to 26 countries, resulting in approximately 8,000 clinical cases and over 700 deaths. The typical SARS clinical presentation was one of initial viral respiratory illness with fever, malaise, and nonproductive cough, followed by an atypical pneumonia with rapid respiratory deterioration. Diarrhea and lymphopenia were also features. Symptoms were milder in children than in adults and the overall crude case-fatality rate was 10% (90). MERS-CoV has been predominantly seen in adults with underlying comorbidities and, although a spectrum from mild to severe disease has been reported, most cases to date have been clinically severe (70, 91, 92). At the time of writing, there had been 160 laboratory-confirmed cases of infection with MERS-CoV including 68 deaths, giving a current crude case-fatality rate of around 40%. The typical clinical course comprises initial viral prodrome with fever, cough, subsequent pneumonia, and respiratory deterioration over several days (91). Severe complications include renal failure and acute respiratory distress syndrome with shock. Gastrointestinal symptoms are commonly reported, along with lymphopenia and other hematological abnormalities (36, 70, 71, 72, 91).

The key to the management of severe HCoV infection is good supportive care, as there is no specific treatment available. Several potential therapeutic agents against SARS-CoV, such as viral protein inhibitors, interferons, and antibodies, have been evaluated in vitro and in animal models (reviewed in reference 93). During the SARS outbreak, several experimental treatments were used in humans, but a retrospective review found no conclusive positive effects of any substance, and some potentially harmful effects (94). Studies have already begun to try to identify agents capable of treating MERS-CoV infection (95–97); however, the biology of MERS-CoV differs in certain important aspects from that of SARS-CoV.

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

HCoVs can be detected in a range of routine URT and LRT specimens, such as nasopharyngeal swabs, nasopharyngeal aspirates (NPA), nasal washes, and bronchoalveolar lavage.
(BAL) fluid. For SARS-CoV and MERS-CoV, higher viral loads or RT-PCR positivity rates have been found in LRT specimens compared to URT specimens. Both should be taken where possible, with LRT specimens the priority. Appropriate infection control precautions must be put in place for sample collection, particularly where aerosol-generating procedures are required. Fecal specimens were useful in the diagnosis of infection with SARS-CoV, particularly in the second week of illness, but MERS-CoV may have a different shedding pattern (68, 90). Detection of CoVs in urine, blood, lung biopsy, and postmortem tissue has also been described. For both SARS-CoV and MERS-CoV, samples should be taken from multiple sites and at several time points to increase the chances of detecting the virus, especially in the first week of illness when viral loads are relatively low. Acute- and convalescent-phase sera should also be taken for retrospective serological diagnosis because of the risk of false-negative RT-PCR results, particularly on URT specimens.

The transport of specimens should be carried out under transport category UN3373 Biological Substance, Category B, with packaging complying with instruction P650 (141). Specimens for the direct detection of HCoV can be handled in Biosafety Level 2 (BSL2) facilities using BSL2 practices, including the use of a biological safety cabinet for potentially aerosol-generating procedures. However, where there is a suspicion of SARS-CoV, MERS-CoV, or other novel CoV infection, virus isolation in culture should not be attempted unless laboratories have the relevant expertise, and work should only be carried out in a BSL3 facility using BSL3 practices. To reduce the risk of laboratory-acquired infection in a novel CoV scenario, nucleic acid-based detection is recommended because it does not require virus propagation and nucleic acid-extraction procedures inactivate the virus. Furthermore, respiratory specimens can be collected, transported, and processed in lysis buffer, thus inactivating the virus at the earliest stage in the diagnostic process.

**DIRECT DETECTION**

**Microscopy**

CoVs can be identified by their characteristic morphology on electron microscopy (EM); virions are spherical or pleomorphic, approximately 80 nm in diameter, and with projections around the virus envelope forming a “corona” (Fig. 1). Thin-section EM and negative-stain EM have typically been used for the identification and characterization of HCoVs propagated in vitro, rather than for direct detection (23, 24, 25). Cell culture enables amplification of the virus to levels sufficient for detection by EM, so therefore EM is not typically carried out directly on respiratory specimens. However, some laboratories do carry out direct detection of CoVs in fecal specimens by EM, although other direct methods are likely to be more suited to the routine diagnostic setting. EM is most relevant as a complementary method in the search for novel CoVs.

**Antigen Detection**

Antigen detection assays have the potential to be the most rapid of all detection methods. HCoV antigen is identified directly in clinical specimens by labeled monoclonal antibodies coupled to a detection system such as microscopy. This process may be more convenient than most nucleic acid-based methods where a laboratory does not have molecular experience. However, assays have been developed predominantly in-house to detect SARS-CoV, with the majority of assays targeting the abundant nucleocapsid (N) protein in enzyme immunoassay (EIA)-based formats. EIAs based on chemiluminescent detection and monoclonal antibodies may be particularly effective (98), with SARS-CoV N antigen detectable in the blood of approximately 60% patients in the 3rd week of illness (99). Other enzyme-linked immunosorbent assay (ELISA)-based antigen-detection assays have found SARS-CoV N antigen in NPA and stool specimens, particularly after 10 days of illness onset, but rarely in urine (100). The use of immunofluorescence by indirect fluorescent assay (IFA) on cellular preparations from throat washes has also been described (101). The sensitivity of endemic HCoV monoclonal antibody IFA or direct fluorescent assays varies depending on the species and is generally lower than RT-PCR (102). More recently, an ELISA-based method was developed for the detection of the N protein from HCoV-229E and HCoV-NL63, but has not yet been clinically evaluated (103).

**Nucleic Acid Detection**

Direct detection of nucleic acids in clinical specimens is the most common diagnostic method in use today for HCoV. Detection of nucleic acids is typically more sensitive and specific than other methods. It relies neither on the binding of antigen to potentially cross-reactive antibodies, nor on the detection of a timely and specific immune response in individuals. Two strategies have been employed in nucleic acid amplification tests (NAATs) for HCoV. The first is to select a target that is as conserved as possible amongst all known HCoVs, a so-called “pan-CoV” assay; the second is to select a region of the genome that is distinct between the different HCoV species, to generate a series of “species-specific” assays. Ideally, all four endemic HCoVs should be sought in diagnostic specimens, given our increasing knowledge of their roles as respiratory pathogens. Recent significant advances in our understanding of HCoVs have been made through nucleic acid-based methods, particularly the ability to randomly amplify and sequence nucleic acids from cultures and to compare them to databases to detect novel CoVs (36). Whole-genome sequencing can be carried out directly on respiratory samples (34), although it is not commonplace at this time in most clinical laboratories.

**Pan-CoV Assays**

Pan-CoV assays enable the detection of CoV infection without anticipation of the species involved. Regions of the conserved polymerase gene within the replicase ORF1a/b have been successfully used in pan-CoV assays, following alignment of known sequences and generation of consensus primers. Some pan-CoV assays use degenerate primers (48), some utilize multiple primer sets (79), and others employ a single set of nondegenerate primers (34). The more degenerate the primers, the lower the sensitivity for known HCoVs, but the higher the likelihood of detecting more distantly related CoVs. Different pan-CoV assays have been shown to vary in their capacity to detect known HCoVs (104), although some have sensitivity equivalent to individual species-specific assays (79). Therefore, the choice of approach will depend on the diagnostic objectives. Pan-CoV assays have been used as an initial screening test (79) and also for the detection of unknown viruses growing in cell culture, leading to the discovery of new HCoVs (34). To identify the CoV species, amplicons from pan-CoV assays need to be sequenced and subjected to restriction enzyme digestion or probe hybridization; positive specimens require further testing with species-specific assays.
Species-Specific Assays

Species-specific NAATs are very sensitive and provide species-level identification without sequencing or other post-amplification processing. The disadvantage of species-specific assays is that they are likely to miss emerging CoVs that are divergent in sequence, though this may also be the case with pan-CoV NAATs. It is possible to multiplex individual species-specific assays into a single reaction without a loss in sensitivity, thus reducing costs and hands-on time (39). However, some authors using other species-specific NAATs have found sensitivity is greater with individual assays (41, 105). Therefore, when setting up HCoV assays, it is wise to assess performance in both formats, in order to find the best arrangement for the individual laboratory. Regions of the N gene have been most commonly used for detection of individual HCoVs; however, several assays have been described targeting the membrane protein (M) gene, polymerase gene (replicase ORF1a/1b), and occasionally the spike protein (S) gene. Due to a transcription gradient across the CoV genome, which is a function of its complex biology, structural genes such as N, M, and S may be transcribed at higher levels than non-structural genes such as the polymerase.

In-House NAATs

NAATs for HCoV mainly utilize PCR technology. As HCoVs have an RNA genome, an initial RT step is required; this can either be carried out separately (two-step RT-PCR) or combined with the PCR assay (one-step RT-PCR). In order to increase sensitivity and specificity, several HCoV RT-PCRs in current diagnostic use are “nested” so that the products of an initial round of amplification using outer primers are reamplified with a set of inner primers (39). Detection of amplified products has been traditionally carried out using gel-based electrophoretic systems and UV visualization of DNA bands of the expected size. The use of hybridization probes on a low-density microarray has also been described for a pan-CoV assay (106). However, real-time detection of amplified products, so-called real-time RT-PCR, is now possible. This is achieved through the use of fluorescent dyes that intercalate nonspecifically into dsDNA (76), or fluorescent probes which bind to the nascent DNA in a sequence-specific manner and emit light through a variety of mechanisms, the most common being hybridization (39). Real-time RT-PCR has the advantage of a closed-tube format; the reaction vessel is never opened after amplification, thereby reducing the opportunity to contaminate the laboratory environment with DNA template, and decreasing the potential for false-positive detection. As it combines amplification and detection in a single step, it is also significantly faster and requires less hands-on time than conventional RT-PCR methods. The sensitivity of real-time RT-PCR is higher than that of conventional RT-PCR (107) and nested RT-PCR (39, 108). Examples of real-time PCR assays that are used for the detection of the four endemic HCoVs are given in Table 1. Real-time RT-PCR can also give a quantitative output; although HCoV viral loads are unlikely to be required in the routine diagnostic setting, viral load profiles are useful in the description of severe disease associated with newly emerging CoVs, where viral load may be a prognostic marker. Non-PCR-based NAATs are infrequently described, although those using isothermal methods such as loop-mediated isothermal amplification (LAMP) have been successful and may be very suitable in resource-limited settings. A simple, low-cost LAMP assay for HCoV-NL63 has been shown to have comparable sensitivity to real-time PCR (109). In most cases, HCoV NAATs have been developed in-house by the diagnostic laboratory or adapted from the published method of another laboratory. In either case, this requires a significant initial time commitment from skilled scientific staff in terms of assay development, validation, and evaluation, as well as ongoing support in the routine use of these assays. However, in-house assays are economical to run and can be readily adapted to take into account oligonucleotide binding-site variation in existing HCoVs, or for the detection of emerging HCoVs, such as SARS-CoV and MERS-CoV, as soon as sequence data are available.

Commercial NAATs

The last 5 years have seen a large increase in the number and variety of commercial NAATs for HCoV detection, driven mainly by the development of respiratory virus panels for a syndromic diagnostic approach (Table 2). All respiratory viruses can cause a range of presenting symptoms and complications, and clinical features of ARI caused by different viruses are often indistinguishable. Large commercial panel assays that enable a specimen to be tested for an array of viruses simultaneously may be a viable alternative to the use of multiple in-house real-time PCR assays for routine detection, as well as in outbreak situations, despite their higher unit costs (110). Commercial assays vary significantly in hands-on time, some require more than one reaction tube per sample, and some are particularly suited to high-throughput (e.g., xTAG RVP/RVP Fast) or low-throughput settings (e.g., Filmarray Respiratory panel). Commercial tests are particularly attractive as an alternative to traditional culture and IF methods in laboratories that require the use of regulatory-body-approved in vitro diagnostic tests and/or in laboratories without molecular experience. However, for HCoV detection in particular, although many tests are CE marked (in Europe), few as yet have U.S. Food and Drug Administration (FDA) approval and not all assays will detect all four endemic HCoVs (Table 2). Direct comparison between commercial and in-house NAATs for HCoV detection has shown a range of performance. However, most comparisons are limited by the overall scarcity of HCoV-positive samples and individual species particularly, making it difficult to draw firm conclusions about sensitivity for individual HCoVs (110–113). Other commercial assay formats such as PCR-electrospray ionization mass spectrometry (ESI-MS) are also on the horizon. This is a rapidly changing field and it is likely that new commercial tests or modifications to existing ones will continue to come onto the market in the near future.

SARS-CoV Detection

Both in-house real-time and nested RT-PCR assays targeting the polymerase (replicase ORF1b gene) were quickly available for SARS-CoV, along with synthetic transcripts to act as positive control material and to enable quantification (27, 28, 30, 31). Later, other NAATs targeting the polymerase and N genes became available, and assays were revised to increase sensitivity of detection, particularly in the first week of illness (114). Isothermal NAATs such as nucleic acid sequence-based amplification and LAMP assays were also described (115), and commercial assays were developed with variable clinical sensitivities and specificities compared to RT-PCR and serology (116, 117). Pan-CoV assays that also detect SARS-CoV are available, but species-specific NAATs are preferred for first-line screening tests (118). A detailed review of NAATs for SARS-CoV, including a comparison of oligonucleotide sequences and assay performance, has been published elsewhere (116).

MERS-CoV Detection
An in-house real-time PCR assay based on a target upstream of the envelope protein (upE) was quickly available for MERS-CoV, along with an alternative but less sensitive real-time PCR assay based on the ORF1b gene, and positive control transcripts (119). Shortly thereafter, a real-time RT-PCR assay based on ORF1a was demonstrated to have higher sensitivity than ORF1b and is now recommended for confirmation, along with two RT-PCR assays for amplification and sequencing of the N and polymerase genes (120, 121). In June 2013 the U.S. FDA authorized the emergency use of an rRT-PCR assay panel targeting the N and upE genes as an in vitro diagnostic test for MERS-CoV (122).

ISOLATION PROCEDURES
Isolation of HCoVs is not effective as a routine diagnostic tool because many commonly used cell lines are not permissive for growth or do not show obvious cytopathic effect (CPE). CPE is generally nonspecific and reagents for immunofluorescent detection in culture are not widely available. The use of RT-PCR to detect HCoV in cell culture supernatant has been described, but it may be more efficient in a routine context to carry out NAATs directly on the specimens. HCoV-229E was isolated originally in human embryonic lung fibroblast cell lines such as WI-28, L132, and MRC-5 (23, 54, 73, 102, 108, 123). HCoV-OC43 was originally isolated in human embryonic tracheal organ cultures (24) and later adapted to suckling mouse brain and then to cell culture in lines including HRT-18, RD, and HEL (102, 107, 108, 124). HCoV-NL63 was originally isolated in tertiary monkey kidney cells and subsequently propagated in Vero and LLC-MK2 monkey kidney epithelial cell lines (10). Although some reports described HCoV-NL63 CPE by day 4 or 5 of inoculation (Fig. 3), other studies have found low viral titers with slowly developing CPE and sustained growth proving difficult (10, 104, 124, 125). HCoV-NL63 growth appears to be more efficient in CaCo-2 cell lines, and this has enabled the development of a cytopathogenic plaque assay (124). The continuous epithelial cell line HuH7 has been demonstrated to be permissive for HCoV-229E, HCoV-OC43, and HCoV-NL63 (60, 104, 126). However, HCoV-HKU1 has not yet been propagated in any common cell line (34). All four HCoVs, including HCoV-HKU1, were recently successfully propagated on primary human bronchial epithelial cells subpassaged to form pseudostratified human airway epithelial (HAE) cell cultures (127, 128). In this system, HCoV-NL63 was still difficult to isolate and there was no visible CPE for any of the viruses. SARS-CoV grows in Vero and fetal rhesus kidney (FRHK4) cells, and in contrast to other HCoVs, focal CPE occurs and rapidly spreads across the monolayer within 2 to 6 days (27, 28, 31). Human cell lines such as HuH7, HEK-293, and Hep-G2 are also permissive for SARS-CoV infection (129). MERS-CoV was originally isolated in LLC-MK2 and Vero B4 cells (36), but also appears capable of infecting primate, pig, and bat cell lines. Inadvertent isolation of a novel CoV in cell culture is therefore a possibility, so where there is a suspicion of SARS-CoV, MERS-CoV, or other novel CoV infection, virus isolation should not be attempted without BSL3 facilities and procedures. NAATs should be used as a first-line test because this involves virus inactivation. Accidental transmission of SARS-CoV to laboratory workers has been described.

SEROLOGIC TESTS
Serological testing for diagnosis of the endemic HCoVs has largely been replaced by more sensitive and specific NAATs. However, serology is useful in epidemiological studies, enhancing our understanding of HCoV infection and aiding the investigation of outbreaks. It has been particularly important in the diagnosis of cases of novel and emerging HCoV infections such SARS-CoV. In these situations, affected patients may not test positive for viral RNA, particularly in the early phase of disease, but retrospectively can be shown to have developed an immune response. The use of viral lysate antigens in ELISA-based serological assays requires propagation of the CoVs to high titers, which is difficult for HCoV-NL63 and not possible for HCoV-HKU1 without HAE cultures. Furthermore, serological assays may lack specificity due to the antigenic relatedness amongst HCoVs, particularly between the alphacoronaviruses HCoV-229E and HCoV-NL63 and between the betacoronaviruses HCoV-OC43 and HCoV-HKU1. The viral nucleocapsid protein N induces a good immune response, and recombinant N protein has been widely used in ELISA-based assays as it can be readily expressed and purified without the need for viral culture. Unfortunately, cross-reactivity of serological assays using the full-length or truncated N protein has been reported, particularly between HCoVs of the same genus (56, 59, 130). However, the carboxy-terminal region of the N protein appears to be significantly less homologous between HCoVs, and recombinant N protein-based ELISAs utilizing this region have been successfully developed for all four endemic HCoVs (44, 56, 59). This may be at the expense of some sensitivity, though, as the carboxy-terminal region of the HCoV-OC43 N protein was recently demonstrated to be less immunogenic than the central region (131). The use of recombinant S-protein-based ELISAs has also been reported for HCoV-HKU1 (58). The difficulty in culturing some HCoVs is an obstacle to the development of neutralization assays; however, neutralization assays using S-pseudotyped HCoV-HKU1 and HCoV-NL63 viruses can circumvent this problem (58, 60).

As with other HCoVs, most serological assays for SARS-CoV were initially based on antibody detection in acute- and convalescent-phase sera by IFA using fixed infected cells and by ELISA using lysates from cell culture (28, 30). Recombinant N protein-based ELISAs were then developed to remove the requirement for BSL3 containment, with confirmation by Western blots targeting antibodies to both the N and S proteins. Neutralization assays also required cultivation of SARS-CoV and were less practical for routine diagnosis. A first-generation, biologically safe IFA was quickly available for MERS-CoV, but due to cross-reactivity with endemic HCoVs, positive results require confirmation by neutralization assay under BSL3 containment (119, 132). A further serological test has since been described, using a recombinant S protein subunit in a protein microarray format, for the detection of antibody to MERS-CoV and SARS-CoV (133). However, additional validation of MERS-CoV serological tests is required, and cases with positive serological test results in the absence of PCR testing or sequencing are currently considered probable cases (121).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS
The cornerstone of management of all HCoV infections is the rapid diagnosis of affected individuals because symptoms
may be similar to those caused by other respiratory pathogens. Accurate and timely diagnosis aids surveillance, ensures that appropriate infection control and public health procedures are instigated, and contributes to antibiotic stewardship by providing a viral diagnosis. The generation of a diagnostic test result in which the laboratory and the end user can feel confident requires, among other things, the proper development and validation of HCoV diagnostic tests. Comprehensive guidelines for the development and validation of NAATs are available (134, 135). Participation in internal and external quality assurance (IQA, EQA) programs is also essential. Performance in the detection of HCoV by NAATs has been shown to vary between laboratories using Quality Control for Molecular Diagnostics (QCMD) EQA panels (136, 137). EQA enables comparison of proficiency between other diagnostic laboratories and identification of problems with sensitivity and specificity. This is particularly relevant for NAATs in which ongoing sequence variation in viral RNA genomes, reaction inhibition, and potential contamination are specific challenges. CoV NAATs should be frequently assessed in the light of new sequence information for their ability to detect new viral variants. Furthermore, the use of internal controls added at the specimen-extraction stage, which are copurified with viral RNA and are detected by NAAT alongside the HCoV gene target(s), is essential for the detection of RT-PCR inhibition. Finally, the use of good laboratory practice when performing molecular amplification assays is crucial and readers are directed to guidance on this subject (135, 138).

It is particularly important in the case of novel or emerging HCoVs such as SARS-CoV and MERS-CoV that nationally or internationally agreed protocols for specimen collection, handling, testing, and reporting should be followed, including the confirmation of positive diagnostic test results at designated reference laboratories and the involvement of public health specialists (121). Errors in the interpretation and reporting of results can have particularly significant adverse consequences in this context. The rapid reaction of the international diagnostic laboratory community to the emergence of SARS-CoV was mirrored in the recent response to MERS-CoV. In a matter of days after notification of the first case of MERS-CoV, an internationally coordinated effort had produced validated NAATs, which were then widely deployed in specialist laboratories (139). This was a testament to the effectiveness of collaborative international laboratory networks, although standardization and quality control of tests for emerging CoVs is a key aspect that must be adequately managed in the roll-out process. In these situations, the development of commercial tests lags behind because of the regulatory approval process, illustrating the importance of maintaining in-house molecular expertise in diagnostic virology laboratories. The widespread occurrence of CoV in mammals and birds and the potential for interspecies transmission events emphasize that we should be vigilant for the emergence of further human pathogenic CoVs in the future.

In summary, the four endemic HCoVs make up a small but significant proportion of the viruses found in patients with ARI. Including HCoVs alongside the more common respiratory viruses such as influenza, respiratory syncytial virus, and adenovirus in diagnostic screening panels will increase the diagnostic pick-up rate in ARI, particularly in a pediatric setting. It will also help to further our understanding of the role of HCoVs in respiratory infection.

Hepatitis A and E Viruses

DAVID A. ANDERSON AND NATAILIE A. COUNIHAN

TAXONOMY

Hepatitis A Virus

Hepatitis A virus (HAV) is the type species of the Hepaovicivirus genus within the family Picomaviridae. HAV is distinguished from other picornaviruses (e.g., poliovirus) by its tropism for the liver, high thermal stability, and a unique assembly process (Fig. 1). There are two major genotype groups found in humans, and a third genotype that is considered to be a true simian strain (AGM-27) (1). Although there is significant genetic diversity between HAV strains, all strains of HAV represent a single serotype and this diversity does not affect the performance of serological assays. Genotyping of HAV is based on sequence analysis around the VP1-2A region, and is primarily useful as a research tool for outbreak investigations (2).

Hepatitis E Virus

Hepatitis E virus (HEV) is the type species of the Hepевичirus genus within the family Hepeviridae (3). Four genotypes of HEV have been described in humans, with genotypes 3 and 4 representing zoonotic infections originating from viruses endemic in swine, deer, and possibly other mammals (4–6) (see reference 7 for a comprehensive review), while genotypes 1 and 2 are endemic in humans. Additional strains of HEV have been recognized in a wide range of mammals, including rats, rabbits, bats, and ferrets, although there is no evidence that these strains infect humans. All mammalian genotypes demonstrate extensive antigenic similarity, but some studies suggest that differences between the prototype human HEV genotype 1 and other genotypes may affect the sensitivity of some diagnostic assays (8), while others have shown no significant differences (9). HEV has also been detected in chickens (10) and an HEV-like virus has been detected in fish (11). Further subclassification of HEV genotypes and subtypes is likely in the future based on extensive analysis of both viral sequences and genome arrangements (12).

DESCRIPTION OF THE AGENTS

Hepatitis A Virus

HAV is a small virus with a nonenveloped, icosahedral capsid of approximately 27 nm in diameter. The viral genome is composed of linear, positive sense RNA and is about 7,500 nucleotides (nt) in length (Fig. 1A). The structure of HAV is characteristic of all picornaviral genomes, being organized into an uncapped 5′ nontranslated region (NTR), then a single open reading frame encoding all known viral proteins, and a short 3′ NTR. Viral particles have a sedimentation coefficient of around 156S and buoyant density of 1.325 g/cm³ in cesium chloride. HAV is resistant to low pH (<3.0) and shows remarkable thermal stability (13). Thorough cooking is necessary to inactivate HAV in contaminated foods.

An outline of the viral replication mechanism is shown in Fig. 1A. The positive-strand RNA genome encodes a single open reading frame (ORF), which is translated to yield a single polyprotein. The virus-encoded 3C protease liberates eight individual proteins including the three capsid proteins, VP0, VP1-2A (also known as PX), and VP3 (14). Five copies of each of the three proteins associate to form pentamers, and 12 pentamers are assembled into empty capsids or combined with RNA to form virions.

Following assembly, HAV is exported from infected hepatocytes, although the precise mechanism by which this occurs is unknown. In vivo, hepatocytes are organized into a complex three-dimensional structure with surfaces facing both the bile (apical surface) and blood (basolateral surface; Fig. 2). Studies have shown that secretion of HAV is towards the hepatic blood supply from the basolateral surface (15), which implies that HAV must traverse the hepatocyte for delivery to the gastrointestinal tract via bile, possibly via transcytosis (Fig. 2, insert). This indirect transport for apical-directed cargo is a common mechanism in hepatocytes and may also be relevant in export of HEV.

Diagnosis and immunization for hepatitis A are not complicated by strain differences because HAV exists as a single serotype worldwide, including the highly divergent simian AGM-27 (1). The antigenic sites of HAV are formed by the complex interactions of the proteins within and between pentamers (16), which has hampered the production of HAV antigenic material through recombinant DNA techniques. As a result, cell culture remains the only reliable source of HAV antigens for serological diagnostic tests and for vaccines. The replication of HAV in cell culture is rather inefficient compared to most picornaviruses, which necessitates very large-scale cell culture production, but the virus is highly immunogenic. A number of highly effective, licensed vaccines are available against HAV: Havrix (Glaxo SmithKline) and Vaqta (Merck) within the United States, together with Avaxim (Sanofi Pasteur MSD).
Hepatitis A and E Viruses

FIGURE 1  Genome replication and proteins of HAV and HEV. (A) Both viruses have positive-strand RNA genomes of around 7,200 to 7,500 nt. HAV replication proceeds via transcription from the genome to give full-length negative- and then positive-strand RNA, which can either be assembled into the virus particle or be used to translate further copies of a single, giant polyprotein which is processed by viral protease to yield the replicative proteins and capsid proteins. Assembly of five copies of each of the three capsid proteins (VP0, VP3 and PX) into pentamers and then 12 pentamers into capsids is required to form the antigenic sites of the virus. (B) Details of HEV replication are unknown, but it most likely produces a full-length negative-strand RNA, then full-length positive-strand RNA (new viral genomes), as well as subgenomic mRNAs which are used to translate the ORF2 (capsid) and ORF3 proteins plus the ORF1 polyprotein which is cleaved at unknown sites to yield the replicative proteins. Cleavage of full-length PORF2 results in assembly of virus-like particles from the truncated product, but the size of the authentic viral capsid protein is unknown. Modified from reference 118 with permission. doi:10.1128/9781555817381.ch91.f1

and Epaxal (Crucell/Berna Biotech) worldwide. A combination hepatitis A and hepatitis B vaccine, Twinrix (Glaxo SmithKline), is also widely available. Epaxal (also sold as HAVpur and Virohep-A in different countries) is formulated with virosomes as adjuvant, while the other HAV vaccines use alum adjuvants.

Hepatitis E Virus

Infectious virions of HEV are nonenveloped, icosahedral particles of approximately 32 to 34 nm diameter, comprising the PORF2 viral protein which encapsidates the single-stranded, positive-sense RNA genome of approximately 7,200 nt. Virions of HEV show much greater sensitivity to heat than HAV (17), although inadequate cooking of pork and deer products is likely to be a major factor in locally acquired HEV infections in developed countries. Virions have a sedimentation coefficient of 183S and a buoyant density of 1.29 g/cm$^3$ (18). The single capsid protein is encoded by ORF2, expected to yield a PORF2 protein of 660 amino acids. Various truncated forms of PORF2 can form virus-like particles; however, the capsid protein of authentic viral particles has not been characterized.

In contrast to HAV, heterologous expression systems for HEV viral proteins have been instrumental in the development of HEV diagnostics and vaccines, whereas continuous cell culture systems for HAV have been less robust than for HAV. The first of these used a subclone of hepatocyte-derived HepG2 cells, and while virus yields remain low, this cell culture system has allowed some key questions of virus replication to be addressed (19–21), and provided a system for the study of virus neutralization (22). An alternative and possibly more efficient cell culture system has been described in PLC/PRF/5 and A549 cells, with isolation of HEV genotypes 3 and 4 from patients with fulminant hepatitis (23, 24) and from samples of swine liver sold as food (25). Infectious cDNA clones of a number of strains of HEV have been described (26, 27) and have been important in elucidating the role of various HEV proteins in replication, including the interesting role of the ORF3 protein (PORF3) in release of progeny virus from cells (28).

A schematic of the HEV genome and encoded proteins is shown in Fig. 1B. The infectious cDNA clone of the SAR-55 strain of HEV described by Emerson and colleagues (26) is 7,204 nt, and most isolates of HEV from humans and swine are close to this length. The avian HEV is substantially smaller at 6,654 nt due to deletions in both ORF1 and ORF2 (29).
FIGURE 2 Export of HAV from hepatocytes. Polarized hepatocytes are organized in complex structures within the liver, with bile canaliculi representing grooves formed from the apical domains of adjacent hepatocytes (insert). Bile is secreted into the canaliculi via the apical membranes and then flows into the small intestine via a network of ducts. The basolateral surfaces of hepatocytes are in contact with the hepatic blood supply and underlying tissue. Following replication in hepatocytes, HAV is exported via basolateral membranes towards the blood supply (step 1, arrow). The virus is then transported back through the cell (step 2, arrow), possibly by transcytosis, to the apical surface and secreted into bile canaliculi. doi:10.1128/9781555817381.ch91.f2

The 5' end of the genome has a 7-methylguanosine cap, while both 5' and 3' ends of the viral RNA have short, highly conserved untranslated regions (UTRs). Three ORFs, organized as 5'–ORF1–ORF3–ORF2–3', encode the viral proteins (described here as PORFs) PORF1 (replicative polyprotein), PORF3 (virus export, other functions), and PORF2 (capsid protein), respectively (Fig. 1B).

Strains of HEV show a much greater degree of genetic diversity than HAV, with four putative genotypes identified as infecting humans (6). Genotype 1 is most common in the Indian subcontinent, Middle East, Eastern Europe, and much of the African continent, and it likely causes the majority of endemic human infections. Genotype 2 is most common in central Africa, cocirculating with genotype 1, and was first identified in Mexico. Genotypes 3 and 4 are endemic in swine worldwide, with genotype 3 predominant in North America, Western Europe, Australia, and New Zealand and genotype 4 in India, Taiwan, and Indonesia; both are common in China and Japan (30). Genotypes 3 and 4 represent the predominantly occurring genotypes in humans in North America, Japan, and Western Europe, where zoonotic transmission greatly outweighs ongoing human transmission, while in China and Eastern Europe the “human” genotype 1 is equally common in humans, suggesting mixed patterns of transmission.

The most recent analysis of available sequence data suggests four major groups of HEV (12): HEV infecting humans and swine (genotypes 1 to 4 plus an additional two genotypes from wild boar, and rabbit HEV); HEV infecting rodents and ferrets; HEV from bats; and HEV from chickens. The HEV-like virus from fish was suggested as a possible second genus on this basis (12).

In contrast to HAV, the genotypic differences between HEV strains are associated with significant antigenic differences, with corresponding effects on the sensitivity of first-generation serological assays. However, HEV in humans appears to exist as a single serotype, with experimental vaccines providing strong cross-genotype protection (31, 32). Improved serological tests are also able to detect all HEV strains (33, 34), although some studies suggest there may be reduced sensitivity for detection of genotype 3 infections when using some assays based on genotype 1 antigens (8, 35).

Two candidate HEV vaccines have shown positive results in phase III trials. The first, based on a truncated HEV ORF2 protein (amino acids 112–607) expressed in insect cells, showed strong efficacy in studies conducted in Nepal during 2003 (36), but has not been made commercially available. The second, based on amino acids 368–606 expressed in Escherichia coli (HEV 239) and now known as Hecolin (Xiamen Innovax Biotech, China), showed 100% efficacy in a very large phase III study in China, with no cases of HEV among 48,693 subjects who received three doses of vaccine versus 15 cases of HEV among 48,663 placebo recipients over 12 months (37). Hecolin was approved for use in China at the end of 2011 for individuals 16 years and older, but is not yet available in other countries.

Epidemiology and Transmission

Despite sharing the primary mode of transmission via the enteric route, HAV and HEV have very different distributions of both disease and infection worldwide. Contributing factors include the presence of zoonotic hosts of HEV strains, the changing incidence of HAV in many countries due to effective use of vaccine, and the higher efficiency of HAV transmission. Infectious particles of HAV are very stable...
and excreted in very high titers, allowing both efficient person-to-person spread as well as waterborne infections, including foodborne outbreaks associated with importation of contaminated fresh produce. In developing countries with the highest disease burden, HEV is more commonly seen in waterborne outbreaks, with minimal person-to-person spread, while in developed countries zoonotic sources of HEV are more common, with transmission most often linked to consumption of meat products from infected animals. However, unresolved questions remain regarding the true prevalence of HEV infection in areas of high endemicity such as Nepal, where infection with HAV is almost universal and yet less than 50% of the population show evidence of exposure to HEV (38, 39), and in regions such as Western Europe, where high levels of antibody prevalence are detected by some assays (40) and yet clinical disease is rare. This is likely to be related to relatively high rates of subclinical infection with these presumably zoonotic infections, but more studies with consistent use of improved serological tests are required to better understand the epidemiology of HEV infection.

**Hepatitis A Virus**

Transmission

The generalized course of infection and serological responses for both HAV and HEV is shown in Fig. 3. Due to its enteric route of transmission, HAV is assumed to infect cells lining the alimentary tract. However, studies suggest that progeny HAV from intestinal epithelial cells is released back into the lumen of the gut rather than into the circulation (40), and the virus is around 10,000-fold more infectious when administered by the intravenous route rather than the oral route (41). This is consistent with early studies that suggested the liver as the primary site of replication, with amplification in the alimentary tract making little or no contribution (42). During the incubation period of 4 to 6 weeks after first exposure to the virus, HAV spreads throughout the liver without causing any cytolytic effects, but liver damage eventually results and is most likely mediated by the cellular immune response to the virus. Virus is excreted through bile to the gut, and very high titers of infectious HAV will be present in most patients at the onset of illness. The virus is generally cleared within several weeks, although prolonged excretion of HAV has been reported in a significant proportion of cases. In general, titers of excreted virus will be highest before the onset of obvious symptoms.

Although the vast majority of progeny virus is excreted in the feces, HAV patients will display a viremia that may last for some weeks around the time of clinical presentation. Transmission of HAV via blood products has been demonstrated, and inactivation procedures to eliminate HAV are clearly required in the manufacture of blood products (43). Fortunately, such processes have now been validated for HAV, and further transmission is unlikely (44, 45).

Epidemiology: High, Low, and Intermediate Rates of Infection

HAV is found worldwide, but with widely varying epidemiological patterns that largely reflect sanitation standards (46). In countries or areas with poor sanitation, high levels of HAV exposure result in most individuals becoming infected at an early age, but in these circumstances HAV is not a major public health problem because the symptoms tend to be mild or absent in children and very few of the adult population are susceptible. However, HAV can certainly cause clinical disease in children, most obviously in foodborne outbreaks in schools of developed countries (47, 48) but also observed in countries such as Turkey, where HAV was the most commonly identified cause of fulminant hepatic failure in children from 1 month to 17 years age (49).

Conversely, in countries or populations with high standards of personal and public sanitation, relatively few individuals are exposed at an early age. In many countries of Western Europe, uniformly high standards of sanitation result in very low rates of HAV disease even though the vast majority of the population is susceptible. Prior to the widespread use of vaccines, sporadic HAV infection continued at a significant level in the United States, Australia, and other countries with generally high sanitation levels but a wide diversity of socioeconomic circumstances, especially in the very young and in disadvantaged communities where standards of personal hygiene are low. Acute infection rates in the United States have been reduced considerably since 1996 due to the progressive introduction of vaccination to at-risk groups, at-risk communities, and the general pediatric population (50). Focal circulation of this highly transmissible virus provides an ongoing source of virus for sustained transmission throughout the broader community, and the most profound reductions in overall attack rates followed the introduction of nationwide pediatric immunization, as observed progressively in the United States since 2006.

In the United States in 2007, international travel was the most frequently identified risk factor for HAV (17.5%), while household or sexual contact with an infected person was next at 7.8%, but risk factor data were not available for 67.7% of reported cases (50). Children in day-care centers were identified as a risk factor in 4.6% of cases, but children are likely to be a factor in a large proportion of the cases where no risk factor was identified (50, 51). An important aspect in the epidemiology and transmission of
HAV is the high titer of virus produced, combined with the very great physical stability of the viral particle, which is relatively insensitive to extremes of heat; infectious virus is readily recovered after heating for 10 minutes at 60°C (13).

HAV disease burden in the United States was estimated at more than 140,000 cases and 80 deaths annually in 1990 (52), but has declined rapidly since then (see reference 53 for a comprehensive review of the early phase of vaccine control). This decline was initially most pronounced in children, from a peak incidence of 39 cases/100,000 in 1990 to around 2 cases/100,000 in 2002, coincident with the introduction of targeted immunization of children from high-risk ethnic and racial groups and geographic areas, but the rate in adults (>18 years) also fell from around 17 cases/100,000 to 2 cases/100,000 during the same period (53). The public health problem of HAV in the United States and other countries with low endemicity is compounded by the potential for large outbreaks of HAV spread by contaminated foods. Food- and waterborne infection with HAV was identified as a factor in 6.5% of cases in the United States in 2007 (50), and a single multistate outbreak associated with pomegranate seeds imported from Turkey led to 162 confirmed cases in 2013. Similarly, frozen berries were implicated in a recent outbreak with 71 cases across Denmark, Finland, Sweden, and Norway (54).

In the past, foodborne outbreaks were largely confined to shellfish, which concentrate viruses such as HAV from large volumes of water and which are generally eaten raw or only lightly cooked. Examples are provided by outbreaks seen in Shanghai in 1988 (55), the United States in 1991 (56), and Australia in 1997 (57). However, the increased trade in foodstuffs between countries now creates additional sources of infection. A number of outbreaks within the United States and other countries have been traced to fresh and frozen foods that had presumably been exposed to contaminated water during production or to contaminated water or infected food handlers during food processing (47, 54, 58, 59).

Intravenous and other illicit drug use is also positively associated with a higher risk of HAV infection and may play a major role in the epidemiology of HAV in some societies (60). Men who have sex with men are at increased risk, and outbreaks in this population in different countries have been described (53).

Residents from developed countries who travel to regions of endemicity, especially individuals visiting friends and relatives in such regions, are at greatly increased risk of HAV infection (61). The relative contribution of travel to the HAV disease burden may be underestimated, because travel history is often overlooked in diagnosis and the majority of HAV cases do not have an identified risk factor.

The greatest disease burden for HAV worldwide falls on countries that have previously had high rates of HAV infection, but are now undergoing rapid economic growth and improvements in public sanitation and infrastructure, resulting in low to intermediate rates of HAV infection and antibody prevalence. Improved sanitation has the effect of sparing many young children from infection, but this results in a much larger pool of susceptible older children and young adults, who experience more pronounced disease. HAV may continue to circulate widely within households and other close contacts, resulting in high rates of clinical disease. Routine infant immunization is likely to have the most impact on disease burden by interrupting transmission cycles as seen in other countries, but the cost of universal immunization programs is a major barrier to control of HAV in many countries.

Hepatitis E Virus

Transmission

Hepatitis E is primarily transmitted via the fecal-oral route in developing countries, but direct ingestion of meat or offal from infected animals is clearly a significant factor in regions such as Western Europe and Japan. HEV RNA is detectable in the feces of 50% of patients 2 weeks after onset (62), and in one uncomplicated case was detected 52 days after onset (63). HEV RNA and infectious HEV have also been identified in fresh liver destined for human consumption (7, 25). HEV infection is generally self-limiting, but chronic infection has been characterized in patients on immunosuppressive therapy (64), and this has now been recognized as a significant clinical problem in developed countries with increasing rates of solid organ transplantation in particular (see below), but is unlikely to contribute significantly to ongoing transmission. Household contact appears to be much less important in transmission of HEV than for HAV (65).

Travel to areas of HEV endemicity is a major source of HEV infections in nonendemic areas such as the United States and Western Europe, but locally acquired (autochthonous) HEV infections also occur, primarily representing zoonotic infections from pigs, deer, or other unidentified hosts (66–69), and HEV should be considered in cases of acute hepatitis regardless of travel history. Cross-species infection has been experimentally established for some strains of swine (genotype 3) and human (genotype 1) HEV (70), although other strains are unable to cross species (71). In Japan and Western Europe, it is clear that consumption of raw or partially cooked liver or meat from swine or deer harboring corresponding strains of HEV is the source of transmission (72, 73); however, the significance of this route in other countries is unclear. Direct occupational contact with swine does not appear to be a significant disease risk although it may result in increased subclinical infections (74).

HEV exhibits a significant viremia, with the majority of patients being positive by reverse transcription-PCR (RT-PCR) at the time of disease onset, and there have been several reported cases of hepatitis E associated with transfusion in both endemic and non-endemic countries (75, 76).

Epidemiology: Areas of Endemicity

In countries where HEV is endemic, sporadic HEV infection is often the most common form of viral hepatitis on an annual basis, accounting for around 70% of cases in Kathmandu, Nepal (77), but above this background, major epidemics also occur with a periodicity of around 7 to 10 years. For example, HEV was shown retrospectively to be responsible for 16 of 17 epidemics of enterically transmitted hepatitis in India (78), but HEV is also responsible for at least 25% of sporadic hepatitis between epidemics (79).

Epidemics are most often associated with the wet season; however, one study has shown an increased rate of infection associated with a period of unusually low rainfall, presumably due to human wastes concentrating in a riverine ecology (80).

Clinical HEV infection in developing countries is most common in adolescents and young adults but occurs to a lesser extent from childhood (81) to late ages. There appear to be considerable differences in exposure rates between countries in which HEV is considered endemic: in Egypt,
around 60% of children were exposed to HEV by the age of 10 (82), whereas in Nepal only 16% of 12-year-olds had evidence of exposure to HEV, peaking at 31% later in life (39). The lack of correlation between many serological assays is also likely to contribute to these differences in observed exposure rates, and further studies are needed. It is likely that the risk of clinical disease increases with age, as for hepatitis A, but while clinical HAV infection is uncommon in many developing countries because of high exposure rates in children, HEV exposure rates are never as high as for HAV and a large proportion of the population remains susceptible through to adulthood.

In developing countries, exposure to water contaminated with human waste is a clear risk factor for disease, and close contact with domestic animals may also be a risk. Importantly, boiling of drinking water appears to be protective (83), but while this will not be practical for all residents in many developing countries, it is advisable for pregnant women because of the high risk of fulminant hepatitis E in this population (see below). The low rate of person-to-person spread of HEV is likely to be due to a combination of lower particle stability (17) and lower virus titers in excreta compared to HAV.

Reported seroprevalence rates for anti-HEV IgG in countries of presumed endemicity vary widely, at least partly due to the different assays used, which show very poor concordance (8). Experimental infections of macaques have demonstrated a strong dose response for the development of clinical HEV disease (84) and the unexpectedly high rate of HEV seroprevalence in countries where clinical HEV is very rare may represent subclinical infection with low doses of zoonotic strains of HEV. There is some evidence for increased exposure to HEV in groups with occupational exposure to swine (74).

Travel to endemic countries remains the greatest risk factor for clinical HEV infection in residents of developed countries. This risk can be assumed to be especially great for travelers visiting friends and relatives, as for HAV (61). However, with the very clear evidence for autochthonous HEV infection from a large number of studies across many different developed countries, HEV infection must be considered in cases of unexplained hepatitis regardless of travel history and is especially important in immunosuppressed patients, where it may become chronic and more severe.

**CLINICAL SIGNIFICANCE**

**Clinical Presentation and Course**

Acute infections with any of the hepatitis viruses cannot be distinguished on clinical characteristics or pathological examinations, and the diseases caused by HAV and HEV will be considered together here. However, HEV infection is unique among the hepatitis viruses in being associated with a high mortality during pregnancy due to fulminant hepatitis with a very rapid onset, approaching 30% in the third trimester, and the rate of fulminant hepatitis for HEV outside of pregnancy is probably around 10-fold higher than for HAV (1% versus 0.1%). In addition, there is some evidence that HEV infection may have more severe sequelae in patients who are deficient for G6PD (85). The reasons for such severe outcomes in HEV infection are not known, but it is clear that women should take all possible precautions to avoid exposure to HEV during pregnancy. A major risk factor in this regard is travel from nonendemic countries to areas of endemicity such as India and Pakistan.

Infection with HAV or HEV can result in a broad range of clinical outcomes, from subclinical infections (especially in children, or with low doses of HEV) through to fulminant hepatitis. Disease severity shows a general increase with age; however, clinical and even fulminant hepatitis A and E do occur in children, and there is no reason to exclude the enterically transmitted hepatitis viruses from diagnostic consideration on the basis of patient age. A retrospective study in Turkey has shown HAV to be the most common identifiable cause of fulminant hepatitis in children (49).

Clinical presentation of acute viral hepatitis commonly begins with nonspecific, "flu-like" symptoms such as fever, headache, anorexia, nausea, and abdominal discomfort. Physical examination will usually reveal an enlarged, tender liver. The first distinctive sign of hepatitis is usually dark urine (excretion of conjugated bilirubin), followed by pale feces and jaundice (yellow discoloration of the skin and sclera), but many patients will not show visible signs of jaundice despite severe symptoms, even when raised levels of serum bilirubin are present. However, it must be stressed that these nonspecific symptoms alone are not sufficient to infer acute viral hepatitis in a patient without jaundice, and liver function tests are an important adjunct to diagnosis (86), with raised levels of aspartate aminotransferase (AST) and alanine aminotransferase (ALT) detectable at the time of onset. Unless there are strong epidemiological grounds for suspicion (such as contact with an index case), hepatitis A or E should not be considered in the absence of one of these biochemical markers or jaundice.

In most developed countries, hepatitis A is much more likely than hepatitis E unless there are specific indications to suggest HEV, such as chronic elevation of liver enzymes in immunosuppressed patients or recent travel to developing countries combined with a history of receiving inactivated HAV vaccine. Patients with proven evidence of past HAV infection will not have HAV, other than those very rare cases that represent relapses after recent HAV infection (87). In developing countries with poor sanitation, clinical cases of HEV are often more common than HAV due to almost universal childhood exposure to that virus, although HEV appears to be relatively infrequent in many parts of South America. Coinfection with HAV and HEV has also been reported, with 14 of 33 outbreaks investigated in Cuba during the period 1998 to 2003 showing strong serological evidence of exposure to both viruses, although a higher proportion of individual patients were infected exclusively with HAV (88), consistent with its more efficient secondary transmission.

Serum aminotransferase levels usually resolve after a period of 3 to 4 weeks. Normalization of liver enzymes usually marks complete recovery; however, many patients will report an intolerance to fatty foods which may last for years. Relapses are rare for hepatitis A, occurring in approximately 7 to 12% of patients beyond 1 month (87). Protracted hepatitis A has been associated with a particular HLA allele (89). Prolonged disease with hepatitis E has also been observed in some areas of endemicity and is frequently characterized by cholestasis with jaundice and itching. Cholestasis can occur with both hepatitis A and hepatitis E.

While both HAV and HEV (outside pregnancy) have low overall rates of fulminant hepatitis, the onset of encephalopathy can be quite rapid (around 7 days from onset of dark urine for hepatitis A). HEV has been found responsible for around 62% of fulminant hepatitis in studies from India and Bangladesh (90), where the virus is highly endemic. Acute HAV infection in individuals with chronic hepatitis C or hepatitis B is associated with more severe outcomes (91).
While chronic HEV infection has rarely been reported in healthy individuals, a significant number of cases have been reported in patients receiving immunosuppressive therapy after solid organ transplantation (64, 92, 93). There is no suggestion that transplantation was the source of infection in these cases, with cases occurring many months or years after transplantation. Rather, these represent sporadic cases of HEV infection that have progressed to chronicity due to ongoing immunosuppression. In the largest study, of 217 French patients with elevated liver enzymes and with no evidence of drug toxicities or other viral causes, 14 patients (6.5%) tested positive for serum HEV RNA and 8 of these progressed to chronic infection (64). Chronic HEV infection has also been noted in HIV-infected patients, along with higher overall rates of HEV infection (94, 95).

In addition to chronic hepatitis with persistent elevation of liver enzymes, neurological symptoms are sometimes evident during chronic HEV infection (96). The chronic infection can have severe or fatal sequelae, further complicated by the poor sensitivity of some available commercial serological assays in order to provide timely antiviral treatment (see below) (97).

**Dose Response to Infection**

HAV and HEV differ markedly in the relationship between infecting dose and the course of infection and disease. For HAV, studies in tamarins have shown a very clear correlation between higher infectious doses and reduced incubation period to develop disease, but no correlation with disease severity (41). Low-dose infections of cynomolgus macaques with HEV have also demonstrated an increased time to seroconversion, but HEV disease severity showed a positive correlation with high infectious doses (84, 98). This attenuation of low-dose infections may help to explain the low secondary attack rates of HEV, and especially the rarity of clinical HEV disease in developed countries despite seroprevalence estimates that range as high as 18 to 29% using assays that include antigens derived from genotype 3 strains of HEV (99).

**Vaccines and Antiviral Agents**

Passive immunization with human gamma globulin has been used for many years to provide short-term protection against hepatitis A and is still used for postexposure prophylaxis (<2 weeks post exposure, including household contacts), especially in individuals at risk of severe disease due to age or pre-existing liver disease and for infants less than 1 year of age. As noted above, there are now a number of highly efficacious, inactivated vaccines available against hepatitis A (Havrix and Vaqta in the United States, plus Avaxim and Epaxal worldwide) or hepatitis A and B (Twinrix), and these have replaced the use of gamma globulin for protection of individuals with future risk of HAV infection. Preliminary studies also suggest that HAV vaccines may be useful for prevention of household transmission when administered no more than 8 days after exposure, but not in those most at risk of severe disease, where gamma globulin is still preferred (100).

In the United States, progressively expanded programs of active immunization against hepatitis A have been implemented, beginning in 1986 with children (>2 years of age) living in communities with elevated rates of hepatitis A, travelers to countries where standards of hygiene and sanitation are low, men who have sex with men, recipients of clotting factors, injecting drug users, and patients with chronic hepatitis (where disease severity is exacerbated) (86). Extension of this program in 1999 to include children in all states/counties reporting more than 10 cases/100,000 population contributed to the rapid decline in HAV disease rates in the United States over the subsequent 7 years, and since 2006, the inclusion of children nationwide from 12 to 24 months of age (following the licensure of vaccines for use beginning at 12 months of age) has led to further reduced disease rates, from 3,579 cases reported in 2006 to only 1,398 in 2011 with an incidence of 0.4 per 100,000 (see Centers for Disease Control, [http://www.cdc.gov/hepatitis/Statistics](http://www.cdc.gov/hepatitis/Statistics)).

Two different vaccines have now shown efficacy in phase III trials for protection against HEV infection: a 56-kDa subunit antigen (amino acids 112–607 of PORF2 expressed in insect cell culture) (36) and a particular subunit antigen, HEV 239 (amino acids 368–606 of PORF2 expressed in E. coli) (37). However, the HEV 239 vaccine is the only commercially available product, with regulatory approval for the vaccine, known as Hecolin (Xiamen Innovax Biotech, China), granted in China in December 2011 for subjects 16 years of age and older.

The progress of vaccine development against HEV was underpinned by studies by Purcell, Emerson, and colleagues at the National Institutes of Health, which first demonstrated that antibody to PORF2 is sufficient to protect against hepatitis E (101). Active immunization of macaques with the candidate 56-kDa subunit antigen vaccine was also shown to confer protection against viral challenge with both homologous and heterologous HEV strains (31, 101, 102).

The 56-kDa vaccine was subsequently acquired by Glaxo SmithKline and completed a phase III clinical trial in Army recruits in Nepal in 2003, with results published in 2007 (36). In that study, 1,794 healthy HEV seronegative adults received three doses of either the 53-kDa vaccine or placebo at months 0, 1, and 6 and were monitored for a median of 804 days. Hepatitis E developed in 66/896 placebo recipients versus 3/598 vaccine recipients, yielding an efficacy of 95.5% (36). However this vaccine has not progressed to licensure, presumably because of concerns about its market viability.

HEV 239 (Hecolin) followed a similar path of development from preclinical studies demonstrating safety and induction of antibody responses (103, 104) before the definitive phase III trial that showed 100% efficacy (37). In this study, 97,556 healthy adult subjects received the 56-kDa vaccine, either 30 μg of Hecolin with alum adjuvant or placebo (hepatitis B vaccine) at months 0, 1, and 6 and were monitored for 12 months after the final dose. Hepatitis E developed in 15/48,663 placebo recipients versus 0/48,693 vaccine recipients (37). Notably, patients with pre-existing antibody to HEV were not excluded from this trial, and follow-up at 2 years was able to show that both naturally acquired and vaccine-induced antibodies were protective against infection (105). Hecolin was approved for use in China at the end of 2011 but is not yet available in other countries. While questions remain about the duration of protection provided by Hecolin (as well as the 56-kDa antigen), it is to be hoped that HEV vaccine may become more widely available, especially in high-burden countries and for use in the face of outbreaks, and further follow-up from the Hecolin trial should clarify the duration of protection. In low-burden countries, vaccine would be most useful for travelers (including the military, Peace Corps, etc.) and potentially for protection of organ transplant recipients and HIV-infected patients to prevent chronic HEV infection associated with immunosuppression (see above).

Numerous recent studies have provided a strong evidence base for the use of ribavirin for the antiviral treatment of...
chronic HEV infection in transplant recipients and other immunosuppressed patients (106–108). Initial studies used combinations of ribavirin with pegylated interferon alpha (as for treatment of hepatitis B and hepatitis C), but the most recent findings suggest that 3 months of therapy with ribavirin alone can provide virological clearance in 95% of patients, with a sustained response in 78% of patients (108).

In contrast, no antivirals are available for treatment of hepatitis A. Experimental inhibitors have been developed that are active against the 3C protease of HAV but clinical development of these is unlikely, as the acute disease is largely immunopathogenic in mechanism and chronic infection is not significant.

No specific symptomatic or anti-inflammatory treatments can be advised for acute hepatitis A or E. Bed rest and attention to diet (avoiding fatty foods) are commonly recommended to minimize symptoms and speed recovery; alcohol intake should be minimized. Pruritis is a feature of cholestatic hepatitis that may justify the cautious use of corticosteroids.

Intensive supportive medical care, as for acute liver failure due to other causes, is required in cases of fulminant hepatitis A or E. Fulminant hepatitis A has a better prognosis for spontaneous recovery than hepatitis B (69 versus 19% [109]). Liver transplantation is less frequently performed, and there is some risk of graft reinfection (110).

### COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Standard methods for collection, transport, and storage of sera or plasma are adequate for the detection of both IgG and IgM antibodies to HAV and HEV. Sera or plasma can be stored at 4°C for weeks, but should be frozen under other circumstances (~20°C or ~70°C for storage; dry ice for shipping). Shipping is most often an issue with HEV testing, which is not available in many routine diagnostic laboratories. IgM is more sensitive to freezing and thawing than IgG is, and repetitive cycles should be avoided. Feces may be collected for epidemiological studies of HAV (genotyping of strains) and are stable as a solid mass or slurries in phosphate-buffered saline or water for years at ~70°C. HEV is difficult to detect in feces, and serum is preferred for RT-PCR and genotyping. Because HEV is more labile than HAV, sera for HEV RT-PCR studies must be tested within 24 hours or frozen and shipped at ~70°C.

Rapid point-of-care (RPOC) tests for HEV-specific IgM are now available outside the United States (33, 34), which can overcome the need for collection and shipping of venous blood. These tests can be used either for fresh whole blood or for serum and plasma as for laboratory assays.

### DIRECT EXAMINATION

#### Electron Microscopy

Electron microscopy, and especially immunoelectron microscopy, are of historical importance for their roles in identifying HAV (111) and HEV particles (18) before the characterization and molecular cloning of the viruses and development of specific diagnostic tests, but they are insensitive and technically difficult and have no diagnostic value.

#### Antigen Detection

HAV

HAV antigen (HAAG) is very stable and readily detected in the acute-phase fecal samples collected from many patients. Viral antigen is detected by enzyme-linked immunosorbent assay (ELISA) using monoclonal antibodies and may be present in very high titers in some patients, but antigen detection is less sensitive than RT-PCR or follow-up serology for detecting the uncommon cases where IgM has not yet developed at initial presentation. There are no commercially available tests for HAAG.

HEV

HEV antigen is less stable than HAV, and no reliable tests are available (either commercially or on research-only basis) for the detection of antigen in clinical samples. It is unlikely that antigen detection would have any clinical value relative to serology or RT-PCR performed on sera (below).

#### Nucleic Acid Detection

HAV

HAV patients are viremic in the prodromal phase, and one study from Brazil has reported around 12% of children during a common-source outbreak to have been RT-PCR positive but IgM negative ("window period") at the time of testing (112). The high proportion of window period cases found in this study contrasts with the high sensitivity of HAV IgM detection in other studies and may be related to high-dose infections with short incubation periods, and/or early case detection due to active surveillance of the outbreak. The authors also reported the detection of HAV RNA in 26% of patients initially classified as acute, sporadic non-A, non-C hepatitis (112). All patients available for follow-up seroconverted, highlighting the utility of follow-up IgM serology or RT-PCR in the uncommon cases of acute hepatitis with unknown etiology, especially in a country where HAV is endemic. Serum is the preferred specimen for nucleic acid detection, but plasma is acceptable provided that anticoagulants do not interfere in the reactions; feces are least suitable, with variable levels of virus and high levels of inhibitors. While RT-PCR is useful for detection of very early (window period) infections and the confirmation of questionable IgM results, accredited assays are not commercially available for routine diagnostic testing of possible acute hepatitis A. In the absence of a mandate for screening of the blood supply for HAV RNA, there may be insufficient test numbers for such assays to be commercialized; conversely, many manufacturers now routinely conduct HAV RT-PCR screens on pools of source plasma for blood products, although virus inactivation methods provide the most important protection for such products. HAV RNA can also be used for genotyping of virus for research purposes using RT-PCR primers in the region of VP1-2A (Fig. 1) (113).

HEV

RT-PCR remains the gold standard in the diagnosis of acute HEV infection. However, levels of HEV RNA are generally low and the sensitivity of RT-PCR for diagnosis is very dependent on patient presentation early in disease, and rapid and careful processing of serum or plasma samples and appropriate transport at ~70°C. Routine tests for HEV RNA have only recently been commercialized (114) and are not widely available, and reference laboratories are therefore generally needed for RNA testing and quality control. Serological tests are preferable for routine diagnosis, especially in regions with high prevalence of HEV (see below). However, RT-PCR has provided the majority of information on zoonotic infections with HEV around the world (4–6, 73, 75) and is likely to remain useful for HEV testing in areas
of low endemicity such as the United States and Western Europe.

**ISOLATION PROCEDURES**

Many primary isolates of HAV have been adapted to cell culture, but virus isolation is insensitive and is not useful in diagnosis or epidemiological studies. Similarly, some primary strains of HEV appear to replicate well in cell lines (23, 115), but virus isolation is not useful for diagnosis.

**IDENTIFICATION AND TYPING SYSTEMS**

As described above, the direct detection of HAV and HEV RNA by RT-PCR and sequence-based genotyping has been used for the identification of potential sources of sporadic cases of HEV in nonendemic countries and for the investigation of common-source outbreaks of HAV. HEV genotyping is usually based on the ORF1 region and to a lesser extent on the ORF2 region (4–6), while HAV strains and genotypes are determined by sequencing in the VP1-2A region of the genome (113).

**SEROLOGIC TESTS**

Despite the very good specificity of most serologic tests for HAV and HEV, their appropriate use and interpretation are dependent on patients meeting the clinical criteria for acute hepatitis, particularly in areas where there is low incidence of the viruses, such as the United States and other developed countries. The clinical criteria for the HAV surveillance case definition in the United States define “An acute illness with discrete onset of symptoms (e.g. fatigue, abdominal pain, loss of appetite, intermittent nausea, and vomiting) and jaundice or elevated serum aminotransferase levels” (86). Serologic testing should be limited to persons who meet the clinical criteria or to persons likely to have been exposed to HAV (86), and in light of the nonspecific nature of the symptoms, the importance of jaundice or elevated ALT or AST in meeting the case definition must be stressed. These same criteria are clearly relevant to HEV. In the absence of these clinical criteria for patients in nonendemic regions, the positive predictive value of the tests will be severely compromised. This is especially relevant given the very low rates of clinical HAV disease in countries with successful immunization programs, and of HEV disease in most developed countries.

**Hepatitis A Virus**

Tests for HAV-specific IgM are commercially available from numerous sources in both manual and automated enzyme immunoassay formats. The technology for detection of HAV-specific IgM is sufficiently well established that there are no significant differences between the diagnostic performance (sensitivity and specificity) of the laboratory-based testing platforms. Choices of diagnostic assays for HAV may reasonably be made on the basis of convenience for the testing laboratory, with a range from single-strip ELISAs for small numbers of specimens, through to completely automated systems for high-volume laboratories.

Test principles are either IgM class-capture or indirect ELISA. In the IgM class-capture assays, plates coated with anti-human IgM are used to capture IgM from patient samples, with HAV-specific IgM being detected by binding of labeled hepatitis A antigen (HAAg; inactivated HAV derived from cell culture). Indirect ELISAs use plates coated with HAAg, to which HAV-specific IgM will bind, and bound IgM is then detected using anti-human IgM conjugates. In both cases, assay reactivity and cutoffs are determined from internal controls supplied with the kits. All commercially available HAV serological assays use inactivated, whole HAV derived from cell culture and thus detect the same antibody specificities.

Total or IgG anti-HAV does not have diagnostic value because antibody persists for life, although a rising titer of IgG (greater than 4-fold in specimens taken 2 weeks apart) is indicative of acute HAV. Total HAV-specific antibody is a marker of immunity and can be used for prevaccination screening to identify those who require immunization, but the cost-effectiveness of screening depends on many factors (116). Postvaccination tests are not required, due to the very high efficacy of available HAV vaccines. Tests for the measurement of total anti-HAV use a competitive ELISA format, where HAAg is coated on plates and specific antibody in patient serum binds to the antigen, resulting in a proportionately reduced assay signal from the binding of labeled monoclonal antibodies to HAAg.

In addition to serum or plasma, saliva can be used for detection of anti-HAV IgM or total antibody (117), but the use of saliva or other samples, such as urine, falls outside the manufacturers’ recommendations for current tests.

RFOC tests for HAV-specific IgM have been developed (118), but are not yet commercially available. In common with the RFOC test for HEV-specific IgM (33, 34) (below), such tests could prove especially useful in outbreak investigations.

**Hepatitis E Virus**

A number of research and commercial immunoassays for HEV-specific IgG and IgM are available in various countries, but with significant differences in their sensitivity and specificity (see below). Only IgG ELISA tests are currently approved for routine diagnostic use in the United States; inhouse IgM ELISAs are available in reference laboratories. The appropriate use and interpretation of current serological assays for HEV infection must take into account differences in assay sensitivity and specificity, the pattern of serological responses (IgG and IgM, and in some cases IgA) to various antigens, and the widely varying prevalence of clinical HEV infection worldwide.

**Laboratory-Based HEV Serological Tests**

Many recombinant and synthetic peptide antigens have been used in diagnostics for HEV over the past 20 years, contributing to the uncertainty regarding seroprevalence rates around the world, as studies using different antigens cannot be compared. However, the general pattern of antibody responses to HEV infection can be implied from a large number of studies (Fig. 3). High titers of IgG are found during acute infection, but can remain at high levels for many years and HEV-specific IgM is therefore preferable for diagnosis, especially in areas with high prevalence of past HEV infection. IgM (and probably IgA) are usually elevated at the time of clinical presentation and remain detectable for some months; however, a small proportion of acute-phase patients will have HEV RNA in serum before antibody responses can be detected.

Improved commercial IgM and IgG tests have now been developed based on well-defined recombinant antigens in both ELISA and immunoblot formats. In studies with patients from developing countries, the MP Biomedicals HEV IgM ELISA 3.0 showed an overall sensitivity of 98.7% (149 positive of 151 confirmed HEV patients) and specificity of 97.6% (203 negative of 208 patients with other forms of
viral hepatitis or other diseases (34). The same antigen is also used in a double-antigen sandwich assay for total HEV-specific immunoglobulin (HEV ELISA 4.0), which is notable in being useful for detection of antibody in potential zoonotic hosts such as pigs, as well as in humans (119).

These assays are based on a genotype 1 HEV antigen that is highly conserved between strains, but the HEV ELISA 3.0 has shown variable sensitivity and specificity for genotype 3 infections in different studies (8, 9).

Alternative commercial tests for HEV-specific IgM and/or IgG have now been developed, including some with incorporation of genotype 3 antigens. Studies focused on sensitivity and specificity for detection of genotype 3 infections have generally demonstrated good sensitivity for an immunoblot for separate detection of IgG and IgM and using genotype 1+3 antigens (Mikrogen recomline, Germany) and for ELISAs from Beijing Wantai (China), Fortress (United Kingdom), and DiaPro (Italy) (8, 9, 120, 121). As noted above, the MP Biomedical ELISA 3.0 showed reduced sensitivity for genotype 3 infections in one study (8), but equivalent in another (9). More comprehensive studies are still required to determine the most appropriate serological tests for detection of IgM for diagnosis, and IgG for prevalence of HEV infection, especially in low-prevalence countries. HEV-specific IgA has also been reported to have utility in HEV diagnosis (122, 123) but further studies are required.

RPOC HEV serological tests

The major disease burden of HEV falls in developing countries and is especially severe among displaced populations such as refugees, with major epidemics observed during 2004–2005 in the Greater Darfur region of Sudan (124) and during 2012–2013 in Kenya (125) and what is now South Sudan (126). Timely access to sophisticated laboratory facilities is not available in these situations, highlighting the need for rapid diagnostic assays that can provide reliable diagnosis at the point of care, with minimal training or infrastructure. RPOC tests for HEV-specific IgM have now been developed in a novel format of immunochromatographic test (Fig. 4) (33, 34); these tests are commercially available in many countries outside the United States. The HEV IgM RPOC test (MP Biomedical, Singapore) has been evaluated in two separate studies. In the first study (34), the RPOC test showed sensitivity of 96.7% (146 of 151) and overall specificity of between 98.6% (205 of 208) and 96.9% (220 of 227) depending on exclusion or inclusion of sera having high levels of rheumatoid factor (RF), a common source of false-positive reactivity in rapid assays. In the second study (33), the RPOC test showed slightly lower sensitivity of 93% (186 of 200), but specificity of 99.7% (320 of 321) against a panel including RF-positive sera and patients with acute Epstein-Barr virus infection, a further source of problems in many RPOC tests. The positive predictive value (PPV) and negative predictive value (NPV) of the test were estimated at 98.0 to 99.5% and 97.6 to 95.0%, respectively (33, 34). These results suggest that the RPOC tests will certainly prove useful for the diagnosis of HEV in field situations of endemic regions. An HEV IgM RPOC test has also been developed by Beijing Wantai (HEV-IgM Rapid Test), but there are no published reports on performance. RPOC tests offer the further benefit of reduced collection of venous blood.

Serological Diagnosis of HEV Infection in Areas of Low Prevalence

In areas with a low but significant incidence of clinical HEV infection, such as the United States and Western Europe, assay specificity will have a very large impact on the predictive value of HEV serologic tests. In order to be useful, HEV diagnostic assays will need to demonstrate very high specificity, high sensitivity, and the ability to detect infections caused by all four genotypes of HEV present worldwide. Assays for HEV-specific IgG are generally unsuitable for definitive serological diagnosis because of high background prevalence and should be restricted to initial screening and prevalence studies. For example, if the incidence of HEV infection among acute hepatitis patients in the United States was 0.2% versus a minimum estimate of HEV prevalence of 2%, then only 1 in 10 patients reactive in a test for HEV-specific IgG would be true positives, leading to an unacceptable PPV. Notably, some assays detect much higher HEV IgG prevalence rates among healthy populations with an even lower PPV for acute HEV infection.

The detection of HEV-specific IgM is therefore the method of choice for diagnosis of acute HEV infection in areas of low prevalence, along with HEV RNA where testing is available. As noted above, a variety of assays are commercially available for this purpose, including an IgM immunoblot using genotype 1+3 antigens (Mikrogen recomline); IgM ELISAs from Beijing Wantai (China), Fortress (United Kingdom), MP Biomedical (Singapore), and DiaPro (Italy); and the HEV IgM RPOC assay (MP Biomedical, Singapore). Many of these new tests appear to be suitable for use in nonendemic regions, but on the balance of evidence published to date, the Mikrogen recomline immunoblot and Beijing Wantai and Fortress IgM ELISAs may have the best sensitivity for genotype 3 infections that are most common in these regions (8, 9, 120, 121).

Serological Diagnosis of HEV Infection in Areas of High Prevalence

The detection of HEV-specific IgG is of little use for diagnosis of acute infection in developing countries where HEV
is endemic and large numbers of patients will have IgG from past infections. Detection of HEV-specific IgM must therefore be the method of choice in areas of endemcity, especially since RNA assays are rarely available.

As HEV accounts for as much as 70% of the acute sporadic hepatitis in countries where hepatitis is endemic, the specificity of assays is less critical in these settings, and assay sensitivity is of primary concern. Because HEV genotypes 3 and 4 are less significant in these settings, all of the commercial IgM ELISAs and the HEV IgM RPOC assay (above) are likely to be suitable. The robustness of assays should also be considered, which may make the IgM immunoblot less suitable in these settings.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

In many developed countries, including the United States, the rarity of HEV infection and rapid decline in rates of HAV infection, coupled with increasing rates of hepatitis C virus infections, provides a challenge in the correct diagnostic test selection for individual patients. In particular, testing for HAV IgM in the absence of clinical or epidemiological features consistent with acute hepatitis A is likely to result in false-positive results (86), and the same is true of HEV. Close attention should be paid to the clinical characteristics and patient history, including overseas travel and immunosuppression, in both the selection of tests to be performed and the interpretation of test results.

Hepatitis A is a reportable disease in the United States, Australia, and many other developed countries, where patient contacts are generally managed by active or passive immunoprophylaxis. In routine laboratories, interpretation of HAV and HEV IgM serological tests is based on reference to internal test controls according to manufacturers’ specifications. Many laboratories test for total HAV Ig, and if positive, retest for HAV IgM, which may be more convenient for sample throughput in areas of low endemicity. There are no standard confirmatory tests for HAV and HEV, highlighting the need for test requests to be justified on clinical and/or epidemiological grounds in order to reduce false-positive results. False-negative results are uncommon for clinically apparent cases of HAV, with IgM almost always detectable at the time of clinical onset, but if false negatives are strongly suspected, for example a negative HAV IgM test in a patient with raised ALTs and contact with a confirmed case of HAV, it may be appropriate to request a second specimen for retesting. Negative results for HEV IgM (or IgG) in immunosuppressed patients with biochemical evidence of hepatitis should be interpreted with care, because a false-negative result can result in delay of appropriate antiviral therapy for chronic HEV infection (97); RNA testing should be considered.

VIROLOGY

Hepatitis C Virus
MICHAEL S. FORMAN AND ALEXANDRA VALSAMAKIS

TAXONOMY
Hepatitis C virus (HCV) is classified within the family Flaviviridae in its own genus, Hepacivirus. Phylogenetic analysis of helicase sequences has been used to probe its relatedness to other viruses in the family (1). The data suggest that HCV is most closely related to the nonpathogenic human virus GBV-C. The next closest relatives appear to be the pestiviruses, viruses that infect nonhuman hosts (bovine viral diarrhea virus and hog cholera virus). HCV is more distantly related to arthropod-borne viruses in the Flavivirus genus that infect humans (yellow fever virus, dengue virus, West Nile virus).

DESCRIPTION OF THE AGENT
HCV has an ~9.6 kb positive-sense RNA genome composed of a long open reading frame (ORF) flanked by terminal 5′ and 3′ untranslated regions (UTRs, Fig. 1). The 5′ UTR is highly conserved and the 3′ UTR has a short variable sequence, a poly(U) tract, and a highly conserved element. Core, p7, E1, and E2 are structural protein genes that encode nucleocapsid, transmembrane, gp33, and gp72 proteins, respectively.

During replication, the HCV ORF is translated into a single polyprotein (approximately 3,000 amino acids) that is subsequently cleaved by host and viral proteases encoded by NS2, 3, and 4A genes. The NS3 gene also encodes a helicase. The p7 region encodes a protein that is essential for replication of infectious virus (2); however, its specific function is unknown. The RNA-dependent RNA polymerase (RDRP) NS5B lacks efficient proofreading activity, resulting in extensive genome mutation during replication and quasispecies generation within an infected individual. NS5A is a multifunctional, nonstructural phosphoprotein (3). It is a key component of the replication complex and binds other constituents of the complex, including RDRP, RNA, and cyclophilin A, a host protein required for HCV RNA replication. NS5A also appears to play a role in virion assembly.

Currently, there are seven major genotypes of HCV and more than 50 known subtypes based on genomic sequence heterogeneity (4). Genotypes and subtypes differ by 30 to 35% and by 20 to 25% of nucleotides, respectively. Genotypes 1 to 3 (Gt1 to Gt3) have a worldwide distribution and account for most HCV infections in Europe and North America. In the United States, the majority of HCV infections in all age groups are Gt1 (75%), followed by Gt2 (13.5%) and Gt3 (5.5%). Gt4 is most prevalent in the Middle East and in North and Central Africa; Gt5 is found primarily in South Africa; Gt6 occurs throughout Asia; Gt7 has been detected in an immigrant from the Congo, and its region of endemicity is unclear. This chapter focuses on Gt1 to Gt4, given their worldwide prevalence.

EPIDEMIOLOGY AND TRANSMISSION
HCV is a globally significant pathogen, infecting over 150 million individuals. In the United States, it is the most common blood-borne infection, causing an estimated 3 million chronic infections (5). Acute hepatitis C occurs in the United States at a rate of approximately 0.3 per 100,000, with estimates of 19,000 new infections per year after adjusting for underreporting and asymptomatic infection (6). In the blood-screening era, most transmission occurs after exposure to a low viral inoculum through intravenous drug use, multiple sexual partners, sex with a chronically infected partner, iatrogenic exposure, and occupational exposure to blood such as needlestick (7). Rates of acute hepatitis C in HIV-infected men who have sex with men (MSM) are rising and greater than those in HIV-uninfected MSM, suggesting that the former is a high-risk group that merits screening (8).

CLINICAL SIGNIFICANCE
The clinical features of acute infection are depicted in Fig. 2. The majority of individuals are thought to be asymptomatic. Spontaneous clearance is observed in approximately 25% of acute infections; the remaining individuals become chronically infected. Signs of hepatitis during acute infection are actually positive indicators, as they represent early, vigorous antiviral T-cell responses associated with spontaneous virus clearance. These responses are minimal or absent in individuals who progress to chronicity (9). Why some individuals clear their infection while others progress to chronic HCV infection is unknown. To investigate the mechanisms governing clearance, genome-wide association studies (GWAS) have been used to identify genetic determinants that predominate in individuals with spontaneous clearance versus progression to chronicity. This approach has identified a single nucleotide polymorphism (SNP) in the DQA1-DQB2 HLA class II region (10) found on reference SNP (rs) 4273729, and multiple SNPs upstream...
from the *IL28B* gene (11, 12; reviewed in reference 13), of which the most strongly associated are variants on rs12979860 (10) that are independently associated with clearance and additively effective. The homozygous G allele on HLA class II rs4273729 and homozygous C allele on *IL28B* rs12979860 are associated with clearance. The homozygous C allele on HLA class II rs4273729 and the homozygous T allele on rs12979860 are associated with chronic infection. Heterozygotes tend more toward chronic infection than clearance. *IL28B* encodes interferon λ3, an interferon that stimulates a signaling cascade similar to interferon α and interferon β, but through a distinct receptor. The worldwide geographic distribution of *IL28B* genotypes appears to explain in part the observed racial differences in acute infection outcome (12, 14). Haplotypes associated with resolution are found more commonly in East Asian populations in whom rates of spontaneous clearance are high. Haplotypes associated with progression to chronic infection occur with higher frequency in individuals of African ethnicity in whom rates of chronic infection are high. How genetic determinants in HLA class II and *IL28B* regulate immune responses that mediate HCV clearance is not yet understood.

Disease progression occurs in a relatively small proportion of patients with chronic hepatitis C infection. Over decades, progressive liver damage produces cirrhosis in 10 to 20% of chronic infections and liver failure or hepatocellular carcinoma in approximately 5% of chronic infections (15). However, the overall disease burden is significant due to the number of infected individuals. In fact, liver failure due...
to chronic hepatitis C infection is the leading cause of liver transplantation in the United States. (16). Risk factors for disease progression include diseases or behaviors that induce additional hepatic injury (such as concomitant hepatitis B virus infection and alcohol consumption) or impair antiviral immunity (such as HIV infection). Epidemiologic descriptors such as male gender and older age at infection are also associated with higher risk and faster rate of disease progression.

Unlike other chronic viral infections such as HIV and hepatitis B virus, virologic parameters including viral load and genotype do not predict disease progression or indicate disease severity in chronic hepatitis C (17, 18). Viral load remains fairly constant once chronic hepatitis C infection is established (18), and rates of progression have been found to correlate more with disease severity in the liver, as manifested by the extent of fibrosis on initial liver biopsy (19), than with the level of hepatitis C virus replication represented by viremia (20).

The HCV treatment landscape has historically been dominated by interferon α, which, in its pegylated form in combination with ribavirin, had reasonable efficacy for Gt2 and Gt3 (~80%) but much lower efficacy for Gt1 (~45%). Genetic determinants of treatment response to interferon α-containing treatment regimens appear to vary from those associated with clearance of acute infection. The DQA1-DQB2 HLA class II region SNP was not found to be associated with therapeutic responsiveness of Gt1 infections (10), whereas loci upstream of IL28B appear to be important (10, 11, 21–23). The allele on rs12979860 appears to be the most significant; the CC haplotype was found to be the strongest pretreatment predictor of response, was associated with more rapid virus clearance kinetics in the first 48 hours of treatment, and occurred in a high proportion of individuals in whom viremia was no longer detectable after only 4 weeks of treatment (24). The role of IL28B SNPs in responsiveness of Gt2 and Gt3 infections to pegylated interferon/ribavirin is controversial; some studies demonstrate supportive data while others have failed to find an association (25).

The overall poor efficacy of pegylated interferon/ribavirin has spurred the development of direct-acting antiviral drugs (DAAs) for the treatment of chronic hepatitis C virus infections. Approval of the first-generation Gt1-specific protease inhibitors boceprevir and telaprevir was greeted with a good deal of optimism given the findings of clinical trials that demonstrated substantially improved efficacy of approximately 70% (26, 27). However, once these drugs were placed into general clinical use, high rates of adverse reactions were observed that limited tolerability and led to premature discontinuation, and enthusiasm for them dampened quickly. With the approval of second-generation DAAs with equivalent (or better) efficacy and apparently improved side-effect profiles, these first-generation agents are no longer recommended for use in U.S. treatment guidelines (http://www.hcvguidelines.org). They figured prominently in European treatment guidelines published in early 2014 (28) but have been dropped in more recent Web-based recommendations (http://www.easl.eu/clinical-practice-guideline).

Newly approved second-generation DAAs include sofosbuvir and simeprevir. Sofosbuvir, an NS5B inhibitor with pan-genotypic activity, is a significant advance in HCV treatment. It is highly effective (response rates of >90% for Gt1, Gt2, and Gt4; 29), can be administered in an oral, interferon-free regimen along with ribavirin for treatment of Gt2 and Gt3, and requires the briefest treatment duration to date for previously untreated patients (12 weeks in combination with pegylated interferon plus ribavirin for Gt1, 12 weeks in combination with ribavirin for Gt2, and 16 weeks in combination with ribavirin for Gt3). It is the first drug approved for use in Gt4 infections. Simeprevir is an NS3/4A (protease) inhibitor with activity against Gt1 and Gt4 that was recently approved for use in combination with pegylated interferon α plus ribavirin in Gt1-infected patients, including treatment-naive individuals and those who have previously failed treatment. Response rates of >80% were observed in treatment-naive individuals (30) and patients who responded to pegylated interferon α plus ribavirin during treatment, but relapse occurred after treatment cessation (31). Treatment duration is reduced by half compared to the standard regimen of pegylated interferon plus ribavirin (24 versus 48 weeks).

Therapy for hepatitis C virus infection continues to evolve. The trend, initiated by sofosbuvir treatment for Gt2 and Gt3, is toward highly potent DAAs that can be dosed orally (interferon-free), once daily, and for short duration (24 weeks or less). Several new combination regimens with these features are notable as they have completed phase III clinical trials and will likely soon be available for clinical use. For Gt1 treatment, response rates of >90% have been observed with therapy as short as 12 weeks for several two-drug regimens and a quadruple-drug regimen (32, 33). The two-drug regimens include simeprevir plus sofosbuvir and NS5a inhibitors plus sofosbuvir (daclatasvir plus sofosbuvir [34] and ledipasvir plus sofosbuvir [35, 36]). This treatment success is particularly remarkable considering the typically low response rates (~40%) of Gt1 infections to standard 48-week pegylated interferon α plus ribavirin regimens. Similar high efficacy was observed with a 24-week treatment course of daclatasvir plus sofosbuvir for Gt2 and Gt3 (34).

Numerous DAAs in the classes of N3/4A protease inhibitors, NS5B polymerase inhibitors (nucleotide and non-nucleotide inhibitors), NS5A replication complex inhibitors, and inhibitors of host cell proteins required for HCV genome replication, such as cyclophilin A, are currently in clinical trials. Given the plethora of agents and drug combinations that are expected to gain approval in the next few years, detailed description is beyond the scope of this chapter, and instead the reader is referred to several excellent reviews (37, 38) and Web-based resources containing the latest recommendations on all aspects of HCV treatment (http://www.hcvguidelines.org, http://www.easl.eu/clinical-practice-guideline).

Treatment for chronic hepatitis C has changed from a “one size fits all” paradigm, in which all patients were treated for 48 weeks with pegylated interferon plus ribavirin, to one of tailored therapy based on genotype and response to treatment as assessed by viral load (termed “response-guided therapy” and used primarily during treatment of Gt1 infections with pegylated interferon/ribavirin and with first-generation DAAs telaprevir and boceprevir). With the advent of highly potent, pan-genotypic DAA combination therapy, the pendulum may eventually swing back to “one size fits all,” resulting in considerably simplified treatment-associated testing. In the interim, diagnostic testing is evolving as new drug regimens are introduced. Change has occurred in the types of tests that are useful and in how they are used. The types of assays that are useful, and their utility during treatment with currently available drugs, are summarized in Table 1 and discussed further in the diagnostic testing sections below.

### COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Serum and plasma are acceptable for HCV NATs and serology tests. Plasma collected in heparin-containing tubes is not acceptable for PCR-based assays since Taq polymerase is inhibited by this anticoagulant. Serum and plasma should be obtained from whole blood as per standard technique, described in chapter 79. Requirements for specimen processing and storage, such as recommended intervals between collection/processing, storage conditions, and freeze-thaw cycles, vary by assay; package inserts should be consulted for specific information. Generally, whole-blood specimens can be transported at 25°C prior to processing. Liver tissue is not typically tested, except for histologic assessment of fibrosis in Gt1-infected individuals.

### DIRECT EXAMINATION

**Microscopy**

By electron microscopy, HCV virions are 55- to 65-nm spheres with 6-nm surface projections. HCV antigens and nucleic acids are detectable in liver sections by immunohistochemistry and in situ hybridization, respectively. However, these methods are insensitive and nonspecific, and therefore HCV detection by microscopy has minimal clinical utility.

In the pre-DAA era, liver fibrosis was usually assessed histologically in Gt1 infections to determine liver disease status to justify the need for therapeutic intervention. Gt1 infections are poorly responsive to pegylated interferon/ribavirin treatment and typically required longer treatment duration. Therefore, therapy for Gt1 infections was usually reserved for patients with advanced fibrosis, in an attempt to prevent cirrhosis. With the availability of highly effective therapy for all HCV genotypes, the rationale for histologic assessment will likely shift from treatment justification to ensuring appropriate management for individuals with bridging fibrosis/cirrhosis such as screening for hepatocellular carcinoma, treatment of cirrhosis-related sequelae, and selection of an appropriate DAA regimen, since infections in these individuals have historically been more difficult to treat (39).

In response to the disadvantages of liver biopsy (its invasive nature, potential complications, and sampling error), noninvasive tests have been developed, including assess-
ment of liver stiffness through ultrasound (transient elastography) and surrogate markers of fibrosis that can be assessed in peripheral blood. Noninvasive tests are useful for detecting advanced fibrosis but are poor at distinguishing intermediate fibrosis stages. Biopsy is therefore preferred if this level of accuracy is necessary. Otherwise, noninvasive tests for the detection of advanced fibrosis/cirrhosis have been advocated in the latest treatment guidelines (http://www.hcvguidelines.org, http://www.easl.eu/_clinical-practice-guideline).

**Antigen Detection**

A core antigen detection/quantification chemiluminescent microparticle immunoassay is marked for use in Europe (Conformité Européenne) (Architect HCV Ag Test, Abbott, Germany) and is available globally. In this test, microparticles coated with anti-core antibodies are used to detect core antigen in pretreated serum or plasma samples. This test is potentially useful in resource-limited settings because of target stability (eliminating the need for sample storage at ultra-low temperatures), simplified instrumentation, and easier technical protocols that reduce labor/transport pressure. The analytical sensitivity ranges from 3 to 13 fmol/liter depending upon genotype (corresponding to approximately 3.0 \(10^{6}\) IU/ml HCV RNA measured by NAT), the assay is linear between 0.5 and 4.0 \(10^{6}\) fmol/liter, and good quantitative correlation with HCV RNA quantification tests has been observed (40–42). For the diagnosis of chronic infection, this test is useful as a surrogate for NAT, to identify seropositive individuals who are viremic (43, 44). However, its inferior performance compared to NAT using seroconversion panels suggests that it is too insensitive for the diagnosis of acute infection (42). This test may be of some use in predicting response to pegylated interferon \(\alpha\)/ribavirin at early times (week 1 and week 2) after treatment initiation (45), but it lacks adequate sensitivity to assess response at end of treatment. It is also unlikely to be of much utility in determining therapeutic response to DAAs, where assays with limits of detection of 10 to 15 HCV RNA IU/ml are required at end of treatment and end of follow-up.

**Nucleic Acid Detection/Quantification Tests**

**Clinical Utility**

**NAT Usage in the Diagnosis of Acute Hepatitis C**

HCV NATs are useful in establishing the diagnosis of acute HCV infection in seronegative individuals because HCV RNA can be detected as early as 1 week after exposure via needlestick or transfusion (46–48) and at least 4 to 6 weeks prior to seroconversion in a number of transmission settings (49). Testing by sensitive qualitative or quantitative NATs (Tables 2 and 3) is recommended (<15 IU/ml in European guidelines, ≤ 50 IU/ml in U.S. guidelines [28, 50]) since viral loads are low and HCV RNA in peripheral blood is intermittently detected early after known exposure (49). Establishing this diagnosis is useful due to the efficacy of therapy. Without therapy, approximately 75% of infected individuals will develop chronic infection and may require future therapy. Sustained response rates of 70 to 80% have been reported when treatment with interferon \(\alpha\) monotherapy is initiated within 12 weeks of acute HCV diagnosis (51, 52). The decision to initiate interferon \(\alpha\) therapy immediately versus waiting to allow for spontaneous clearance is complex; deferral can be considered if factors associated with spontaneous resolution, such as favorable IL28B genotype and symptoms of hepatitis, are present (53, 54). The potential availability of highly efficacious DAAs that require short treatment courses may significantly simplify this decision in the future.

**NAT Usage in the Diagnosis of Chronic Hepatitis C**

Given the asymptomatic nature of most acute HCV infections, the majority of patients will present symptomatically in the chronic phase. The diagnosis of chronic HCV is established with antibody screening tests to document infection and with HCV RNA NAT to demonstrate viral replication. NAT is particularly important in identifying chronic HCV infection in the setting of HIV, where the prevalence of HIV/HCV coinfections is high. Approximately 5% of HIV-1-infected individuals have HCV viremia but no HCV antibodies as detected by second- and third-generation serologic assays; low CD4 cell counts (<200 cells/\(\mu\)l) have been found to be a risk factor (55, 56). NAT should therefore be performed regardless of serology results to accurately diagnose chronic infection in infected patients whose humoral responses may be impaired.

**NAT Usage in the Management of Chronic Hepatitis C Therapy**

NATs continue to be diagnostically important as new DAAs are introduced; however, their roles are changing (summarized in Table 1). HCV genotype and viral load should be determined at baseline. Genotype is used to determine treatment regimen and duration, depending upon the drug. In the pegylated interferon-\(\alpha\)/ribavirin era, genotype was also useful in predicting response to therapy; however, response rates to DAAs are generally uniformly high across genotypes. Three viral load assessments are common to all therapeutic regimens: baseline, end of treatment, and end of follow-up. Baseline testing is critical as it is the starting point in documenting treatment-induced elimination of viremia. End-of-treatment testing is performed to ascertain that adequate clearance of viremia occurred during drug treatment. End-of-follow-up testing is performed months

<sup>b</sup>Manual extraction, automated reaction setup.
after the end of treatment, to assess durability of clearance in the absence of drug. Individuals who have no detectable viremia by NAT at end of follow-up are defined as having achieved sustained virologic response (SVR) and are considered cured (57). Viral load monitoring for SVR was conventionally performed 24 weeks after end of treatment with pegylated interferon α/ribavirin and first-generation DAAs. A follow-up period of 12 weeks has been shown to be comparably predictive of SVR at 24 weeks (58); the attainment of SVR after 12 weeks of follow-up is now incorporated into analysis of all DAA trials and is being used for patient management with all new DAA combinations.

The need for therapeutic monitoring during treatment is regimen-dependent. Less potent therapies requiring long treatment courses are administered under the paradigm of response-guided therapy, in which viral load assessments at various times during treatment are used to differentiate responders from nonresponders and to tailor treatment duration accordingly. In rapid responders, shorter drug courses are effective, while longer courses are required for individuals who clear virus more slowly. Treatment is stopped early in nonresponders, defined as those who fail to meet clearance milestones as defined by each drug regimen. The newest highly potent DAA combinations are used for short courses and are so effective that on-treatment monitoring to assess therapeutic efficacy is largely unnecessary. In the future, it is likely that on-treatment testing will be performed solely to assess compliance and to allow counseling of individuals with residual on-treatment viremia regarding the requirement for adherence to therapy.

NATs that are acceptable for use in management with DAAs are more sensitive than conventional PCR and transcription-mediated amplification (TMA) are available (Table 2; see chapter 4 for description). TMA is more sensitive than conventional RT-PCR. Qualitative NATs are approved for the detection of HCV RNA in seropositive individuals to document chronic infection. None of the available assays is approved for use in assessment of treatment response to DAAs; however, TMA-based tests are adequately sensitive (limit of detection, <15 IU/ml) for use in accurately determining clearance of viremia at end of treatment and SVR at end of follow-up.

Qualitative Tests

Nucleic Acid Preparation for HCV NAT

Nucleic acid extraction is the first step in almost all HCV NATs. Some extraction methodologies are HCV specific while others target total RNA, total nucleic acids, or total viral RNA in clinical samples (Tables 2 and 3). Although semi-automated assays that consist of manual extraction with automated downstream processes are still available, most testing is currently performed with automated commercial test systems that include instrumentation for front-end nucleic acid extraction, reaction setup, and back-end qualitative detection or quantification (Tables 2 and 3). There have been no comprehensive comparisons of these automated extraction platforms using a single HCV NAT to determine extraction efficiencies and overall performance.

Quantitative Tests

A World Health Organization international calibration standard has been available since 1997; HCV RNA is therefore quantified in International Units per milliliter (IU/ml). The 4th International Standard is currently in use. It consists of plasmas from three different Gt1a-infected individuals collected prior to seroconversion that have been pooled and then further diluted in HCV-seronegative/HCV RNA-negative pooled human plasma. It is a biological standard whose concentration was derived by testing at multiple sites with currently approved quantitative HCV NATs (Table 3), plus one additional commercial assay not approved for use in the United States (Versant HCV kPCR v1.0). To permit longitudinal consistency in quantification, the 4th International Standard has been calibrated in parallel with the 2nd and 3rd International Standards and has been assigned a value of 5.4 log_{10} IU/ml.

Most quantitative NAT testing is performed with commercially available tests that have obtained regulatory approval (Table 3); some large reference laboratories use their own proprietary laboratory-developed NATs. Results are reported as IU/ml. The Versant HCV RNA 3.0 is a branched DNA (bDNA)-based microwell plate assay that does not
require nucleic acid extraction. HCV virions are lysed and viral genomes are captured with probes. Genomes are quantified by hybridization using a series of probes that contain iso-C and iso-G oligonucleotides to reduce nonspecific hybridization and increase assay sensitivity. Luminescent signal emission is enhanced through preamplifier and amplifier probe hybridization. Quantification is performed using external calibrators that are included on each plate. The advantages of this assay are its simple genomic isolation procedure, high upper limit of quantification (ULQ), genotype inclusiveness, and reproducibility. The greatest drawback is its lower limit of quantification/limit of detection that is greater than that of real-time RT-PCR assays. This test is insufficiently sensitive for monitoring response to DAA therapy.

HCV RNA quantification can be performed by real-time PCR with commercially available reagents (Table 3) that amplify 5′ UTR sequences but employ slightly different amplicon detection chemistry. The probe in the Abbott RealTime HCV ASR assay is labeled with a 5′ fluorophore and a 3′ quencher. Unhybridized probe is randomly coiled and fails to fluoresce due to fluorophore and quencher proximity. Major fluorescence occurs upon probe hybridization; a minor amount of fluorescence is produced due to cleavage of the 5′ labeled nucleotide by Taq polymerase. Reduced genotype bias is achieved through low-temperature hybridization that permits binding of probes despite probe-target mismatches. Quantification is performed via an internal calibrator. This assay has a limit of detection and measurable range suitable for use with DAAs (59).

In the Cobas AmpliPrep/Cobas TaqMan HCV real-time PCR test, total nucleic acid extraction and reaction setup are performed by the AmpliPrep, and amplification occurs on the TaqMan instrument. Two versions are available. The first test version demonstrated genotype bias, with an inability to detect some Gt4 infections and underquantification of others (60–62). A second, newer version has numerous modifications from sample preparation through target amplification to improve genotype inclusiveness and increase sensitivity while allowing lower sample input volume (650 μl versus 1 ml for version 1.0 [63, 64]). A third real-time PCR test combines viral RNA extraction with manual spin column (High Pure) with TaqMan 2.0 real-time PCR. These assays are calibrated externally by the manufacturer; lot-specific calibration coefficients are used by system software to calculate HCV RNA concentrations. An internal quantitative standard is added prior to extraction to quantitatively correct for potential inhibitors within individual samples. The 2.0 versions have limits of detection and measurable ranges that are suitable for use with DAAs (Table 3).

### ISOLATION PROCEDURES AND IDENTIFICATION

HCV is a fastidious virus that is not recoverable with mammalian cells (primary or transformed) carried in routine or reference clinical virology laboratories. Virus can be propagated in specialty laboratories using systems for recovery of infectious virus after transfecting permissive cells with HCV molecular clones (65–67) or using a newly reported hepatoma cell line (68). These advances are powerful tools for the development of DAAs and vaccines, but they have not been adopted for diagnostic use.

### GENOTYPING

Genotyping of HCV is useful for determining drug treatment regimen (Table 1). Genotype determination is also useful for counseling patients on the likelihood of therapeutic response to pegylated interferon/ribavirin. For highly effective DAAs, the prognostic value of genotyping is likely to be more limited and regimen dependent. For example, SVR rates to sofosbuvir/ribavirin are at least 30% greater for Gt2 than for Gt3; larger differences were observed in cirrhotics and individuals who had failed prior interferon α/ribavirin treatment (29).

Subtyping of Gt1 (determination of Gt1a versus 1b) is important in the DAA era. Response to certain protease inhibitor regimens can be subtype dependent. For example, SVR rates to protease inhibitors are 15% higher for Gt1b than for Gt1a (26, 27, 69). Gt1 subtyping is also important in the selection of certain DAA regimens. Individuals with Gt1a infections can harbor viruses with preexisting mutations that confer resistance to protease inhibitors, specifically the point mutation in NS3 resulting in glutamine-to-lysine change at amino acid 80, or in Q80K, which confers resistance to simprevir. In prescribing information for simprevir, it is recommended that individuals with Gt1a infections be further tested for Q80K to determine suitability for treatment with regimens containing this protease inhibitor.

HCV genotypes and subtypes can be determined by commercially and user-developed NATs based on a variety of biochemical methods (summarized in Tables 4 and 5). Assays based on 5′ UTR sequences are generally acceptable for genotype determination but must be carefully designed for subtyping because of the degree of sequence conservation among different viruses. More accurate subtype determination can be achieved through analysis of NS5b, core, and/or core-E1 genes.

As of this writing, there is one U.S. Food and Drug Administration (FDA)-approved HCV genotyping product available in the United States, the RealTime HCV Genotype II test. This assay employs reverse transcription/real-time PCR using TaqMan chemistry and multiple hydrolysis probes in three different reactions to detect all HCVVs, to identify Gt1-5, and to differentiate Gt1a from Gt1b. The 5′ UTR is used as the target for genotype discrimination, and NS5B sequences are used to for Gt1 subtyping. The test is highly accurate compared to direct sequencing (70). Indeterminate rates of approximately 2% have been reported, with most issues arising from Gt3 determination; an inability to distinguish Gt1 subtypes was observed for approximately 5% of samples (71). Direct (Sanger) sequencing is considered the gold standard in accuracy for HCV genotype and subtype determination. Sequences generated from samples are compared to reference genotype and subtype sequence libraries. Mixed genotype infections can be difficult to detect when the proportion of one genotype greatly exceeds the other. Although it is too laborious for use in clinical laboratories, amplicon cloning may help to detect minority genotype populations (below 10%); however, analysis of large numbers of clones may be required. Sequencing methods require specialized instrumentation and analysis software. These methods are generally labor-intensive, and time to result is usually longer than with other methods.

Reverse hybridization is probably the most common method adopted by clinical laboratories. It is more reliable than direct sequencing for the detection of mixed infections. Low-throughput formats use paper strips; higher-throughput microwell plate and microarray formats have been developed (Table 4).

For tests that have received regulatory approval, laboratories must verify accuracy of test performance in-house. More extensive assay verification is required for laboratory-

Developed tests. From the perspective of accuracy, genotype determination of the more common viruses (Gt1 to Gt3) is fairly straightforward because these samples are readily accessible. Gt4 through Gt6 are more problematic as they are found less commonly. Samples containing HCV are available commercially (Gt1 through Gt3 from ProMedDx, Norton, MA; Gt1 through Gt4 from Acrometrix, Benicia, CA; Gt1 through Gt6 from BocaBiometrics, Coconut Creek, FL, and SeraCare, Milford, MA) for use in preimplementation accuracy studies. One strategy for samples found to putatively contain these less common genotypes is to refer them to a reference laboratory for genotype confirmation.

SEROLOGIC TESTS
The diagnosis of chronic HCV infection is usually established with serology assays. In addition to risk-based testing found in previous hepatitis C screening recommendations, new screening recommendations include one-time serology testing for individuals born between 1945 and 1965 (72), the cohort with the projected highest prevalence of chronic hepatitis C (Table 6). Birth-cohort screening has been recommended because previous recommendations were ineffective in identifying what is thought to be the bulk of chronic infections.

Serologic testing for HCV has undergone considerable evolution. The first serologic assay comprised a single NS4 peptide (c-100-3) and was introduced in 1990 shortly after HCV was identified as a major cause of non-A, non-B hepatitis. This assay represented a significant advance, particularly in identifying contaminated blood products and preventing transfusion-transmitted hepatitis C; however, its flaws of low sensitivity and specificity were soon apparent (sensitivity, ~70%; positive predictive values in low- and

Abbreviations: RFLP, restriction fragment length polymorphism; PSEA, primer-specific extension analysis; PSMEA, primer-specific mispair extension analysis.

high-prevalence populations, 30 to 50% and 70 to 85%, respectively [73]). Increased sensitivity and specificity were achieved in second-generation blood screening tests. These tests (one of which is still marketed) were better able to detect acute infections due to the incorporation of NS3 and core antigens (Table 7 and Fig. 3), two targets of early antibody responses. The reasons for improved performance of third-generation blood screening assays that incorporate NS5 and contain reconfigured NS3 antigen (Fig. 3) are unclear. Improved antigenicity of the alternate NS3 antigen leading to increased detection during early seroconversion has been argued [74]. However, the finding of HCV RNA-positive donors who were consistently reactive by EIA 3.0 but remained unreactive by EIA 2.0 for over 6 months suggests that more complex immunologic factors may be responsible [75].

Using seroconversion panels in which infection has been documented by serology only, the seroconversion window has been documented to decrease from approximately 16 to 10 to 8 weeks with the introduction of first-, second-, and third-generation serology tests, respectively. It is important to note that when infection is documented with NAT, the seroconversion window using second- and third-generation serology screening tests is much longer (Fig. 2) [49, 76]. Table 7 contains information on HCV serology screening and diagnostic tests available in the United States; numerous other assays are also available globally [77].

Despite improvements in performance characteristics, spurious serology results can still be observed. Second-generation assays are still available (Abbott HCV EIA 2.0 [Fig. 3 and Table 7]) and can yield false-negative results due to low sensitivity compared to third-generation assays. Therefore, in the appropriate clinical setting (for example, an individual with sudden-onset hepatitis, or an occupational exposure such as needlestick from an HCV-infected individual), alternative testing (third-generation EIA or NAT) should be considered in a patient with a negative EIA 2.0 result. Alternative testing should also be considered for any negative serology test result if acute hepatitis C is suspected (see “Evaluation, Interpretation, and Reporting of Results/Interpretation of Results in Acute Hepatitis C” below for additional discussion). False-negative results have also been observed in immunocompromised patients (HIV with CD4 <100, chemotherapy-treated oncology patients); therefore, NAT should be performed to definitively exclude infection in these patients [56, 78].

For most antibody screening assays, a positive result is considered initially reactive and repeat testing in duplicate is required. Results are reported as reactive if two or more replicates are positive. One advantage of certain chemiluminescent and microparticle immunoassays (AxSYM Anti-HCV [Abbott]; Architect anti-HCV [Abbott]; VITROS Anti-HCV [Ortho]; Advia Centaur HCV [Siemens]) (Table 7) is that initial positive results can be reported as reactive; repeat testing is not required due to the high sensitivities and specificities of these tests.

HCV serologic tests were originally developed as screening assays, with an emphasis on sensitivity and consequent potential for false-positive results. Early recommendations

(79) therefore advised confirming all positive results by recombinant immunoblot assay (RIBA) before proceeding to NAT to avoid erroneous diagnoses. Confirmation of all reactive screening test results was never widely adopted by clinicians or laboratorians outside the blood-screening arena largely due to the availability of more definitive NATs and the conviction that RIBA did not represent an adequate confirmatory test as it employed the same antigens as antibody screening tests. Subsequent recommendations included a complex algorithm and advised the confirmation of screening results with low signal/cutoff (S/CO) ratios by RIBA, since false positives were most likely to occur in these samples (80). RIBA is no longer being manufactured, and current screening algorithms for chronic HCV (outlined

![Figure 3](https://doi.org/10.1128/9781555817381.ch92.f3)
in Fig. 4) have largely jettisoned the concept of confirmatory testing unless a spurious positive result is suspected in an individual with no risk factors. In these instances, S/CO ratios are still useful as thresholds for confirmatory testing although they are not formally mentioned (see Table 7 for assays available in the United States and Europe; S/CO ratios for other assays are described in reference 81).

**ANTIVIRAL SUSCEPTIBILITY**

To date, there is limited clinical utility of antiviral susceptibility testing in the treatment of chronic hepatitis C. The viral genetic determinants associated with suboptimal response to pegylated interferon/ribavirin were poorly understood and were never directly determined. Protease resistance mutations were readily detectable after treatment with first-generation DAAs; however, testing for mutations was never used in pretreatment to guide drug regimen selection in Gt1-infected patients. The findings of a number of clinical studies of resistance in treatment-naive individuals undergoing therapy with first-generation protease inhibitors plus pegylated interferon α/ribavirin demonstrated that this testing was not clinically useful for the first DAAs. For example, SVR could be achieved in treated individuals with preexisting mutations at baseline (82). Some patients who failed therapy did not have drug-resistant mutations at baseline, even with detection methods as sensitive as next-generation sequencing (83). Not all patients who failed protease inhibitor therapy had resistant virus that dominated in the posttreatment quasi-species; in fact most had wild-type virus (84). Even in those with preexisting mutations who failed triple therapy, other more highly resistant variants emerged de novo (83).

Currently, baseline drug resistance testing for next-generation DAAs is limited to simeprevir, based on phase III clinical trial data demonstrating that Gt1a-infected patients with the point mutation resulting in glutamine-to-lysine change at amino acid 80, or Q80K, had diminished cure rates to simeprevir/pegylated interferon/ribavirin compared to patients without this mutation (31). The prevalence of this mutation varies geographically, appearing in approximately 10% of Gt1as in South America, 20% in Europe, and almost 50% in North America (85). Prescribing information for simeprevir therefore recommends that individuals with Gt1a infections be further tested for Q80K to determine suitability for treatment with regimens containing this protease inhibitor. Detection of the Q80K resistance mutation is performed by direct sequencing and is available through specialty reference laboratories. The need for the development of Q80K detection tests for more general use is questionable given that simeprevir, a drug approved for use with interferon α for the treatment of Gt1 infections only, is likely to have limited appeal and longevity in a marketplace that is shifting toward pan-genotypic, interferon-free drug regimens.

IL28B haplotype testing to detect host genetic markers of interferon refractoriness was important in Gt1-infected individuals before initiating treatment with interferon α-containing regimens, to determine probability of response. Real-time PCR and direct sequencing methods have been described (86–88), and testing is available at large centers and in reference laboratories. The utility of IL28B haplotype determination prior to treatment with next-generation interferon-free combination DAA regimens is unclear. This test may have a limited lifespan.

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

**Interpretation of Results in Acute Hepatitis C**

Establishing the diagnosis of acute hepatitis C can be challenging. Most cases of acute hepatitis C are asymptomatic; therefore, serum aminotransferase elevations can be helpful if present but should not be relied upon as the sole indicator of infection. Additionally, seroconversion can be delayed and viremia can be sporadic. Serology and RNA assessment should therefore both be performed to optimally detect infection. Diagnostic accuracy also requires testing at multiple time points. Single HCV NAT results do not reliably predict exposure outcome. Transient HCV RNA negativity has been documented early postinfection in individuals who become chronically infected, and later, at the time of seroconversion
Transient positive results have been found in those who spontaneously clear virus. Antibody screening has been recommended 4 to 6 months after a known exposure, since the majority of individuals seroconvert by this time. These public health guidelines have not been updated since the accumulation of evidence regarding early treatment efficacy and the increasing adoption of acute HCV treatment into clinical practice. More recent practitioner recommendations advocate serologic (and NAT) testing at multiple time points prior to 6 months because it may provide complementary and confirmatory information that is helpful in shaping the decision to start treatment.

Interpretation of Results in Chronic Hepatitis C

Issues regarding NAT interpretation in chronic hepatitis C include reporting of quantitative data, sources of variability in quantification, interpreting changes in viremia, and using HCV RNA quantification to define therapeutic response.

Interpreting Changes in Viremia

Changes in viremia must be interpreted in the context of assay precision and variability in viremia over time in untreated chronic infection. Using a quantitative assay with excellent precision, viral load was observed to vary up to 10-fold in stable, untreated chronic hepatitis C. During treatment, a viral load change of at least this magnitude must therefore occur in order to be biologically significant.

Using HCV RNA Quantification to Define Therapeutic Response

Determination of response to treatment has evolved over time as more is understood regarding response to a given regimen, as more sensitive tests with broad measurable ranges have become available, and as these newer tests are incorporated into clinical trials of new drugs. Testing during treatment became an essential feature of treatment with pegylated interferon and ribavirin as clinical studies determined that response-guided therapy (successfully shortening treatment in GT1-infected patients who responded rapidly) and futility rules (early treatment discontinuation when certain quantitative milestones were not achieved) were effective in therapeutic management. Phase III clinical trials of first-generation DAAs defined response-guided therapy criteria and futility rules that were unique to each drug. Testing during treatment was therefore an essential management tool as soon as these drugs were approved. In the future, the need for on-treatment testing is likely to be highly variable and drug dependent. For the new, highly potent next-generation DAAs, testing during treatment is becoming less necessary as inhibition of replication and virus elimination are rapid. For example, directions for simeprevir use include stopping rules but not response-guided therapy, and no testing is indicated in sofosbuvir prescribing information. Prescribing information should be consulted to determine the need for testing during treatment with future drug regimens. If on-treatment testing is applicable, the assay used to determine response during clinical trials should be noted, performance should be compared to the laboratory's test of record, and interpretive guidance should be provided if differences exist. Such appraisals are necessary because disparate results can be obtained with tests that vary in performance, which can lead to inappropriate management decisions. Clinical samples with low HCV RNA concentrations near the limits of detection can be particularly problematic since assays that have comparable analyti-

for identification of HCV genotypes 1a, 1b, 2a, 2b, 3a, 3b, 4, 5a, and 6a. J Clin Microbiol 35:201–207.

Acute infectious gastroenteritis is a common illness affecting infants, children, and adults worldwide, resulting in a substantial public health burden with significant morbidity and mortality. Children under 5 years of age, the elderly, and individuals with compromised immune systems are particularly prone to more severe illness. The disease is characterized by inflammation of the stomach and intestines and major symptoms include some combination of diarrhea, vomiting, nausea, and cramping abdominal pain. Many different microorganisms can cause gastroenteritis, including viruses, bacteria, and parasites. However, in developed countries, viruses account for most of the infectious gastroenteritis. The major enteric viruses are genetically and antigenically diverse groups of RNA- and DNA-containing viruses belonging to four separate families, and include rotaviruses, caliciviruses (noroviruses and sapoviruses), astroviruses, and the enteric adenoviruses. Rotaviruses are the most important cause of severe acute gastroenteritis in young children, while noroviruses are the most widely recognized cause of nonbacterial epidemics of gastroenteritis attacking people of all ages. Most disease caused by sapoviruses, astroviruses, and enteric adenoviruses is observed in young children. Other viruses, such as coronavirus, torovirus, Aichi virus, picobirnavirus and bocavirus, have been implicated in human gastroenteritis, but their etiologic role is not well established and these viruses will not be discussed in detail in this chapter.

**TAXONOMY**

**Rotaviruses**

Rotaviruses are classified as members of the *Rotavirus* genus within the family *Reoviridae* (Table 1), which contains 10 other distinct genera. Based on group-specific antigens of the major viral structural protein VP6, rotaviruses are divided into seven groups (A to G) (1). Group-specific epitopes are also found on other structural proteins as well as on some nonstructural proteins. Group A to C rotaviruses infect both humans and animals, with the group A rotaviruses infecting humans most frequently and causing disease mainly in young children. Groups B and C cause infections in swine but have occasionally been associated with foodborne outbreaks of human disease in China (group B) and Japan (group C). Group D to G rotaviruses are mainly animal pathogens. Within each group, rotaviruses are further classified into serotypes based on neutralization assays using antibodies against two major outer capsid proteins, VP4 and VP7. VP4 is a spike protein on the capsid surface which is sensitive to protease cleavage; therefore, the types based on the VP4 protein are also called P types (protease sensitive). VP7 is a glycoprotein and the types based on this protein are also called G types. Both P and G types are also classified as genotypes based on the sequences of the VP4 and VP7 genes. In 2008, a new nucleotide-sequence-based, complete genome classification system was recommended (2, 3) and a Rotavirus Classification Working Group composed of specialists in molecular virology, infectious diseases, epidemiology, and public health was formed to assist in delineation of new genotypes. This system assigns a specific genotype to each of the 11 genome segments of a particular rotavirus strain, and scientists discovering a potentially new rotavirus genotype are invited to send the novel sequence to the Rotavirus Classification Working Group, where the sequence will be analyzed and the new strain will be assigned the complete descriptor of Gx-P[y]-Ix-Rx-Cx-Mx-Ax-Nx-Tx-Ex-Hx. G and P typing are still most commonly used for monitoring rotavirus genetic evolution and vaccine development. To date, 26 G-genotypes and 35 P-genotypes have been reported (4). Genotypes G1P[8], G2P[4], G3P[8], and G4P[8] are most common in North America, and genotypes do vary from one geographic location to another in different parts of the world.

**Caliciviruses**

Caliciviruses belong to the family *Caliciviridae* (Table 1) and are a diverse group of human and animal viruses which includes five classified genera, *Norovirus* (formerly called Norwalk-like viruses), *Sapovirus* (formerly called Sapporo-like viruses), *Nebovirus*, *Lagovirus*, and *Vesivirus* and four newly proposed genera, *Bassovirus*, *Nacovirus*, *Recovirus*, and *Valovirus* (5–7). Caliciviruses within the *Norovirus* and *Sapovirus* genera mainly cause gastroenteritis in humans. Within each genus, strains are further grouped into genogroups (G) and genotypes or clusters. Noroviruses are classified into five genogroups (GI-V), with GI, GII, and GIV found mainly in humans, GII and GIII in pigs and cattle, and GV in mice (8). Based on sequence variations in open reading frame 1 (ORF1) and ORF2, at least 14 genotypes

doi:10.1128/9781555817381.ch93
of GI and 29 genotypes of GII have been reported (9, 10). A single genotype of norovirus (genogroup II, genotype 4, [GI4]) has been found to be the most predominant in the past decade, causing up to 80% of all norovirus gastroenteritis outbreaks (11) in many countries. Norovirus GI4 has demonstrated a much faster evolution than other strains, and new GI4 clusters or variants appear to emerge every 2 to 5 years; the latest variant, called the “Sydney strain,” caused global epidemic outbreaks during 2012 (12–14). Similar to noroviruses, sapoviruses are grouped into 14 genotypes within five genogroups (15, 16). Genogroups GI, GII, GIV, and GV contain human strains of sapovirus and GII contains the porcine strains (15).

### Enteric Adenoviruses

Human adenoviruses (HAdVs) are members of the family Adenoviridae (Table 1) and are divided into seven species (A to G). The different species have different tissue tropisms and propensity for causing different clinical syndromes; species F is the group most closely associated with gastroenteritis. Recently, the Human Adenovirus Working Group has proposed using whole-genome sequence analyses to characterize and name adenoviruses (16) instead of “serotype” to rectify the misclassification of human adenoviruses previously characterized by the serological methods of serum neutralization and hemagglutination inhibition that target two small conservative regions on the hexon gene (17, 18). There are now 68 types of HAdVs based on serological assays, whole-genome sequencing, and phylogenomics (17–19). Many AdVs are readily isolated from human stools, but their role in the etiology of acute gastroenteritis is unclear. There are two types, however, AdV40 and AdV41 in species F, which are definitively associated with infantile diarrhea and are referred to as enteric adenoviruses (EAdVs). These EAdVs are also known as “fastidious adenoviruses” because they are difficult to grow in cell culture. More recently, other HAdV types, namely HAdV-52 belonging to species F and HAdV-67 belonging to species D, have been implicated as potentially causing gastroenteritis (19, 20).

### Astroviruses

Astroviruses belong to the Astroviridae family (Table 1) and are so named because of their characteristic star-like surface structure. Two genera of astroviruses, Mamastrovirus and Avastrovirus, have been described according to their host species; the first group infects mammals and the latter group infects birds (21). Within each genus, there are multiple species of astroviruses named after the hosts in which they replicate. Human astroviruses have been divided into eight types based on antigenic and genetic typing (22). Type 1 appears to be most common, but all eight types have been detected throughout the world.

### Other Viruses Causing Gastroenteritis

Other enteric viruses that have been implicated in acute gastroenteritis of humans include coronaviruses and toroviruses, two genera in the Coronavirus family (23), Aichi virus in the genus Kobuvirus of the Picornaviridae family (24), picobirnaviruses in the Picobirnaviridae family (25), and human bocavirus (HBoV) in the genus Bocavirus within the Parvoviridae family (26). A detailed discussion of these viruses is beyond the scope of this chapter.

### DESCRIPTION OF THE AGENTS

#### Rotaviruses

Rotaviruses are nonenveloped and are among the few human viruses that possess a segmented, double-stranded RNA genome (Table 1). Mature viral particles are approximately 70 nm in diameter with a wheel-like appearance ("rota" = wheel in Latin) and possess a triple-layered icosahedral protein capsid composed of an outer layer, an intermediate layer, and an inner core (Fig. 1). The double-stranded RNA genome contains 11 segments ranging in size from ∼3,300 (segment 1) to ∼660 (segment 11) base pairs (bp) and each segment codes for a single gene product. The gene coding assignments of the 11 genome segments has been determined; these segments encode six major structural proteins (VP1, VP2, VP3, VP4, VP6, and VP7) that appear on the mature viral particles and six nonstructural proteins (NSP1-NSP6) that are expressed in infected cells and play important roles in viral genome replication, protein synthesis, capsid assembly, and maturation. The outermost layer of the nucleocapsid contains VP4 and VP7, the middle layer is composed of VP6, and the innermost core is composed of VP2 and contains a polymerase complex composed of VP1 and VP3. One of the nonstructural proteins, NSP4, is considered to be a viral enterotoxin (27). Similar to influenza viruses, having a segmented genome allows for genetic reassortment of rotavirus strains, resulting in the possible formation of new virus types.

#### Caliciviruses

Caliciviruses are small (30–38 nm), round, nonenveloped viruses possessing a single-stranded, positive-sense RNA ge-
Gastroenteritis Viruses

name (Table 1). Sapoviruses have the typical morphology of caliciviruses with the “star of David” appearance with cup-shaped depressions (calyx = cup in Latin) on the surface of the virus (Fig. 1). Noroviruses possess a smoother surface structure and therefore also have been called “small round structured viruses” (28). Cryo-electron microscopy (EM) and X-ray crystallography analysis of recombinant viral-like particles (VLPs) have revealed that noroviruses possess a T = 3 icosahedral capsid composed of 180 proteins that form 90 dimeric capsomers. Each capsid protein possesses two major domains, the shell (S) and the protrusion (P) domains. Expression of the P domain in Escherichia coli has resulted in self-formation of a subviral particle, the P particle, which maintains the VLP’s properties of receptor binding and antigenic recognition (29). This P particle is highly stable and easy to make and has been proposed as a potential subunit vaccine for noroviruses.

The RNA genome of noroviruses is poly(A) tailed and is ~7.5 kb in length (30). It is organized into three open reading frames (ORFs), with ORF1 encoding the nonstructural proteins, ORF2 the VP1 capsid protein, and ORF3 a minor structural protein. The sapovirus genome is slightly different in that sequences encoding the nonstructural and capsid proteins are fused into one large ORF.

Enteric Adenoviruses

AdVs were named from the Greek word aden, meaning “gland,” after their original isolation from adenoid tissue and were also called “adenoid-associated viruses.” HAdVs have been linked to a number of diseases, including respiratory illness, conjunctivitis, and diarrhea (31). AdVs are nonenveloped, icosahedral particles that are 70 to 100 nm in diameter (Table 1). Mature virions consist of a DNA-containing core surrounded by a capsid composed of hexon, penton, and fiber proteins (Fig. 1). The genome is a linear, nonsegmented, double-stranded DNA of 30 to 38 kb which varies in size from group to group. The capsid is composed of 252 capsomeres, of which 240 are hexons and 12 are pentons. There are a total of 11 viral structural proteins, of which the hexons, penton bases, and fibers are of important clinical relevance. These proteins are involved in viral entry (fiber) and intracellular transportation. The fiber proteins extend from the surface of the capsid and interact with primary cellular receptors, which for the majority of AdVs, including the EAAdVs, is the coxsackievirus B-adenovirus receptor, a transmembrane protein belonging to the immunoglobulin family. The hexon and fiber proteins also contain the major neutralization epitopes.

Astroviruses

Astroviruses are small (28 to 30 nm in diameter), round, and nonenveloped viruses with a typical five- or six-pointed star-like appearance (astron = star in Greek) (Fig. 1). As determined by X-ray crystallography and computer modeling, the virus has some structural resemblance to the caliciviruses, but even more strongly resembles the hepatitis E virus. The virions contain a single-stranded, positive-sense RNA genome of about 6.8 kb in length (Table 1). The viral genome contains three ORFs, with ORF1a and ORF1b encoding the nonstructural proteins. ORF1a has a protease motif, transmembrane helices, nuclear localization signals, and a ribosomal frameshifting signal, whereas ORF1b has an RNA polymerase motif. ORF2 encodes the capsid precursor protein, which is approximately 87 kDa in size and is further cleaved to smaller peptides of 25 to 34 kDa to form mature virions.

EPIDEMIOLOGY AND TRANSMISSION

Viral gastroenteritis occurs in all age groups and socioeconomic classes and in all parts of the world. Important epidemiological features include age, season of the year, duration of symptoms, severity of disease, and exposure and vaccination history (Tables 2 and 3). Severe illness is seen most commonly in children younger than 5 years of age, with the peak incidence observed in children between the ages
of 6 months and 2 years. Viruses account for 50 to 90% of acute gastroenteritis requiring hospitalization and 3 to 10% of all pediatric hospital days in this age group. Sporadic illness and outbreaks in healthy adults, elderly populations, and immunosuppressed patients have been described.

Gastroenteritis viruses are transmitted by the fecal-oral route through close contact with infected persons or indirectly by contact with contaminated fomites (e.g., shared eating utensils, environmental surfaces, toys in playrooms). Transmission is highly efficient because of the physical hardness of gastrointestinal viruses, the high amounts of virus particles concentrated and shed in stools, the small infectious dose required, and resistance of these viruses to various environmental conditions (32). Enteric viruses are stable over wide pH and temperature ranges and even after drying, heating, or freezing, and they are able to survive on human hands and inanimate objects for extended times. Certain enteric viruses, particularly rotavirus and norovirus, are readily transmitted directly by contact with contaminated fomites (e.g., shared eating utensils, environmental surfaces, toys in playrooms), and indirect transmission of rotaviruses has been demonstrated, indicating a potential for zoonotic disease between animals and humans (33).

Rotaviruses are the leading cause of severe dehydrating diarrhea in infants and children less than 2 years of age and are a major cause of childhood deaths in developing countries. The mortality caused by rotavirus infection is much lower in developed countries, but in the prevaccine era, the disease burden was high, representing approximately 2.7 million diarrheal episodes each year in the United States, with significant numbers of physician visits and hospitalizations and substantial medical and societal costs. Infants usually acquire the disease from their siblings or from their parents, who may have subclinical infection. Shedding of rotavirus in stools can occur prior to onset of illness. Enteric viruses are also thought to be transmitted through respiratory secretions, but this has not been fully proven. Most viral diarrheal diseases are endemic, with significant disease burden in both developing and developed countries. Caliciviruses, especially the noroviruses, also cause epidemics of acute gastroenteritis, which is an important public health concern. In countries with temperate climates, viral gastroenteritis does not have the typical summer peak of most bacterium- and parasite-caused gastroenteritis. Instead, viral gastroenteritis is more common in colder seasons, with a typical winter-spring peak. Hospital-associated spread of the enteric viruses, particularly for rotavirus and norovirus, is common without the implementation of appropriate infection prevention and control measures.

Caliciviruses

Noroviruses are highly contagious and have been recognized as the most important cause of nonbacterial acute gastroenteritis in both developing and developed countries (34). Both common-source outbreaks and sporadic disease can occur. The disease is endemic in children, but all ages can be infected due to potential incomplete protective immunity following a childhood infection or reinfection with antigenically different strains. Noroviruses are now recognized as the leading cause of acute gastroenteritis in children in the United States since the number of cases of acute gastroenteritis associated with rotavirus has declined due to introduction of the rotavirus vaccines (35). Noroviruses commonly cause large outbreaks in closed communities and in a variety of settings, such as hospitals, child care centers, schools, restaurants, nursing homes for the elderly, cruise ships, and military communities or camps. Particular attention has been paid to foodborne outbreaks occurring in nursing homes for the elderly and on cruise ships in the United States and European countries. Chronic diarrhea, increased mortality, and prolonged fecal shedding of noroviruses is often seen in immunocompromised hosts. In recent years, noroviruses have been reported to recognize the ABH (secretor) and Lewis histo-blood group antigens as receptors (36), and susceptibility of individuals to norovirus infection is based on the expression of these antigens on the gut epithelium; persons devoid of H type 1 epitopes are resistant to infection with noroviruses. Direct evidence of zoonotic transmission of noroviruses remains absent, although noroviruses closely related to human strains have been detected in domestic and wild animals.

Sapoviruses cause disease mainly in children, and sporadic cases and outbreaks in daycare centers and institutional settings have been reported. However, these viruses were recently found to be very common in adult gastroenteritis outbreaks in North American and Europe (37–39).

Enteric Adenoviruses

While the role of EAdVs in acute gastroenteritis is widely accepted, the incidences of AdV-related gastroenteritis differ considerably in various studies and locations, with an average of ~5% of cases of pediatric diarrhea being caused by EAdVs. Outbreaks of EAdV-associated diarrhea have been reported in hospitals and child day care centers. Human EAdV infection does not have the typical winter seasonality of the rotaviruses and caliciviruses, and sporadic cases are reported year round. Like other enteric pathogens, human EAdVs are frequently detected in stools of children without gastroenteritis. As many as 41% of children acquire EAdV infection during hospitalization for other diseases (40). EAdVs also cause prolonged or chronic diarrhea in immunocompromised patients, especially in hematopoietic stem cell transplant recipients, which is an increasing concern in the clinical care of these patients (41, 42).

Astroviruses

Human astroviruses cause mainly pediatric gastroenteritis. Cases in caregivers of sick children, immunocompromised adults (43), military troops (44), and nursing homes (45) have been reported. Astrovirus infection can be linked to 2 to 10% of cases of pediatric gastroenteritis worldwide, depending on settings and diagnostic tests used. Asymptomatic infections are common in all ages. There is a 70 to 90% seroprevalence of astroviruses among school-aged children, indicating frequent infections during childhood.

Clinical Significance

Acute viral gastroenteritis is characterized by a variety of symptoms and signs, including fever, diarrhea, vomiting, abdominal cramps, irritability, lethargy, and dehydration, with rotavirus gastroenteritis considered to be the most severe. Although symptoms of gastroenteritis due to noroviruses, sapoviruses, astroviruses, and the enteric adenoviruses are considered to be milder that those of the rotaviruses, increasing data show that noroviruses are frequently detected in hospitalized children and emergency room visitors with acute gastroenteritis, indicating that noroviruses may also cause severe gastroenteritis (35). Headache, anorexia, malaise, myalgia, and nausea may also be observed. Clinical illness is similar for all gastrointestinal viruses, making it difficult, if not impossible, to distinguish which virus is causing the disease based on symptoms alone. The clinical presentation can vary widely and symptoms can appear alone or together and can mimic noninfectious conditions. In general, with the exception of adenoviruses, viral gastroenteritis has a sudden onset following a short incubation period of 1 to 2 days (Table 3). The duration of symptoms is normally less than 7 days, and virus shedding in stools of infected individuals is approximately 1 to 2 weeks in most cases but may last longer depending on the virus and host. The stools are usually watery or loose with no mucus or blood, and fecal leukocytes are typically absent or present only in minimal numbers. Viral gastroenteritis is normally self-limited in well-nourished, immunocompetent individuals, and asymptomatic infections or mild disease are common. Severe illness can be seen among infants, younger children, the elderly, and immunocompromised individuals who are unable to effectively rehydrate following loss of fluids due to vomiting and diarrhea, and can result in significant morbidity and hospitalizations. For rotaviruses, severe dehydration can be lethal and remains an important cause of infant mortality in developing countries.

Rotaviruses can cause chronic infection in immunocompromised individuals, such as patients who have undergone organ transplantation and those infected with human immunodeficiency virus (HIV), and in rare cases, the viruses can disseminate systemically and involve other organ systems. Norovirus illness can also become debilitating and life-threatening in immunocompromised patients (46). Increased numbers of studies have shown that noroviruses are among the pathogens associated with immunocompromised hosts, causing up to 18% of chronic diarrhea, with prolonged viral shedding in the stools of recipients who underwent allogeneic hematopoietic stem-cell and solid organ transplantations (47). Noroviruses also can cause necrotizing enterocolitis in children (48, 49). Enteric adenovirus infections in immunodeficient individuals, such as hematopoietic stem-cell and solid organ transplant recipients, HIV patients, and other individuals with immunosuppressive therapy, are also of growing clinical importance (41). AdV infection in these individuals can lead to mild gastroenteritis, asymptomatic infection, or severe disease, including gastroenteritis, pneumonitis, hemorrhagic cystitis, hepatitis, and disseminated infection associated with high mortality. Patients can excrete AdVs in stool for weeks to months after infection. Potential treatment of AdV infection in such clinical settings includes reduction of immunosuppressive drugs, intravenous immunoglobulin, and intravenous antiviral therapy with cidofovir (50).

There are no effective antivirals that can be used for the treatment or prevention of infection and disease caused by gastroenteritis viruses. Treatment involves supportive care
and rehydration therapy; restoration of electrolyte balance is the most important procedure for severely dehydrated cases and for reducing the mortality in developing countries.

The lack of antiviral drugs against rotaviruses and the significant disease burden of rotavirus gastroenteritis were the main driving forces behind the development of rotavirus vaccines. After decades of research and the failure of some earlier vaccine products, two live attenuated rotavirus vaccines were licensed for use in the United States and are now being used worldwide; the pentavalent bovine-human reassortant vaccine containing G1P[8] and F[8] types (Rotarix; GlaxoSmithKline, Inc.) was licensed in 2006 and the monovalent attenuated human G1P[8] vaccine (RotaTeq; Merck & Co., Inc.) was licensed in 2008. Both vaccines have been shown to be effective and safe in children, providing 80 to 100% protection against severe disease and 70 to 80% protection against rotavirus gastroenteritis of any severity in high- and middle-income countries. A relatively low protection with the two current vaccines against rotavirus gastroenteritis was observed in low-income countries. A major reason for the decreased efficacy of the vaccines was due to high prevalence of heterotypic strains circulating in these countries (51). Both vaccines were not associated with intussusception in large trials prior to its licensure (52). The Advisory Committee on Immunization Practices (ACIP) recently updated its recommendations for rotavirus vaccination to include the use of Rotarix and RotaTeq for prevention of rotavirus gastroenteritis (53). However, it was reported in very recent postlicensure studies that both Rotarix and RotaTeq vaccines had increased rates of intussusception after vaccination in U.S. populations, suggesting that the potential risks and benefits of these vaccines should be considered (54, 55).

Since noroviruses cause the great majority of epidemics of viral gastroenteritis, development of vaccines and antivirals against noroviruses is needed. Approaches to develop a norovirus vaccine include transgenic plant-, baculovirus-, or E. coli-expressed recombinant VLPs or P particles as a subunit vaccine. Challenges in development of the vaccines above are the lack of understanding of herd immunity after infection, particularly the mechanism of the short duration of protective immunity following a natural infection, and the lack of a cell culture and suitable animal model for efficacy studies. The high genetic and antigenic diversity of noroviruses also makes it difficult to select vaccine targets for broad protection. A randomized, double-blinded, and placebo-controlled multicenter clinical trial of norovirus genotype GI.1 VLP vaccine was recently reported. In this trial, immunization with the GI.1 VLP vaccine significantly reduced the frequencies of norovirus gastroenteritis (56). Although the GI genotype is not the major epidemic genotype of norovirus-associated gastroenteritis around the world, this trial shed light on the potential of vaccination against norovirus infection using this unique approach.

At present, preventive and control strategies for gastrointestinal virus infections are aimed at identifying and eliminating the source of infection by promoting standard and contact precautions and good personal hygienic practices (e.g., careful and thorough hand washing with soap and water), performing proper disinfection of environmental surfaces, and identifying and avoiding sick contacts and other potential sources of infection and spread. Certain gastrointestinal viruses (e.g., noroviruses) may be resistant to some common disinfectants and cleaning solutions; sodium hypochlorite is most effective at inactivation of the enteric viruses.

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

Gastroenteritis viruses replicate and cause disease mainly in the intestine, and stool is the foremost specimen of choice for laboratory diagnosis. It is preferable to collect specimens within the first 48 hours of illness since viral shedding is at its maximum at this time and increases the likelihood of virus detection. Specimens collected later in the course of disease have a lower detection rate, although prolonged shedding of some gastroenteritis viruses has been reported after the onset of illness. Stool specimens of a few grams are sufficient for detection by EM and antigen or nucleic acid detection methods. The samples can be collected with a bed pan and then transferred into smaller containers or test tubes. Specimens can be recovered from a diaper with a wooden tongue depressor which is then placed in an appropriate container for transport to the laboratory. Rectal swabs may be easy to obtain, but they are poor specimens for viral diagnosis and are not recommended. If it is necessary to collect a rectal swab, a sufficient quantity of fecal material (at least a pea-sized amount) should be obtained. If fecal material is not clearly visible on the swab, the specimen is most likely inadequate. Rectal swabs should be immediately placed in a suitable viral transport medium. Vomitus material can be used for the detection of gastrointestinal viruses as a supplement to stool specimens, but is not routinely recommended for diagnostic testing. Additional details of specimen collection and processing are given in chapter 79.

In general, the best results are obtained by testing fresh stool samples, particularly when viewing viral size and morphology by EM. Stool samples should be stored at 4°C immediately after collection and promptly transported to the laboratory for processing. Single-use aliquots of processed specimens should be placed in multiple cryovials for testing and storage, particularly if multiple tests are planned for different types of pathogens or for confirmation of results. By processing in this manner, specimens are not frozen and thawed repeatedly and are never returned to the original specimen cryovial, thereby avoiding possible degradation of viral particles, proteins, and/or nucleic acids and decreased detection rates and cross-contamination of specimens, respectively. If not tested immediately, specimens should be promptly frozen and stored at −70°C. Stool samples can be shipped on wet or dry ice, depending on their storage conditions (e.g., short- or long-term storage). Unnecessary freezing and thawing between shipment and storage should be avoided.

Serum samples can be used for detection of IgG antibodies against the gastroenteritis viruses. Documenting seroconversion between acute- and convalescent-phase serum samples has been particularly useful for screening for viral infection in outbreak investigations. However, such testing is performed mainly in research laboratories and is not suitable for clinical diagnosis of acute infection since the results are obtained retrospectively and are not always predictive of active disease. The acute-phase serum sample should be collected as soon as possible after onset of illness and tested simultaneously with the convalescent-phase serum sample. Processed serum specimens may be stored at 2 to 8°C for several days pending completion of testing or can be stored frozen at −20°C or colder for prolonged storage. Repeated freezing and thawing should be avoided and specimens should not be stored in frost-free freezers.

Drinking water, foods, other beverages, or other environmental specimens are normally collected and used to investigate outbreaks of viral gastroenteritis, mainly those caused
by noroviruses. If a food item or water is suspected as the source of an outbreak, samples should be obtained as early as possible in the outbreak and stored under appropriate conditions as described above, depending on when the testing will be performed. Since testing of these specimen types is not routinely performed in clinical laboratories and often requires special handling and processing (e.g., filter concentration of 5 to 100 liters of water and processing of food to remove food debris), a laboratory with the capability to test these specimens should be contacted (e.g., a local or regional health department or the Centers for Disease Control and Prevention in Atlanta, GA).

DIRECT DETECTION

Electron Microscopy

EM has been successfully used for the rapid examination of stool samples for the simultaneous detection and identification of viral agents of gastroenteritis based on characteristic size and shape of intact viral particles when visualized by negative staining on a support grid. It offers the main advantages of speed and simplicity, but is limited by the availability and high cost of the instrument, the requirement for specialized facilities and expertise, and a moderate to low sensitivity and specificity. To be detected by EM, gastrointestinal viruses must be present in high concentrations, usually 10⁵ to 10⁹ viral particles/ml of processed stool. Liquid stool samples can be applied to the grid after clarification by low-speed centrifugation at 2,000 × g for 10 min. For a solid stool sample, a 10 to 20% suspension can be prepared first using either distilled water or a 1% ammonium acetate solution. One drop (5 to 10 μl) of the preparation is added directly to a 300- to 400-mesh copper support grid, or a sample drop can be placed on a piece of Parafilm and the grid is then floated on the top of the drop. After incubation for approximately 1 min, excess specimen is drawn off the surface of the grid with absorbent filter paper. A longer incubation may be used to facilitate the capture of more virus particles, but the sample should not be allowed to completely dry to the surface of the grid. If the resulting stool suspension is too thick and difficult to examine by EM, the sample may require further dilution. The grid is then stained with a drop of 2% phosphotungstic acid (pH 7.0) for 10 to 30 s and then blotted with an absorbent filter paper. The dried grid is then ready for EM examination.

Under EM, negatively stained virus particles appear as lighter structures surrounded by a dark background (Fig. 1) (57). The most definitive of the viral particles are the adenoviruses and rotaviruses, whose icosahedral capsids are readily discerned. Each of the smaller round viruses, including the noroviruses, sapoviruses, and astroviruses, has its unique surface appearance: sapoviruses have a rigid surface structure with cup-like depressions of a typical “star of David” appearance with a dark center to the star shape; noroviruses have a less rigid surface appearance, lacking of the star of David structure; and astroviruses possess a distinct five- to six-point star appearance (Fig. 1). Other viral particles of different shapes and sizes and particles lacking well-defined features are also commonly seen and can pose a diagnostic dilemma. Bacteriophages in stool specimens may also be confused with small gastroenteritis viruses, especially if their tails are absent. Thus, a confident diagnosis relies on repeated observations of viral particles of identical morphology and size in multiple EM fields on the surface of the support grid.

For stool specimens containing low amounts of virus, a concentration step using ultracentrifugation or agar diffusion may be required. High-speed centrifugation at 100,000 × g for 1 h is used to pellet most of the viral particles. Following the centrifugation, the pellet is resuspended in distilled water and processed for making the grids as outlined above. A Beckman Airfuge with an EM-90 rotor is useful to deposit the viral particles onto support grids when using small-volume specimens. For agar diffusion, a drop of prepared stool suspension is placed on a small block of 1% agar prepared in distilled water and the grid is floated on the surface of the drop. The support grid is not removed until the drop is completely absorbed into the agar; it is then processed for EM as described above. This procedure not only concentrates the virus particles but also removes excessive quantities of salts that may precipitate on the grid and obscure visualization of the viruses.

Immunoelectron microscopy (IEM) has played an important role in the discovery of a number of gastroenteritis viruses, including the prototype strain of norovirus (57, 58). The principle of the technique is to allow viral particles to form aggregates when stool suspensions are mixed with virus-specific antibodies. These aggregates are much easier to identify by EM than single particles alone. A solid-phase IEM can be used to reduce the background when reading the prepared specimen grid by capturing the viral particles using virus-specific antibodies precoated to the surface of the grid (59).

In general, EM has been largely replaced by alternative methods for the diagnosis of gastroenteritis viruses and is seldom available in diagnostic laboratories in the United States.

Antigen Detection Assays

Immunologic assays have been used for the direct detection of gastrointestinal viruses in processed stool samples and commercial kits are available for some of the viruses (Table 4). Common formats of antigen-detection assays include conventional 96-well microplate enzyme immunoassays (EIA), latex agglutination tests, and rapid membrane-based immunochromatographic assays. These antigen assays are rapid, inexpensive, and simple to perform and are highly suitable for use by most, if not all, clinical laboratories. Stool suspensions of 10 to 20% are normally prepared in phosphate-buffered saline (pH 7.4) or sodium carbonate buffer (pH 9.5) for use in the tests. Overall, the number of commercially available antigen-detection assays is limited, and tests remain unavailable for some of the enteric viruses because of the lack of specific antibodies used to capture and detect appropriately conserved viral antigens. In addition, even the performance of existing assays needs to be vastly improved for better sensitivity and specificity. Because of the high degree of genetic and antigenic diversity of enteric viruses, the sensitivity of many antigen-detection assays is relatively low to moderate, although still higher than the sensitivity of EM. Monoclonal or hyperimmune antibodies against specific viral capsid proteins, such as the VP6 protein of rotaviruses and the capsid protein or the P domain of the capsid protein of noroviruses, have been used in the development of these antigen-detection tests. Due to the lack of a cell culture for human noroviruses, recombinant viral capsid proteins expressed in an in vitro system have been used as the source of reagents for assay development.

The more recently developed membrane-based immunochromatographic assays are valuable for small- to moderate-sized laboratories with a demand for diagnosis of sporadic viral gastroenteritis (60). These immunochromatographic kits are designed as dipsticks or self-contained cassettes and usually include built-in positive controls to ensure that the

*CE, Conformité Européenne.

The tests require minimal equipment and the results can be readily visualized. Because of their speed, simplicity, and low cost, immunochromatographic kits are amenable for point-of-care testing. In general, the immunochromatographic assays have a slightly lower sensitivity and specificity than the more conventional EIA-based 96-well microplate systems for detection of rotavirus and norovirus (61–63).

The latex agglutination tests use latex beads coated with virus-specific antibodies and are based on the agglutination of these beads when virus particles or viral antigens present in the specimens bind to the antibody-coated beads. Since some fecal specimens can cause nonspecific agglutination, latex particles coated with nonviral antibodies are also included in the kits. Particulate matter found in some prepared stool suspensions may interfere with the correct reading of the agglutination, and the stools are normally clarified by low-speed centrifugation before the supernatants are mixed with the latex reagent. A positive reaction is indicated by visible clumping (agglutination) occurring within minutes of performing the test. The assays are generally less sensitive than EIAs and immunochromatographic assays but are most useful in small- to moderate-sized diagnostic laboratories (61).

Conventional 96-well microplate EIAs for rotaviruses and AdVs have been on the market for years and are still widely used due to their reasonably high sensitivity and specificity and consistent test results. Immunochromatographic tests for rotaviruses and AdVs were introduced later and have been readily adopted for diagnostic use. In a cross-comparison of seven commercially available immunochromatographic assays with an EIA for the detection of group A rotaviruses in fecal samples, the results of six immunochromatographic assays were shown to be comparable with those of the EIA, and only one immunochromatographic assay had a significantly lower positive detection rate (62).
Immunochromatographic tests for the detection of multiple pathogens, such as both rotaviruses and AdVs, have also been developed. Direct-comparison studies have shown that these assays have the sensitivity and specificity comparable to those of the more traditional EIAs and are useful for rapid diagnosis in ambulatory practice (64, 65). Of note, most commercially available AdV antigen-detection assays are not specific for the EAdV types 40 and 41 with the exception of the Premier Adenoclone-Types 40/41 EIA from Meridian Bioscience (Cincinnati, OH).

Although a number of antigen-detection tests are now being developed and commercialized for noroviruses and astroviruses, most of these assays are only CE marked in the United States. Only a single norovirus assay (RIDASCREEN Norovirus 3rd Generation EIA) from R-Biopharm AG (Darmstadt, Germany) has been licensed by the U.S. Food and Drug Administration for preliminary identification of norovirus when testing multiple specimens during outbreaks. Due to their limited sensitivity and specificity, currently available norovirus antigen assays are used mainly for research and are not recommended for routine clinical diagnosis of individual cases of sporadic disease (66, 67). Several studies on evaluation of commercial EIA and immunochromatographic kits for detection of norovirus antigens showed much lower sensitivity compared to results obtained using reverse transcription-PCR (RT-PCR), resulting in the detection of significantly lower numbers of GI and GII viruses (66-68).

Molecular Detection Assays

Diagnosis of viral gastroenteritis based on the identification of viral genomes includes direct detection of viral RNA or DNA by electrophoresis, amplification of viral DNA or RNA by PCR or RT-PCR, and DNA sequencing. Such molecular methods are extremely sensitive and play an increasingly important role in the rapid and accurate detection of the enteric viruses (69). Nucleic acid amplification tests like PCR are now the method of choice for the detection of viruses causing gastroenteritis, and a growing literature now exists to demonstrate the overall utility of these assays.

Direct Staining of Nucleic Acid following Electrophoresis

The segmented, double-stranded RNA genome of rotaviruses has traditionally been the target for direct detection and genotyping using electrophoretic methods (70). The viral RNA is extracted from stool specimens and then subjected to separation by polyacrylamide gel electrophoresis followed by silver staining for detection. This technique has been available for many years and is used primarily in research laboratories; the method is as sensitive as EM. It also has been applied to the classification of rotaviruses, in which the appearance of an unusual electropherotype may denote a novel strain or group of rotaviruses. Schematic diagrams of electropherotypes of group A to G rotaviruses have been compiled as a reference. Direct detection and genotyping of viral DNA using this technique has also been applied to the diagnosis of human EAdVs following digestion of the adenoviral genomic DNA with restriction enzymes.

PCR and RT-PCR

Extraction of Nucleic Acids for PCR or RT-PCR

One of the major challenges of viral detection in stool specimens by PCR or RT-PCR is the presence of inhibitors in the samples, which could lead to false-negative results. Such inhibitors can be monitored by adding an internal control to the sample during the nucleic acid extraction and purification process. Approaches to reduce inhibition include dilution of stools and/or extracted nucleic acids; treatment of samples with chelating agents, detergents, or denaturing chemicals during RNA extraction (71); and inclusion of amplification facilitators such as bovine serum albumin and betaines during the PCR (72). Most commercial nucleic acid extraction protocols now use silica- or magnetic bead-based extraction technologies that are simple and efficient and provide appropriate amounts of nucleic acids of high quality that are essentially free of contamination with cellular proteins, carbohydrates, and lipids that may act to inhibit or interfere with downstream amplification.

Nucleic acids extracted from stool specimens usually contain large amounts of nonviral nucleic acids from different microorganisms and host cells that may be nonspecifically amplified by virus-specific primers. These nonspecific PCR products cannot be completely eliminated even under the high stringency conditions of the reaction. In this case, hybridization with virus-specific probes is usually required as part of the PCR process to confirm the results.

Conventional PCR

Conventional PCR (cPCR or cRT-PCR) refers to the more traditional amplification process in which amplified product is allowed to accumulate and plateau as the thermal cycling goes to completion or end-point before the detection or analysis steps are performed. This type of PCR normally relies on the detection of amplified PCR products by size fractionation using agarose or polyacrylamide gel electrophoresis. By using type-specific primers, cPCR has been widely used to determine the molecular epidemiology of viral gastroenteritis. For example, cRT-PCR is used for genotyping of group A rotaviruses using primers specific to the gene regions that code for the two major viral surface neutralization proteins VP7 (G types) and VP4 (P types) (73). cPCR followed by sequencing of the PCR products also has been commonly used for studies of the molecular epidemiology of noroviruses, the assessment of genetic variation among the various norovirus strains, and the investigation of outbreaks of gastrointestinal disease (8). The major disadvantages of cPCR include the requirement for multiple complex, labor-intensive, and time-consuming steps; low throughput and high variability; and the significant risk of contamination due to the open system and manipulations of amplified products. While cPCR is still commonly used in many research laboratories that study enteric viruses, it does not have wide applicability in diagnostic laboratories.

Real-time PCR

Currently, real-time PCR is the most common approach for establishing a diagnosis of viral gastroenteritis and, to this end, a number of assays have been developed and implemented by individual laboratories for the detection of the major enteric viruses (Table 5). Simply put, real-time PCR allows for simultaneous detection of specific nucleic acid sequences in real time by using nonspecific intercalating dyes or fluorescent dyes bound to target-specific probes. With real-time PCR, the amplified product is being measured at each PCR cycle. Advances in this technology include pre-optimized universal reagents and universal conditions for amplification, simplified assay development and design of primers and probes, multiple amplicon-detection chemistries...

</table>

and many choices of thermal cyclers, higher throughput capabilities and enhanced reproducibility, flexibility to multiplex assays to detect multiple viruses in a single reaction, a low risk of contamination because of the closed system, increased sensitivity and specificity over the more traditional detection methods, and software-driven operations.

Laboratory-developed real-time PCR assays for the detection of gastroenteritis viruses have been shown to have superior performance characteristics and are much better than any combination of EM and/or antigen-detection methods (for references, see Table 5). These assays can readily detect coinfections with different enteric viruses and can be coupled with other assays that detect nonviral enteric pathogens. Their specificity and sensitivity are high, with detection limits of 1.5 to 3.6 viral particles per PCR for rotavirus (77) and less than 10 RNA copies per PCR for noroviruses (82). The primers of these assays have been selected according to highly conserved regions of the viral genomes, such as those in the VP6, VP2, and NP3 genes of rotaviruses. Primers targeting the rotavirus NP3 gene are particularly useful for broad detection and are capable of detecting most of the common genotypes (G1 to G4 and G9) as well as some rare genotypes, such as G10 and G12 of rotaviruses (77, 90).

The ORF1-ORF2 junction region is the most conserved region of the norovirus genome, and primers targeting this region have been used for the development of real-time PCR assays that are highly sensitive for broad detection of many genotypes of noroviruses (78). With primers specific to individual genogroups (GI and GII), a multiplex real-time PCR which is highly sensitive and useful for typing noroviruses has also been developed (78). The multiplexed assay increases testing efficiency by decreasing test time by 50% and reducing reagent costs compared with those of other real-time PCR methods. A LightCycler real-time RT-PCR assay with additional primers and a probe targeting the GIV norovirus has also been developed (82). Currently, this and the multiplex assays are widely used in clinical and research laboratories worldwide, especially in North America.

Laboratory-developed real-time PCR assays for the detection of sapoviruses, astroviruses, and the EAdV also have been developed and have been shown to be highly sensitive and specific with increased detection rates over EM and available antigen-detection assays (75, 83–89).

**Isothermal Amplification Assays**
Nucleic acid sequence-based amplification (NASBA) and loop-mediated isothermal amplification (LAMP) assays...
have been applied to the detection of noroviruses from stool specimens and are categorized as isothermal amplification methods. These assays involve single-temperature amplification with no thermal cycling. Similar to real-time PCR, the assays have been shown to be extremely sensitive. NASBA has been used to detect norovirus RNA, but the detection specificity does not appear to be acceptable for clinical diagnostic use because of the decreased stringency when amplifying viral RNA at relatively low temperatures of 40°C (91). The LAMP technology has the added advantages of speed and simplicity, with the reaction being performed in a single tube and requiring no more than 1 hour to complete. Reactions normally show a high tolerance to biological products so that extensive nucleic acid extraction is often not necessary and assays require no large equipment and only simple heat blocks or water baths since amplification occurs in low and unchanged temperature conditions, normally at 60 to 65°C. The by-product of LAMP is the production of magnesium pyrophosphate. In positive samples, it precipitates out of solution, causing a turbid reaction that can easily be read using a small turbidity reader. A fluorescent metal indicator can also be added to enhance the readability of the produced turbidity. The simplicity of LAMP assays makes them applicable to laboratories with limited resources and experience in performing molecular methods and which desire rapid turnaround times or testing at point of care using a robust assay system. Laboratory-developed LAMP assays have been applied to the detection of GI and GII and have demonstrated comparable results with real time RT-PCR (92–94). Recently, a commercial LAMP kit for detection of norovirus GI and GII developed by Eiken Chemical Co. (Tokyo, Japan) has improved the detection sensitivity in comparison with laboratory-developed LAMP assays (94). With further development and validation, LAMP assays may prove to be an acceptable alternative to current real-time PCR assays for the detection of enteric viruses.

Application of Nanotechnology to Nucleic Acid Testing

The field of nanotechnology is growing considerably and being aggressively applied to the commercial development of molecular diagnostics. Advances in microelectronics, microfluidics, and microfabrication have paved the way for new and more standardized technologies with the ultimate goals of offering ever simpler and cost-affordable molecular platforms that use smaller quantities of reagents and samples. These assays are capable of highly multiplexed testing for comprehensive syndrome-specific assessment of the etiology of specific diseases and sample-in/answer-out testing for all laboratories regardless of size, resources, or capacity.

To this end, the first commercial highly multiplexed, syndrome-specific molecular testing assay for the detection of enteric organisms, the xTAG Gastrointestinal pathogen panel (GPP), was developed by LumineX (Austin, TX) and recently licensed by the U.S. Food and Drug Administration (FDA) for the simultaneous detection of 23 gastrointestinal pathogens from stool samples, including rotavirus type A, norovirus types GI and GII, EAdV types 40/41, human astrovirus serotypes 1 to 8, and sapovirus serotypes I, II, IV, and V. The FilmArray platform is a fully closed and automated system for sample preparation, nested multiplex PCR, and result analysis that uses integrated electrophoretic and chemical circuits in a reaction pouch with an approximate turnaround time of 1 hour and 2 to 5 minutes of total hands-on time. This system shows great potential for use at point of care for the identification of enteric pathogens associated with acute gastroenteritis. SIMilar devices are being developed by other companies including GenMark Dx (Carlsbad, CA).

ISOLATION PROCEDURES

Cell Culture

While growth in cell culture can be used to detect and identify many different viruses from clinical specimens, it is generally time-consuming and not considered sufficiently rapid to contribute to meaningful management of a disease like acute gastroenteritis. In addition, most of the enteric viruses causing human gastroenteritis are fastidious in cell culture and require multiple passages before they can readily grow in cell culture from their primary isolation. Therefore, cell culture is not routinely used in the clinical diagnosis of viral gastroenteritis.

Cell lines for isolation of rotaviruses include MDCK, PK-15, BSC-1, ILC-MK2, MA104, CaCo-2, and HRT-29. To grow the viruses in cell culture, the culture medium must be supplemented with proteases such as trypsin or pancreatin. This approach has been adapted for titration of viruses by plaque assay and serotyping by virus neutralization.

Propagation of human caliciviruses in cell culture has not yet been achieved. A method of using a three-dimensional organoid model of human small-intestinal epithelium for cultivation of human noroviruses was reported but has not been reproduced by other laboratories. The porcine enteric calicivirus, a sapovirus, has been successfully adapted in porcine kidney cell lines but only in the presence of intestinal contents of pigs as a supplement in the culture medium. The murine norovirus has been reported to replicate in primary dendritic cells and macrophages (95).

EAdV types 40 and 41 grow best in the Graham 293 human embryonic kidney cell line, which has been transformed by AdV type 5 DNA. A plaque assay has been developed recently for the detection of EAdVs types 40 and 41 (99).

Isolation of astroviruses from clinical samples is difficult, although most of the astrovirus serotypes have been adapted in HEK or ILC-MK2 cell culture (100). Propagation of astroviruses in cell culture requires the presence of trypsin in the culture medium.

ANTIGENIC AND GENETIC TYPING SYSTEMS

Both antigenic and genetic typing methods are important in understanding the classification and epidemiology of many viruses, and AdV 40/41 (96), and comparable results to laboratory-developed molecular methods (97).

Another highly multiplex assay, the FilmArray Gastrointestinal Panel, is currently under development by BioFire Diagnostics (Salt Lake City, UT). The goal of this assay is to provide rapid sample-in/answer-out results for the simultaneous detection of 23 gastrointestinal pathogens from stool samples, including rotavirus type A, norovirus types GI and GII, EAdV types 40/41, human astrovirus serotypes 1 to 8, and sapovirus serotypes I, II, IV, and V. The FilmArray platform is a fully closed and automated system for sample preparation, nested multiplex PCR, and result analysis that uses integrated electrophoretic and chemical circuits in a reaction pouch with an approximate turnaround time of 1 hour and 2 to 5 minutes of total hands-on time. This system shows great potential for use at point of care for the identification of enteric pathogens associated with acute gastroenteritis. Similar devices are being developed by other companies including GenMark Dx (Carlsbad, CA).

### Gastroenteritis Viruses

Both antigenic and genetic typing methods are important in understanding the classification and epidemiology of many
gastroenteritis viruses and for developing preventive strategies against the diseases caused by these pathogens. Typing of gastroenteritis viruses is used mainly in research laboratories since typing does not affect clinical care and management decisions.

According to antigenic and genetic variations in the two major surface proteins of rotaviruses, VP7 and VP4, a dual system of antigenic (serotyping) and genetic typing has been used for the classification of human group A rotaviruses. The antigenic typing is accomplished by characterizing the specific interaction of a rotavirus with a panel of monoclonal antibodies representing individual G (VP7) and P (VP4) types of rotaviruses. The genetic typing is performed by RT-PCR using type-specific primers targeting unique regions of the VP7 and VP4 genes. Using this classification system, each strain of rotavirus is dually assigned to a G[P] type by either the antigenic or the genetic typing method. The antigenic typing results are highly correlated with the genetic typing for the G types, while the correlation between antigenic and genetic typing for the P types is low. Due to a limited supply of type-specific antibodies, P genotyping is commonly used. Frequent genetic and antigenic drifting of rotaviruses may result in newly emerging variants that are no longer detectable by the current typing assays (73). It becomes necessary to update the methods and reagents continuously, such as with type-specific monoclonal antibodies for the antigenic typing and primers for the genotyping. The virus types are also typeable based on the genetic variations in the major structure protein VP6 and the putative viral enterotoxin nSP4 genes. The recently recommended new classification system based on sequence information for all 11 genomic RNA segments is an extension of the previous classification systems (3). While this new system is challenging due to the requirement of sequencing all 11 genomic segments, it will eventually influence our understanding of the genetic variation, host-pathogen interaction, evolution, and potentially zoonotic nature of human rotaviruses.

Genetic typing has been used mainly for human norovirus identification and classification due to the lack of an efficient cell culture or animal model for a neutralization assay. The wide genetic diversity of human noroviruses also limits the methods used for the G and P typing based on type-specific primers, although genogroup-specific RT-PCR using the GI and GII group-specific primers has been developed (101). Thus, genetic typing of human noroviruses is based mainly on sequencing of the amplified DNA products following RT-PCR detection. Primers from the highly conserved RNA-dependent RNA polymerase genes have been commonly used. However, primers targeting the viral capsid proteins are recommended because the viral capsids are directly involved in host-receptor interaction and immune responses. Sequence alignment followed by phylogenetic analysis has been commonly applied for the classification of human noroviruses, and there are ~40 genotypes associated with acute human gastroenteritis in two major genogroups (GI and GII) of noroviruses.

Genomic DNA restriction enzyme analysis was commonly used before monoclonal antibody-based EIA typing was developed for the detection and typing of EAdVs. In addition, typing PCR or PCR in combination with restriction enzyme analysis has also been developed for the detection and typing of AdVs (102, 103). Recently, a quantitative real-time PCR assay was described for detecting HAdVs and identifying EAdVs of types 40 and 41 (104). Field surveillance using various methods suggests that the choice of diagnostic method may influence the epidemiologic picture and disease burden attributed to EAdV infections. There are 68 types of human adenovirus (HAdVs) grouped into 7 subgroups (A to G) based on serological, whole-genome sequencing, and phylogenomics assays (17–19).

For typing of astroviruses, immunologic assays, such as IEM and a typing ELISA, have been described but are not commercially available (59). The most commonly used RT-PCR typing methods for astroviruses are summarized in a recent review by Guix et al. (105).

**SEROLOGIC TESTS**

Antibody-neutralization tests based on plaque reduction or epitope-blocking assays using type-specific monoclonal antibodies have been described for rotaviruses. There is no neutralization-based serologic test for most other gastroenteritis viruses. However, ELISAs for antibody detection using specific viral proteins as the capture antigens have been used in epidemiology studies of gastroenteritis viruses. Recombinant viral capsid proteins of caliciviruses and astroviruses generated in a baculovirus vector and other systems are an excellent source of viral antigens for these studies (106). Application of these assays in sero-surveillance against gastroenteritis viruses has played an important role in understanding the importance of these viruses in different populations. Monitoring seroconversion based on a collection of paired acute- and convalescent-phase sera has been used in outbreak investigations.

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

There are many issues involved in the laboratory diagnosis of viral gastroenteritis and detection of gastroenteritis viruses can be quite difficult. As a result, much of viral gastrointestinal disease goes unrecognized. Enteric viruses do not grow well, if at all, in conventional cell culture systems used in clinical laboratories, and there is a definite lack of available reagents and assays for clinical use. Commercial rapid antigen-detection tests are available for rotavirus and, to a much lesser extent, for adenoviruses, noroviruses, and astroviruses; they offer speed in the diagnosis of viral gastrointestinal disease but are not completely sensitive or specific and only detect the pathogen of interest. In recent years, PCR has offered great promise for the diagnosis of viral gastroenteritis and has emerged as the most sensitive and specific method for the detection of viral causes of diarrhea. Real-time PCR is the most widely used molecular method for detecting the viral agents of gastroenteritis.

There are many reasons to attempt a laboratory diagnosis in individuals suspected of having a viral gastrointestinal disease. A prompt diagnosis of viral gastroenteritis may provide benefit in the management of individual patients by limiting unnecessary antibiotics, laboratory tests and hospital procedures; reducing hospital stay and sequelae; guiding treatment decisions; and providing earlier informed-decision making for better care. Increasing data have also shown that the major gastroenteritis viruses, such as rotaviruses, noroviruses, and EAdVs, can cause chronic gastroenteritis with prolonged shedding of viruses in the stools of recipients of transplanted organs, HIV patients, and other immunocompromised individuals. Prompt diagnosis in these clinical settings is important to adjust immunosuppressive therapy, to assess prognosis, and to stop the transmission of the...
disease. Rapid identification and monitoring of the source of infection in outbreaks of acute gastroenteritis, such as water, food, and environmental surfaces, is also important for disease control and prevention in the community. Early identification of food handlers with subclinical infection or chronic shedding of viruses is believed to be important for the prevention of food-borne outbreaks.

EM remains a simple and rapid method for clinical diagnosis of viral gastroenteritis, although it is less sensitive than most molecular diagnostic methods. It also requires experienced individuals who are familiar with the morphologies of different gastroenteritis viruses and who are able to differentiate atypical viral particles from unrelated cellular and microbial debris and structures commonly seen in stool specimens. The use of reference grids (57) containing viral particles with typical morphologies of the different gastroenteritis viruses is helpful for a person who is new to the field to gain such experience. IEM is useful for identifying unknown viral pathogens that may be an etiology of acute gastroenteritis, but this method is not widely used in diagnostic laboratories.

The antigen-detection methods, although moderate in sensitivity, may be a practical and inexpensive choice for the initial screening of stool samples if tests are available for a specific virus. Commercial antigen-detection assays for rotaviruses, EAdVs, and astroviruses can be applied to clinical diagnosis (Table 4). Also, antigenic tests based on type-specific monoclonal antibodies against the G and P types of rotaviruses and various types of astroviruses are widely used in research laboratories. Commercial antigen-detection assays for human noroviruses suffer from a lack of sensitivity and specificity and are not recommended for clinical diagnosis, although they may be useful for outbreak investigations.

Nucleic acid-based assays, particularly real-time PCR, are highly sensitive and specific and are increasingly used as the primary test of choice for clinical diagnosis. While less useful in clinical diagnosis, cPCR with type-specific primers and sequencing of the amplified product is appropriate for determining the molecular epidemiology of viral gastroenteritis.

Most gastroenteritis viral families are genetically diverse, which makes clinical diagnosis using PCR and RT-PCR difficult. Human noroviruses have over 40 recognized genetic clusters within three genogroups (9, 10). Using primers targeting highly conserved regions of the genome, the majority of known human noroviruses are detected, but there is probably no single primer pair that can detect all strains. In this case, multiple primer sets targeting different regions of the genome can be used to enhance the detection rates. In addition, degenerate primers based on sequence variations of known viral family members have also been used (15).

Diagnosis of viral gastroenteritis remains difficult because of the lack of readily available commercial kits and reagents for many viral families. The fact that a variety of microbial pathogens—including bacterial and parasitic agents in addition to viruses—as well as noninfectious conditions can cause acute gastroenteritis in humans further complicates the situation. Furthermore, many viral pathogens are known to cause subclinical infection. Others, such as AdV, can be shed for prolonged periods in stools. In some cases, more than one pathogen is detected in the same clinical sample or during the same episode of clinical illness, complicating efforts to determine the true etiology. Thus, care needs to be taken in the interpretation of laboratory results for gastroenteritis viruses. Proper epidemiologic case-control studies are necessary to address these issues.

Rabies Virus*
LILLIAN A. ORCIARI, CATHLEEN A. HANLON, AND RICHARD FRANKA

TAXONOMY
There are numerous etiologic agents in the genus Lyssavirus which result in an acute, fatal encephalomyelitis known as rabies in both humans and animals (1). These agents are single-stranded, bullet-shaped RNA viruses of the order Mononegavirales and family Rhabdoviridae. The genus includes 14 species, the prototype Rabies virus, and the less commonly known species of rabies-related lyssaviruses: Aravan virus, Australian bat lyssavirus, Duvenhage virus, European bat lyssavirus 1, European bat lyssavirus 2, Ikuta virus, Khujand virus, Lagos bat virus, Mokola virus, West Caucasian bat virus, Shimoni bat virus, Bokeloh bat lyssavirus, Ikoma lyssavirus, and a proposed new species, Lleida bat virus, http://www.ictvonline.org/index.asp (Fig. 1) (2–5). The lyssaviruses were first characterized by serologic neutralization, which was useful in classifying them into related or more distant groups (6). More recently, differences have been defined by nucleotide sequence analysis, and lyssaviruses are grouped as different genotypes or species (7). Current commercial human and animal vaccines are based on the rabies virus and provide adequate crossprotection against most other lyssaviruses, with the exception of those that are highly divergent from rabies virus, Lagos bat virus, Mokola virus, West Caucasian bat virus, Ikoma virus, and by inference, Lleida bat virus (since no virus isolate is available for analysis).

DESCRIPTION OF THE AGENT
The virions are rod-shaped, approximately 180 by 75 nm, and consist of five structural proteins: the glycoprotein (G), matrix protein (M), nucleoprotein (N), phosphoprotein (P), and large polymerase protein (L) (Fig. 2). The virus is contained in an envelope bilayer derived from the host cell cytoplasmic membrane during budding. Peplomers, G protein trimeric spike inserts of approximately 10 nm, are found within the surface of the virus envelope. The rabies virus G protein binds with host cell surface receptors (adsorption), initiating a cascade in the infectious cycle and replication. Virus-neutralizing antibodies produced to the G protein after vaccination or natural infection may inhibit this process. The inner surface lining of the envelope is formed by the M protein, which binds with the G protein and envelope and the ribonucleoprotein (RNP) core.

The RNP is composed of tightly wound wound RNA, encapsidated by the phosphorylated N protein and associated with the P and L polymerase proteins. All lyssaviruses contain nonsegmented genomes (RNA) of approximately 12 kb. The RNA-nucleoprotein complex is responsible for transcription of genomic RNA to five polyadenylated mRNAs, which are translated into the structural proteins, and for viral replication by providing a template to synthesize complementary full-length (negative sense) genomic RNA. During assembly, the coiling of RNP-M protein binds with the G protein as the completed virus buds from the plasma membrane (8). From a diagnostic viewpoint, the N and G proteins and viral RNA have been the focus of most laboratory research evaluations. Rabies diagnosis in postmortem brain tissues is based on the ability to detect intracellular viral inclusions, which are collections of RNP. Because the rabies virus G protein and host cell receptor interactions initiate the infection cycle, the G protein is directly involved in pathogenesis and virulence, induction of immune responses, and binding of neutralizing antibodies. Vaccines prepared from whole virions, purified rabies virus G proteins, and recombinant viral vaccines encoding rabies virus G proteins have been used to successfully immunize and protect animals from rabies virus infections (9,10). In addition, detection of antibody to the G protein has been used as a method to evaluate vaccine potency. More detailed reviews of virus replication and virus pathogenesis have been published (11–13). Descriptions of the rabies virus epidemiology, transmission, clinical signs, and diagnosis are generalizable to the other lyssaviruses.

EPIDEMIOLOGY AND TRANSMISSION
Rabies is a zoonotic disease (primarily an animal disease that may be transmitted to humans). All mammals are susceptible. Although rabies viruses are endemic on five of seven continents, the geographic distributions of the other lyssaviruses are more localized: Lagos bat virus, Shimoni bat virus, Mokola virus, Duvenhage virus, and Ikoma virus have been detected only in Africa; European bat lyssavirus, Bokeloh bat lyssavirus, and Lleida bat virus only in Europe; Australian bat lyssavirus exclusively in Australia; and Aravan bat virus, Khujand bat virus, Ikuta bat virus, and West Caucasian bat virus restricted to single isolations in Eurasia. In the United States, more than 6,000 rabies cases are diagnosed annually in animals. The predominant terrestrial reservoir species are raccoons in the Eastern states, skunks in California and the

FIGURE 1  Lyssavirus diversity was demonstrated by limited sequence analysis (400 nucleotides) of gene sequences performed using neighbor joining and maximum likelihood methods and bootstrap analysis of 1,000 trees. Full gene sequences were available for all lyssaviruses in GenBank, except for Lleida virus. Phylogroup 1 is composed of rabies viruses and closely related nonrabies lyssaviruses against which the currently available rabies biologics are effective. These biologics are, however, not effective with the divergent lyssaviruses in phylogroups II and III.

doi:10.1128/97815555817381.ch94.f1
North Central and South Central states, gray foxes in Texas and Arizona, Arctic and red foxes in Alaska, and mongooses in Puerto Rico. In addition, there are more than 16 distinct rabies viruses associated with unique species of insectivorous bats throughout their ranges in North America. Although dogs represent a major reservoir species in most developing nations, enzootic canine rabies transmission was pushed to extinction in the United States and other developed countries, primarily due to mandatory dog vaccination and stray animal control (14, 15).

Human rabies cases are rare in developed countries where canine rabies is controlled and access to prophylactic biologics is ideal. Fewer than eight cases are reported annually in the United States. Despite the relative ease of disease prevention in an exposed human, it is estimated that more than 55,000 preventable human deaths worldwide occur annually. Beyond avoiding contact with wild animals and unvaccinated, stray, or domestic animals with unknown immunization histories, access to appropriate human rabies postexposure prophylaxis remains an urgent global public health need to avert this preventable human mortality.

The main route of transmission is via the bite of a rabid animal. Virus is shed in the saliva, often in high amounts. Human rabies cases due to nonbite exposures are extremely rare. Nonbite exposures include scratches, open wounds, and mucous membranes contaminated with a source of rabies virus such as infected saliva or central nervous system (CNS) tissues from a rabid animal. Nosocomial infection (inhalation of accidentally aerosolized rabies virus) and subsequent mucous membrane contact is a potential source of nonbite exposure. Infection by this route is rare but has been documented (16, 17). No human rabies cases have been substantiated from fomite (surface contamination) exposures, most likely because the virus is readily inactivated by drying and agents such as detergents. In the event of an exposure, immediate wound cleansing with soap and water is indicated, followed by appropriate urgent medical care; delays in initiation of human rabies postexposure prophylaxis may result in death.

Lyssaviruses are susceptible to a number of common laboratory disinfectants such as 1:256 quaternary ammonium compound, 0.5% sodium hypochlorite (10% bleach), 70% isopropanol, and 70% ethanol. Chemical disinfectants are less effective when used on items contaminated with brain tissues or heavy suspensions of brain tissue. Decontamination of instruments, laboratory glassware, and disposable waste is best achieved by autoclaving at a minimum of 121°C at 15 lb for 60 minutes (18).

**CLINICAL SIGNIFICANCE**

The initial clinical presentation of rabies in humans and animals may be rather unremarkable and nonspecific. The majority of incubation periods range from several weeks to several months after exposure. Following the prodromal period, an acute neurological phase develops. The majority of rabies cases manifest as an encephalitic form, and less than 20% are observed as a paralytic presentation. Among patients exhibiting classical encephalitic symptoms, generalized arousal or hypereactivity, including periods of confusion, hallucinations, agitation, or aggressive behavior, may occur, with intermittent lucid periods. Clinical progression may be characterized by difficulty swallowing, hypersalivation, lacrimation, sweating, dilated pupils, and autonomic dysfunction. Cranial nerve dysfunction may include anisocoria and facial or tongue paralysis. Hydrophobia and aseptic spasm may be severe. Cardiopulmonary complications and instability usually result in cardiac arrest and death (19).

There is no definitive treatment for rabies after clinical signs are apparent. Appropriate management of a patient with rabies is supportive, usually progressing rapidly to respiratory protection through sedation and intubation, as well as complex medical management in attempts to stabilize cardiopulmonary and other major organ system function. Despite the successful outcome of intensive medical management of a high school student from Wisconsin in 2004, specific rabies antiviral treatment does not exist, and the prognosis remains inexorably grim. The latest information on experimental management of rabies cases may be found on the Medical College of Wisconsin website: <http://www.mcw.edu/Pediatrics/InfectiousDiseases/PatientCare/rabies.htm>.

Administration of rabies vaccine and human rabies immune globulin (RIG) to patients with laboratory-confirmed rabies has no proven efficacy, may complicate antemortem testing, and may accelerate the disease process and patient demise.

All potential rabies virus exposures need to be evaluated on a case-by-case basis. True exposures (bite or mucous membrane) to suspect animals or animals proven rabid should receive prompt medical intervention and postexposure prophylaxis as outlined in the ACIP guidelines.

Unvaccinated individuals exposed to a rabid animal should receive RIG at dose of 20 international units (IU)/kg of body weight. The RIG should be infiltrated around the wound, and any remaining volume should be given at a site distant from where the vaccine was administered. In addition, four or five doses of a human rabies vaccine licensed for use in the United States should be administered on days 0, 3, 7, and 14 and, if indicated, 28 following exposure. Individuals who previously received immunization against rabies require only two doses of vaccine on days 0
and 3, regardless of the current rabies virus-neutralizing antibody titer (20).

Individuals at high risk for rabies virus exposure (laboratorians, field biologists, veterinarians) are recommended to receive pre-exposure rabies prophylaxis. According to the current ACIP guidelines for Prevention of Rabies in Humans, a series of three doses of modern cell culture rabies vaccine (licensed for use in the United States) should be administered intramuscularly in the deltoid on days 0, 7, and 21 or 28. For all individuals in the high-risk group, determination of rabies virus-neutralizing antibody (VNA) titer is recommended every 2 years. Individuals working under somewhat higher risk for rabies exposure, such as in research or high-volume diagnostic laboratories, typically have their VNA levels monitored more frequently, such as every 6 months. Pre-exposure vaccination and monitoring of detectable neutralizing antibodies does not ensure protection from a particular exposure. On exposure, cleansing of the wound and postexposure rabies vaccine boostering (days 0 and 3) are essential for aversion of clinical disease.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

A summary of tests, required samples, and shipping and storage conditions may be found in Table 1. Diagnosis of rabies in animals requires postmortem examination of the brain. An adequate sample consists of a full cross-section of the brain stem (pons, medulla, or midbrain area) and cerebellum (vermis and right and left lateral lobes inclusive). Removal of CNS tissues should be performed by trained, vaccinated personnel wearing personal protective equipment (gown or lab coat with sleeves, double latex or heavy rubber gloves, N95 respirator, face shield). Information on sample collection for postmortem rabies diagnosis in animals may be found at http://www.cdc.gov/rabies/pdf/rabiesdfaspv2.pdf.

Information regarding samples for diagnosis of rabies in humans is available at http://www.cdc.gov/rabies/specific_groups/doctors/ante_mortem.html. The antemortem diagnosis of rabies in humans requires the collection of fresh saliva (no preservatives or transport media), a full-thickness skin biopsy from the nape of the neck (including hair follicles placed on saline moistened gauze) (no preservatives or transport media), and serum and cerebrospinal fluid (CSF). The saliva is subjected to nested reverse transcription PCR (RT-PCR). Part of the skin sample is also subjected to nested reverse transcription PCR (RT-PCR). The serum and CSF samples are analyzed for rabies virus antigen. Tissues placed in 10% buffered formalin should remain in the fixative a minimum of 24 to 48 hours at ambient temperature. Formalin-fixed brain tissues should be stored in 70% ethanol at room temperature for long-term storage and never frozen. Paraffin-blocked tissues and tissue sections (slides) should be stored at ambient temperatures and never frozen.

The ideal storage and shipping conditions of saliva samples for RT-PCR and virus isolation are at −80°C or below. Skin biopsy samples for RT-PCR and antigen detection should also be stored at −80°C. Samples for antigen detection may be stored for short intervals at −20°C before testing. Serum and CSF samples for rabies serologic testing should be stored at −20°C or below. Samples may be stored for short intervals prior to testing at 4°C. Whole blood samples should be centrifuged and the serum removed prior to freezing. Whole blood should never be shipped in the same container with samples on dry ice, because there is a risk of freezing and hemolysis regardless of packing insulation. Hemolyzed and chylous serum samples are unsatisfactory for testing. Other biological fluids (e.g., vitreous fluids, tracheal washings, tears) for RT-PCR or virus isolation require storage at −80°C or below.

DIRECT DETECTION METHODS

Direct methods may be used to detect histopathological changes and viral antigen (inclusions) and to observe virion morphology. These methods provide rapid diagnosis within minutes to hours without the need for amplification of virus isolation such as in cell culture or amplification of genome via RT-PCR.

Microscopic Methods

Microscopic examination methods may utilize routine stains (e.g., hematoxylin and eosin) to examine abnormal histopathology consistent with encephalomyelitis, or more specialized stains (e.g., Sellers, Mann’s, and Giemsa) to observe typical viral eosinophilic intracytoplasmic inclusions such as classical Negri bodies within neurons (21,22). Historically, Sellers stain (2:1 methylene blue and basic fuchsin) was most often used for Negri body detection. In contrast with more advanced, sensitive antigen detection methods, this staining procedure is most successfully performed on brain tissues (hippocampi, cerebral cortex pyramidial cells, cerebellum, and Purkinje cells) during the later stages of disease, when inclusions are most abundant and more easily detected. Brain impression slides are stained for 2 to 10 minutes in Sellers stain (the time needed varies depending on the thickness of the impression) and then rinsed with tap water. Typically, rabies virus infection demonstrates intracytoplasmic magenta inclusions that are oval or round with dark blue basophilic granules inside. Although of historical importance, this method has limitations in specificity and sensitivity. For example, when properly performed, the Sellers staining technique may identify Negri bodies in 50 to 80% of rabid animals. Observation of virions by electron microscopy (EM) allows examination of the ultrastructure, shape, and size. The technique provides supportive evidence of a rabiesvirus infection but requires careful examination by expertly trained personnel of numerous observational fields of the sample. As such, it is impractical and too costly for routine diagnosis (23).

Antigen Detection

Direct Fluorescent Antibody Test

The standard test for rabies virus antigen detection in CNS tissues is the direct fluorescent antibody (DFA) test. This test is relatively easy to perform and highly specific, approximates 100% sensitivity, and can be completed in 3 or 4 hours. The “Protocol for Postmortem Diagnosis of Rabies in Animals by Direct Fluorescent Antibody Testing” may be obtained at http://www.cdc.gov/rabies/pdf/rabiesdfapw2.pdf. In contrast to the nonspecific staining of viral infection observed with histologic stains, the rabies virus diagnostic conjugates consist of antibodies to the whole virion or the RNP, labeled with fluorescein isothiocyanate (FITC). Within infected brain cells there are abundant collections of rabies virus proteins (antigen), especially RNP. The conjugates may be hyperimmune polyclonal or monoclonal antibodies directed against highly conserved rabies virus epitopes.

Impression slides are prepared from a cross-section of brain stem and cerebellum (right, left, and vermis) or hippocampi (right and left) and are fixed in acetone for a minimum of 1 hour at –20°C. The brain impression slides are tested with two different anti-rabies virus conjugates to ensure antigen detection of the diverse rabies virus variants. When the conjugates are added to rabies virus-infected brain impressions and incubated for 30 minutes at 37°C, the labeled antibodies bind with the rabies virus proteins (antigens) and form specific antigen-antibody-FITC complexes.

After the impression slides are washed in phosphate-buffered saline (PBS) twice for 3 to 5 minutes, specific antigen-antibody complexes remain. These complexes fluoresce an intense sparkling apple-green color when observed with a fluorescence microscope equipped with an FITC filter combination. Morphologically, rabies virus antigen may appear as fluorescing large or small, oval or round inclusions, dust-like particles, or strands (Fig. 3).

Direct Rapid Immunohistochemistry Test

The direct rapid immunohistochemistry test (DRIT) is an alternative procedure for rabies virus antigen detection (24). The DRIT uses a cocktail of purified biotinylated anti-rabies virus nucleocapsid monoclonal antibodies to detect rabies virus antigen. To date, the test has demonstrated sensitivity and specificity equal to that of the DFA test in detecting rabies virus antigen. Anticipated use for this test method includes confirmatory DFA testing as well as augmentation of passive public health surveillance since, in contrast with fluorescence microscopy, light microscopy is adaptable to field use. The test is currently applied to augment surveillance in samples from animals that have not exposed humans to the virus. Advantages of the procedure include rapid procedure (1 hour to completion); inactivation of virus in samples through fixation in formalin, whereas acetone fixation in the standard protocol does not; and minimized equipment requirements (ambient incubation temperatures, standard light microscope). The sample requirements for DRIT are the same as those of DFA and other antigen-detection methods. (Refer to the section “Collection, Transport, and Storage” of this chapter for detailed information.) The DRIT is performed on brain touch impressions prepared the same as with the DFA. Slides are fixed in 10% buffered formalin for 10 minutes, rinsed in PBS with 1% Tween 20 (TPBS), then pretreated with hydrogen peroxide for 10 minutes before primary antibodies are applied. The test is a multistep process (biotinylated primary antibodies, streptavidin-peroxidase, and 3-amino-9-ethylcarbazole [AEC]): first an incubation with biotinylated rabies virus monoclonal antibodies for 10 minutes followed by rinsing in TPBS; then incubation with streptavidin-peroxidase for 10 minutes followed by rinsing with TPBS; then incubation with peroxidase substrate (AEC) for 10 minutes to initiate (red) color development followed by rinsing with distilled water. Slides are counterstained with Gill’s hematoxylin for 2 minutes, rinsed with water (and a cover glass added with water-soluble mounting media), and observed with a standard light microscope. Rabies virus antigen appears as bright red, large or small, oval or round inclusions, dust-like particles, or strands against a contrasting blue background (Fig. 3).

Formalin-Fixed Tissues

Formalin-fixed CNS tissue samples cannot be tested by the standard DFA test. The fixation process causes chemical crosslinking of proteins. Formalin-fixed tissue samples that have been processed, embedded in paraffin, and sectioned may be tested by a modification of the DFA for formalin-fixed samples. Rabies virus antigen detection, whether by standard DFA, DRIT, or modified DFA on formalin-fixed samples, requires the same tissue sampling of a complete cross-section of brainstem and cerebellum. Modifications of the standard DFA for formalin-fixed samples include heating the slides to 55 to 60°C to melt the paraffin, deparaffinization in xylene, and rehydration of tissue sections in graded alcohols. In addition, a proteinase K digestion for 30 minutes at 37°C is needed, presumably to dissociate chemical bonds formed during formalin fixation such that rabies virus epitopes are available for detection. Incubation with antibodies FITC conjugate is longer than the standard DFA incubation (i.e., 1 hour instead of 30 minutes), and the wash times in PBS (twice at 15 minutes) are longer to clear unbound conjugate from tissue sections (25). The reliability of this method depends on the availability of...
a high-affinity, highly concentrated polyclonal anti-rabies virus conjugate, because the modified standard DFA test for formalin-fixed tissues may require a working dilution of rabies virus conjugate as much as 5 to 10 times more concentrated for sensitive and specific detection of rabies virus antigen in these tissue samples.

An immunohistochemistry (IHC) test for rabies virus antigen detection is an alternative method for formalin-fixed tissues samples that have been processed, embedded in paraffin, and sectioned (26). The IHC protocol also requires enzyme digestion but with pronase instead of proteinase K to disassociate crosslinking of protein bonds. The IHC test is similar to the DRIT, but it is performed on paraffin-embedded tissues. It is a multistep process: first digestion with pronase followed by a rinse in TPBS, then 3% hydrogen peroxide for 10 minutes to remove endogenous peroxidase activity. Then normal goat serum is added and slides are incubated for 15 minutes to block nonspecific binding of the primary antibody. The primary anti-rabies virus monoclonal or polyclonal antibodies are added and incubated for 60 minutes. The secondary antispecies biotinylated antibody is added and incubated for 15 minutes, followed by a rinse in TPBS and incubation with streptavidin-peroxidase for 15 minutes. After rinsing with TPBS, slides are incubated with peroxidase substrate, AEC, for 5 to 10 minutes to initiate (red) color development, followed by rinsing with distilled water. Finally, slides are counterstained with Gill’s hematoxylin for 2 minutes, rinsed with water, and cover slips are added with water-soluble mounting media. Slides are observed with a standard light microscope. Rabies virus antigen appears as bright red, large or small, oval or round inclusions or dustlike particles within the cytoplasm of infected neurons against a light blue background of the hematoxylin-stained tissue. Advantages of the IHC test over the standard DFA modified for formalin-fixed samples include the ability to test for rabies virus antigen and other etiologies simultaneously by including antibodies to the other agents; the ability to examine the histopathology of tissues; and the ability to observe slides with a standard light microscope rather than fluorescence microscopy. Disadvantages are the time required for the procedure (approximately 6 hours) and the high complexity of the method, requiring optimization of multiple antibodies and reagents.

DFA Test of Nuchal (Neck) Biopsy Specimens
Antemortem DFA tests for rabies virus antigen are performed on serial 5- or 6-μm tissue cryosections of neck skin biopsies and provide a rapid method for viral antigen detection in nerves at the base of hair follicles. The DFA test on tissue sections is performed exactly as the standard DFA test on CNS tissues. In its antemortem application, the method has optimized sensitivity but may remain negative (false negative) in early stages of the clinical disease or in later clinical stages, presumably if antigen is masked or bound by the endogenous antibodies sometimes present.
in the terminal patient. On rare occasions, nested RT-PCR on the same sample may confirm the diagnosis while rabies antigen is not present in sufficient quantity to visualize with the DFA on skin sections.

Nucleic Acid Detection
RT-PCR methods are the most sensitive tests for rabies virus diagnosis. The sensitivity of RT-PCR depends in part on the sample (type and condition), the integrity of sample handling and storage to preclude contamination and degradation, the particular method of RNA extraction and RT-PCR, the primers selected for amplification, the quality of reagents, individual technical expertise, interpretation of the results, and confirmation methods. The usefulness of RT-PCR as a routine diagnostic test on postmortem (fresh and fixed) CNS tissues is limited. Highly sensitive, broadly reactive, less expensive, and less time-consuming procedures for antigen detection by DFA are more efficient routine tests for rabies diagnosis. RT-PCR is an essential tool for molecular analysis and, in some cases, to confirm a suspected diagnosis on CNS tissues (e.g., those that are compromised in quality), but its maximum utility is the detection of nucleic acid in non-CNS samples (e.g., antemortem saliva, skin, cornea impressions, tears, eye swabs, throat swabs, postmortem vitreous fluid) when fresh CNS tissues may be unavailable (27). When all conditions are optimal, RT-PCR can detect as little as 1 infectious unit of rabies virus. Nested RT-PCR increases the sensitivity (10- to 100-fold) below 1 infectious unit of virus (28). RNA may be limited or degraded when examining non-CNS samples, and nested (or heminested) RT-PCR is usually required. Until recently, the diversity among lyssaviruses and the lack of specific nondegenerate universal primers have discouraged use of real-time PCR for detection of rabies virus RNA in non-CNS samples when the rabies virus variant or lyssavirus species is unknown. A real-time RT-PCR for human antemortem diagnosis has been developed with degenerate primers and probes, with reported sensitivity to detect all major rabies virus variants (genotype 1), including Aravan virus and Khujand virus. The future incorporation of real-time techniques that detect all lyssaviruses will allow more rapid diagnosis, less chance of cross-contamination, and test automation (29, 30).

ISOLATION OF RABIES VIRUS
Isolation methods are useful in detecting infectious virus in samples and are sometimes used as a confirmatory test alternative to the standard DFA. The classical methods include in vitro isolation in animals (usually intracerebral inoculation of suckling mice) and in vitro virus isolation in cell cultures. For most routine diagnostic needs, the inoculation of cell cultures such as mouse neuroblastoma (MNA; Bionwittaker, Walkersville, MD) or a similar alternative cell culture line, CCL 131 (ATCC, Rockville, MD), provides the same sensitivity as animal inoculation but with quicker results and without the maintenance required for the use of laboratory animals. For these purposes, 0.4 ml of supernatant from a 20% brain suspension prepared in tissue culture medium with 10% fetal calf serum (MEM10) is inoculated into a suspension of 4 × 10^6 MNA cells/2 ml and incubated for 1 hour at 37°C. To maximize infection of the cells, gentle mixing of the suspension is performed every 15 minutes. The cell suspension is diluted to a volume of 10 ml with MEM10, 6 ml is transferred to one 25-ml cell culture flask, and the remaining suspension (4 ml) is transferred to 12 Teflon-coated 6-mm slides (or other cell culture slides). At least one slide should be acetone-fixed daily and examined by DFA for rabies virus antigen. At least one additional passage of the cell culture (performed in 3 to 5 days) is required to rule out rabies. Ideally, in vitro testing use should be reserved for efficacy and safety studies for biologics or virulence and pathogenesis studies. Cell cultures may be useful in the propagation, amplification, and quantification of viruses and antibodies; the production of vaccines; determination of the safety of vaccine lots; and the study of rabies virus pathogenesis in particular cells (31, 32).

IDENTIFICATION
As previously described in detail, identification of a Lyssavirus infection is made typically by direct examination of brain impressions and demonstration of specific viral inclusions (antigen) by DFA. Isolates are also identified in brains of inoculated mice and cell cultures by DFA. Electron microscopy may be used to determine the morphologic identification of lyssaviruses by examination of the virion ultrastructure in cell cultures or CNS tissues.

Further secondary characterization of Lyssavirus infection may be made by antigenic typing with monoclonal antibodies, genetic typing with sequence analysis, or investigating patterns of cross-neutralization.

TYPING SYSTEMS
Rabies viruses may be readily identified by antigenic and molecular methods as being associated with the broad groups of carnivore and bat variants. Through antigenic analysis, at least five major reservoirs are detectable among carnivores in the United States. Genetic typing adds resolution and identifies seven distinct virus lineages among the current variants. Antigenic typing is less useful in certain cases involving rabid bats. Nucleotide sequence analysis adds resolution when studying these samples. Typing methods are useful in a variety of circumstances, such as determining the rabies virus variants in human cases with unclear or unknown exposure histories, discovering the emergence of new viruses, monitoring the epidemiologic spread or re-emergence of virus in defined geographical areas, detecting spillover or host-switching of variants from the predominant host species to another species, and monitoring the success of rabies vaccination programs through characterization of positive samples.

Antigenic Typing
Antigenic typing with monoclonal antibodies (MAbs) can be performed by an indirect fluorescent antibody test (IFA) on acetone-fixed brain impression slides and rabies virus-infected cell culture slides or by the indirect rapid immunohistochemistry test (IRIT) on formalin-fixed brain impression slides or cell culture slides (33, 34). If direct brain impressions are used, the best results are obtained if 75 to 100% of the microscope fields contain viral antigen. If insufficient antigen is present, it is necessary to amplify the virus by inoculating cell cultures or animals. A panel of seven commercially available murine anti-rabies-virus-N MAbs is used to distinguish rabies virus variants by the different reaction patterns. Antigenic typing methods are inexpensive, rapid, and easily performed to determine rabies virus variants in a few hours. Limitations include the necessity for amplification when antigen amounts are inadequate and a lack of resolution for certain terrestrial and bat rabies virus variants. If antigenic typing results are inconclusive,
additional testing can be performed at reference laboratories such as the Centers for Disease Control and Prevention (CDC), which has a more extensive panel of MAbs and resources for sequence analysis (35).

Nucleotide Sequence Analysis
Genetic typing methods for molecular epidemiologic studies have become routine since more laboratories are able to extract RNA, perform RT-PCR tests, and sequence viruses. The N protein gene has been the one most frequently used in molecular epidemiology studies. Studies have focused the analyses on short sequences of less than 400 nucleotides; however, current technologies have expanded the focus from partial gene sequences to whole viral genomes (5). Currently, there are thousands of N gene sequences (complete and partial) in GenBank for comparison. Lyssavirus researchers typically focus on the G, P, and L genes (4, 28). These data may assist in understanding evolutionary relationships between lyssaviruses (Fig. 1), understanding specific gene functions in host species, and predicting viral pathogenesis, replication, and virion formation.

SEROLOGIC TESTS
The serologic tests for rabies virus antibody include rabies virus neutralization assays and antibody-binding assay methods. Each varies in sensitivity, specificity, type of antibody detected, and the viral antigen (protein) recognized. These methods, most robust when applied in parallel on sequential samples, are routinely used to diagnose rabies in humans (36, 37).

Neutralization Tests
Neutralization tests are largely embraced as the most powerful for prediction of an adequate response to immunization against rabies and for the specific diagnosis of rabies during the later clinical stages. Neutralization of rabies virus relies on antibodies directed to the outer glycoprotein antigens; these are functional assays measuring performance against active viral infection of cells in culture, or historically, in mice intentionally infected with rabies, along with dilutions of test serum. The historic mouse neutralization (MNT) has been largely replaced by the rapid fluorescent focus inhibition test (RFFIT) and a simplification of it, the fluorescent antibody virus neutralization test (FAVN). All of these test methods measure the ability of rabies virus antibodies in serum or CSF samples to neutralize a known standard challenge virus dose. The RFFIT and FAVN, a modification of the RFFIT microneutralization test performed in microtiter plates instead of chamber slides, are most frequently used to determine the immunization status of vaccinated humans and animals, respectively. When performed in qualified laboratories by qualified personnel, both test methods demonstrate acceptable and similar sensitivity and specificity in determining rabies virus neutralizing antibodies; tests results are best compared when converted to international units per milliliter on the basis of prior criteria specifying acceptable performance of an international reference standard in each particular run of an assay method (36–39).

IFA Tests
IFA tests are sensitive methods for detection of IgM and IgG antibodies that have bound to rabies virus antigen within infected cells. Binding activity may be present in human serum and CSF and is thus a useful component of the battery of tests applied for antemortem diagnosis (27, 37). It appears that the IFA is useful for the measurement of antibodies against internal rabies virus proteins such as RNP rather than G. Serum or CSF samples are titrated and added to acetone-fixed cell culture slides infected with rabies virus (CVS-11). The endpoint antibody titer is the last dilution demonstrating specific fluorescence. The IFA titers are not comparable with levels of in vitro viral neutralizing antibody to the rabies virus G surface proteins.

ANTIVIRAL SUSCEPTIBILITIES
As previously described, no specific rabies antiviral biologics are currently licensed, and the prognosis remains inexorably grim. Once clinical signs are present, rabies remains fatal in greater than 99% of cases. For the most current information on experimental recommendations and approaches, consult the rabies registry at the Medical College of Wisconsin website: http://www.mcw.edu/Pediatrics/InfectiousDiseases/PatientCare/rabies.htm. Antiviral drugs previously used in human treatment regimens include ribavirin, ketamine, amantadine, and interferon alpha. Although effective against RNA virus infections, ribavirin is contraindicated for rabies treatment due to the depression of the immune response. However, the use of ketamine (anesthetic and antiviral) and amantadine (neuroprotectant and antiviral) is included in current human rabies treatment. Interferon alpha has demonstrated toxicity and is now contraindicated.

EVALUATION, INTERPRETATION, AND REPORTING RESULTS
Written protocols, which include quality assurance and quality-control measures, are essential for all diagnostic tests. All reagents should be optimized before use with known positive samples from two or more rabies virus variants endemic to the geographical region and known negative control samples. The accuracy and limitations of each diagnostic test should be understood before interpretation of the test results (Table 1). The national standard protocol in the United States for rabies diagnosis in postmortem brain tissues is the DFA test. Procedural requirements of the standard DFA, DRIT, RT-PCR, and isolation methods maximize sensitivity by testing the CNS tissues most likely to be positive in rabid animals (brain stem and cerebellum). Problems of crosscontamination in direct detection and amplification methods can be avoided by processing necropsy samples separately, using separate containers for acetone fixation and washing of DFA tests, and using different dedicated laboratory areas for processing RNA and cDNA samples for RT-PCR. Multiple readers are required to evaluate each of the diagnostic tests and provide quality assurance. Since there are no universal primers for all lyssaviruses, multiple broadly reactive or degenerate primers are needed to rule out rabies by RT-PCR. Confirmatory testing is required for all rabies diagnostic tests with weak reactions or unusual results (artypical morphology, artypical reactions patterns, and epidemiologic inconsistencies). Samples with nonspecific reactions and inconclusive results should be sent to a reference laboratory for confirmation and alternative testing methods. The timeliness of reporting results directly affects medical intervention in humans and management of exposed animals. Ideally, a primary rabies diagnosis from CNS tissues of suspect animals (or humans) should be made in 24 to 48 hours so that potentially exposed humans and animals may be appropriately managed for the optimal prevention of human and animal rabies.
We thank Pamela A. Yager and Todd G. Smith for assistance in the preparation of this chapter and Michael Niezgoda for providing photomicrographs. We also acknowledge the contributions of other members of the CDC Rabies Team.

Arboviruses
ELIZABETH HUNSPERGER

TAXONOMY
Arthropod-borne viruses (arboviruses) transmit to a vertebrate host through the bite of an infected arthropod and cause more than 80 diseases in humans. These viruses have been grouped based on transmission by their arthropod vector: mosquito, tick, sand fly, midges, and others (Table 1). There are more than 500 taxonomically diverse viruses listed from seven distinct families of viruses: Togaviridae, Flaviviridae, Bunyaviridae, Reoviridae, Rhabdoviridae, Orthomyxoviridae, and Asfarvirdae. The medically important arboviruses are primarily from Togaviridae, Flaviviridae, and Bunyaviridae, and this chapter focuses on these three families. The complete list and characterization of the first discovery and isolation of these viruses can be found in The International Catalog of Arboviruses (http://wwwn.cdc.gov/arbocat/index.asp).

DESCRIPTION OF THE AGENT
All arboviruses are RNA viruses of either positive or negative polarity (with the exception of African swine fever virus in the family Asfarvirdae). Typically, they are enveloped viruses containing single-strand and/or segmented RNA genomes and are capable of replication in both arthropod and mammalian cells. Arboviruses range from 40 to 100 nm in size and have a RNA genome of approximately 10 to 12 kb. Many arboviruses have been genetically sequenced (full length or partial, e.g., structural genes) and available on GenBank for diagnostic test and vaccine development.

Some arboviruses have developed divergent genomic sequences within species based on geographical location and are referenced as genotypes, subtypes, or lineages. These genotypes result from the evolution of these virus species within restricted ecological niches, allowing for evolutionary divergence for improved adaptation within these niches. Genotypes have been described for virus species in all three families/genera: (i) Flaviviridae, Flavivirus: Japanese encephalitis virus (JEV), dengue virus (DENV), yellow fever virus (YFV), West Nile virus (WNV); (ii) Togaviridae, Alphavirus: eastern equine encephalitis virus (EEEV), western equine encephalitis virus (WEEV), Venezuelan equine encephalitis virus (VEEV); and (iii) Bunyaviridae, Bunyavirus: LaCrosse virus (LACV).

EPIDEMIOLOGY AND TRANSMISSION
The epidemiology of arboviruses is dependent on the virus, vector, and geographical constraints based on the presence of the vector and amplifying host. Many arboviruses are geographically restricted and have limited circulation confined to certain continents or specific regions of the world (e.g., tick-borne encephalitis virus [TBEV] circulates in Europe and parts of Asia). Environmental changes favorable to the vector or virus can cause either epidemics or expansion of arboviruses into new regions. Changes in the vector ecology or number of susceptible individuals in a given population also play an important role in arbovirus transmission. Worldwide globalization has been implicated as the major cause of the introduction of new vectors into regions where not previously present. This includes increases in travel of infected humans, animals, or vectors into new regions, providing a unique environment in which the pathogen adapts and thrives due to the abundance of susceptible hosts (1). For example, chikungunya virus (CHIKV) is transmitted principally by the mosquito vector Aedes aegypti; however, a single point mutation in the membrane fusion glycoprotein increased its adaptation to the tiger mosquito vector Aedes albopictus and led to the outbreaks observed in tropical areas of the Indian Ocean (2, 3). Genetic analysis suggested that the emergence of WNV in the Americas was due to importation of WNV into North America from the Middle East. The method of introduction either by mosquito or host was not fully determined. Nevertheless, WNV swept across the United States at alarming speed following its emergence in 1999 in New York because the New World avian hosts were more susceptible than the Old World avian host. Hence, the epizootic transmission of WNV in North America caused an alarming number of avian deaths, particularly among corvids and especially the American crow (Corvus brachyrhynchos) (4). Current transmission of most medically important arboviruses worldwide is available on the Centers for Disease Control and Prevention (CDC) and World Health Organization (WHO) websites (http://www.who.org and http://www.cdc.gov).

The transmission cycle of all arboviruses includes an arthropod vector and a vertebrate animal reservoir as the amplifying host. Some viruses have evolved an urban and a sylvatic transmission cycle as observed with CHIKV and YFV. Arboviruses may cause seasonal epidemics often linked to the abundance of the vector, intermediate amplifying host, susceptible hosts, and introductions of new genotypes, subtypes, or lineages. Humans have become the principal amplifying host without the need for an intermediate vertebrate amplifying host for certain arboviruses, such as DENV, YFV, and CHIKV.

\(^b\)2013 emergence in Caribbean islands.
Other sources of arbovirus transmission include infected blood and/or organ donations. This method of infection was best described for WNV following its emergence in the U.S., where transplantation of infected organs caused fatalities in organ recipients (5). These studies prompted the investigation of other arbovirus infections via blood and organ donations, especially DENV, which causes a high rate of asymptomatic infections (75%) with sufficient viral titer to infect transfusion or organ recipients (6).

**CLINICAL SIGNIFICANCE**

Many of the medically important arboviruses that are human pathogens cause varied clinical presentations from mild flu-like symptoms, such as fever, malaise, and headache, to severe disease with hemorrhage and encephalitis, occasionally leading to death. These clinical symptoms can be categorized by viruses that are primarily either viscerotropic or neurotropic. Viscerotropic viruses cause febrile illnesses that often present with rash and arthralgia. Additional reported clinical symptoms include hepatitis, jaundice, respiratory symptoms, photophobia, and others. A summary of viral tropism and associated complications resulting from severe disease in humans for the commonly reported arboviruses is listed in Table 1. Although published reports often focus on severe cases, those clinical cases classified as mild forms of disease can cause significant morbidity and sequelae. For example, individuals with dengue fever (a mild form of the disease) may be absent from work or school for 7 days or more with occasional sequelae of fatigue and general malaise that can last for months (7).

Commonly observed clinical symptoms for neurotropic arboviruses include coma, meningitis, flaccid paralysis, encephalitis, and Guillain-Barré syndrome. Neurotropic arboviruses include the genera Flavivirus (JEV and TBEV subcomplex), Alphavirus (VEEV, EEEV, and WEEV), and Bunyavirus (LACV). Neuropathogenesis includes two important yet distinct factors: neuroinvasiveness and neurovirulence. Neuroinvasiveness is the capacity of the virus to invade the central nervous system (CNS) and/or the peripheral nervous system (PNS). Neurovirulence is defined as the replication of the virus within neuron or glial cells in the CNS and/or PNS. Within the virus genus Flavivirus, JEV and TBEV subcomplex groups have adapted to replicate in the nervous system. Although many cases of encephalitis involving nonneurotropic arboviruses have been reported, these viruses are not neurotropic in nature and the reported encephalitis is often observed as an element of multiorgan failure associated with fatal cases (Table 1). The envelope glycoprotein is an important determinant for neurotropism in the genus Flavivirus and is linked to the glycosylation variants of the envelope gene product. The most important host risk factors for severe flavivirus infection are age, genetics, immunocompromise, and preexisting flavivirus immunity. Most flavivirus infections cause either an asymptomatic or an inapparent infection. The rate of neuroinvasive disease is often 0.1% but varies with the prevalence of the virus in the population. For example, during the peak of the WNV transmission season in the United States, the rate of neuroinvasive disease was 1 in every 150 infections with a mortality rate of 5 to 10% (8, 9). WNV epidemics in 2012 had increased rates of neuroinvasive disease compared to previous nonepidemic years, with neuroinvasive rates comparable to rates observed in the 2002 U.S. epidemic (10).

Age is the most common host risk factor documented in both human clinical studies and animal models. Younger individuals have a higher susceptibility to neuroinvasive disease, implying that the developing nervous system is more susceptible to the virus. Children are more susceptible to JEV, and thus encephalitis and severe disease are primarily observed in children younger than 9 years of age. For WNV, younger patients have a higher risk for aseptic meningitis, whereas elderly patients have a higher risk of encephalitis with poor outcome. For the elderly, the risk of neuroinvasive disease is most likely related to a compromised immune system or preexisting medical conditions. Preexisting systemic conditions such as autoimmune diseases, diabetes, and obesity are some of the risk factors associated with WNV severe disease (11). These preexisting systemic conditions resulting in a less functional and responsive immune system are also associated with the reduction in vaccine responsiveness in elderly individuals.

Viscerotropic arboviruses include DENV, YFV, Rift Valley fever virus (RVFV), and others (Table 1). Common symptoms for these viruses are fever, malaise, headache, photophobia, and occasionally rash and arthralgia. Other symptoms include hepatitis and jaundice, which is sometimes mistaken for hepatitis virus infection. A distinct clinical manifestation for these viruses is hemorrhage and shock syndrome. However, only a relatively small percentage of patients will develop hemorrhagic shock for a relatively short period of time, followed by multiorgan failure and eventually death. Other viruses that present with viral hemorrhagic syndrome, such as Lassa virus (arenavirus) and Ebola and Marburg viruses (filoviruses), can be confused with hemorrhagic arbovirus syndromes. However, there are clinical differences between arboviral and other hemorrhagic viral infections as well as geographical constraints that would facilitate proper clinical diagnosis.

Since there are few pathognomonic symptoms associated with each arbovirus, there is often misdiagnosis due to non-specific clinical symptoms during the early acute stage of an infection. Other diseases that have available prophylaxis or are vaccine preventable, such as rubella/measles, influenza, leptospirosis, and malaria, have been misdiagnosed as arboviral infections. Clinical misdiagnosis will delay appropriate medical treatment and triage of patients. Common misdiagnoses for viscerotropic arboviruses are malaria and leptospirosis. Many patients, particularly in the African continent, are treated with antimalaria medication due to clinical manifestation for these viruses is fever, malaise, headache, photophobia, and occasionally rash and arthralgia. Other symptoms include hepatitis and jaundice, which is sometimes mistaken for hepatitis virus infection. A distinct clinical manifestation for these viruses is hemorrhage and shock syndrome. However, only a relatively small percentage of patients will develop hemorrhagic shock for a relatively short period of time, followed by multiorgan failure and eventually death. Other viruses that present with viral hemorrhagic syndrome, such as Lassa virus (arenavirus) and Ebola and Marburg viruses (filoviruses), can be confused with hemorrhagic arbovirus syndromes. However, there are clinical differences between arboviral and other hemorrhagic viral infections as well as geographical constraints that would facilitate proper clinical diagnosis.

Vaccines and antiviral medications for prophylaxis or treatment are limited for most arboviruses (Table 1). Clinicians principally rely on supportive care including fluid replacement, analgesics, and transfusion of blood products. Diagnosis of arboviruses should always consider the geographical location where the infection was acquired. Patient information such as vaccine history, travel history, and exposure to vector should be considered. While many arboviruses circulate in restricted geographical regions, other arboviruses, such as DENV, now circulate in most tropical and subtropical regions of the world due to its rapid geographical expansion. Clinical diagnosis can be considerably narrowed by using known incubation periods, risk of infection based on geographical distribution of the virus, and presence of vector. Concurrent infections either with cocirculating arboviruses or with other infectious or parasitic diseases (e.g., leptospirosis, influenza, and malaria) can occur (13–15).
There is no clear evidence that concurrent infections have higher morbidity or mortality rates, due to the small sample size that prohibits studies with sufficient statistical power.

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

Human specimens for laboratory testing include sera, whole blood, and/or cerebrospinal fluid (CSF) from acutely infected patients. Virus can be detected in serum specimens of infected patients for most arboviruses during the first 48 hours following symptoms or fever onset. Nucleic acid amplification tests (NAATs) are the most sensitive tests for case confirmation. Specimens collected during the viremic phase (days post onset of illness [DPO], 0 to 5) should be stored at −80°C. Freeze-thaw of these specimens usually degrades the RNA rather quickly and can significantly reduce viral titers by as much as 1 log following a single freeze-thaw cycle. When humans are the primary amplifying host such as for DENV and YFV, viral titers in blood and tissue are approximately 10^3 to 10^9 genome equivalent copies/ml and readily detected by most molecular diagnostic tests. Other arboviruses such as WNV, St. Louis encephalitis virus (SLEV), and JEV have a vertebrate amplifying host, such as avian or swine, and humans are dead-end incidental hosts. For these viruses, identification in blood is less probable since viral titers range from approximately 10 to 1,000 PFU/ml, which is often below the limit of detection of many reverse transcriptase PCR (RT-PCR) tests (16). These neurotropic viruses can be successfully isolated in culture or RT-PCR amplified from CSF, particularly in patients clinically diagnosed with encephalitis or meningitis. However, in neuroinvasive cases, identification in blood must be performed prior to the development of encephalitis. A few studies have indicated arbovirus persistence in humans and include WNV and Colorado tick fever virus (CTFV), where viral RNA was detected for weeks following initial infection (17).

Serum specimens tested for immunodiagnostic tests should be collected during both the acute phase (DPO, 0 to 5) and convalescent phase (DPO, 6 to 14). Paired specimens provide the highest likelihood of a confirmed test result by seroconversion. For CSF specimens obtained from patients suspected of a neurotropic arboviral infection, IgM antibodies are detected earlier in the course of infection than in sera; however, both specimens (serum and CSF) should be obtained for best results. A single positive serum specimen provides a diagnosis of a recent arbovirus infection; however, acute infection cannot be confirmed due to persistence of the IgM response for some arboviruses (e.g., WNV) (18).

Postmortem tissue specimens are collected for direct detection methods from fatal cases. Other specimens collected for diagnostic testing include arthropods such as ticks, mosquitoes, sandflies, and midges. These specimens are used for virus isolation and/or tested for the presence of viral nucleic acids. Arthropod field tests for virus identification in the vector include rapid tests, such as dipstick, using antibodies directed against viral antigen (e.g., envelope glycoprotein). These tests are commercially available for WNV, DENV, EEEV, and RVFV (19–21).

**DIRECT EXAMINATION**

**Microscopy**

Viral identification using immunohistochemistry on biopsy or tissue specimens is primarily performed postmortem. The types of tissue specimens obtained are dependent on the suspected arbovirus infection. Because autopsies are not practiced and/or culturally accepted for many of the regions of the world where arboviruses circulate, pathology studies for arbovirus-related fatalities are few. The most complete pathology information from fatal cases is primarily from flavivirus-related deaths (JEV, WNV, YFV, and DENV). The specific tissue sampled is determined by viral tropism and varies by arbovirus family and species. For neurotropic viruses that infect the CNS, tissue specimens are collected and tested for the presence of viral antigens or nucleic acid from regions of the CNS including the cortex, cerebellum, and brain stem. For JEV, brain autopsies primarily test tissue specimens with NAAAT and cell culture virus isolation techniques for confirmation (22, 23). For viscerotropic viruses, such as DENV and YFV, other organs are considered for immunohistochemistry and RT-PCR testing, such as liver, kidney, lymph nodes, spleen, and heart (24, 25). Few pathology studies have been published for genera Alphavirus and Bunyavirus. Another method of detection is nested RT-PCR techniques in formalin-fixed, paraffin-embedded human tissue to detect viral genome in tissue specimens (26, 27).

**Antigen Detection**

Viral Antigen Enzyme-Linked Immunosorbent Assay (ELISA) Viral antigen detection tests have been primarily developed for rapid virus identification field testing for arthropod specimens, in contrast to highly sensitive RT-PCR used primarily for testing of human specimens. Recently the nonstructural protein 1 (NS1) antigen test for DENV has been used for diagnosis from human serum specimens successfully, due to the microplate enzyme-linked immunosorbent assay (ELISA) format and ease of use compared to RT-PCR. The DENV NS1 ELISA can be implemented in many resource-poor countries for virus surveillance. The NS1 protein is a glycoprotein expressed by all flaviviruses and is essential for viral replication. During viral replication, NS1 is secreted as a hexamer composed of dimer subunits. NS1 produces a humoral response and is known as a complement-fixing antigen.

The sensitivity of the first DENV NS1 antigen-capture ELISA ranged from 1 to 4 ng/ml; however, commercial tests have sensitivities of 50 ng/ml of serum (28–30). Results from earlier studies suggested that NS1 levels in blood correlated with disease severity among DENV patients, although these results were not corroborated by later studies (29, 30). The NS1 ELISA has the capacity to distinguish between DENV serotypes (31). The NS1 antigen test is less sensitive in secondary DENV infections due to an immune complex formed from multiple DENV exposures. The NS1 test is commercially available for DENV, and many investigators have evaluated its sensitivity and specificity (32–35) (Table 2). Because of the relatively higher specificity of the NS1 test compared to the IgM test, it may also be useful in differentiating between flaviviruses. However, many of the viruses in the JE serocomplex group and other flaviviruses do not develop sufficiently high viral titers such as those observed in DENV infections; therefore, it is unlikely that the NS1 antigen detection test for these flaviviruses will be used for diagnostics. Other antigen ELISAs include RVFV and EEEV tests, but these tests have only been used for mosquito specimens.

**Nucleic Acid Detection**

There are various NAAT methods to detect arbovirus nucleic acid, including RT-PCR (standard and real time) and

*As reported by manufacturer.
reverse transcription-loop mediated isothermal amplification (LAMP). The main advantages of NAAIs are confirmation of the infecting virus and rapid turnaround time for results. The potential for laboratory contamination with target analyte or amplicons is the main disadvantage of these techniques. When laboratories are unable to provide separate rooms dedicated to template-free procedures and nucleic acid amplification procedures, there is a higher probability of contamination. Contamination by exogenous template provides false-positive results that may have a public health impact and possibly become life threatening to the patient.

RT-PCR

Currently the most routinely used technique is real-time RT-PCR that utilizes fluorescently labeled probes. This is due to its simplistic format (tubes are not opened after amplification, decreasing the risk of contamination), generally high sensitivity, multiplex capacity, and the ability to quantify the amount of virus present. Primers and fluorescent probes are designed to target the conserved regions of the genome for the most specific result. Some tests are designed to detect any virus within a particular genus, using consensus sequences (e.g., Flavivirus, Alphavirus, and Bunyavirus) referred to as “pan or universal” format (36, 37). These pan/universal primers are useful for emerging infectious disease detection where the pathogen is a suspected arbovirus. Once the genus of the unknown virus is determined, then specific primers for each species within that genus are used to identify and confirm the infecting pathogen. The fluorescence is measured and captured as cycle threshold values (Ct) that are often correlated to either genome equivalent copies or PFU determined with a standard curve.

Standard RT-PCR uses gel electrophoresis, in which the molecular size (kilobases) of DNA fragments generated from test samples is compared with that of amplified DNA fragments of known viral standards. This test cannot be used for nucleic acid quantification since gel electrophoresis uses ethidium bromide as a method of detection. The sensitivity of the test is dependent on ethidium bromide limit of detection (1 to 5 ng of nucleic acid).

LAMP

The loop-mediated isothermal amplification (LAMP) nucleic acid detection technique has been developed for various arboviruses. The assay requires only one standard temperature (64°C) and is considered a low-cost alternative to standard and real-time RT-PCR because the technique does not require thermal cycling. The reaction is a strand displacement reaction that uses four different primers that recognize six different regions of the target gene using Bst polymerase instead of Taq polymerase. The amplified product can be visually identified by either white precipitate or SYBR green yielding a green or yellow color change. This test has been developed for WNV, JEV, CHIKV, DENV, and RVFV (38-42).

Isolation Procedures

Isolation of arboviruses is generally performed for virus characterization studies and as a confirmatory test for RT-PCR positive specimens. Most arboviruses can be isolated from blood or tissue if the integrity of the specimen is maintained by appropriate storage at −80°C. These viruses require various levels of biological containment (biosafety level 2 [BSL2] or BSL3) and laboratories should consult the Biosafety and Microbial and Biomedical Laboratories (BMBL) manual for proper biosafety practice (http://www.cdc.gov/biosafety/publications/bmbl5/). The virus isolate can generate enough material for sequencing purposes to determine origin of the virus, and these viral isolates then become reference viruses for future characterization studies. Low-passage virus is preferred for phylogenetic analysis since these viruses mutate at a rate of 10⁻⁶ substitutions/site/year. Interestingly, arboviruses’ mutation rates are 0.21 magnitudes lower on average and their rates of synonymous substitutions are lower than those of all other RNA viruses (43).

Virus isolation can identify novel viruses especially when an RT-PCR positive sample cannot be categorized by a species-specific RT-PCR assay. For example, a positive specimen by panflavivirus NAAI that cannot then be amplified in a flavivirus species-specific RT-PCR can then be isolated and sequenced to determine whether the virus is a new species within this family/genus.

Arbovirus isolation is performed in either primary cell cultures or cell culture lines. Primary cultures typically include primary duck, chicken embryo, monkey, and hamster kidney cells. The classic mammalian cell lines include Vero, LLCMK2, BHK-21, CER, SW13, and PK cells. The infecting virus causes characteristic cytopathic effects (CPE) (e.g., plaques, cell fusion, and/or syncytium formation). CPE patterns can assist in determining the genus and possibly the family of virus. Another viral amplification technique includes the intracerebral inoculation of specimen into 2- to 3-day-old suckling mouse brain (SMB). If virus is present, the mice will develop paralysis and die within 2 weeks of inoculation. Occasionally viruses require multiple passages in SMB for neuroadaptation of the viral isolate. Other organ specimens should also be harvested from mice, including liver and kidney. For example, certain orthobunyaviruses replicate at a higher titer in liver compared to brain. Adaptation of the viral isolate in cell culture requires inoculation using infected homogenized infected tissue followed by multiple passages of the virus isolate in cell culture.

Many arboviruses, including DENV and Sindbis virus (SV), can also be amplified by direct injection into competent mosquitoes such as Aedes, Culex, and Toxorhynchites species (reviewed in reference 44), or in mosquito cell lines (C6/36 and AP61) (45, 46). Occasionally these viruses can cause persistent infections in mosquito cell lines with no apparent CPE. Careful quality control is required for maintenance of mosquito cell lines to monitor persistent infection by a virus contaminant.

When specimens are submitted to a reference laboratory for virus isolation, multiple cell lines or methods of virus isolation are used depending on where the specimen is obtained, based on common circulating viruses in the region. Typically, the specimen is first inoculated into cell culture using at least one mosquito cell line and various mammalian cell lines, particularly Vero and BHK21. The inoculated cell culture flask is monitored daily for CPE. To maintain virus infectivity, a neutral pH is maintained in the cell culture flask throughout the virus growth procedure and checked daily. Acidic environments (pH <6) cause conformational changes in the virus structural proteins and render the virus noninfectious in cell culture. In the absence of CPE, a sample of the culture is tested for the presence of viral antigens using an immunofluorescent assay (IFA) that probes with cross-reactive monoclonal antibodies (mAbs) to identify viral family/genus. The virus isolate is usually stored in cell culture medium containing at least 10 to 20% fetal bovine serum and stored at −70°C for future characterization studies. Currently, inoculation in SMB is not permitted in many labs due to Institutional Animal Care and Use Committee (IACUC) rules that prohibit this method of virus amplification. For culture of human or animal serum, undiluted sera, and two additional sera
dilutions of $10^{-1}$ and $10^{-2}$ (to avoid viral interference for high-titered virus specimens) are inoculated. If a tissue specimen is received, it is homogenized and diluted by weight to volume basis (10 to 20%).

**IDENTIFICATION**

Virus detected in cell culture is identified by IFA using virus-specific mAbs that target the structural gene products, because they are the most divergent yet conserved within species. Antigenic characterization using species-specific mAbs cannot differentiate between genotypes or lineages and is only useful for viral species-specific identification. Polyclonal antibodies are also used to determine the virus family followed by testing with species-specific mAbs. Some of the targeted mAbs cross-react with epitopes identified in all species within a family/genus of viruses. These broadly cross-reactive mAbs or polyclonal antibodies identify the family of virus, which can then be tested with specific mAbs that target epitopes within the structural proteins that are conserved between species. Some limitations of IFA are false-positive results due to background and nonspecific antibody reactivity. Additionally, IFA is a subjective test and highly vulnerable to operator error. Depending on the tissue specimen, the background from the fluorescently tagged antibody can vary significantly. Autofluorescence can occur in certain specimens with high lipid content or an abundance of chitin protein found in insects. Sequence analysis provides finer differentiation between viruses within families and within serocomplex groups that determines the origin and the molecular epidemiology of the virus. Phylogenetic analysis can assist in tracking the virus movement and transmission within a region or throughout the world by spatial and temporal analyses (reviewed in reference 47). This analysis can determine the introduction rate of specific viruses in a region and the rate of evolution. Arbovirus evolution is interdependent on the host and the vector; thus, phylogenetic analysis cannot predict the dominant evolutionary change for increased adaptation to either host or vector (reviewed in reference 1).

Novel methodology for virus identification, such as deep sequencing, ultra-deep sequencing, or amplicon sequencing (sequencing the same DNA target amplicons many times to find rare mutations), may enhance the identification of new species or families of viruses from tissue, arthropod, or blood. Sequencing provides the advantage of identifying new subtypes of existing viruses or new species in vectors or vertebrate host prior to their emergence in the human population. Viruses that may rapidly evolve to infect humans as their amplifying or dead-end incidental host can be rapidly identified for prevention and control measures. For example, Chiu et al. reconstructed a newly discovered virus in less than 24 hours, which was significantly faster than conventional sequencing techniques (48). These researchers identified the Lone Star virus in the genus Bunyavirus, carried by Amblyomma americanum tick and related to the Heartland virus, an illness recently reported among farmers in Missouri (http://www.cdc.gov/ncezid/dvbd/heartland/index.html.)

**SEROLOGIC TESTS**

**Hemagglutination**

The hemagglutination inhibition assay (HIA) is a classic test used for arbovirus diagnostics and was the basis for virus family classification prior to genome sequencing. The test was first described in 1958 by Clarke and Casals and later adapted to a microtiter plate format in 1980 (49). HIA is not antibody isotype specific; hence, it does not differentiate between IgM and IgG. The presence of anti-arbovirus host antibodies in serum specimens inhibits the agglutination of the goose erythrocytes as observed by a button-like appearance of the erythrocyte in the 96-well microtiter plate. Defining a positive HIA titer is influenced by (i) the titer of the positive control used in the test and (ii) whether the infection is a primary or secondary arbovirus infection within the same genus. The results are subjective and vary by the experience of the laboratory technician performing the test.

The main advantage of HIA is that it can be used for surveillance involving multiple hosts since the test is not species-specific. Public health laboratories located in regions where multiple arboviruses are cocirculating routinely use HIA for vertebrate sentinel surveillance. ELISAs have essentially replaced the HIA in human specimen testing due to the difficulty in standardizing HIA reagents and buffers and the availability of goose erythrocytes. Additionally, the interpretation of the results for HIA is subjective and cross-reactivity between viruses within the same group or subgroup yields nonspecific results.

**Enzyme-Linked Immunosorbent Assay**

**IgM**

One component of the acquired immune response following an arbovirus infection is the synthesis of IgM antibodies. IgM is detectable in the late acute and the convalescent phase of the infection and is an indication of an acute or recent arbovirus infection. During the acute phase of infection (the first 5 days post onset of symptoms), a relatively small percentage (~<30%) of patients have detectable IgM antibodies; however, this varies by patient and virus. The peak IgM antibody titer occurs in the convalescent phase of the infection (6 to 14 days post onset of fever) and ELISA testing during this period yields the most reliable results. Commercially manufactured ELISAs for some arboviruses are available with varied sensitivities and specificities (Table 2).

IgM antibody capture ELISA (MAC-ELISA) format is preferred by most diagnostic laboratories and commercial diagnostic kits. There are two main reasons for this widespread use. First, the MAC-ELISA is based on capturing IgM antibodies on a microtiter plate using an anti-human IgM antibody, thus minimizing the interference of the high-avidity IgG antibodies binding to the antigen. Second, because many antigens are unpurified heterogenous protein products and often are composed of a mixture of viral antigens, the MAC-ELISA removes nonspecific antibody binding, allowing for many different sources of antigen to be used. In MAC-ELISA format, the antigen can be used in excess in combination with broadly cross-reactive mAbs that are generally arbovirus group-specific. Another advantage of the MAC-ELISA format is that antigens can be interchanged to compare antibody response to many different arboviruses within the same family, mainly due to the use of broadly cross-reactive monoclonal antibodies conjugated to a detector molecule. The MAC-ELISA is a sensitive test; however, the specificity of the test varies and is dependent on other arboviruses circulating that can cause cross-reactivity in the test. For example, in countries where DENV and JEV cocirculate, there is a high degree of cross-reactivity in the IgM ELISA results that may require confirmation with a neutralization test.
The sensitivity and specificity of the MAC-ELISA are dependent on the source of the antigen, the detector antibody, the conjugated chromogen, serum condition (unacceptable conditions include hemolyzed, lipemic, or contaminated with bacteria), and the dilution of the specimen used for the test. The viral antigens used in the MAC-ELISA are produced by virus inoculation in SMB, virus inoculated in cell culture, and/or recombinant antigens produced in bacteria expression vectors. SMB-derived antigen provides the highest sensitivity in the MAC-ELISA because it is composed of a high-titer mixture of all viral antigens, yet it is the least specific due to its impurity. Conversely, recombinant antigens, developed from immunogenic structural gene products, can be less sensitive but provide better test specificity. Recombinant antigens may maintain the native conformation or glycosylation of arbovirus structural proteins, which are essential for antibody binding. Those recombinant antigens that maintain the native form of the protein tend to provide the most sensitive and specific result.

IgM kinetics can vary by arbovirus family, genera, and species and by primary versus secondary infections. For example, secondary DENV infections (>1 DENV infection) had lower IgM titers compared with primary DENV infections (50). In these unique cases, IgG seroconversion is the serologic confirmatory test (51). In other atypical cases, the IgM response may persist for at least 3 months or as long as a year, as observed with WNV and JEV infections (52–54). IgM persistence observed with some arboviruses infections has prompted the development of IgG-antibody avidity tests to assess the infection status (acute, recent, or past) (55).

For encephalitic arboviruses, the detection of IgM antibodies in CSF differs from detection in serum. For JEV infections, anti-JEV IgM is detectable in serum approximately 9 to 13 days following onset of symptoms; however, in the CSF IgM is detectable as early as 1 day post onset of symptoms (56). When testing serum specimens with HIA, Burke et al. assessed that this test was inadequate to confirm 34% of the encephalitis cases as JEV infection when compared to MAC-ELISA (57). In addition, anti-JEV IgM antibodies can be present in the CSF for as long as a year, suggesting persistent JEV infection of the CNS (58).

IFA has also been used as an indirect IgM test to assess reactivity against arboviruses. Fixed arbovirus-infected cells are spotted onto a slide and patient serum specimen is added. Following several washes to remove excess antibodies, a fluorescently labeled anti-human IgM- or IgG-specific mAb is then added to the slide. The result is a subjective determination of fluorescence observed by microscopic analysis (Table 2).

Reference and public health diagnostic laboratories may use in-house developed IgM tests; however, many commercial IgM and rapid tests are available for some of the medically important arboviruses including WNV, JEV, YFV, and DENV (59–61) (Table 2). Some of these commercial tests have very good sensitivity and specificity when compared to gold standard or reference tests. Prior to implementing a commercial assay, each diagnostic laboratory should perform a comprehensive independent evaluation (62).

IgG

The presence of anti-arbovirus IgG antibodies is an indication of a long-term acquired immunity from past arbovirus infection. These IgG antibodies can be detected for up to 60 years after the initial infection, as determined for DENV (63). There are two primary methods to measure IgG, direct and indirect ELISA. Direct IgG ELISA is less sensitive than the indirect method and requires purified viral antigen. The indirect IgG ELISA is more sensitive and uses a capture antibody to immobilize the viral antigen to a solid surface. This capture step is especially important for unpurified antigens generated from virus infection of SMB, since this antigen is less immunogenic unless it has been captured and concentrated (64). The captured antigen is then detected with a secondary anti-human IgG-enzyme conjugated antibody. The indirect IgG ELISA has essentially replaced HIA because of its ease of use and improved specificity. The IgG ELISA results are reported as qualitative, quantitative, or as end-point dilutions (51, 64). However, due to cross-reactivity within families and between species of viruses, the IgG ELISA lacks specificity and may require additional confirmatory testing such as a neutralization test for virus identification. The IgG ELISA will bind all available anti-arbovirus IgG (neutralizing or nonneutralizing antibodies); hence, the test tends to be more sensitive and less specific than the plaque reduction neutralization test (PRNT). Another test for IgG detection in serum specimens is the IFA as previously described (Table 2).

Some investigators have explored the use of other structural antigens besides the envelope protein to increase the specificity of the IgG ELISA for flaviviruses. Cardosa et al. demonstrated that the IgG response to premembrane (prM) protein has greater specificity when differentiating between DENV and JEV (65). Other researchers have improved the specificity in the IgG ELISA by using a recombinant polypeptide located in the N-terminal portion of the envelope protein (66). IgG avidity ELISAs have proven useful in differentiating primary versus secondary flavivirus infection (67, 68). The avidity assay uses stringent 3 to 6 M urea wash buffer in order to remove nonspecific IgG binding. This stringent wash step has been useful in differentiating acute from past arbovirus infections during unique circumstances in which the IgM response persists (55, 69).

Analyses of IgG by subclass have been studied as markers of disease severity (70–72). For JEV, subclass IgG1 is the most abundant antibody in the CSF following confirmed cases of clinical encephalitis. Thakare et al. found undetectable levels of IgG2 subclass in sera or CSF of JEV patients and postulated that the IgG1 subclass is more cytophilic than other IgG subclasses and may be more effective in viral clearance (70). For DENV patients, IgG1 and IgG4 subclasses are risk markers for the development of dengue hemorrhagic fever and dengue shock syndrome (the more severe presentation of the disease) (71, 72).

Neutralization

PRNT is the most specific serologic tool for the determination of type-specific antibodies and is typically used to confirm the infecting arbovirus in convalescent-phase sera (73). This biological assay is the specific interaction of virus and antibody in vitro, resulting in the inactivation of the virus such that it is no longer able to infect and replicate in cell culture. PRNT results are presented as the endpoint titer of neutralizing antibodies from sera to a specific virus and may suggest the level of immune protection against the infecting virus. Two main uses of PRNT are (i) for vaccine studies to determine immune protection and (ii) for virus confirmation in IgM- or IgG-positive specimens.

PRNT is the confirmatory test used to assess the infecting virus when cross-reactivity is observed in IgM and IgG tests. Because PRNT requires from 4 to 10 days for a result (depending on the virus), it is not typically used for clinical diagnosis. Additionally, this test is not routinely performed...
in most diagnostic laboratories because it is expensive and requires a tissue culture facility and highly skilled technical staff. To obtain reliable and reproducible PRNT results, laboratories must standardize viral strains and cell lines. Unfortunately, there is no consensus of the percent of antibody-induced plaque reduction that determines a positive result in the test. Some laboratories set a positive test result at 70% reduction of the total input plaquing virus and others use 90% reduction. Although a 90% reduction in plaques provides higher specificity, it is often less sensitive. In vaccine studies, 50% reduction in plaques provides the sensitivity needed because of the relatively low neutralization titer produced following vaccination with attenuated strains of viruses in naive subjects. The challenge of PRNT is the standardization among all end users. As stated previously, three variables account for most of the inconsistent results observed between laboratories: interpretation of the results (PRNT 90%, 70%, 50% reduction), the cell lines used for plaquing the virus, and the laboratory viral strains. In an attempt to standardize the PRNT worldwide for DENV, subject matter experts from around the world published guidelines for PRNT standardization (74).

Antibody neutralization has been studied extensively in animal models, natural infections in humans, and in vitro cell culture experiments. Neutralizing antibodies are primarily directed against the structural proteins of the virus. The neutralization epitopes for genus Flavivirus are located throughout the E glycoprotein, including domain I, domain II, and the surface of domain III (75–77). For the Flavivirus genus, the neutralizing epitopes have been mapped primarily to the E2 envelope protein, which is also important for receptor binding and cell entry. Similar E2 epitope clustering in the glycoprotein has been identified for many of the members of the genus Alphavirus (e.g., VEE and SV) and Ross River virus (RRV) (78, 79). Lastly, for the genus Bunyavirus, the neutralizing epitopes are found within the G1 glycoprotein (80).

Viral neutralization requires that multiple antibodies occupy the surface of the virion to inhibit the viral infection. This is referred to as the multihit mechanism (81, 82). A homologous antibody response would be more effective in virus neutralization than a heterologous response. A combination of neutralizing, nonneutralizing, and subneutralizing antibodies has a synergistic effect. In other instances, heterologous antibodies are hypothesized to potentiate or enhance viral entry as observed with DENV and WNV (83–85).

Flaviviruses have both group-specific and type-specific antibody neutralization determinants. The type-specific determinants are cross-reactive when tested in heterologous reactions, causing the cross-reactivity observed in serological IgM and IgG tests. The neutralizing antibody titer required for protective immunity is still not well understood. Vaccine studies have provided information on protective antibody titers for flaviviruses, such as YFV, JEV, and DENV; however, many of these studies were from primary infections with attenuated vaccine strains.

Commercial Tests

Many commercial tests have been developed for the identification of arbovirus infections (Table 2). These tests include molecular tests, antibody tests, and IFA. The formats vary from standard microtiter plate tests to rapid diagnostic tests with variable sensitivity and specificity as evaluated by the manufacturer or by independent investigators. Advantages of commercial tests include (i) standardization of the ancillary reagents, which allows for reproducible results between testing laboratories, and (ii) production of tests under good manufacturing practice (GMP). Commercial tests may provide the end user with higher quality assurance often not associated with in-house developed tests. However, commercial assays can vary in quality (lot-to-lot variations) and in reliability (test availability). Companies on occasion discontinue manufacturing these tests when the market is not profitable, leaving the end user, in particular reference laboratories, with no other option than to maintain laboratory-developed tests (LDTs). Additionally, commercial tests may be cost-prohibitive in comparison to LDTs, resulting in a preference to use LDTs despite the fact that LDTs may not be as sensitive as their commercial counterparts. Other aspects of the tests unrelated to their performance that may determine their use in laboratories are technical time needed to perform the test, storage requirements, reagent stability, and ease of use.

Another factor to consider is commercial test quality. Each country has different regulatory agencies of manufacturing and distribution that determine test quality. U.S. commercial laboratories require Food and Drug Agency (FDA) approved tests for clinical diagnostics. In order to reduce duplicative efforts, some countries rely on the U.S. FDA regulatory approval process for the use of commercially available tests for clinical diagnosis. Other countries have developed their own internal assessment requirements. The risk of a false-positive or false-negative result is dependent on the disease and clinical treatment. There are limited available commercial tests for most arboviruses, with the exception of DENV, JEV, CHIKV, and WN, and even fewer FDA approved tests (Table 2). Although many of these tests claim very good performance for sensitivity and specificity, independent evaluations are important corroboration of the company’s results. Recent studies involving DENV diagnostics for both IgM tests and NS1 tests determined that the performance for some of the companies was below the acceptable range for use. This study also determined that tests that depend on subjective reading of results, such as rapid diagnostic tests, often have large variation due to reader-to-reader variation (59).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

The testing algorithm for diagnosing acute arboviral infection is a matrix divided into acute and convalescent specimen collection (Fig. 1). The acute serum or CSF specimen (DPO, ≤5) is tested for the presence of virus by NAAT, virus isolation, or viral antigen tests, or for IgM in CSF for encephalitic viruses. The convalescent-phase serum or CSF specimen (DPO, >5 to <14) is tested for the presence of IgM and IgG antibodies. An acute arbovirus infection is defined as the detection of virus by isolation or NAAT or seroconversion by IgM and/or IgG. A single specimen with an IgM positive test result suggests a recent infection. Rare cases of viral RNA persistence have been reported, notably for WN and CTFV. The detection of only IgM in a specimen is an indication of a past infection unless paired specimens indicate seroconversion. IgM seroconversion in paired specimens is defined as a negative test result in the acute-phase specimen followed by a positive test result in the convalescent-phase specimen. IgG seroconversion is the same as for IgM (negative in acute, positive in convalescent) or a 4-fold rise in IgG titer from the acute specimen to the convalescent specimen with a minimum of 5 to 7 days between specimens. Because of the high degree of cross-reactivity observed within arbovirus genera, serology results are generally
confirmed with neutralization tests when definitive diagnosis is required. The testing algorithm for other specialized epidemiological studies, including seroconcentration and/or serosurveys to measure the prevalence in the population, is different than that for defining acutely ill patients, and testing must be modified. Serosurveys and seroconcentration studies assess the transmission of arboviruses and the prevalence within the population typically used for vaccine or public health intervention studies. Because these epidemiological studies rely on measuring acute, recent, and past infection, the testing algorithm and the interpretation of the test results differ and require other relevant study subject information, such as travel history, vaccination history, age, and other demographics, to accurately determine the prevalence of specific arbovirus infections within a particular population.

Hantaviruses
CHARLES F. FULHORST AND MICHAEL D. BOWEN

Hemorrhagic fever with renal syndrome (HFRS) and hantavirus pulmonary syndrome (HPS, also referred to as hantavirus cardiopulmonary syndrome, HCPS) are rodent-borne zoonoses caused by certain members of the virus family Bunyaviridae, genus Hantavirus. A hallmark of HFRS and HPS is a reversible increase in the permeability of small blood vessels. Diagnosis early in the course of disease is critical to the successful management of HFRS and HPS.

TAXONOMY
The International Committee on Taxonomy of Viruses currently recognizes 24 species in the genus Hantavirus (http://www.ictvonline.org/index.asp). Strains of 12 of these species and 11 other named hantaviruses have been causally associated with HFRS or HPS (Table 1).

Specific rodents (i.e., one or two closely related members of the order Rodentia) are the principal hosts of the hantaviruses known to cause human disease. Other natural hosts of hantaviruses include shrews (2) and moles (3), which are members of the order Soricomorpha. The geographical distribution of human disease caused by a particular hantavirus subsumes the geographical range of its principal rodent host(s) (Table 1).

The rodent-borne hantaviruses are divided into three groups based upon the taxonomic assignment of their principal host(s): family Muridae, subfamily Murinae (Old World rats and mice); family Cricetidae, subfamily Arvicolinae (voles and lemmings); and family Cricetidae, subfamilies Neotominae and Sigmodontinae (New World rats and mice). Murine rodents and voles are the principal hosts of the hantaviruses known to cause HFRS; neotomine rodents and sigmodontine rodents are the principal hosts of the hantaviruses known to cause HPS (Table 1). Many rodent-borne hantaviruses, particularly those associated with voles or lemmings, have not been associated with human disease. The degree of genetic and antigenic relatedness among rodent-borne hantaviruses typically correlates with the degree of (phylo)genetic relatedness among their respective principal hosts.

DESCRIPTION OF THE AGENTS
Hantavirus is pleomorphic, averages 100 nm in diameter, and possesses a lipid-bilayer envelope (1). The envelope displays a grid-like pattern that is apparent when negatively stained virions are viewed by electron microscopy (Fig. 1) (4). Protruding from the lipid envelope are spikes, approximately 6 nm in length, which are formed from the virus glycoproteins Gn and Gc (1). The virion interior contains ribonucleocapsids—segments of single-stranded genomic RNA complexed with nucleocapsid protein and L protein (an RNA-dependent RNA polymerase).

The genomes of hantaviruses consist of three unique negative-sense, single-stranded RNA molecules, designated L (large, approximately 6.5 to 6.6 kb), M (medium, 3.6 to 3.7 kb), and S (small, 1.7 to 2.1 kb) (1). These RNA molecules encode the L protein, the glycoprotein precursor (which is cotranslationally cleaved to yield the envelope glycoproteins Gn and Gc), and the nucleocapsid protein, respectively. The S segments of some hantaviruses appear to encode a functional nonstructural (NSs) protein (5). The ribonucleocapsids display helical symmetry and form circular structures as a result of base pairing by highly conserved, inverse complementary nucleotide sequences at the termini of each genomic segment (1).

EPIDEMIOLOGY AND TRANSMISSION
Hantaan virus, the prototypical member of the genus Hantavirus, is the cause of a severe form of HFRS in South Korea, China, and eastern Russia; Dobrava-Belgrade virus is an agent of a severe form of HFRS in the Balkans, Greece, and Russia; Seoul virus is an agent of a relatively mild form of HFRS in Asia, Europe, and the Americas (6); and Puumala virus is the agent of nephropathia epidemica, which is a relatively mild form of HFRS in Europe and western Russia. Other hantaviruses known to cause HFRS include Saaremaa virus in Europe (7) and Amur virus in eastern Russia (8). The case-fatality rate of HFRS ranges from 0.2% (Puumala virus) to 15% (Hantaan virus). Approximately 30,000 HFRS cases occur worldwide each year (9); the majority of these cases occur in Asia and are caused by Hantaan or Seoul virus.

The geographical distribution of HPS includes Canada, the contiguous United States, Panama, and eight South American countries (Table 1). Arguably, Sin Nombre virus and Andes virus are the major causes of HPS in North America and South America, respectively. From 1993 through 2009, 510 HPS cases in the United States were reported to the National Notifiable Diseases Surveillance...

<sup>a</sup>Other named hantaviruses that have been associated with human disease include Amur virus (eastern Russia, HFRS); Monongahela virus (United States, HPS); Choclo virus (Panama, HPS); Central Plata virus (Uruguay, HPS); Bermejo, Leciguana, and Oran viruses (Argentina, HPS); and Anajatuba, Araarauquara, Castelo dos Sonhos, and Juquitiba viruses (Brazil, HPS). The Korean field mouse (Apodemus peninsulae) is the principal host of Amur virus; the white-footed mouse (P. leucopus) is the principal host of Monongahela virus; sigmodontine rodents are natural hosts of Anajatuba, Araarauquara, Bermejo, Central Plata, Choclo, Jaquitiba, Leciguana, and Oran viruses; and the natural host(s) of Castelo dos Sonhos virus are not known.

<sup>b</sup>HFRS, hemorrhagic fever with renal syndrome; HPS, hantavirus pulmonary syndrome.

<sup>c</sup>Murinae, Old World rats and mice; Arvicolinae, voles and lemmings; Neotominae and Sigmodontinae, New World rats and mice.

Humans usually become infected with hantaviruses by inhalation of aerosolized droplets of urine, saliva, or respiratory secretions from infected rodents or by inhalation of aerosolized particles of feces, dust, or other organic matter contaminated with secretions or excretions from infected rodents. The aerosol transmission of hantaviruses from rodents to humans has been well documented (12, 13). Other means of infection include contamination of cutaneous injuries with infectious virus, contact of infectious materials with mucous membranes, ingestion of food contaminated with infectious rodent secretions or excretions, and—only in the case of Andes virus—contact with an HPS case during the acute phase of illness (14). Note that person-to-person transmission of hantavirus has never been documented in Europe, Asia, or North America.

In nature, the risk of infection in humans depends upon occupational or recreational activities, ecological factors that affect the abundance of infectious rodents, and other variables that influence the frequency and intensity of human exposure to infected rodents and their secretions or excretions. The cleaning of closed quarters occupied by infected rodents has been repeatedly associated with an increased risk of infection (15–17), and a recent outbreak of HPS among visitors to a national park in the western United States created far-reaching (i.e., global) challenges with regard to locating persons potentially exposed to hantavirus-infected rodents immediately before or during the outbreak (18).

CLINICAL SIGNIFICANCE

The clinical and pathological features of nephropathia epidemica, severe HFRS, and HPS were reviewed recently (19). Both syndromes are associated with acute thrombocytopenia and a reversible increase in microvascular (capillary) permeability. A major difference between the two syndromes is that the retroperitoneum is the major site of the vascular leak in HFRS, whereas the lungs and thoracic cavity are the major sites of the vascular leak in HPS.

The length of the incubation period in HFRS and HPS usually is 2 to 4 weeks but can range from a few days to 2 months. The clinical course of HFRS can be divided into five phases: prodrome (typically 3 to 7 days), hypotensive (several hours to 4 days), oliguric (4 to 5 days), diuretic (7 to 11 days), and convalescent (weeks to months). Similarly, the clinical course of HPS can be divided into four phases: prodrome (3 to 6 days), cardiopulmonary (7 to 10 days), diuretic (1 to 3 days), and convalescent (weeks to months). Death in HFRS is usually due to shock in the hypotensive or diuretic phase. Death in HPS is usually attributed to hypoxia (pulmonary edema) or shock in the cardiopulmonary phase.

In severe HFRS caused by Hantaan virus or Dobrava-Belgrade virus, the prodrome usually begins with an abrupt onset of high fever, chills, headache, blurred vision, malaise, and anorexia, then includes severe abdominal or lumbar pain, gastrointestinal symptoms, facial flushing, petechiae, and an erythematous rash or conjunctival hemorrhage. The hypotensive phase begins with a characteristic drop in platelet number followed by defervescence and abrupt onset of hypotension, which may progress to shock and more apparent hemorrhagic manifestations. Other abnormalities may include elevated serum levels of aspartate transaminase (20). In the oliguric phase, blood pressure returns to normal or becomes high, urinary output falls dramatically, concentrations of serum creatinine and blood urea nitrogen increase, and severe hemorrhage may occur. Spontaneous diuresis, with polyuria greater than 3 liters per day, heralds the onset of recovery. Distinct clinical phases are less obvious in HPS caused by Seoul virus and nephropathia epidemica, and visible superficial hemorrhages usually do not occur in nephropathia epidemica (21). Pathological findings in HFRS at autopsy include effusions in body cavities, retroperitoneal edema, and enlarged, congested, hemorrhagic kidneys (22).

HPS was first recognized in 1993 as a highly fatal disease in the southwestern United States (23). The original description of HPS (24) subsequently was modified to include mild infections that do not result in radiographic evidence of pulmonary disease (25). It is now recognized that HPS sometimes includes renal impairment and, at least in South America, bleeding manifestations (26, 27). The prodrome in HPS is characterized by fever, myalgia, and malaise. Other symptoms that may occur during the prodrome include headache, dizziness, anorexia, abdominal pain, nausea, vomiting, and diarrhea. Nonproductive cough and tachypnea usually mark the onset of pulmonary edema. Fully developed HPS is characterized by rapidly progressive (time span of 4 to 24 hours) noncardiogenic pulmonary edema, hypoxemia, large volumes of pleural effusion, and cardiogenic shock. Hypotension and oliguria are the result of shock. Myocardial depression may occur and contribute to shock (28). The diuretic phase is characterized by rapid clearance of pulmonary edema and resolution of fever and shock. Hematologic abnormalities in HPS at hospitalization include thrombocytopenia, hemococoncentration, and the presence of large, reactive (immunoblastic) lymphocytes (29, 30). Other laboratory abnormalities may include elevated levels of hepatic enzymes, hypoalbuminemia, metabolic acidosis, and, in severe cases, lactic acidosis. The gross abnormalities in fatal HPS at autopsy include copious amounts of frothy fluid in bronchi and other airways; heavy, edematous lungs; and large volumes of pleural fluid (30, 31).

Therapy

Successful management of HFRS and HPS begins with prompt recognition of the disease and hospitalization of the patient. Shock in HFRS usually can be effectively managed by judicious administration of vasopressors and intravenous fluids. Intravenous ribavirin given within the first few days of the onset of clinical disease has been shown to significantly decrease morbidity and mortality in HFRS in the People’s Republic of China (32). The oxygen status of an HPS patient should be closely monitored so that oxygen supplementation and mechanical ventilation can be provided if required. Transfer to a state-of-the-art critical care facility with the capacity for extracorporeal membrane oxygenation should be an early consideration since life-threatening pulmonary edema and cardiogenic shock can develop rapidly in HPS (28). Immune (neutralizing) serum may prove beneficial in the treatment of HPS because (i) survival in HPS cases has been positively correlated with neutralizing antibody titers at admission (33) and (ii) post-exposure passive antibody therapy has protected Andes virus-infected laboratory rodents against lethal HPS-like disease (34). The effect of ribavirin on the course and outcome of HPS has not yet been rigorously investigated (see “Antivirals” below).

Vaccines

There are no World Health Organization-approved hantavirus vaccines available; however, inactivated vaccines have been developed in Asia and used locally in South Korea and China for the protection of humans against HFRS (35). These vaccines were prepared from the brains of suckling rats or mice or from cell cultures infected with Hantaan virus or Seoul virus. Hantaan virus (Great Lakes Biological Laboratories, Inc., Cleveland, Ohio) and other inactivated vaccines that have been tested in humans yielded only low levels of neutralizing antibodies at 1 year after the last vaccine dose, raising concern about the duration of protection afforded by these vaccines (36–38). Optimization of vaccination schedules and advances in adjuvant technology may increase the duration of immunity elicited by inactivated vaccines.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

The clinician should consult with local health authorities and national (or international) reference laboratories that maintain diagnostic capability for hantaviruses before shipping clinical specimens to a diagnostic laboratory.

Infectious hantavirus has been isolated from blood, serum, urine, and cerebrospinal fluid collected soon after the onset of clinical disease (39). Thus, blood, serum, urine, respiratory secretions, and other biological materials from HFRS and HPS patients, especially specimens collected during the acute phase of illness, should be considered potentially infectious to humans. Laboratory workers should use standard procedures for infection control and should follow Centers for Disease Control and Prevention guidelines for handling infected human tissues (39). The exact infectious dose has never been defined; however, ribavirin, a potent inhibitor of hantavirus replication, has been shown to effectively reduce the viral load in experimental infections of susceptible animals (39–41). The use of ribavirin for patients with HPS is currently under consideration. The first case of HPS originating in the United States was transmitted to laboratory personnel (42, 43). Proper handling of hantavirus-infected tissue and body fluids is essential to ensure that it is not transferred to personnel or equipment.

Proper handling of hantavirus-infected tissue and body fluids is essential to ensure that it is not transferred to personnel or equipment.
tions for the handling of hantavirus clinical specimens: (i) sera from potential HFRS or HPS cases should be handled at biosafety level 2 (BSL-2), (ii) potentially infectious tissue specimens should be handled at BSL-2 using BSL-3 practices, (iii) all procedures that could result in splatter or aerosolization of human body fluids should be done inside a certified biological safety cabinet, and (iv) propagation of virus in cell culture and virus purification should be carried out in a BSL-3 facility using BSL-3 practices (40). Hantaviruses are thermolabile (41) and can be inactivated by acids, alcohols, bleach, paraformaldehyde, detergents that disrupt lipid membranes, many commercial disinfectants, and UV irradiation (7, 39, 42, 43).

Blood, serum, and plasma samples for serology may be stored at 4°C and shipped to the diagnostic laboratory on cold packs if there is no significant delay between collection and testing. Otherwise, these specimens should be stored at −20°C or colder and shipped on dry ice. Blood, blood clots, solid tissues, and other samples intended for RNA extraction or virus isolation should be stored continuously at −70°C or colder, subjected to as few freezethaw cycles as possible, and shipped on dry ice in order to preserve the integrity of the viral RNA and infectivity of the virus. Samples shipped by air should be packaged, documented, and shipped in accordance with International Air Transport Association Dangerous Goods Regulations (http://www.iata.org). In the United States, ground shipments must comply with regulations issued by the U.S. Department of Transportation (49 CFR parts 171 to 178).

DIRECT EXAMINATION

Laboratory assays that have been used for diagnosis of hantaviral infections in humans have not been standardized; as such, no hantavirus diagnostic assays have received approval from the U.S. Food and Drug Administration. Diagnostic test kits that are commercially produced in Europe are sold “for research use only” in the United States.

Microscopy

Direct electron microscopic examination of tissues is of limited diagnostic value but has been used to detect virions and viral replicative structures in autopsy samples. Electron microscopic examination of autopsy tissues from HFRS and HPS patients found that mature virions are infrequent in tissues and can be difficult to identify due to considerable polymorphism in size and shape. Structures determined to be hantaviral inclusion bodies were seen more often than intact virions (31, 44).

Antigen Detection

Immunohistochemistry has been used to detect hantaviral antigens in tissues from fatal HFRS cases, biopsy materials from nephropathia epidemica cases, and tissues from fatal HPS cases (Fig. 2) (31). Polyclonal antibodies (e.g., immune sera from humans, experimentally infected rabbits, experimentally or naturally infected rodents) and murine monoclonal antibodies have been used as primary antibodies in immunohistochemistry assays. Fatal HPS is associated with widespread distribution of hantaviral antigen in lung, liver, spleen, kidney, and heart tissues, with antigen primarily localized within endothelial cells of capillaries and other small blood vessels (31). Immunohistochemistry assays for diagnosis of hantaviral infections in humans are limited to the few institutions that have access to the appropriate primary antibodies and control (comparison) tissues.

Nucleic Acid Detection

Since the 1993 outbreak of HPS in the southwestern United States, reverse transcription PCR (RT-PCR) assays have been employed extensively to (i) detect hantaviral RNA in clinical samples from HPS and HFRS patients and (ii) obtain amplicons for viral characterization by DNA sequencing. Total RNA can be extracted from blood, plasma, serum, and solid tissues (e.g., kidney and lung), and can be protected from RNase degradation by using methods that employ chaotropic salts such as guanidinium isothiocyanate. Other specimens that may yield measurable levels of hantaviral RNA include urine and saliva. Sets of oligonucleotide primers have been designed to anneal to regions of the S and M genomic segments that are highly conserved among the hantaviruses (23, 45, 46). RT of hantaviral RNA and subsequent PCR amplification of the resulting cDNA usually can be accomplished by using a “one-step” single-tube format in which a single set of oligonucleotides is used to prime both enzymatic reactions. Clinical specimens rarely yield an RT-PCR product that can be visualized by UV transillumination of agarose gels stained with ethidium bromide or other DNA-binding dyes; consequently, a second (i.e., nested) PCR amplification usually must be performed to obtain amplicons that can be detected on gels and purified for sequencing. The lower limit of detection for nested RT-PCR assays for hantaviruses has been reported to be less than one viral fluorescent focus unit or (approximately) 316 median cell culture infectious doses of virus per 1.0 ml (47, 48). RT-PCR assays have been used to detect hantaviral RNA in fixed, paraffin-embedded tissues (49). Real-time RT-PCR assays have been developed for some hantaviruses and are being used increasingly for routine diagnosis (47, 50–54). These assays match or exceed the sensitivity of nested RT-PCR assays (with less manipulation of reaction components and shorter times to detection compared to conventional RT-PCR assays) and can provide precise estimates of viral load in clinical samples.

ISOLATION PROCEDURES

Isolation of infectious hantavirus from blood, serum, urine, or solid tissues using cultured cells or live laboratory animals...
is significantly less sensitive and requires considerably more time than for established RT-PCR assays for hantavirus-specific RNA. Thus, virus isolation is not commonly used for the diagnosis of hantaviral infections in humans.

The Vero E6 cell line (ATCC CRL-1586) has been used to isolate infectious hantaviruses from blood, solid tissue, and/or urine samples from HFRS patients and from serum and urine of HPS cases caused by Andes virus (55, 56). Typically, monolayer cultures of Vero E6 cells are inoculated with a crude or clarified tissue homogenate and then maintained under a fluid overlay for 10 to 14 days. Successful virus isolation may require repeated blind passages of inoculated cell culture material. Hantaviruses usually are neither cytopathic in cultured cells nor pathogenic in laboratory rodents; consequently, detection of infection in cultured cells and in tissues of laboratory rodents often requires an indirect method (e.g., fluorescent antibody test for viral antigen or RT-PCR assay for hantavirus-specific RNA).

IDENTIFICATION

Serologic Methods

Historically, serologic methods were used to define taxonomic relationships among the hantaviruses. Neutralization of infectivity in vitro, immunofluorescent antibody assays (IFA), enzyme-linked immunosorbent assays (ELISA), and a variety of other serologic methods have been used to characterize hantaviruses isolated from clinical samples and rodents. The antibodies used in these assays have included immune sera from HFRS or HPS patients, immune sera from experimentally or naturally infected rodents, and immune mouse ascitic fluids. Overall, serologic cross-reactivity within the genus Hantavirus is greatest between hantaviruses principally associated with phylogenetically closely related rodent species, and usually is higher in antigen-binding assays such as IFA and ELISA than in neutralization assays. Neutralization of infectivity has been measured by plaque reduction in monolayer cultures of Vero E6 cells maintained under an overlay containing agarose (57) or methylcellulose (58). The focus-reduction neutralization test is used more widely than the plaque-reduction neutralization test because some hantaviral strains do not consistently produce readily discernible plaques in monolayer cultures of cells stained with neutral red. Foci of infected cells (viral antigen) in the focus-reduction neutralization test can be revealed by immunochemical staining (59) or chemiluminescence (60).

Genetic Methods

The use of genetic sequence data to define taxonomic relationships within the genus Hantavirus has become standard practice, in part because a majority of hantaviruses have never been adapted to growth in cultured cells and because our knowledge of the serologic relationships among some hantaviral species is based on one strain per species. Since an RT-PCR or nested PCR product can be amplified directly from RNA extracted from clinical materials and then sequenced, analysis of sequence data (particularly from the nucleocapsid protein gene or Gc region of the glycoprotein precursor gene) usually provides the most rapid and specific means for determination of the species identity of a hantavirus.

TYPING SYSTEMS

Analysis of nucleotide sequence data provides the fastest and most discriminating method for typing of hantaviruses. In pairwise comparisons, nonidentities among the complete glycoprotein precursor gene sequences and among the complete nucleocapsid protein gene sequences of strains of different hantaviral species ranged from 17.5% (Saaremaa virus [GenBank accession no. AJ009774] and Dobrava-Belgrade virus [AJ410616]) to 49.1% (Bayou virus [GQ244521] and Thottapalayam virus [DQ825771]) and from 19.3% (Bayou virus [GQ200820] and Black Creek Canal virus [L39949]) to 46.5% (Seoul virus [AY273791] and Thottapalayam virus [AY526097]), respectively (Maria N. B. Cajimat, unpublished data). An advantage of sequence data is that it is not affected by variation between lots of antibodies or lots of antigens used in serologic typing. Furthermore, analysis of nucleotide sequence data enables subtyping of hantaviruses, which often can identify geographic variants and variants associated with particular rodent-host subspecies or populations.

SEROLOGIC TESTS

Virtually all HFRS and HPS patients have high levels of anti-hantavirus immunoglobulin M (IgM) in serum or plasma at or soon after the onset of clinical disease (61–64). Many of these patients also have measurable levels of anti-hantavirus IgG during the acute phase of their illnesses (62, 65–68). The IgM and IgG responses are directed first against the nucleocapsid protein and then against the glycoproteins (62, 69–72). Anti-hantavirus IgM may persist as long as 6 months after the end of the acute phase of illness in nephropathia epidemica (67) and longer than 2 months after the end of the acute phase of illness in HPS (65). The level of anti-hantavirus IgG increases through the end of the acute phase of illness, remains high for months or years, and then declines gradually (72). Anti-hantavirus IgG may persist as long as 10 years in HFRS cases (72) and more than 3 years in HPS cases (33).

Neutralizing antibodies may appear during the acute phase of HFRS and HPS and are reactive against the glycoproteins Gn and Gc. A strong neutralizing antibody response early in the course of infection has been positively associated with successful recovery from HPS caused by Sin Nombre virus (58). High titers of neutralizing antibodies have been found 10 to 20 years after infection in nephropathia epidemica cases (73) and as long as 11 years after infection in HPS cases (74). Antibodies (IgM and IgG) from patients infected with one hantavirus may cross-react with the nucleocapsid proteins or glycoproteins of other hantaviruses (66, 69, 75, 76), but IgG against Gn usually is more specific than anti-nucleocapsid protein IgG (62, 77). Neutralizing antibody, even in acute- or early convalescent-phase sera, can efficiently neutralize strains of several different hantaviral species and thus may not yield a species-specific diagnosis (78).

A variety of methods have been used to detect antibodies against hantaviruses in serum or plasma. These methods include high-density particle agglutination, IFA, immunoprecipitation, radioimmunounassay, hemagglutination inhibition, plaque- and focus-reduction neutralization, Western (immuno)blotting, IgM-capture (μ-capture) ELISA, and IgG ELISA. The most widely accessible and perhaps the best serologic method for diagnosis of HFRS and HPS in the face of disease is the IgM-capture ELISA, which is done by many national public health laboratories, some state and regional public health laboratories, and some commercial reference laboratories. Note that ELISA for anti-hantavirus IgM, which employs hantaviral antigen bound to a solid substrate, appears to be significantly less accurate (i.e., less
specific, with a higher rate of false-positive results) than IgM-capture ELISA (79).

The IgM-capture ELISA typically uses a lysate of hantavirus-infected cells for the test antigen and should include an uninfected cell lysate for the control (comparison) antigen and appropriate positive and negative control sera (63, 64, 80, 81). The IgM-capture ELISA can be highly sensitive for detection of anti-hantavirus IgM but may not be specific for the virus that was used to prepare the test antigen. For example, an IgM-capture assay for detection of antibody to a Sin Nombre virus antigen has detected IgM to all known agents of HPS in the Americas (63, 69, 82–84).

The antigens used in serologic assays for anti-hantavirus antibodies traditionally were prepared from cultures of virus-infected cells, concentrated virus, or tissues of naturally or experimentally infected rodents. Antigens must be rendered noninfectious prior to use. Inactivation of hantavirus usually is accomplished by gamma irradiation (60Co source). Heat treatment is an alternative method for making hantavirus antigens noninfectious prior to use in serologic assays (41).

Recombinant nucleocapsid proteins or glycoproteins expressed in bacteria, yeasts, insect cells, or mammalian cells, as well as synthetic peptides, have been used as antigens in IFA and ELISA for the detection of anti-hantavirus antibodies. The recombinant protein and synthetic peptide antigens can be more specific than native viral proteins in distinguishing between etiological agents of HFRS or HPS.

ANTIVIRAL SUSCEPTIBILITIES

Currently, there are no antiviral compounds approved by the U.S. Food and Drug Administration for the prevention or treatment of HFRS or HPS. However, ribavirin (1-β-D-ribofuranosyl-1,2,4-triazole-3-carboxamide) has been shown to have a significant therapeutic effect on the severity of HFRS in clinical studies done in South Korea and the People’s Republic of China (32, 85), and protected ANDV-infected laboratory rodents against lethal HPS-like disease when treatment was initiated early in the course of infection (86). In contrast, an open-label study done in the United States failed to demonstrate an appreciable effect on the lethality of HPS (87).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Early diagnosis is critical to the successful management of HFRS and HPS and, at least in the case of HPS caused by Andes virus, to implementation of appropriate isolation procedures to prevent virus transmission to health care providers and other persons. Diagnosis early in the course of disease is difficult because the hantaviral prodrome is similar to the prodrome of many other diseases. Fever and severe myalgia are prominent during the prodrome in HFRS and HPS. These symptoms, especially in patients who develop thrombocytopenia, should lead health care providers in regions of endemicity to suspect hantavirus disease.

The laboratory criteria for diagnosis of HPS established by the Centers for Disease Control and Prevention (see http://www.cdc.gov/hantavirus/health-care-workers/hrs-case-definition.html) are as follows:

- Presence of hantavirus-specific IgM in persons who meet the case definition for HPS (see http://www.cdc.gov/hantavirus/health-care-workers/hrs-case-definition.html) or a 4-fold or greater increase in titers of hantavirus-specific IgG in paired acute- and convalescent-phase serum samples
- Positive RT-PCR assay for hantavirus-specific RNA in plasma or other types of biological specimens
- Positive immunohistochemistry assay for hantavirus antigen in lung, spleen, kidney, or other solid tissues

These criteria could be used for laboratory diagnosis of HFRS as well.

As indicated previously, many HFRS cases and HPS cases have measurable levels of anti-hantavirus IgG during the acute phase of illness (62, 65–68). As such, confirmatory tests (i.e., assays for hantaviral RNA) should be done on diagnostic specimens from cases that are positive for anti-hantaviral IgM and negative for anti-hantaviral IgG.

The extreme sensitivity of RT-PCR assays, especially those employing nested PCR or real-time PCR, predisposes these tests to generating false-positive results as a consequence of template contamination. Accordingly, nucleic acid detection assays should include the proper negative controls and be supported by the results of tests for hantavirus-specific antibodies or antigen. Also, the proper controls for IgM-capture ELISA and IgG ELISA (e.g., sera from laboratory-confirmed HPS cases) and immunohistochemistry assays are essential for correct interpretation of the results of these assays. Most local laboratories do not have direct access to these materials. Thus, diagnostic testing is often limited to federal laboratories, research institutions that have a specific interest in HFRS or HPS, and a small number of commercial laboratories.

As noted previously, testing procedures for the detection of hantavirus infections in humans have not been standardized. Thus, confidence in the results reported from individual laboratories varies substantially according to the tests used and the rigor of the standards for diagnosis. In an external quality control study for serological diagnosis of hantavirus infections involving 18 laboratories in Europe and Canada, only 53 and 76% of IgM- and IgG-positive samples, respectively, were diagnosed correctly (88).

The requirement for reporting HFRS and HPS varies among local health agencies and from country to country. In the United States, reporting of HPS cases is mandated at the state level, and HPS is listed as a notifiable disease in the National Notifiable Diseases Surveillance System maintained by the Centers for Disease Control and Prevention, although reporting is not compulsory. Confirmatory laboratory tests (i.e., μ-capture ELISA for anti-hantavirus IgM, ELISA for anti-hantavirus IgG, and assays for hantavirus-specific RNA) at the Centers for Disease Control and Prevention typically are completed 24 to 48 hours after delivery of diagnostic specimens to the Viral Special Pathogens Branch (Centers for Disease Control and Prevention, 1600 Clifton Road, Atlanta, GA 30333; phone, [404] 639-1115; fax [404] 639-1118) (Pierre E. Rollin, personal communication). The results of these assays likely enhance the accuracy of the national surveillance system. Undoubtedly, the results of confirmatory tests on diagnostic specimens from all persons in the United States who are diagnosed with HPS would improve the epidemiological value of the national surveillance system.

The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the CDC. The use of product names in this manuscript does not imply their endorsement by the U.S. Department of Health and Human Services.
REFERENCES

This chapter focuses on the viral hemorrhagic fever (VHF) viruses from two taxa, the families Arenaviridae (1) and Filoviridae (2). Some, but not all, members of these virus families cause severe, frequently fatal VHF in localized areas of the world. Although exotic in North America, these viruses are important public health problems in Africa and South America and have the potential of being introduced into the United States by travelers returning from these areas. The arenaviruses and, particularly, the filoviruses have been associated with serious nosocomial outbreaks involving health care workers and laboratory personnel. However, more recent outbreaks have generally been in settings where infection control has been lax. The lack of nosocomial transmission associated with Lassa or Marburg HF cases imported into the United States or Europe would suggest that the implementation of standard infection control practices are sufficient to prevent virus spread within the medical care setting. During the ongoing West African Ebola outbreak, several infected health care workers have been evacuated to the United States and Europe. The U.S. guidelines for patient evaluation and management, sample collection, shipping and processing have been updated (http://www.cdc.gov/vhf/ebola/index.html). Unfortunately, such practices are not always possible in resource-poor regions within Africa or South America (http://www.cdc.gov/vhf/ebola/hcp/international/managing-patient-flow.html). Continuing detection and isolation of new arenavirus and filovirus species from new geographic locations remain important for public health. The similarity of initial isolation, clinical management, and viral diagnostic procedures for patients with suspected arenavirus or filovirus infections is the rationale for grouping these taxonomically distinct viruses in this chapter. Viruses from other taxonomic families, including Bunyaviridae and Flaviviridae (chapters 95 and 96), have also been associated with VHF (3).

**TAXONOMY AND DESCRIPTION OF AGENTS**

**Arenaviridae**

The family Arenaviridae comprises 43 named viruses which have unique morphologic and physiochemical characteristics. Antigenic relationships are established mainly on the basis of broadly reactive antibody binding assays, historically the complement fixation test (4), the indirect fluorescent-antibody (IFA) test (5), and, more recently, the enzyme-linked immunosorbent assay (ELISA). Both serologic and phylogenetic analyses of the viruses divide the arenaviruses into two complexes. The lymphocytic choriomeningitis (LCM) or Old World complex contains LCM virus and the Lassa viruses, including a number of apparently benign Lassa-like but unique viruses, Mopeia virus from Mozambique and Zimbabwe and Mobala and Ippy viruses from the Central African Republic. All have been isolated from rodents of the family Muridae. More recently, new arenaviruses have been isolated, or identified through molecular detection and sequencing, from rodents, for example, Merino Walk virus (6), Menekre and Gbagroube viruses (7), Kodoko virus (8), Morogoro virus (9), Lemniscomys and Mus minutoides viruses (10), and Luna virus (11), or from humans, in the case of Lujo virus from an outbreak of human fatal HF with person-to-person transmission (12, 13). The Tacaribe or New World complex includes Tacaribe, Junin, Machupo, Amapari, Cupixi, Parana, Latino, Pichinde, Tamiami, Flexal, Guanarito, Sabia, Oliveros, Whitewater Arroyo, Pirital, and Bear Canyon viruses (14); Ocococoautla de Espinosa virus (15); Allpahuayo virus (16); Tonto Creek and Big Bushy Tank viruses (17); Real de Catorce virus (18); Catarina virus (19); Pampa virus (20); Skinner Tank virus (21), and Chapare virus (22). Some of the viruses have not yet been isolated and are known only from molecular sequence data. All the rodent isolates of New World complex viruses have been from rodents of the family Muridae, subfamily Sigmodontinae, and Tacaribe virus was originally isolated from bats. Highly divergent arenaviruses have recently been identified in boa and boid snakes with snake inclusion body disease (23, 24). The Old and New World arenavirus complexes are distantly related; only when very-high-titer antisera are used can cross-reactions be observed. Monoclonal antibodies with specificities for structural proteins of arenaviruses suggest that the N protein is the group-reactive determinant, whereas the envelope glycoproteins (G1 and G2) are responsible for type specificity (1, 25).

The morphology of arenaviruses is distinctive in thin-section electron microscopy (26) and was the basis for first associating LCM virus with Machupo virus and ultimately associating these viruses with all the viruses in the present family. Three major virion structural proteins are usually found (25). The virus glycoprotein precursor (GPC) is processed...
into two glycoproteins, G1 (50,000 to 72,000 Da) and G2 (31,000 to 41,000 Da), which constitute the virion envelope and spikes and which both serve as highly type-specific neutralization targets. In addition, a stable signal peptide is retained as an essential subunit in the mature glycoprotein complex (27). The third major protein is the N protein (63,000 to 72,000 Da), which is clearly associated with the virion RNA and is considered the nucleocapsid protein. Four RNA species can be isolated from intact arenavirus virions. Two are virus specific and are amenable to in vivo infection: the small (S) RNA (22S) (encoding the N and GPC), and the large (L) RNA (31S) (encoding the viral L polymerase and the Z protein, a regulatory element) (1). In addition, ribosomal 28S and 18S species are isolated in virions in different proportions depending on external conditions.

Arenaviruses mature by budding at the cytoplasmic membrane, and host proteins are incorporated into the virion envelope. Vero cells infected with each of the viruses contain distinctive intracytoplasmic inclusion bodies, immuno-reactive with anti-N but not anti-G1 or anti-G2 antibody. All arenaviruses are readily inactivated by ethyl ether, chloroform, sodium deoxycholate, and acidic media (pH less than 5). β-Propiolactone (28) and gamma irradiation (29) are both reported to inactivate arenavirus infectivity while preserving reactivity in standard serologic tests.

Filoviridae

The filoviruses, including both Ebola viruses and Marburg viruses, have a common morphology and similar genomic organizations and complements of structural proteins (30). Marburg virus and Ebola virus virion RNAs are nonsegmented, negative-sense, and single-stranded RNAs, 19.1 kb long, and 4.0 × 10^6 to 4.5 × 10^6 Da. The viral genomes are linearly arranged in a manner consistent with other nonsegmented, negative-sense, and single-stranded RNA viruses. Some sequence similarity to the paramyxoviruses, especially in the nucleocapsid and polymerase proteins, was noted. However, comparison with other filovirus protein sequences confirms that filoviruses are highly distinct. Furthermore, filoviruses are sufficiently distinct by ultrastructural and serologic criteria to warrant separate taxonomic status as members of the family Filoviridae (2, 31, 32).

Marburg viruses and Ebola viruses have at least seven virus-specific structural proteins, expressed from seven genes (2). For Ebola viruses, the ribonucleoprotein complex contains L (180 kDa), N (104 kDa), VP30 (30 kDa), and VP35 (35 kDa) in loose association. L is an RNA-dependent RNA polymerase, and VP35 may play a role similar to that of the P protein of paramyxoviruses and rhabdoviruses. GP (125 kDa) is the major spike protein; VP40 (a matrix protein) plus VP24 make up the remaining protein content of the multilayered envelope (31, 33). The GP of Ebola viruses and Marburg viruses can be differentiated by the presence or absence of N- and O-linked glycans and by the lack, in Marburg viruses, of the second open reading frame coding for the small soluble glycoprotein expressed during Ebola virus infection in vitro and in vivo (34). When grown in Vero or MA-104 cell cultures, the GP of Marburg virus is totally devoid of terminal sialic acid, whereas the GP of Ebola virus has abundant (2-3)-linked sialic acid. Phylogenetic analysis of GP genes from filoviruses clearly separates these viruses into two genera, Ebolavirus and Marburgvirus. The Ebolavirus genus contains five species: Zaire ebolavirus, Sudan ebolavirus, Reston ebolavirus, Tai Forest ebolavirus (formerly known as Ivory Coast ebolavirus), and Bundibugyo ebolavirus (35), each containing one virus (Ebola virus, Sudan virus [SUDV], Reston virus [RESTV], Tai Forest virus, and Bundibugyo virus [BDBV], respectively). The Marburgvirus genus has just a single virus species, Marburg marburgvirus, which contains two viruses, Marburg virus and Ravn virus (36).

Despite their unusual long rod-like morphologic properties, filoviruses resemble the other lipid-enveloped viruses, including the arenaviruses, in being susceptible to heat, lipid solvents, β-propiolactone (28), formaldehyde, UV light, and gamma radiation (29). These viruses are stable at room temperature for several hours but are inactivated by incubation at 60°C for 1 h.

**Epidemiology and Transmission**

*Arenaviridae*

Arenaviruses are maintained in nature by association with specific mammalian hosts (Table 1), in which they produce chronic viremia and/or viruria. The viruses are routinely isolated from blood and urine samples of their specific rodent host. Naturally occurring human disease can usually be traced to direct or indirect contact with infected rodents. Aerosol infectivity is thought to be an important natural route of infection as well. Attempts to implicate arthropod vectors have been unsuccessful, but ectoparasites taken from viremic mammalian hosts have occasionally yielded arenavirus isolates. Of the 39 named mammalian members of the family *Arenaviridae*, 9 are known to be human pathogens. Nosocomial transmission is well described for Lassa and Marburg viruses. Lujo virus was identified during a nosocomial outbreak involving five persons, four of whom died (12). Because of the high level of virus circulation in West Africa (mostly Nigeria, Sierra Leone, Guinea, and Liberia), Lassa fever is the VHF most frequently exported to areas where VHF is not endemic, including several instances in the United States.

*Filoviridae*

Marburg and Ebola HFIs are caused by taxonomically distinct viruses which form two genera, *Ebolavirus* and *Marburgvirus*, within the family *Filoviridae* (2). Marburg virus was first recognized in 1967, when 31 persons in Germany and Yugoslavia became infected following contact with monkey kidneys, primary tissue cultures derived from monkeys imported from Uganda, or sick patients (37). Ebola viruses first emerged in two major disease outbreaks, which occurred almost simultaneously in Zaire and Sudan in 1976. Over 500 cases were reported, with case-fatality rates of 88% in Zaire and 53% in Sudan. Despite their simultaneous emergence, these viruses were shown to be two distinct viruses (now named Ebola virus and SUDV) representing two different species, *Zaire ebolavirus* and *Sudan ebolavirus*, based on serologic and sequence analysis criteria (38). In 1989 and 1990, a new distinct species of Ebola virus, RESTV, was isolated from cynomolgus monkeys being held in quarantine in Reston, VA, and Perkasie, PA, following their importation from the Philippines (39). RESTV reappeared in monkeys exported from the Philippines to Siena, Italy, in 1992 (40, 41) and to Alice, TX, in 1996 (42). In 1994, another genetically distinct species of Ebola virus, Tai Forest virus, was associated with disease in a human and deaths among chimpanzees in the Ivory Coast (Côte d’Ivoire) (43). In 1995, Ebola virus reappeared in Zaire, and subsequently (1996 and 2000 to 2005), a number of outbreaks have occurred in Gabon and adjacent areas of the Republic of Congo among apes and humans. Some human cases were associated

</table>
with exposure to infected nonhuman primates (44, 45). In 2000, SUDV was responsible for a large outbreak in Gulu, in the northwest of Uganda. Approximately 425 persons were infected, and 53% of them died (46, 47). In Yambio (South Sudan) in 2004, 17 persons were infected by SUDV, and 7 of them died (48). An outbreak due to Marburg viruses, involving gold miners and secondary contacts, started in 1998 and continued into 2000 in eastern Democratic Republic of Congo (DRC) (49). Several bats collected in the mine were found to be positive for Marburg viruses using reverse transcription (RT)-PCR (50). In spring 2005, a large outbreak of Marburg HF occurred in Uige, northern Angola. A total of 252 cases and 277 deaths from Marburg HF were reported as of 24 August (51).

In 2005, fruit bats positive for Ebola virus by RT-PCR were found in Gabon (54). In 2007 and 2008, Ebola virus was responsible for two small outbreaks in the same area of Kasai-Occidental (DRC) (55; http://www.who.int/csr/don/2009_02_17/en/index.html). A new distinct species of Ebola virus, BDBV, was isolated during an outbreak centered in and around Bundibugyo in western Uganda (35). A total of 131 cases of suspected, probable, or confirmed cases were reported from August to December 2007. In 2008, RESTV was isolated from swine tissues during the laboratory investigation of samples from a 2007 outbreak of high mortality in swine in farms in the Philippines, which was thought to be atypical porcine reproductive and respiratory syndrome (PRRS) (56). PRRS and Circo 2 viruses were also isolated from the swine, leaving it unclear the extent to which RESTV was contributing to the disease symptoms. The exact role of RESTV in the clinical process is still under investigation through field surveillance. Experimental infections of swine with RESTV isolated from Philippine pigs did not cause clinically notable disease, although the virus was shed and detectable antibodies developed in experimental infections in the laboratory (123). This virus species appears to be less virulent for humans than other filovirus species, since four workers at the U.S. quarantine facility in 1990 were found to have antibody to RESTV without having experienced disease and several slaughterhouse and pig farm workers from the more recent outbreak in the Philippines were also found with antibody without associated clinical disease (http://www.who.int/csr/resources/publications/HSE_EPR_2009_2.pdf).

In 2007, four workers from a lead ore mine near Ibamba, Uganda, were infected with Marburg viruses. Two patients died, and the subsequent investigations led to the identification of Marburg virus RT-PCR-positive Rousettus aegyptiacus fruit bats and, for the first time, the isolation of Marburg viruses from this potential reservoir (57, 58). In 2008, Marburg HF was diagnosed in 2 tourists who independently visited the same bat-inhabited cave (Python Cave, Queen Elizabeth National Park) in western Uganda. The first patient was a Dutch woman who subsequently died of Marburg HF in the Netherlands (59). The second patient was an American woman from Colorado who recovered and was diagnosed retrospectively (60). A single case of Ebola HF associated with SUDV was reported in 2011 in Uganda (61) but in 2012, four additional outbreaks occurred: SUDV in Kibaale (Uganda) in July and August, BDBV in Isiro (DRC) from August to October, Marburg virus in Kabale (Uganda) in October and November, and SUDV in Luwero (Uganda) in November (62). In the spring of 2014, the Guinean Ministry of Health reported an outbreak of Ebola HF in the forest region of the country. It is now (as of January 2015) the biggest outbreak ever, with more than 21,000 confirmed and probable cases mostly in Guinea, Sierra Leone, and Liberia, multiple medical evacuations of infected medical responders to Europe and the United States, and infected travelers with sometimes secondary cases reported in Senegal, Mali, Nigeria, and the United States (an update can be found at http://www.who.int/csr/disease/ebola/situation-reports/en/).

**CLINICAL SIGNIFICANCE**

Patients with VHF frequently present with similar, nonspecific clinical signs resembling malaria, typhoid fever, and pharyngitis. A detailed travel history, coupled with a high index of suspicion and availability of definitive virologic tools, should facilitate rapid diagnosis and the timely implementation of appropriate patient isolation, clinical management procedures, and public health measures. For Ebola, U.S. guidance documents are available online (http://www.cdc.gov/vhf/ebola/index.html).

** Arenaviridae **

Among the known arenavirus human pathogens, LCM virus produces the least severe infection (63). A modest proportion of LCM virus infections are subclinical. A “typical” LCM case is usually heralded by fever, myalgia, retro-orbital headache, weakness, and anorexia. Especially during the first week, prominent symptoms include sore throat, chills, vomiting, cough, retrosternal pain, and arthralgia. Rash occurs but is infrequent. In about one-third of the patients, fever recurs, coinciding with the onset of frank neurologic involvement, usually aseptic meningitis, but less frequently meningencephalitis. Complete recovery is almost always the rule. Thus, LCM virus infections are temporarily debilitating but rarely fatal, even when neurologic complications arise. Although recognized only recently, in utero infections with LCM virus are a cause of significant birth defects of the central nervous and ocular systems (64, 65). Fatal forms of LCM infections were reported recently in several clusters following transplantation of organs from LCM virus-infected donors to immunosuppressed recipients (66–68).

Lassa, Junin, and Machupo virus infections are much more severe. Lassa fever patients usually present at the hospital within 5 to 7 days of onset and complain of sore throat, severe lower back pain, and conjunctivitis. These signs and symptoms usually increase in severity during the following week and are accompanied by nausea, vomiting, diarrhea, chest and abdominal pain, headache, cough, diziness, and tinnitus. Later, pneumonitis and pleural and pericardial effusions with friction rub frequently occur. A maculopapular rash may develop, but frank hemorrhage is seen only in a proportion of the more severe cases. Bleeding from puncture sites and mucous membranes and melena are more common. Although mild or unapparent infections occur, approximately 15 to 20% of hospitalized patients die, usually as a result of sudden cardiovascular collapse resulting from hepatic, pulmonary, and myocardial failure. Few Lassa fever patients develop central nervous system signs, although tinnitus or deafness may develop as recovery begins. Lassa fever is a particularly severe disease among pregnant women, for whom mortality rates are somewhat higher. The disease course in children is similar to that in adults, but in infants a condition described as swollen-baby syndrome, characterized by anasarca, abdominal distension, and bleeding, is typical. Clinical laboratory studies are not usually helpful for Lassa fever; specific virologic testing is required, especially in a setting where Lassa fever is less common or where mild, atypical cases are occurring.
The clinical pictures for Argentinian HF (AHF) due to Junin virus and Bolivian HF (BHF) due to Machupo virus are well characterized; for Venezuelan HF due to Guanarito virus, Sabia virus in Brazil, or Chapare virus (with a single confirmed case in Bolivia), less information is available (3). However, all these infections are sufficiently similar to each other to be discussed as a single entity, South American or New World arenavirus HF (SAHFs). Incubation periods range from 7 to 14 days, and very few subclinical cases are thought to occur. Following gradual onset of fever, anorexia, and malaise, i.e., over several days, constitutional signs involving the gastrointestinal, cardiovascular, and central nervous systems become apparent by the time patients present to the hospital. On initial examination, AHF and BHF patients are febrile, acutely ill, and mildly hypotensive. They frequently complain of back pain, epigastric pain, headache, retro-orbital pain, photophobia, diziness, constipation, or diarrhea, and coughing. Flushing of the face, neck, and chest and bleeding from the gums are common. Enanthem, petechiae or tiny vesicles spread over the erythematous palmar and plantar surfaces is almost universally present. Neurologic involvement, ranging from mild irritability and lethargy to abnormalities in gait, tremors of the upper extremities, and, in severely ill patients, coma, delirium, and convulsions, occurs in more than half of the patients. During the second week of illness, clinical improvement may begin or complications may develop. Complications include extensive petechial hemorrhages, blood oozing from puncture wounds, and mucosal hematemesis. The manifestations of capillary damage and thrombocytopenia do not result in life-threatening bleeding loss. However, hypotension and shock may develop, often in combination with serious neurologic signs, among the 15% of patients who subsequently die. Survivors begin to show improvement by the third week. Recovery is slow; weakness, fatigue, and mental difficulties may last for weeks, and a significant proportion of patients relapse with a “late neurologic syndrome,” which includes headache, cerebellar tremor, and cranial nerve palsies. In contrast to the case with Lassa fever, clinical laboratory studies are frequently useful. Total leukocyte counts usually fall to 1,000 to 2,000 cells/mm$^3$, although the differential remains normal. Platelet counts fall precipitously, usually to between 25,000 and 100,000/mm$^3$. Routine clotting parameters are usually normal or slightly abnormal; however, patients with severe cases may show evidence of disseminated intravascular coagulation.

In the single Lujo virus outbreak in Southern Africa, involving 5 confirmed cases, the patients presented with nonspecific febrile illness with headache and myalgia following an incubation ranging from 7 to 13 days (12). A morbilliform rash was evident in 3 African patients on days 6 to 8 of illness, but not in 2 African patients. In the four fatal cases, the disease course was biphasic. The second phase, starting around 1 week postonset, was characterized by a rapid deterioration with respiratory distress, neurologic signs, and circulatory collapse. All patients had thrombocytopenia on admission to hospital (platelet count range $20 \times 10^3$ to $104 \times 10^3$ /liter). Three patients had normal white cell counts and two had leukopenia on admission, while four developed leukocytosis during the illness. The last patient (the only one surviving) was treated with the antiviral drug ribavirin.

In fatal arenavirus infections, histopathologic findings include multifocal hepatocellular necrosis with minimal inflammatory response, interstitial pneumonitis, myocardiitis, and lymphoid depletion. Extensive arenavirus antigens are seen in parenchymal cells as well as cells of the mononuclear phagocytic system, much more than morphologic lesions would suggest (see Fig. 4).

Filoviridae

Marburg and Ebola HF cases are clinically similar, although the frequencies of reported signs and symptoms vary among individuals. Following incubation periods of 4 to 16 days, onset is sudden and is marked by fever, chills, headache, anorexia, and myalgia. These signs are soon followed by nausea, vomiting, sore throat, abdominal pain, and diarrhea. When first examined, patients are usually overtly ill, dehydrated, apathetic, and disoriented. Pharyngeal and conjunctival infection is usual. Within several days, a characteristic maculopapular rash over the trunk, cutaneous petechiae, spleen, kidneys, skin, and gonads are extensive. Extensive hemorrhagic bleeding, accompanied by intense epigastric pain, is common, as are petechiae and bleeding from puncture wounds and mucous membranes. In the current Ebola outbreak, hemorrhage is rare but profuse diarrhea is frequently observed and is responsible for severe dehydration (http://www.cdc.gov/vhf/ebola/hcp/clinician-information-us-health-care-settings.html). Shock develops shortly before death, often 6 to 16 days after the onset of illness. Abnormalities in coagulation parameters include fibrin split products and prolonged prothrombin and partial thromboplastin times, suggesting that disseminated intravascular coagulation is a terminal event and is usually associated with multiorgan failure (69). Clinical laboratory studies usually reveal profound leukopenia early sometimes moderately elevated at a later stage. Platelet counts decline to 50,000 to 100,000/mm$^3$ during the hemorrhagic phase. Severe hypokalemia can occur as a consequence of profuse vomiting and diarrhea. Liver enzymes and creatinine levels parallel the liver and kidney failure encountered in the latter stages of the disease.

In fatal filovirus infections, disseminated infection and necrosis in major organs such as the liver, spleen, lungs, kidneys, skin, and gonads are extensive. Extensive hemorrhagic necrosis associated with the formation of characteristic viral inclusions is seen in fatal Ebola virus infections. Lymphoid depletion and microvascular infection and injury are seen in all filovirus infections. Abundant antigens and nucleic acids can be seen in all major organs by using immunohistochemistry and in situ hybridization (see Fig. 2 and 3).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Safety and Security

Some arenaviruses (Lassa, Junin, Machupo, Sabia, Guanarito, Chapare, and Lujo viruses) and several filoviruses are classified as biosafety level 4 (BSL4) agents, as there is a high risk of infection of laboratory personnel and appropriate precautions must be taken (70) (http://www.cdc.gov/vhf/ebola/hcp/interim-guidance-specimen-collection-submission-patients-suspected-infection-ebola.html#update1). Most are also classified in the United States as select agents by the Department of Health and Human Services and should be handled as such (https://www.selectagents.gov/SelectAgentsAndToxinsList.html and http://www.selectagents.gov/Regulations.html). Ebola viruses and Marburg viruses have recently been classified as tier 1 select agents, and additional regulations exist for possessing, using, or transferring tier 1 select agents and toxins (http://www.selectagents.gov/faq-general.html#sec146). At a minimum, barrier nursing procedures should be implemented and personnel caring for the patient and handling diagnostic specimens should wear...
disposable caps, gowns, shoe covers, surgical gloves, and face masks (preferably full-face respirators equipped with high-efficiency particulate air filters) (71, 72). Gloves should be disinfected immediately if they come in direct contact with infected blood or secretions. Manipulation of these specimens and tissues, including sera obtained from convalescent-phase patients, may pose a serious biohazard and should be minimized outside a BSL4 laboratory (70, 72). Use of Vacutainer tubes (e.g., BD Vacutainer) is considered safer than use of syringes and needles, which must be disassembled before their contents are transferred to another tube. Procedures which generate aerosols (e.g., centrifugation) should be minimized and performed only if additional protective measures, such as keeping the equipment in a class I or II laminar-flow hood, are taken. For specialized procedures, the infectivity of samples may be greatly reduced if not totally inactivated, by the addition of Triton X-100 and heating. Heating to 60°C for 1 h renders diagnostic specimens noninfectious and is acceptable for measurement of heat-stable substances such as electrolytes, blood urea nitrogen, and creatinine. When the equipment is available, sterilization by 60Co gamma irradiation is the preferred method of inactivation. Extraction of RNA from infectious samples by using guanidinium thiocyanate (with a proper ratio, at least 1 to 5 or 1 to 10, of lysis reagents) should be conducted in a laminar-flow hood. After this step, the extracted RNAs are no longer infectious.

**Specimen Collection**

For virus isolation, antigen detection, and RT-PCR, serum, heparinized plasma, or whole blood should be collected during the acute, febrile stages of illness and frozen on dry ice or in liquid nitrogen vapor. In the United States, the guidance for Ebola virus sample collection and submission has been updated (http://www.cdc.gov/vhf/ebola/hcp/interim-guidance-specimen-collection-submission-patients-suspected-infection-ebola.html). Storage at higher temperatures (above ~70°C) leads to losses in infectivity. Blood obtained in early convalescence for diagnostic purposes may be infectious despite the presence of antibodies, and it should be handled accordingly (70–72). In addition to blood samples, throat wash specimens have also been used for virus isolation during infections with arenaviruses (Lassa, Junin, and Machupo viruses). LCM virus may be recovered from acute-phase serum samples obtained during the first week after onset but more likely from cerebrospinal fluid during the period of meningeal involvement, and from the brain at autopsy, but it is rarely, if ever, recovered from throat washings or urine specimens. LCM has been easily isolated from the blood of immunocompromised organ transplant recipients. Chapare and Lujo viruses were isolated from blood during the acute phase of the disease. Filoviruses are usually recovered from acute-phase serum samples; various specimens, including throat washings, oropharyngeal secretions, urine, soft tissue effusions, semen, and anterior eye fluid, have yielded filovirus isolates, even occasionally when the specimens were obtained late in convalescence.

**Postmortem Specimens**

Lassa, Machupo, and Junin viruses, Marburg viruses, and Ebola viruses are all readily isolated from specimens of eye fluid, eye secretions, urine, soft tissue effusions, semen, and anterior eye fluid. These particles, 20 to 25 nm in diameter, are usually recovered from acute-phase serum samples; various specimens, including throat washings, oropharyngeal secretions, urine, soft tissue effusions, semen, and anterior eye fluid, have yielded filovirus isolates, even occasionally when the specimens were obtained late in convalescence.

**DIRECT EXAMINATION**

**Electron Microscopy**

Individual arenavirus virions are pleomorphic and range in size from 60 to 280 nm (mean, 110 to 130 nm) (Fig. 1A). A unit membrane envelops the structure and is covered with club-shaped, 10-nm projections. No symmetry has been discerned. The most prominent and distinctive feature of these virions is the presence of different numbers of electron-dense particles (usually 2 to 10), which may be connected by fine filaments. These particles, 20 to 25 nm in diameter, are identical to host cell ribosomes by biochemical and oligonucleotide analysis (26). Immunoelectron microscopy techniques also work well for diagnosis of arenavirus infections, although the morphology of the virions is less striking for arenaviruses than filoviruses.

Marburg viruses and Ebola viruses have been successfully visualized directly by electron microscopy of both heparinized blood and urine obtained during the febrile period as well as in tissue culture supernatant fluids. The combination of the size and shape of the virions is sufficiently characteristic before death or at autopsy. Formaldehyde-fixed tissues and paraffin-embedded blocks are also suitable for histopathology and immunohistochemical identification of viral antigens and should be conserved and shipped at room temperature.

**Shipping**

If an arenavirus or filovirus infection is suspected on clinical and epidemiological evidence, and before sending the specimens, the clinicians should consult with the local health authorities and the relevant following laboratories that maintain BSL4 facilities and a diagnostic capability for these agents. For all testing of infectious material, samples should be packaged in accordance with current recommendations (International Airline Transportation Association [IATA]) (http://www.iata.org/index.htm). The package should be sent by rapid courier, and preliminary results could be expected within 24 to 48 h after reception of the specimens.

Several BSL4 laboratories are available in Europe (http://www.enivd.de/index.htm), and in the United States, other BSL4 laboratories with diagnostic capability may be available in the near future.
to allow a morphologic diagnosis of filovirus (32, 39, 73). The virus particles are very large, typically 790 to 970 nm long and consistently 80 nm in diameter. Bizarre structures of widely different lengths are frequently found in negatively stained preparations, sometimes exceeding 14,000 nm, as well as branching, circular, or “6” shapes, probably resulting from coenvolvement of multiple nucleocapsids during budding (Fig. 1B) (32, 72, 74).

Ebola virus inclusions are often seen in thin-section electron micrographs of liver. The inclusions consist of viral nucleocapsids mostly seen in sinusoidal spaces (Fig. 2B). These virions can be differentiated and identified as Marburg viruses or Ebola viruses by immunoelectron microscopy techniques (74–76).

Antigen Detection

Immunohistochemistry

IFA staining of impression smears or air-dried suspensions of the liver, spleen, or kidney have been used successfully to detect cytoplasmic inclusion bodies associated with Marburg virus infection; clumps of Marburg virus antigen have also been observed by IFA examination of infected, dried, citrated blood smears. This approach was successfully adapted to the diagnosis of RESTV in impression smears from blood, tissues, and nasal turbinates, as it was to the detection of Junin virus-infected cells in peripheral blood and urinary sediment. Hematoxylin and eosin staining of the liver reveals hepatocellular necrosis and numerous intracytoplasmic and eosinophilic Ebola virus inclusions, as well as sinusoidal dilatation and congestion (Fig. 2A). The development of immunohistochemical techniques for detection of filovirus and arenavirus antigens in formalin-fixed tissues has recently advanced to the point that their results are far more satisfactory than those of IFA examination of frozen, acetone-fixed sections (38, 77–80). Obtaining frozen sections for diagnosis is rarely worth the biohazard incurred, especially since the threshold sensitivity for detection exceeds $6 \log_{10}$ PFU per g. For filoviruses, paraffin blocks of tissues are sectioned. Sections are deparaffinized, hydrated, digested with protease, and stained for the presence of viral antigens with immune rabbit serum or cocktails of murine monoclonal antibodies (39, 79, 80). Biotinylated secondary antibody is then reacted, and the product is developed with a streptavidin-alkaline phosphatase system. Substitution of other chromogens can further increase sensitivity while reducing background (77). In the 2007–2008 epizootic of Reston virus in swine in the Philippines (56), Ebola virus antigens were detected in different tissues, including lymph nodes (Fig. 3A). Remarkable success was reported in the application of immunohistochemistry to the demonstration of Ebola virus antigens in formalin-fixed skin biopsy specimens obtained from deceased Ebola HF patients in Zaire in 1995 (80, 81) (Fig. 3B). Immunohistochemistry was used to confirm the diagnosis of a fatal Lassa fever case in a New Jersey patient returning from West Africa (Fig. 4A). More recently, it was the immunohistochemistry assays on a liver biopsy specimen (Fig. 4B) which first indicated the arenavirus etiology of a disease observed in South Africa, leading to the description of Lujo virus (12). In the cluster of LCM cases occurring through organ transplants (66, 67), very abundant LCM virus antigen could be found in a number of organs (Fig. 4C).

Antigen Capture ELISA

Development of an antigen capture ELISA for quantitative detection of arenavirus and filovirus antigens in viremic sera and tissue culture supernatants has facilitated the early detection and identification of these agents (82–85). These assays reliably detect antigens in samples inactivated by heat-detergent treatment, β-propiolactone, or irradiation; therefore, they can be conducted safely without elaborate containment facilities. The threshold sensitivities for these assays are approximately 2.1 to 2.5 $\log_{10}$ PFU per ml, and so they are sufficiently sensitive to detect antigen in most acute-phase VHF viremias and to detect viruses at the concentrations present in throat wash and urine samples. Substitution of one or several monoclonal antibodies of high avidity and appropriate specificities for polyclonal sera (mostly against nucleoprotein and VP40) generally increases the sensitivities and specificities of these antigen capture ELISAs (85–88).

Nucleic Acid Detection

RT-PCR followed by genome analysis is rapidly replacing diagnostic methods based on antigen-antibody methods and has the advantage of complete inactivation of the samples in the first extraction step and lower limits of detection. However, as RT-PCR is more prone to cross-contamination problems, we would still encourage its use in combination with traditional methods (virus isolation and/or serology). Real-time RT-PCR assays have more recently supplanted older RT and amplification methods because of the automation and
Arenaviridae

The considerable genetic variation among Lassa viruses requires caution in primer design if diagnosis of infections originating in more than one geographic area is being considered (90–93). To remediate this problem, primers targeting the 5′ region of the S RNA have been developed (94) and are used on a routine basis on a very large set of patients presenting at Irrua Specialist Teaching Hospital in Nigeria (95). In limited-resource settings, real-time PCR assays would reduce the reported low rate (13/1,650 samples [0.8%] in Irrua) of PCR contamination, but they still lack field validation. Likewise, various strategies for RT-PCR have been devised to detect Junin virus RNA in clinical materials (20, 90, 91, 96). Some of these are reputed to be far more sensitive than conventional isolation procedures, especially in the presence of antibody. Any method which promises to be a reliable substitute for procedures that entail the manipulation of infectious BSL4 virus deserves attention. However, the ability to isolate and retain the virus has obvious advantages and should not be abandoned. Even in instances in which the etiological agent has been identified, the shipment of clinical material to an appropriate reference laboratory should be highly encouraged.

Filoviridae

Protocols which maximize detection are usually based on conserved sequences within the N, VP40, VP35, or L genes, while fine discrimination and phylogeny are based on the more variable GP region (2, 36, 97, 98). The sensitivity of RT-PCR for various Ebola virus species is similar to that of conventional isolation. During the SUDV outbreak in Gulu, an RT-PCR-based assay was very valuable because of its ability to identify early patients prior to identification by any other available tests, and for early convalescent-phase specimens, which had already cleared detectable antigen. Using nucleoprotein-based real-time quantitative RT-PCR, the viral load was found to correlate with disease outcome (47, 99). During the 2005 Marburg HF outbreak in Angola and the 2012 outbreak in Uganda, Marburg virus real-time PCR assays were developed and effectively applied, respectively, in the laboratories (Luanda and Entebbe) and in the field (Uige and Kabale) (53, 62, 100). Other platforms are available (98, 101, 102), and recently, RT-loop-mediated isothermal amplification has been proposed, but it has not yet been field tested (103). In the current Ebola outbreak, real-time PCR, targeting NP and VP40, is used in the field in West Africa and also in suspected and confirmed cases in Europe and the United States.

ISOLATION PROCEDURES

Cell Culture

Virus culture should not be attempted in BSL2 laboratories, and if inadvertently inoculated, cultures must be autoclaved and destroyed. Clinical specimens and clarified tissue homogenates (usually 10% [wt/vol]) are diluted in a suitable maintenance medium and adsorbed in small volumes to cell monolayers grown in suitable vessels, such as T-25 tissue culture flasks. If no antigen is detected by IFA by 14 days, the sample is considered negative, but supernatant fluids
FIGURE 3  (A) Using immunohistochemistry, abundant Ebola virus antigens (in red) are seen in the lymph node of a pig infected by Ebola Reston virus. Original magnification, ×158. (B) Skin showing massive viral burden as seen in this section immunostained for Ebola virus antigens. Original magnification, ×50 (immunoalkaline phosphatase staining; naphthol fast red substrate with light hematoxylin counterstain). doi:10.1128/9781555817381.ch97.f3

should be blind passaged to confirm the absence of virus. To confirm the presence and identity of the virus, scraped cells are tested by immunofluorescence assay and supernatant fluids are tested by antigen capture ELISA or RT-PCR techniques.

Arenaviridae
Cocultivation of Hypaque-Ficoll-separated peripheral blood leukocytes with susceptible cells has increased the isolation frequency of Junin virus. Cocultivation of lymphocytes from spleens of experimentally infected animals has yielded Lassa virus late in convalescence, even after neutralizing antibody has appeared. The technique merits systematic development for the remaining arenavirus and filovirus pathogens.

Although historically Machupo and Junin viruses were isolated by inoculation of newborn hamsters and mice, respectively, Vero E6 cells are approximately as sensitive and are far less cumbersome to manage in BSL4 containment. Furthermore, Vero cells usually permit isolation and identification within 1 to 5 days, a significant advantage over the use of animals, since 7 to 20 days of incubation is required for illness to develop in the animals.

Filoviridae
The best general method currently available for isolation of filoviruses is the inoculation of appropriate cell cultures (usually Vero cells), followed by IFA or other immunologically specific or nucleic acid-specific testing of the inoculated cells for the presence of viral antigens or genomic RNA at intervals. Other cell lines, including human diploid lung (MRC-5) and BHK-21 cells, also work; MA-104 cells (a fetal rhesus monkey kidney cell line) may be more sensitive than Vero cells for some strains.

Animal Inoculation

Arenaviridae
Intracranial (i.c.) inoculation of weanling mice is still regarded by some as the most sensitive established indicator of LCM virus (104), although adequate cell culture systems exist for the isolation of LCM virus. Care must be taken to use mice from a colony known to be free of LCM virus. Many LCM virus isolates produce a characteristic convulsive disease within 5 to 7 days, which is nearly pathognomonic. Brains from dead mice may be used to prepare ELISA antigens or may be subjected to IFA or immunohistochemical staining to obtain presumptive identification. Clarified mouse brain may also be used as the antigen for confirmatory testing by neutralization or RT-PCR.

Most LCM virus strains are also lethal for guinea pigs. The pathogenicity of virulent Lassa virus strains for outbred Swiss albino mice inoculated i.c. seems to vary with different sources; mice should not be seriously considered for Lassa virus isolations. Strain 13/N guinea pigs develop hemorrhagic disease after Lujo virus inoculation (105). For the New World arenaviruses, particularly Junin virus, young adult guinea pigs inoculated either i.c. or peripherally have been used. Guineapigs die 7 to 18 days after Junin virus inoculation. Strain 13/N guinea pigs are exquisitely sensitive to most Lassa virus strains and uniformly die 12 to 18 days after inoculation; outbred Hartley strain guinea pigs are somewhat less susceptible. Newborn mice (1 to 3 days old) are highly susceptible to Junin virus inoculated i.c.; newborn hamsters are believed to be more sensitive to Machupo virus.

Filoviridae
Marburg viruses and the Ebola viruses and SUDV produce febrile responses in guinea pigs 4 to 10 days after inoculation; however, none of these viruses kill guinea pigs consistently on primary inoculation, and only Ebola virus and Marburg virus have been adapted to uniform lethality by sequential guinea pig passages. Ebola virus is usually pathogenic for newborn mice inoculated i.c., but SUDV, RESTV, and Marburg viruses are not.
IDENTIFICATION OF VIRUS

Typing Antisera

Detection of viral antigens in infected tissue culture cells (usually Vero or MA-104) permits a presumptive diagnosis, provided that the serologic reagents have been tested against all the reference arenaviruses and filoviruses expected in a given laboratory, thus permitting an interpretation of virus cross-reactions. Virus isolates in cell culture supernatant fluids or tissue homogenates are presumptively or specifically identified by their reactivity with diagnostic antisera in various serologic tests (see below). Specific polyclonal antisera are prepared in adult guinea pigs, hamsters, rabbits, rats, or mice inoculated intraperitoneally with infectious virus. Rhesus and cynomolgus monkeys that are convalescent from experimental infections are also reasonable sources for larger quantities of immune sera. Polyvalent polyclonal "typing" sera or ascitic fluids made by immunization with a number of viruses within the families have also been useful in early identification of virus isolates and in immunohistochemistry on unknown patient materials. Diagnostic antisera produced by single injection of infectious virus are less cross-reactive and usually have higher titers than those produced by multiple injections of inactivated antigens. To further reduce the induction of extraneous antibodies, input virus should be derived from tissues or cells homologous to the species being immunized; likewise, the virus suspension should be stabilized with homologous serum or serum proteins. Sera produced for use in the IFA tests and ELISA should be collected 30 to 60 days after inoculation; sera for neutralization tests should be collected later. All sera must be inactivated and rigorously tested for the presence of live virus before being removed from a BSL4 environment.

Production and use of specific murine monoclonal antibodies with fine specificities for N and GP epitopes of LCM virus, Lassa virus, Junin virus (106, 107), and other arenaviruses have been reported, as have monoclonal antibodies against the different proteins of the filoviruses. Reference reagents for all of these viruses are not generally available outside the appropriately equipped specialized laboratories.

Immunofluorescence

To process infected cells for IFA examination and presumptive identification, inoculated cell monolayers are dispersed by using glass beads or a rubber policeman or trypsinization, washed, and placed onto circular areas of specially prepared Teflon-coated slides. These "spot slides" are air dried, fixed in acetone at room temperature for 10 min, and either stained quickly or stored frozen at −70°C. Although acetone fixation greatly reduces the number of infectious intracellular viruses, spot slides prepared in this manner should still be considered infectious and handled accordingly. Gamma irradiation has been used to render spot slides noninfectious (29), with no diminution in fluorescent-antigen intensity. Alternatively, infected cells may be biologically inactivated with β-propiolactone (28). Gamma irradiation is recommended if the appropriate equipment is available.
For direct FA tests, specific immunoglobulins conjugated to fluorescein are used with Evans blue counterstain. Specific viral fluorescence is characterized by intense, punctate to granular aggregates confined to the cytoplasm of infected cells. Specific Marburg virus and Ebola virus fluorescence may include large, bizarrely shaped aggregates up to 10 μm across. Nonspecific fluorescence is characterized by intense, punctate fluorescence. Detection of Marburg virus, Ebola virus, Lassa virus, and LCM virus antigens by the IFA test is usually considered sufficient for a definitive diagnosis, although Lassa and LCM viruses cross-react at low levels in this test (5). Detection of Junin or Machupo virus antigens by the IFA test constitutes a presumptive diagnosis, since these viruses can be reliably distinguished from each other only by neutralization tests or sequencing. IFA formats for viral detection are more cumbersome and cross-reactive but can be used if direct conjugates are unavailable. Immuno-histochemical techniques for detecting arenaviruses (77) and filoviruses (78, 79) with a variety of chromogens can also be applied.

SEROLOGIC DIAGNOSIS

IFA Test

Until the early 1990s, the IFA test was widely regarded as the most practical single method for documenting recent infections with filoviruses or for large prevalence studies (108). Preparation of spot slides with infected Vero cells is identical to the procedure described above. Some refinements to enhance reproducibility and quality between spot slides lots have been suggested (109). Although monovalent spot slides are usually desired and are prepared with cells optimally infected with a single virus, polyvalent spot slides can also be prepared by mixing cells infected with different viruses selected from these or other taxonomic groups which have similar geographic distributions (110). The requirement for a BSL4 facility to produce the spot slides could be avoided by using recombinant-antigen-expressing cells (111). Discrepancies in titers determined by different laboratories, or even different investigators, are common. In addition, in most of the severe and fatal forms of these diseases, the patients may not develop a humoral response and die without detectable antibodies. This technique is not recommended for acute diagnosis of HFIs.

ELISA for Detection of IgG and IgM Antibodies

For all intents and purposes, the IgG and IgM ELISAs have replaced the more subjective IFA tests as the serologic tests of choice (83, 112). ELISA procedures for Lassa virus-specific IgG and IgM have been developed and successfully used on field-collected human sera (82, 87). When this ELISA is used in combination with the Lassa antigen capture ELISA described above, virtually all Lassa fever patients can be specifically diagnosed within hours of hospital admission. A simplification of this procedure, which entails the use of infected Vero cell detergent lysate as the antigen, diluted in phosphate-buffered saline and adsorbed directly to the microtiter plate wells, has been developed for Ebola virus (83, 84, 113). Test sera are serially diluted with a 1:100 initial dilution, and incubated with antigen in a format analogous to the antigen capture ELISA described above. Following incubation, washing, and addition of horseradish peroxidase-conjugated anti-human antibodies, 2,2′-azino-bis(3-ethylbenzthiazoline-6-sulfonic acid) (ABTS) substrate is added for color development. Species-specific conjugates allow testing of other animal species during epidemiological studies. To avoid the use of several conjugates during epidemiological studies, a protein A-protein G conjugate can be used. More recently, a competition assay using antibody-phage indicator has been proposed, but it has never been used in the field (114). Samples are considered positive if the optical density at 410 nm exceeds the mean plus 3 standard deviations for the normal-serum controls. This procedure can be further modified to detect virus-specific IgM by coating the plates with anti-human IgM followed by test serum dilutions and cell slurry antigens and then using the antigen capture protocol. These IgG and IgM ELISA procedures have worked well with specimens obtained from humans during natural infection and from animals experimentally infected with Lassa, Machupo, and Junin viruses and filoviruses. A simplification of the ELISA plate procedure, substituting filter paper disks, has been reported for RESTV (115); it appears to sacrifice some sensitivity and precision in comparison with the more established procedures but may find application in a field setting. All of these developmental assays are sufficiently robust to warrant field testing. Recombinant full or truncated proteins have also been proposed and used as antigens for ELISAs (116, 117).

Neutralization Tests

For the arenaviruses, plaque reduction tests with Vero cells are generally used. For measuring the levels of neutralizing antibody to Lassa and LCM viruses, which are both difficult to neutralize and are poor inducers of this antibody, test sera are diluted, usually 1:10, in medium containing 10% guinea pig serum as a complement source and mixed with serial dilutions of challenge virus. Titers are expressed as a log10 neutralization index, defined as log10 PFU in control minus log10 PFU in test serum. For Junin and Machupo viruses, the more conventional serum dilution-constant virus format is normally used, although the constant-serum-virus dilution format is equally useful for distinguishing among virus strains. Neutralizing-antibody responses require weeks to months to evolve but persist for years (118). Performance of these tests is restricted to laboratories equipped to handle the infectious viruses.

In survivors, neutralizing antibodies to Lassa virus first appear very late in convalescence (6 weeks or later), long after the viremia has disappeared. This pattern of early IFA and delayed neutralizing-antibody response is similar for LCM virus infections. Neutralizing antibodies against Junin and Machupo viruses become detectable 3 to 4 weeks after onset, soon after the termination of viremia. While these antibodies are thought to be important in protection against reinfection, their role in resolution of acute infections is less firmly established (119, 120).

As described above, reliable tests for measuring the levels of neutralizing antibody to filoviruses are not currently available.

Western Blotting

Western blotting is feasible for demonstrating antibodies to arenaviruses and filoviruses. However, it has never been applied systematically or routinely to diagnosis, although it was proposed as a confirmatory test to supplement the IFA test for filovirus antibodies (109). Detection of the nucleocapsid (N) band plus either VP30 or VP24 was taken as diagnostic. The Western blotting procedure was further refined by miniaturization, using the Phast system sodium dodecyl sulfate-polyacrylamide gel electrophoresis and Trans-Blot apparatus (Phast Western blot system). This test has not been routinely used for antibody detection.
Other Serologic Tests

Other serologic tests have been applied to diagnosis but have largely been abandoned: gel diffusion precipitation test for arenaviruses, the complement fixation test, reverse passive-hemagglutination (and inhibition) test utilizing Lassa virus antibody-coated erythrocytes, and a radioimmunoassay using ^{125}I-labeled staphylococcal protein A for Ebola virus. Western blotting and radioimmunoassay procedures are used in specialized laboratories to determine the fine specificities of monoclonal antibodies and occasionally to confirm the results of individual sera found to be positive by ELISA.

ANTIVIRAL SUSCEPTIBILITIES

Therapy of VHF follows general principles: symptomatic treatment with careful maintenance of fluid balance and management of bleeding diathesis. The antiviral drug ribavirin, if used early in the course of the disease, is effective in Lassa HF in reducing mortality and duration of disease (3). Ribavirin is also effective in Junin HF and has been used to treat BHF, Lujo virus infection, and LCM virus infection in immunocompromised patients (3, 12, 67). The side effects are limited because of the short duration of therapy, but the drug is teratogenic. No antiviral drugs against filovirus are yet commercially available, but some postexposure treatment has showed some efficacy in nonhuman primate models, such as recombinant human activated protein C, small interfering RNA, or immunotherapy using cocktails of monoclonal antibody (121). During the current Ebola outbreak, convalescent-phase immune plasma, cocktails of monoclonal antibody, and antivirals have been administered to patients through compassionate-use programs, and clinical trials are starting in West Africa.

EVALUATION AND INTERPRETATION OF RESULTS

Early diagnosis of arenavirus and filovirus infections is desirable since specific immune plasma and appropriately selected antiviral drugs are in certain cases effective when treatment is initiated soon after onset. Early recognition of these infections should also trigger strict isolation procedures to prevent the spread of disease to patient contacts. In areas where specific viruses are endemic, the index of suspicion is high, and experienced clinicians may be remarkably accurate in rendering an accurate diagnosis of fully developed cases on clinical grounds alone. However, even in these areas, specific virologic and serologic tests are required to confirm clinical impressions, since many other diseases, including malaria, typhoid, rickettsial infections, idiopathic thrombocytopenia, and viral hepatitis, may masquerade as an arenavirus or filovirus infection. In other countries where evacuated suspected (or confirmed) patients or recent travelers showing symptoms are evaluated, a rapid confirmation is needed and RT-PCR or real-time PCR is the test of choice.

Since patients with most of the severe and fatal forms of these diseases can die without developing detectable levels of antibody, timely diagnosis requires a means of detecting RNA, infectious virus or antigen in the field. The RNA detection assays are definitively the most sensitive assays and are widely used. The antigen capture ELISA holds promise for use in detecting clinically relevant concentrations of virus in infectious or inactivated sera, body fluids, and tissues of humans and nonhuman primates infected with Machupo, Lassa, Ebola, and Marburg viruses (39, 42, 82–84).

RT-PCR assays may eliminate the need to isolate infectious virus to establish a definitive diagnosis, but virus isolation remains important for subsequent genetic and pathogenesis studies. The ability to amplify viral genomes from infected tissues and even from formalin-fixed tissues, and to sequence the reaction products, has eclipsed serologic methods of identification and classification of arenaviruses (90–92) and filoviruses (35, 47). With the exception of LCM virus, which may be handled at a lower containment level, attempts to isolate these viruses should not be made outside a BSL4 laboratory (70). A combination of several laboratory techniques should be used to confirm any clinical suspicion of HF.

Among arenaviruses, Lassa virus is usually able to be detected (virus isolation, antigen detection, and RT-PCR) from acute-phase sera of hospitalized patients soon after admission, frequently in the presence of specific IgM antibody, and a detectable antibody response does not necessarily signal imminent recovery; viremia frequently persists, and some patients die despite an antibody response. Junin, Machupo, and LCM viruses are recovered less frequently, and diagnosis is usually based on the detection of specific antibodies later in the course of the disease. The presence of specific IgM ELISA-detectable antibodies in the cerebrospinal fluid of LCM patients constitutes a definitive diagnosis, and for all arenavirus infections, the presence of specific IgM antibodies is indicative of recent infection. The extent to which heterologous arenavirus infection and/or reinfec tion broadens antibody specificity has not been systematically evaluated for any of the available serologic tests. Neutralizing antibodies against arenaviruses persist for long periods, perhaps for life, and thus provide the most reliable basis for determining the minimum resistance of a population to reinfection. The role of neutralizing antibody in acute recovery is less clear. The protective efficacy of passively administered immune plasma is believed to be a direct function of neutralizing-antibody titers, and plasma should be selected on this basis, especially for Junin and Lassa fever (119, 120).

For filoviruses, RT-PCR, antigen detection, and IgM are the more valuable techniques for acute-case diagnosis. Because of the time required for culture and the biohazard, isolation data for these viruses are usually available only retrospectively. Marburg virus and Ebola viruses are usually easily isolated from acute-phase serum samples. A rising IgM or IgG ELISA titer constitutes a strong presumptive diagnosis. Since IgM titters do not persist for long, a decreasing titer suggests a recent infection which occurred perhaps only within several months. In general, IgG and IgM antibodies show a stronger reactivity to homologous Ebola virus antigens. Because of the low sensitivity of the IgM ELISA to heterologous antigen, there are some limitations in using the IgM ELISA prior to identification of the virus species. In contrast, IgG antibodies are relatively cross-reactive to heterologous antigens (122).

The IFA test has yielded misleading results when applied in diagnostic settings and population-based surveys and should be abandoned. For unknown reasons, the filoviruses are notoriously poor inducers of neutralizing antibody. The role of neutralizing antibodies for Ebola virus protective immunity is unclear; passively administered IgG with very high neutralizing-antibody titers conferred only partial protection to experimentally infected primates (120).
The highest priority for future development is refinement of the available diagnostic tools to permit definitive diagnosis and virus identification in the field. PCR-based assays add another dimension to the capability of field laboratories to diagnose acute disease almost in real time. Proper tailoring of primers should permit the design of tests with the proper degree of specificity. The emergence of new arenaviruses, as well as BDV, in the past decade serves as a reminder that broadly reactive, grouping reagents are still required to augment the newly evolving tools of conventional and real-time PCR and capture ELISAs based on extremely specific monoclonal antibodies and gene sequences.

An investment in rapid diagnosis should result in more timely intervention with effective implementation of appropriate public health measures and use of evolving treatment regimens. The implementation of appropriate infection control measures has been demonstrated to greatly reduce the transmission and dissemination of these highly virulent viral pathogens.

DNA Viruses

Herpes Simplex Viruses and Herpes B Virus
KEITH R. JEROME AND RHODA ASHLEY MORROW

TAXONOMY
Herpes simplex virus (HSV) types 1 and 2, formally designated human herpesvirus 1 and human herpesvirus 2, respectively, are members of the family Herpesviridae. Along with varicella-zoster virus (human herpesvirus 3) and a number of viruses primarily affecting nonhuman hosts, they comprise the subfamily Alphaherpesvirinae.

DESCRIPTION OF THE AGENT
The herpesviruses are thought to have coevolved with their hosts (1, 2), and thus the earliest documentation of presumptive herpes simplex infection appears shortly after the development of writing and clinical observation. The infectious nature of HSV was demonstrated in 1919 (3). The concepts of seropositivity and recurrence developed in the 1930s (4, 5). In the 1960s, antigenically distinct strains (HSV-1 and HSV-2) were identified. HSV-1 and HSV-2 are 2 of 8 known human herpesviruses (6). In addition, herpes B virus (“herpes simiae”), a herpesvirus infecting macaques, is an important zoonotic pathogen in humans.

The linear, double-stranded genome is 152 kbp for HSV-1 and 155 kbp for HSV-2. HSV-1 and HSV-2 share 83% nucleotide identity within their protein-coding regions. The genome is organized into a unique long and unique short region, each of which is flanked by inverted-repeat regions. Although significant stretches of sequence are conserved between unrelated clinical isolates, identification of isolates can be achieved by sequencing (7–9), PCR (10), or restriction endonuclease digestion (11).

The HSV virion is 120 to 300 nm in diameter, with a central electron-dense core containing the DNA, an icosahedral capsid consisting of 162 capsomeres surrounding the core, and a tegument layer surrounded by a spiked envelope containing viral glycoproteins that aid in attachment, penetration, and immune evasion (6). The envelope is a trilaminar, lipid-rich layer derived largely from the nuclear membrane of the infected cell. Because the viral envelope is lipid rich, the virus is readily inactivated. Lipid solvents, such as 70% ethanol or isopropanol (but not alcohol >95%), Lysol, or bleach, or exposure to a pH of <5 or >11 or temperatures of >56°C for 30 min will all eliminate infectivity (12, 13).

Viral replication begins with attachment to the target cell via cell type-dependent host receptors (14, 15). After attachment, the viral envelope and cell membrane fuse, releasing the capsid into the cell. The capsid is translocated to the nuclear pores (16, 17), and DNA is released into the nucleus. The tegument protein VP16 induces expression of the immediate early, or alpha, proteins which in turn transactivate the expression of the early, or beta, genes. The early genes are maximally expressed 5 to 7 h after infection and are involved in the synthesis of progeny viral DNA. DNA replication is required for optimal synthesis of the late, or gamma, genes which code for mainly structural proteins. Progeny DNA is processed and assembled into preformed capsids within the cell nucleus. The DNA-containing capsids attach to patches of the nuclear membrane that contain viral tegument proteins and viral glycoproteins.

In sensory ganglion neurons, the virus establishes latency, and episomal HSV DNA is maintained for the lifetime of the infected individual. Upon reactivation, nucleocapsids are transported anterograde to the axon terminus, where the final assembly of enveloped virus occurs (18), typically with infection of surrounding epithelial cells. The replication cycle is complete within about 20 h in epithelial cells.

Innate immune mechanisms such as activation of macrophages, NK cells, and interferon production play a predominant role in the control of primary infection, while both innate and adaptive immunity are important in the control of recurrences. Although both cellular and humoral immunity are thought to be important, persons with defective cellular immunity often show severe HSV infections, while those with agammaglobulinemia do not (19). CD4+ T cells infiltrate mucocutaneous lesions early in lesion development (20), followed by cytotoxic T lymphocytes (21). HSV-specific T cells can be detected early in lesion development and persist at the lesion site after healing (22, 23). T cells also play an important role in controlling viral reactivation from the dorsal root ganglia, via noncytotoxic mechanisms that do not result in neuronal death (24).

Functional antibody responses include complement-independent and complement-dependent viral neutralization (25). Immunoglobulin G (IgG), IgM, and IgA responses to individual viral proteins arise within the first weeks after infection (19). IgM wanes after 2 to 3 months, appearing sporadically thereafter, and in about a third of patients, after recurrent genital herpes episodes. Antibody titer may or may not rise after recurrences (26). However, IgG titers are maintained for years after primary infection.

Most epitopes are shared between HSV-1 and HSV-2. As a result, it is difficult to distinguish antibodies to HSV-1
from those to HSV-2 (27). In particular, in HSV-1-seropositive patients, seroconversion to HSV-2 is accompanied by brisk anamnestic responses to HSV-1, resulting in the predominant antibody response being directed toward HSV-1 rather than to HSV-2 for prolonged periods (27). While type-specific epitopes have been demonstrated on the major viral proteins, only glycoprotein G (gG) elicits predominantly type-specific responses.

EPIDEMIOLOGY AND TRANSMISSION
HSV infections occur worldwide with no seasonal distribution. The virus is spread by direct contact with virus in secretions. Incubation periods range from 1 to 26 days. The prevalence of HSV-1 infection increases gradually from childhood, reaching 80% or more in later years (28). In contrast, the seroprevalence of HSV-2 remains low until adolescence and the onset of sexual activity. The incidence of antibodies to HSV-2 in the United States reached 21% in the period 1988 to 1994 (29); however, in more recent years seropositivity rates have apparently declined to 17% for the period 1999 to 2004 (30). The rate of seropositivity varies widely, reaching more than 50% in some demographic groups (30, 31). In general, the seroprevalence of HSV-2 is higher in the United States than in other developed countries (32, 33).

Importantly, a large percentage of individuals seropositive for HSV-1 and/or HSV-2 are unaware of the infection (29, 30). Such persons comprise an important reservoir of infection. The risk of genital HSV transmission has been reported to be reduced by 30 to 50% through the use of condoms (34, 35), and a more recent case-crossover analysis of previous study data suggests that the reduction of transmission may be substantially more than previously estimated (36). Transmission is also reduced approximately 50% by disclosure of HSV infection status to sexual partners (37). Over half of such persons recognize and present with symptoms after education regarding manifestations of HSV disease (49, 50). In addition, about 20% of patients presenting with first episodes of genital herpes have serologic evidence of having been infected for some time (51). These episodes most closely resemble recurrent disease, with relatively mild symptoms. The risk of recurrence is similar between patients presenting with true primary and first recognized recurrent episodes (26). Most patients with genital herpes have episodes of subclinical virus excretion from anogenital sites; these constitute an important source of transmission. The copy number of HSV DNA can sometimes be as high during subclinical episodes as when symptoms occur (52). In general, oral shedding of HSV-1 occurs somewhat less frequently than genital shedding of HSV-2 (53). Oral shedding of HSV-2, or genital shedding of HSV-1, are comparatively rare, particularly outside the setting of newly acquired disease (48, 53, 54).

CLINICAL SIGNIFICANCE
Primary Infection
Most HSV-1 infections are acquired early in childhood as subclinical or unrecognized infections (39). Young children may present with classic primary HSV-1 infection characterized by gingivostomatitis, fever, and marked submandibular lymphadenopathy. Oral lesions progress to ulceration and heal without scarring over 2 to 3 weeks. Adolescents may present with pharyngitis and mononucleosis.

Primary infection with HSV-2 classically presents as herpes genitalis, with extensive, bilateral vesicles, fever, inguinal lymphadenopathy, and dysuria (40). Lesions ulcerate and heal without scarring within 3 weeks. Secondary lesions may develop in the second to third week. Subclinical or unrecognized primary infection with HSV-2 is common. The proportion of primary genital infections due to HSV-1 is decreasing (41), from about 10% in 1983 to 32% in 1995 (40, 42), and now represents the major cause of first-episode anogenital infections at least some populations (43–45). In a large study of young women, 18 to 30 years of age, primary infection with HSV-1 was more than twice as common as infection with HSV-2 (45), and of clinically recognized primary HSV-1 infections, more than 75% were genital rather than oral. This trend is thought to result from changing sexual practices, including increased oral-genital exposure (43). The clinical presentation of primary genital HSV-1 cannot be distinguished from that of HSV-2. However, recurrent disease (see below) is less common with genital HSV-1 than HSV-2 (40, 46), and thus, determining the infecting virus type is useful for prognostic purposes.

Latency and Recurrent Disease
Primary infection with HSV-1 or HSV-2 is followed by the establishment of latency in the dorsal root ganglia, typically the trigeminal ganglia for orolabial disease and the lumbosacral ganglia for genital disease. Periodically, the virus reacts and travels via the nerve axon to oral or genital sites, resulting in release of infectious virus and, in some cases, lesion formation. Recurrent disease has milder symptoms and a shorter time to lesion healing than primary episodes (39, 40). The frequency of HSV-2 genital recurrences varies widely among individuals, ranging from none to 12 or more per year (47), with a mean rate of 0.33 recurrences/month. Orolabial HSV-1 recurrence rates are lower, with a mean of 0.12 episodes/month, while genital HSV-1 infection occurs even less frequently (mean, 0.02 episodes/month) (48). While HSV-2 may be isolated from the pharynx during primary genital herpes episodes, orolabial HSV-2 recurrences are extremely infrequent (48).

Asymptomatic or Subclinical Infection
Approximately 70 to 90% of individuals with HSV-2 antibodies have not been diagnosed with genital herpes (29, 30). Over half of such persons recognize and present with symptoms after education regarding manifestations of HSV disease (49, 50). In addition, about 20% of patients presenting with first episodes of genital herpes have serologic evidence of having been infected for some time (51). These episodes most closely resemble recurrent disease, with relatively mild symptoms. The risk of recurrence is similar between patients presenting with true primary and first recognized recurrent episodes (26). Most patients with genital herpes have episodes of subclinical virus excretion from anogenital sites; these constitute an important source of transmission. The copy number of HSV DNA can sometimes be as high during subclinical episodes as when symptoms occur (52). In general, oral shedding of HSV-1 occurs somewhat less frequently than genital shedding of HSV-2 (53). Oral shedding of HSV-2, or genital shedding of HSV-1, are comparatively rare, particularly outside the setting of newly acquired disease (48, 53, 54).

Neonatal Herpes
The most serious consequence of genital HSV infection is neonatal herpes (55). Infection usually occurs during vaginal delivery when the infant is exposed to HSV in maternal secretions. The risk of maternal-to-infant transmission is 10-fold higher in mothers experiencing unrecognized primary infection during the time of labor than in those shedding HSV as a result of recurrent, subclinical reactivation. This conclusion was drawn in part from the finding that the neonatal infection rate is 54 per 100,000 among HSV-seronegative mothers, 26 per 100,000 among mothers with only HSV-1 antibody, and 22 per 100,000 among all mothers with HSV-2 antibody (56, 57). Transmission of HSV-1 occurs at a significantly higher rate than that of HSV-2 (57, 58). The high rate of transmission during primary disease means that 50 to 80% of all cases of neonatal herpes occur in children of women who acquire genital HSV infection near term (59, 60). Pregnant women who present with HSV infection should undergo both a type-specific serologic
assay and viral typing to identify those infants at highest risk for infection (61). Infected neonates can present with HSV disease localized to the skin, eyes, and mucosa or more serious central nervous system (CNS) or disseminated disease but often have non-specific presentation (55, 62). The mortality rate for untreated neonates with disseminated disease exceeds 70%. Early diagnosis and antiviral therapy while disease is localized to the skin can substantially reduce the morbidity and mortality associated with neonatal infections (63, 64). PCR should be used to test samples from lesions, other mucosal sites, cerebrospinal fluid (CSF), and blood (55, 65–67). Although culture has continued to be advocated for surface specimens (68), the superior sensitivity of PCR for surface specimens is well established (52).

**Herpes Central Nervous System Disease in the Immunocompetent Host**

HSV is the most common cause of fatal sporadic encephalitis in the United States (69). HSV encephalitis presents as fever, behavioral changes, and altered consciousness, resulting from localized temporal lobe involvement. Without treatment, mortality exceeds 70%, and few survivors recover normal neurologic function. Early treatment with acyclovir reduces morbidity and mortality; however, residual neurologic impairment is common (70). HSV PCR of CSF is the test of choice (71, 72). Culture of CSF is not acceptable for diagnosis of HSV encephalitis.

Genital HSV may be followed by sporadic meningitis or recurrent meningitis (Mollaret’s syndrome) characterized by headache, fever, photophobia, and lymphocytic pleocytosis (73, 74). The condition is self-limiting and typically resolves within one week (73). HSV also can be associated with myelitis, radiculitis, ascending paralysis, autonomic nerve dysfunction, and possibly Bell’s palsy.

**Systemic HSV Infection in Hospitalized Adults**

HSV can sometimes be detected by PCR in the blood during primary HSV disease (75) and in recurrent herpes labialis (76). It can also occasionally be detected in the blood of hospitalized adults, either immunocompetent or immunocompromised (77, 78). Hospitalized patients with detectable HSV viremia frequently have clinical symptoms, including hepatitis, fever, CNS alterations, skin lesions, abdominal pain, or sepsis, although it has not been established that HSV is the cause of these symptoms. Nevertheless, hospitalized patients with detectable HSV viremia do have a high rate of mortality, suggesting a role for testing.

**Ocular Herpes Infections**

HSV is the most common viral cause of corneal infection in the United States, affecting 400,000 to 500,000 people (79, 80). Most corneal HSV infections are limited to the epithelial layer, causing characteristic branching ulcerations, pain, photophobia, and blurred vision. HSV epithelial keratitis responds well to oral or topical therapy (see below). Such superficial infections heal without loss of vision. HSV infection may extend to the corneal stroma, leading to scarring and opacification of the cornea. Stromal HSV infections respond favorably to a combination of corticosteroids and topical or oral antivirals (81, 82).

**Herpes in the Immunocompromised Host**

Immunosuppressed individuals with defective cell-mediated immunity frequently develop symptomatic HSV disease. HSV infections in such individuals can be severe, with extensive mucocutaneous necrosis and involvement of contiguous tissues leading to esophagitis or proctitis. Disseminated HSV, which can lead to meningoencephalitis, pneumonitis, hepatitis, and coagulopathy, may be more common in immunocompromised and hospitalized patients than is generally recognized (77, 83). Disseminated infections require intravenous antiviral therapy and monitoring for development of antiviral resistance.

**Antiviral Therapy**

Several antiviral drugs, including acyclovir, valacyclovir, penciclovir, and foscarnet, are now widely used to treat mucocutaneous and genital herpes (84, 85) and for long-term suppression of recurrent episodes. These drugs are selectively activated by the viral thymidine kinase and have minimal side effects. Suppressive therapy reduces the risk of viral transmission between HSV-discordant partners (38). N-Docosanol, a nonprescription topical medication, and topical acyclovir are used for the treatment of herpes labialis. HSV conjunctivitis, blepharitis, and dendritic keratitis are either treated topically with trifluridine, idoxuridine, or vidarabine or orally with acyclovir, valacyclovir, or famciclovir (81). In cases with stromal involvement, the addition of topical corticosteroids reduces the persistence of inflammation (81). Neonatal herpes, herpes encephalitis, and severe infections in immunocompromised patients require prompt intravenous antiviral therapy (86). The alternative agents foscarnet, cidofovir, and vidarabine are generally reserved for acyclovir-resistant herpes infections (85, 87). New compounds targeting the HSV helicase/primase complex (88) have shown efficacy in clinical trials (89) and are likely to provide additional therapeutic options in the future.

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

Samples for DNA amplification (PCR) require careful collection and handling, which are essential to ensure adequate specimen and avoid contamination of the sample with exogenous viral DNA. For lesions or mucocutaneous sites, a dedicated specimen should be collected with a Dacron swab in viral transport medium (VTM) or digestion buffer (90). Serum, plasma, and CSF do not require special handling. Blood from neonates is collected in lavender-topped tubes (EDTA) for PCR of peripheral blood mononuclear cells and plasma (65). Heparin can inhibit PCR and therefore should not be used. Samples for DNA amplification require prompt intravenous antiviral therapy and monitoring for development of antiviral resistance. For culture, specimens from lesions or mucocutaneous sites should be placed in VTM and kept at controlled temperature to retain optimal infectivity. VTM is made of balanced salt solutions such as Hanks balanced salt solution, Stuart’s medium, Leibovitz-Emory medium, veal infusion broth, or tryptose phosphate broth buffered to maintain a neutral pH. Protein stabilizing agents such as gelatin or bovine serum albumin are added as well as antibiotics to prevent bacterial overgrowth (93). Most VTM are inappropriate for bacterial or chlamydial transport. However, multipurpose M4 media from Remel (Lenexa, KS) and universal transport medium (UTM) from Copan (Murrieta, CA) are suitable for viruses, Chlamydia, Mycoplasma, and Ureaplasma. It is important that laboratories validate the suitability of the selected media for their particular applications, as performance can vary. For example, in one study, M4 or the
UTM system from Copan supported detection of low-titer HSV better than other media (94). Necrotic debris or exudate should be removed from mucosal sites (endocervix, anogenital areas, conjunctiva, and throat) or lesions with a cotton swab prior to sampling. The area must be vigorously rubbed with Dacron, rayon, or cotton swabs on aluminum shafts to ensure that infected cells at the base of the lesion are collected. Calcium alginate swabs and swabs with wooden shafts inhibit infectivity (93, 95). Swabs are then placed into VTM for transport. Several manufacturers offer combined swab/media packaging, such as the Copan UTM system and the Remel multimicrobe M4 system.

Samples should be shipped cold (on ample ice packs) but not frozen. Prolonged (>48 h) storage should be at −70°C. HSV stability is reduced significantly at 22°C compared with 4°C; in one study, median half-lives of virus in Copan UTM were 6.8 days (HSV-1) and 4.9 days (HSV-2) at 4°C but only 1.9 (HSV-1) and 3.8 (HSV-2) days at 22°C (94). With other transport media, reported half-lives of HSV-1 have ranged from 0.5 to 4 days at 22°C and from 1 to 180 days at 4°C (96).

A single transport vial may provide specimen for both viral culture and direct antigen detection tests. Alternatively, slides for direct fluorescent antibody detection can be prepared immediately after collection by gently spreading the material on a swab in a thin layer over a clean microscope slide. The slide is air-dried and fixed in cold acetone before transport.

Fluids such as tracheal aspirates should be collected aseptically and transported without VTM. Urine should be collected by clean catch and refrigerated before transport. Once in the laboratory, urine is diluted 1:1 with culture medium. Corneal samples are obtained with a scalpel blade, and cells are suspended in VTM. Tissue is placed in VTM in a sterile container. Prolonged storage of tissue requires immersion in sterile 50% neutral glycerol in saline or, alternatively, in culture medium with 5% fetal bovine serum. Fresh tissue samples can also be frozen, sectioned, applied to slides, and fixed in acetone.

DIRECT DETECTION
Detection of virus in patient samples without an intervening culture amplification step provides the most rapid diagnosis. PCR or other DNA amplification techniques provide the best sensitivity of the direct detection approaches and have become the method of choice for many laboratories. Immunostaining methods to detect antigen require less expertise than cytopathic effect (CPE)-based culture methods and are usually less expensive than culture or DNA amplification.

DNA Amplification
PCR or other amplification approaches are the most sensitive methods for direct detection of HSV (97). This is especially important in situations where sensitivity is critical, such as CSF, but recently, PCR has been increasingly adopted for anogenital and other specimen types as well. For many years, DNA amplification for HSV was available in the United States only through laboratory-developed tests. In 2010, however, the FDA granted the first of several clearances to DNA-based HSV tests, and the availability of FDA-cleared assays has accelerated the trend from culture toward DNA testing.

Whether testing is done in an FDA-cleared or laboratory-developed test format, precautions to prevent contamination of the sample and the inclusion of frequent negative controls within the assay are critical (98, 99). Some laboratories include isosorders and uracil-N-glycosylase in their PCR amplifications, preventing the amplification of PCR products in subsequent reactions. The likelihood of laboratory contamination by amplicon is reduced by using real-time PCR detection systems that eliminate the need for postamplification manipulation of the PCR product. Laboratories performing PCR testing should participate in a regular proficiency testing program, such as those provided by the College of American Pathologists (www.cap.org) or Quality Control for Molecular Diagnostics (www.qcmd.org).

Depending on the primers and detection methods, PCR can be set up to detect both HSV-1 and HSV-2, or to allow distinction of HSV-1 from HSV-2, or to allow distinction of HSV-1 from HSV-2. PCR primers have been described for amplifying portions of HSV genes encoding thymidine kinase (U1, 32); DNA polymerase (U1, 30); DNA binding protein (U1, 42); glycoproteins B, C, D, and G (U1, 44, U1, 44, U1, 44, respectively); and many others (102). The choice of target gene is probably not a critical factor for HSV PCR, and efficient and sensitive assays have been developed using a variety of target genes. Instead, laboratories should ensure that the primers and probes in any contemplated assay follow the principles of efficient PCR assay design (103). Distinction of HSV-1 and HSV-2 can be achieved using type-specific primers or probes, melting curve analysis, restriction enzyme analysis, or direct sequencing. At our institution, we detect both HSV-1 and HSV-2 by PCR using a real-time detection system (see below) with type-common gB primers and probe (92). To differentiate HSV-1 from HSV-2, we use a multiplex PCR assay containing type common gB forward primers that amplify both viruses with equal efficiency. Differentiation is achieved using an HSV-1 probe labeled 5′ with VIC and 3′ with TAMRA (6-carboxytetramethylrhodamine), and an HSV-2 probe labeled 5′ with FAM (6-carboxyfluorescein) and 3′ with TAMRA (104). Test results are available on the same day as receipt of specimen.

Traditional methods to detect PCR products include intercalating agents such as ethidium bromide, Southern blot hybridization, and liquid hybridization. A major improvement was the development of HSV assays using real-time detection of PCR products (90, 105–108). Real-time systems allow constant monitoring of the amount of PCR product by detection of a fluorescent signal that increases as the PCR product accumulates. These systems decrease the likelihood of laboratory contamination. Laboratory contamination is of particular concern for CSF specimens, where reliable detection of low viral loads is of major clinical significance, and can occur when such specimens are processed together with lesion or other specimens with high viral load. Careful technique and systematic monitoring of negative controls is essential.

Real-time PCR allows more accurate quantification than is possible with older quantitative-competitive assays (90). Quantitation of virus may be useful in monitoring response to antiviral therapy, particularly in HSV encephalitis or neonatal herpes infections (109). Using these or other primer/probe sets, a large number of labs offer in-house validated assays with real-time detection and quantitation.

Despite the lack of FDA-approved tests, PCR is the gold standard for detection of HSV in CSF, neonatal, and ocular specimens and is increasingly used with other sample types as well. Substantial differences in performance have been reported in interlaboratory comparisons, particularly in sensitivity for detection of low-positive specimens (110). There is no consensus on the required sensitivity for CSF testing, and interlaboratory differences are exacerbated by the cur-
rent lack of an international reference standard for HSV. Thus, it is important to carefully consider the laboratory’s reputation, performance data, and test turnaround times before selecting a provider of DNA amplification testing.

As stated above, only recently have commercial molecular assays for HSV achieved FDA approval (Table 1), while CE-marked assays have been available in Europe for several years. Importantly, none of the commercial assays are FDA-cleared for use with CSF specimens. The Eragen Multi-Code-RTx HSV 1 & 2 kit was FDA-cleared in 2010 for qualitative detection and typing of HSV in vaginal lesion swabs from symptomatic female patients only and is now available from Luminex Corp (Austin, TX). The assay is based on PCR amplification using a synthetic isoC:isoG DNA base pair. It was initially cleared for use on samples extracted using the Roche MagNa Pure LC instrument and amplified on the Roche LightCycler real-time PCR instrument (Basel, Switzerland). FDA clearance was subsequently obtained for specimens extracted using the bioMérieux NucliSens easyMag extraction system.

The ProbeTec herpes simplex virus (HSV 1 & 2) Q²xQ amplified DNA assays (BD, Franklin Lakes, NJ) use strand displacement amplification for the qualitative detection and differentiation of HSV-1 and -2. The assays are performed on the fully automated BD Viper system in extracted mode and were FDA cleared in 2011 for testing of clinician-collected external anogenital lesion specimens. In a large head-to-head comparison, the assay proved to be far more sensitive than culture and had a specificity and sensitivity of 95.1 to 100% compared to the University of Washington PCR assay (111).

Finally, BioHelix Corp (Beverly, MA) offers the IsoAmp HSV assay, which was FDA cleared for detection of HSV-1 and -2 in genital and oral lesion specimens from symptomatic patients. The IsoAmp HSV assay is based on a helicase-dependent amplification technology and a unique single-use handheld disposable detection device, allowing rapid (1.5 h) turnaround time. The assay does not differentiate between HSV-1 and -2. In a comparison with viral culture, the IsoAmp HSV assay had a sensitivity of 100% and a specificity of 96.3%; the analytical sensitivities for HSV-1 and HSV-2 were 5.5 and 34.1 copies per reaction, respectively (112).

### Other Nucleic Acid-Based Tests

In situ hybridization or solution hybridization methods are not as widely used as DNA amplification, indirect fluorescent antibody assay, or direct fluorescent antibody assay (DFA). These tests use DNA or RNA probes, some of which are type specific. The sensitivity of direct hybridization methods is limited (approximately 1 × 10⁵ copies/ml), and thus, these approaches have been largely replaced by PCR or other amplification methods.

### Microscopy

Changes that are characteristic for HSV are sometimes visible in fixed, stained cells from lesions (Tzanck preparations) or cervical scrapings (Papanicalou stains) or hematoxylin and eosin stained of fixed tissue (113). Enlarged or degenerating cells, syncytium formation, chromatin margination, a “ground glass” appearance of the cytoplasm, and nuclear inclusions are typical of HSV-infected cells. These methods are widely available but lack sensitivity and specificity (114). Virus-specific methods are preferred.

### Antigen Detection

Slides are prepared with cells from the patient’s specimen, fixed, and coated with antibody preparations against HSV-1 and HSV-2 or against type common epitopes. Some manufacturers offer dual anti-HSV and anti-varicella-zoster virus (anti-VZV) reagent combinations. If the antibodies are linked to a fluorophore such as fluorescein isothiocyanate, the test is a DFA. If bound anti-HSV antibodies are detected with secondary antibodies conjugated to fluorophore, the test is an indirect fluorescent antibody assay. Same-well testing can be performed using antibody conjugates with different fluorophores for HSV-1 and HSV-2 (115). DFA is 10 to 87% as sensitive as culture with higher sensitivity from vesicular lesions and poor sensitivity from healing lesions (48). DFA is far less sensitive than PCR (116), and validated commercial kits for DFA are not readily available.

Changes that are characteristic for HSV are sometimes visible in fixed, stained cells from lesions (Tzanck preparations) or cervical scrapings (Papanicalou stains) or hematoxylin and eosin stained of fixed tissue (113). Enlarged or degenerating cells, syncytium formation, chromatin margination, a “ground glass” appearance of the cytoplasm, and nuclear inclusions are typical of HSV-infected cells. These methods are widely available but lack sensitivity and specificity (114). Virus-specific methods are preferred.
An effective modification of DFA employs a cytocentrifuging step to apply cells to the sample to slides for subsequent DFA testing. The cytocentrifugation step results in better adherence of cells to the slides and fewer inadequate specimens than dip application methods (117) while allowing for a less-than-2-h turnaround time. The reported sensitivity of cytocentrifuged DFA has varied widely in one study; it was higher than culture for detecting HSV from swab specimens (117), while another study, using different DFA antibody and cell culture systems, reported sensitivity of 31% versus culture (118). The Light Diagnostics SimulFluor assay (Millipore, Billerica, MA) has been reported to have a sensitivity of 80.0% and a specificity of 98.8% compared to culture (115) and a sensitivity of 86.2% in a multimethod comparison including two PCR-based assays (119).

Antibodies give their own distinct patterns depending on the viral antigens recognized (Table 2). DFA can vary from lab to lab, depending on sample quality, the method of preparation of slides, the reagent used, and other factors. Staining patterns require skill to interpret; nonspecific staining needs to be distinguished from staining of viral antigen by a trained reader. It is important to ensure that antibody reagents are validated for use directly on clinical samples; some antibodies intended for culture confirmation can give spurious results in other settings.

Enzyme immunoassay (EIA) is rapid and amenable to automation. Sensitivity can be as good as culture for diagnosis from lesions (120) or as low as 35% in asymptomatic patients (121, 122). EIA for direct detection of virus has been largely supplanted by other methods.

The enzyme-linked virus inducible system (ELVIS) is based on BHK cells with a reporter gene for β-galactosidase that is driven by the promoter from the HSV-1 UL39 gene (129). Other viruses do not transactivate this promoter. Infected cells express the reporter gene, resulting in a color change visualized by light microscopy. The ELVIS HSV test system (Diagnostic Hybrids) allows HSV-positive cells to be further tested to distinguish HSV-1 from HSV-2. ELVIS-based systems can have comparable sensitivity to standard culture (130) and spin-amplified cell culture (131).

SEROLOGIC TESTS

Because nearly all HSV structural proteins have extensive antigenic cross-reactivity, only IgG tests based on the type-specific HSV glycoprotein gG accurately distinguish HSV-1 and HSV-2 antibodies (27, 132, 133). Tests based on crude antigen mixtures are still marketed but have unacceptably low sensitivity and specificity, especially for detecting new HSV-2 infections in those with prior HSV-1 (27, 132, 134, 135). Type-specific IgM tests are not available. FDA-approved IgM tests decrease the time to detecting seroconversion in new infections but cannot accurately distinguish new from established infections (136). IgM-based tests can also be prone to false-positive results (137, 138) and thus should be confirmed by other approaches. Tests for HSV-2 antibody avidity can discriminate accurately between first episodes (low avidity) and recurrent episodes (high avidity) in most cases (139). However, these tests are not commercially available.

Western Blot

The HSV Western blot (WB) used by the University of Washington laboratory uses nitrocellulose blots prepared with human diploid fibroblast-infected cell proteins. WB detects antibodies to multiple viral proteins, including those to the type-specific glycoproteins gG-1 and gG-2 (140). About 20% of sera must be preabsorbed against Sepharose beads coated with HSV-1 or HSV-2 proteins and restested to give definitive results. This combination of tests gives a very accurate determination of HSV-1 versus HSV-2 antibody status (140) and is considered the gold standard for comparison of other serologic assays.

Commercial Type-Specific gG-Based Assays

A number of manufacturers now offer FDA-approved assays using gG as the target antigen. As noted above, gG-based assays are preferred over those based on crude antigen mixtures, due to their ability to distinguish antibodies to HSV-1 versus HSV-2. Microplate format EIAs include the HerpeSelect enzyme-linked immunosorbent assay (ELISA) from Focus Diagnostics (Cypress, CA), the Captia HSV-1 and HSV-2 IgG type-specific ELISA test kits (Triumph Biotech, Bray, Ireland), the anti-HSV-1 and anti-HSV-2 ELISA IgG kits from Euroimmun (Lubeck, Germany), and the Zeus ELISA HSV-1 and -2 test systems (Raritan, NJ). The Roche Elecsys HSV-1 IgG and HSV-2 IgG assays are FDA-cleared for use on several automated immunoassay instruments. Some newer assays utilize microparticle-based detection technology, which provides the possibility of multiplexing and offers potential advantages in assay throughput and reproducibility. The Plexus HerpeSelect 1 and 2 IgG test kit (Focus, Cypress, CA), the BioPlex 2200 HSV 1 and 2 kit (Bio-Rad), and the ArtheNA Multi-Lyte HSV-1&2 (ZEUS Scientific, Raritan, NJ) utilize Luminex detection technology (Austin, TX). The LIAISON HSV-1 and HSV-2 type-specific IgG tests are bead-based chemiluminescent immunoassays requiring the use of the Liaison analyzer (DiaSorin, Saluggia, Italy). Finally, simple gG-based lateral flow assays are available that are designed for point-of-care testing. Some include the HerpeSelect Express IgG (Focus Diagnostics), which distinguishes antibodies to HSV-1 and HSV-2, and the Biokit HSV-2 rapid test (Biokit, Barcelona, Spain).

The commercial gG-based tests perform well in clinical use in North America. When compared with the University of Washington WB, HerpeSelect ELISA had 91 to 96% sensitivity with 92 to 95% specificity for HSV-1 and 96 to 100% sensitivity with 96 to 97% specificity for HSV-2. HerpeSelect Immunoblot had 99 to 100% sensitivity with 93 to 96%
specificity for HSV-1 and 97 to 100% sensitivity and 94 to 98% specificity for HSV-2 (133). The BioPlex assay had sensitivities and specificities of 85 and 98% for HSV-1 and of 100 and 95% for HSV-2 when compared to WB (136). The Luminex-based assays show good agreement with the Focus HerpeSelect EIA: 94.9% for the AtheNA Multi-Lyte HSV-1&2, 97.8% for the BioPlex 2200 HSV 1 and 2 kit, and 97.4% for the Plexus HerpeSelect 1 and 2 IgG test kit (141). For point-of-care tests, the POckit-HSV-2 test (now Biokit HSV-2 rapid test) had 93 to 96% sensitivity with 95 to 98% specificity in comparison tests (133). While performance characteristics against WB are not available, the HerpeSelect Express IgG assay had 100% sensitivity and 97.3% specificity when compared to the HerpeSelect ELISA (142). The median time to seroconversion is approximately 2 to 3 weeks for HerpeSelect HSV ELISA and the Biokit HSV-2 rapid test, the only FDA-approved tests for which extensive data are available (143, 144).
ANTIVIRAL SUSCEPTIBILITIES

Acyclovir-resistant strains of HSV typically result from mutation of the gene encoding the viral thymidine kinase and, more rarely, from mutations in the HSV polymerase. Prolonged use of antivirals can lead to selection of resistant strains, especially in immunocompromised individuals and neonates (145). Strains with detectable in vitro resistance can also be isolated from patients who have never received acyclovir (146). Such isolates are rarely of clinical significance in immunocompetent individuals, and these persons generally respond well to acyclovir (147). However, resistance can occasionally be observed in immune-privileged sites even in immune-competent individuals (148). Acyclovir-resistant HSV can lead to treatment failure (147), and thus laboratory confirmation of resistance can inform patient management decisions (149). Some patients with suspected acyclovir-resistant virus respond to an increased dosage of the drug. For most patients, second line therapy requires the use of less desirable drugs such as foscarin or cidofovir. However, since some mutations in the HSV polymerase cause acyclovir resistance but do not affect sensitivity to penciclovir, testing for susceptibility to individual antivirals may be warranted in certain circumstances (145), as it may allow use of a less toxic drug.

Susceptibility testing can be performed by genotyping or phenotypic assays. A major drawback of genotypic assays is that frameshift or nonsense mutations are possible throughout the thymidine kinase gene, requiring complete sequencing of the gene for definitive results (145). Among phenotypic assays, plaque reduction is considered the gold standard (145, 147). Alternative phenotypic assays include antigen reduction by EIA and genome reduction by DNA hybridization (145). In general, a 50% inhibitory concentration of <2 μg/ml is used as the threshold for susceptibility and correlates relatively well with clinical response (150). However, false determinations of resistance are common in the various phenotypic assays, and interlaboratory variability is significant (145). Thus, clinical correlation of testing results is essential.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Laboratory results are best interpreted in the context of the patient’s presentation and history and with the knowledge of the natural history of HSV infection.

Interpretation of Virus Detection Tests

Interpretation of positive test results depends upon the specificity of the test. Specificity of culture is extremely high if confirmatory tests are performed. In situ techniques for antigen detection (FA or immunoperoxidase staining of infected cells) have better specificity than other antigen detection methods because the staining pattern allows the technologist to confirm that the signal is specific (Table 2). Given its extreme sensitivity, PCR is quickly becoming the test of choice in many situations. PCR is most reliable when closed system methods are used and lab practices are strictly met to avoid contamination of specimens with exogenous HSV DNA. Given these caveats, in practice, positive culture or PCR results are highly diagnostic in patients with lesions due to gingivostomatitis, genital herpes, or ocular infections. Positive FA tests from lesions or ocular swabs are considered reliable. HSV found in the CNS, tissues, blood, or the eye by culture or PCR is diagnostic. Positive cultures or positive PCR tests in symptomatic infants at 1 to 3 weeks of life are highly diagnostic (151).

For other patients, interpretation of a positive viral detection test requires caution. One potential confounding issue is the simultaneous presence of multiple potential pathogens. For example, respiratory secretions from immunocompromised patients may contain HSV in addition to the presumably causative agent such as respiratory syncytial virus, influenza, parainfluenza, or adenovirus (152, 153). HSV may also be shed concurrently with other pathogens from oral or anogenital sites or may not be the cause of the episodic syndrome that triggered testing. Syphilis and chancroid are the most likely alternative causes of genital ulcers in the United States. In a series of patients with genital ulcers other than those typical of herpes (vesiculopustular lesions), 65% had only herpes detected while 20% had both syphilis and herpes detected (154). HSV results from such patients need to be interpreted in the context of laboratory testing for other pathogens in the differential diagnosis. Symptoms of HSV gingivostomatitis or genital infection can be mimicked by noninfectious causes, such as Stevens-Johnson syndrome, or by other infectious agents. Because of the sporadic nature of asymptomatic HSV shedding (155), swabs of oral or anogenital sites can also yield positive HSV culture, PCR, or antigen tests when the underlying cause of disease is not herpes.
Positive cultures or PCR results from skin, conjunctival, mouth, or nasal swabs from neonates less than 24 h old may reflect maternal virus rather than neonatal infection. Neonates born to mothers shedding HSV from the genital tract at labor and delivery may be tested 24 to 72 h after birth, the likely time frame for receiving maternal culture or PCR results. Most babies developing neonatal herpes are present between 9 and 14 days of life (156), well beyond the time frame where maternal viral contamination would be a problem. However, early initiation of therapy is strongly associated with a favorable outcome (157), and thus, current opinion favors aggressive monitoring and treatment (55).

False-negative PCR, culture, or DFA tests may occur because of poor technique in sampling, resulting in the failure to obtain virus or infected cells. For culture, negative cultures can result because of prolonged transport time, exposure of samples to high ambient temperature, or because the specimen has low levels of virus; these are less problematic for PCR testing. Recurrent herpes episodes yield lower levels of virus for shorter periods (40). In many cases, a combination of tests or repeated testing is the most sensitive approach. Performing both culture and FA can increase sensitivity by 20% or more from genital lesions; repeating testing at a later recurrence nearly doubles the sensitivity (158). PCR is the most sensitive test available and is the test of choice for herpes encephalitis, disseminated neonatal herpes, and increasingly, diagnosis of anogenital herpes (52, 159). However, in areas without local PCR testing, direct or indirect FA methods and culture may yield more timely results. Antiviral therapy should be started empirically if disseminated herpes, neonatal herpes, or encephalitis is suspected.

PCR has adequate sensitivity to detect shedding of HSV in individuals with asymptomatic infection or negative cultures (160–162) and also to detect HSV in CSF, a specimen with a low yield of HSV by culture. The sensitivity of PCR for HSV encephalitis has been reported to be about 96% and the specificity 99% (163). Since the viral load in CSF can be quite low in HSV encephalitis, it is critical that PCR assays are optimized to provide the best possible limit of detection. Importantly, none of the commercial molecular tests for HSV have been approved for use on CSF. PCR has much greater sensitivity than culture for detection of genital HSV-2 both from lesions and during periods of subclinical shedding (52). PCR can detect virus early in lesion development before culture positivity and can remain positive for several days after HSV lesions become negative by culture (160, 164). PCR positivity in such cases probably represents infectious virus below the limit of detection by culture, and PCR positivity is quickly lost in the absence of active shedding (164). False negatives can occur in PCR, due to reaction failure or the presence of inhibitors in clinical specimens (165–167). It is therefore critical that only negative reactions accompanied by positive internal controls be accepted as true negatives (168). In addition, PCR false negatives can occur due to sequence variation in the primer- or probe-binding regions (119). Importantly, a negative PCR result for HSV does not rule out HSV disease, since specimens taken very early or late in the course of disease may not have viral DNA (169). This is especially true in pediatric populations; for example, in one series, nearly 25% of infants with CNS HSV infections had negative CSF PCR results (151). The specificity of PCR for detection of HSV encephalitis has been reported to be greater than 98% (170); thus, all HSV-positive PCR results demand immediate attention. In patients with CNS HSV infections, HSV PCR may become negative after about 7 days of antiviral therapy (163). The persistence or reemergence of virus after antiviral therapy has been associated with a poor clinical outcome (171).

Quantitative PCR may be useful in monitoring the response to antiviral therapy. Successful therapy is associated with a decline in viral load in the CSF (159, 166, 172, 173), and a long duration of viral detectability is associated with poor outcome (174). Quantitation of HSV may also have prognostic value. Patients with higher viral loads have been reported to have worse clinical outcomes (175); in one study, those with >100 copies/μl (100,000 copies/ml) of HSV had worse outcomes than patients with lower levels (173). However, other groups have reported no association between CSF viral load and clinical outcome (166, 172, 174, 176).

**Interpretation of Type-Specific Serology**

Type-specific serology is useful when culture or other virus detection methods are not available, when specimen collection or transport is inadequate, or for evaluation of serostatus in the absence of clinical disease. Serology based on gG-1 and gG-2 is useful for diagnosing subclinical and unrecognised HSV infections. In fact, many experts believe that better recognition of genital HSV-2 infections by increased use of accurate gG-based serologic tests could help slow the spread of genital herpes (177–179).

As with other herpes laboratory tests, serology tests based on gG must be ordered and interpreted with care. First, due to the low specificity of non-gG-based commercial tests, it is important to ensure that a gG-based test is used. If so, a positive test for HSV-2 antibodies in a patient with genital lesions is highly likely to be a true positive. A positive HSV-2 antibody test in a patient without a history compatible with genital herpes may be a false positive and should be confirmed by testing with a different type-specific test (180). Negative HSV-2 test results in a patient with symptomatic genital disease may indicate genital HSV-1. No test can distinguish between antibodies elicited by oral versus genital HSV-1, and definitive diagnosis in such cases rests on direct detection of virus. False-negative test results may also occur during seroconversion; sera drawn 4 to 6 weeks later should also be tested. While “index values” in HSV-2 EIA have been shown to rise during seroconversion, index values alone are not reliable indicators of early versus established infection (181). IgM tests based on gG-1 and gG-2 are not available commercially. The available IgM tests cannot distinguish new from established symptomatic episodes with sufficient accuracy and are not recommended (136).

As noted above, type-specific serology is critical for identifying pregnant women with new HSV infections, who are at high risk for transmitting virus to their neonates (55, 179). Determining HSV-2 serostatus early in pregnancy has been recommended so that treatment options can be considered (179). If a herpes culture from the anogenital region is positive at labor or delivery, a negative maternal type-specific serology indicates high risk (30 to 50%) for neonatal herpes. A positive maternal serology by Western blot or equivalent test indicates a lower risk of transmission (1 to 3%).

**HERPES B VIRUS**

**Description of the Agent**

Herpes B virus, also known as Macacine (formerly Cercoce- thecine) herpesvirus 1 or monkey B virus, is similar to HSV in terms of genome size and structure and in terms of virion
morphology. Herpes B virus DNA has 161 ± 12 kbp (182) and is extremely (approximately 75%) G+C rich.

The replication cycle of herpes B virus is very similar to HSV. Herpes B virus is detectable as soon as 6 h postinfection, and titers of virus stabilize by 24 to 36 h (183). At least nine herpes B virus glycoproteins have been identified, and at least two of these share antigenic determinants with glycoproteins B and D of HSV (184). As an enveloped virus, herpes B virus can be inactivated by lipid solvents, UV light, or heat, and thus, cell-free virus is inactivated rapidly in the environment.

**Clinical Significance**

Herpes B virus is the simian counterpart to HSV in Old World monkeys of the genus Macaca, including the rhesus, cynomolgus, Japanese, Taiwan, and stump-tail macaques. The virus can affect the oropharynx or genital areas and is spread between animals via biting, sexual activity, or other close contact (185, 186). The seroprevalence of herpes B virus among adult macaques in the wild is nearly 75% (187). Among animals housed in outdoor breeding corrals, the seroprevalence is approximately 22% before 2.5 years of age, rising to more than 97% among animals 2.5 years or older (188). Primary infection in the macaque is often asymptomatic, but the virus establishes latency and can reactivate. Reactivation can be triggered by stress, such as the transition of animals from freedom to captivity, or crowded conditions. Recurrent disease in macaques is typically characterized by vesicular lesions of the tongue and buccal mucosa, progressing to ulceration. Encephalitis is rare but can occur. Asymptomatic shedding of virus can occur.

In 1932, a researcher was bitten by a macaque and developed ascending myelitis and encephalitis culminating in death. Herpes B virus was subsequently described (189). Sporadic cases of herpes B virus infection in humans have subsequently been described in the literature. Humans can be infected via animal bites, mucosal or eye exposure (190), inoculation of broken skin, needle sticks, or potentially, via aerosols. The possibility of herpes B virus transmission makes macaques unsuitable as pets (191). Safety precautions for workers with close contact with macaques and recommendations for postexposure management have been published (192). Primary cell cultures from macaques also represent a potential source of virus (192).

Herpes B virus disease is severe in humans with a mortality rate of 70% or higher without treatment. The first symptoms usually appear 3 to 5 days after exposure (although they can appear up to several weeks later) and include a localized vesicular lesion at the site of inoculation, erythema, and edema. Lymphangitis and lymphadenopathy follow, with fever, myalgia, vomiting, and cramping. Neurologic signs develop quickly, starting with meningeval irritation, diplopia, and altered sensation, progressing to paralysis, altered mentation, respiratory depression, seizures, and death within 10 days to 6 weeks. Human-to-human transmission appears to be extremely rare (193). Asymptomatic infection in humans also appears to be rare. In one study of over 300 primate handlers (of whom more than 150 had a history of exposures), none had antibody to herpes B virus (194).

Acyclovir is effective against herpes B virus, although the 50% effective dose is 10-fold higher than for HSV. Ganciclovir is somewhat more effective than acyclovir (195), although clinical experience with ganciclovir is limited. Foscarnet has also been used in some cases (190). Postexposure therapy can often prevent the development of acute disease (196). The preferred drug for postexposure prophylaxis is oral valacyclovir (192), due to its improved bioavailability (192). Clinical disease necessitates intravenous antiviral therapy. Intravenous therapy should be continued until symptoms resolve and two or more viral cultures are negative after having been held for 10 to 14 days, at which time therapy can be switched to oral antivirals (192).

Reactivation and relapse has occurred in some patients upon cessation of antiviral therapy. Many clinicians therefore recommend continuing oral antiviral therapy indefinitely.

**Collection, Transport, and Storage of Specimens**

Because herpes B virus should be propagated only under biosafety level 4 conditions, diagnostic specimens are best handled by specialized reference laboratories (see below). Precautions should be taken by other laboratories to ensure that herpes B virus specimens are not confused with HSV specimens and thus cultured under lower biosafety conditions, since amplification of virus in culture increases the risk to laboratory personnel. Lesion swabs should be taken from each collection site using a separate, sterile Dacron or cotton swab with a wooden or plastic shaft. Swabs or biopsy tissue should be placed into separate tubes containing 1 to 2 ml of VTM. Specimens can be stored in the refrigerator for up to 1 week or at ≤−60°C indefinitely.

**Reference Laboratories for Herpes B Virus**

Advice regarding proper specimen collection and submission of specimens for herpes B virus diagnosis can be obtained from the CDC [http://www.cdc.gov/herpesbvirus/index.html] or from the National B Virus Resource Laboratory, Atlanta, GA [phone, (404) 413-6550; http://www.gsu.edu/bvirus].

**Identification of Virus and Serodiagnosis**

Herpes B virus can be cultured in monkey kidney and chick embryo cells. A characteristic cytopathic effect similar to that of HSV is seen, with polykaryon formation and intranuclear Cowdry type A inclusion bodies. Confirmation of herpes B virus in culture can be done using monoclonal antibodies or molecular techniques. PCR for herpes B virus (197–199) is generally preferred over culture for diagnostic purposes, since it is comparatively rapid and highly sensitive and specific and avoids the need to amplify infectious virus to high titers.

Serodiagnosis of herpes B virus infections has been complicated by extensive cross-reactivity with HSV-1 and HSV-2. However, careful ELISA and Western blot tests have been developed that allow discrimination of antibodies to herpes B virus, HSV-1, and HSV-2 (200–202). Serologic testing can be useful for evaluation of potentially infected animals involved in human exposures and for screening research animals. Serial determinations of serostatus from potentially exposed individuals are also useful adjuncts for diagnosis (190, 192).

Varicella-Zoster Virus
ELISABETH PUCHHAMMER-STÖCKL AND STEPHAN W. ABERLE

TAXONOMY
Varicella-zoster virus (VZV) belongs to the family Herpesviridae, based on morphological criteria, and is one of the eight human-pathogenic herpesviruses identified so far. On the basis of its biological properties, it is classified, together with herpes simplex virus (HSV), as a member of the subfamily Alphaherpesvirinae (genus Varicellovirus, species Human herpesvirus 3 [HHV-3]).

DESCRIPTION OF THE AGENT
VZV is an enveloped virus with a diameter of about 180 to 200 nm (Fig. 1). It contains an icosahedral nucleocapsid surrounded by a tegument structure, a lipid envelope that allows the virus to be degraded by lipid solvents, and a linear double-stranded DNA genome (1). The viral genome has an approximate length of 125,000 bp, making it the smallest of the human herpesviruses (2), and it carries at least 70 viral genes. The VZV genome consists of a unique long region (UL), a unique short region (US), and flanking internal and terminating repeat regions, and it can exist in four isomeric forms (Fig. 2).

VZV may infect susceptible cells either by fusion at the cell surface or by endocytosis. Virus replication takes place in the nucleus of the infected cell, and similar to other herpesviruses, the progression of viral gene expression is highly regulated. Not all VZV gene functions are yet known. The especially well-characterized ones include some transcription regulator proteins (IE 61 to IE 63), viral enzymes such as thymidine kinase (TK, open reading frame [ORF] 36), the DNA polymerase (ORF 28), and various VZV glycoproteins, such as gB (ORF 31), gE (ORF 68), and gH (ORF 37), which are required for virus attachment and for inducing a host immune response.

VZV exhibits low genomic diversity among isolates in comparison to other herpesviruses (3). From full-genome sequencing, five major VZV clades and two provisional genotypes have been established (4, 5). There is no evidence that naturally circulating VZV strains differ significantly in virulence.

CLINICAL SIGNIFICANCE
Varicella (chicken pox) is the manifestation of primary infection with VZV. The clinical appearance of chicken pox is usually dominated by a generalized vesicular rash. Sometimes, symptoms such as fever, malaise, or abdominal pain are seen as prodromal symptoms 24 to 48 hours before and during the first days after the onset of the rash. New vesicles develop during the first 3 to 6 days of varicella. Due to its characteristic clinical appearance, the diagnosis of varicella is often a clinical one and does not require laboratory confirmation. Clinical reinfection with VZV has been described for immunocompetent and immunosuppressed individuals (9) and might occur more frequently than usually supposed (10).

Complications associated with chicken pox can occur, and before vaccination was introduced, up to 4 of 1,000 cases of chicken pox in the United States required hospitalization each year (11). Older age, immunosuppression, and pregnancy are considered to be generally associated with a higher
complication rate with varicella. The most frequent complications seen with chicken pox are secondary bacterial infections of the skin lesions, which can lead to abscesses, lymphadenitis, and rarely, also to bacteremia and sepsis. In healthy adults especially, varicella may be complicated by VZV pneumonia, which is 25 times more frequent in these patients than in children and has been described to be especially severe in pregnant women (12). The hospitalization rate among adults with varicella is about 32 per 1,000 reported cases, which is more than 6 times higher than the rate for children (13).

VZV encephalitis can occur during chicken pox, due to primary infection or to postinfectious processes, and often presents with symptoms of acute cerebellar ataxia (14). Other varicella complications include hepatitis, nephritis, or acute thrombocytopenia. In immunosuppressed patients, extensive general dissemination can occur, leading to multiorgan infection and death if not treated early.

Primary infection with VZV during the first 21 weeks of gestation may lead to congenital varicella syndrome in the fetus, characterized by cutaneous scarifications, atrophy of the extremities, and in rare cases, seizures, microcephaly, and other sequelae. The association between the clinical syndrome and VZV has been confirmed by detection of viral DNA by PCR in fetal tissue (15). The incidence is low, <1% in the first 2 trimesters (16). Neonatal varicella can result in severe disseminated infection in babies born within 4 days before to 2 days after the maternal varicella rash appears.

After primary infection, VZV persists in the host in a latent state in sensory trigeminal and dorsal root ganglia. VZV reaches the sensory ganglia, most likely by retrograde axonal transport from skin lesions, and eventually also by hematogenous spread (1). Variable amounts of virus, ranging from 10 to about 55,000 viral genome copies per 100,000 ganglion cells, have been detected in latently infected hosts (17–19). During VZV latency, transcription and translation of different genes are observed (20). The virus is kept under control mostly by the host’s VZV-specific T-cell immunity. When this immunity decreases due to immunosuppression or older age, reactivation of the virus may occur.

Reactivation of VZV can lead to limited subclinical local infection, or the virus may spread via neurons to the skin, resulting in the clinical syndrome herpes zoster. Herpes zoster is mostly characterized as a vesicular rash, typically limited in immunocompetent hosts to the dermatome innervated by a single sensory nerve (1). It is often preceded and accompanied by intense neuropathic pain due to sensory neuron involvement. The eye may be affected, resulting in zoster ophthalmicus. An increase in the VZV-specific T-cell response limits viral spread. The most frequent complication of herpes zoster is postherpetic neuralgia, which presents as severe pain and may last for up to several months after herpes zoster.

In immunocompetent hosts, the most severe complications of herpes zoster are associated with VZV infections of the central nervous system (CNS). Viral meningitis, myelitis, or encephalitis may be observed, with encephalitis probably occurring due to neuronal spread. Cases of facial palsy syndrome are also seen. In most cases, the diagnosis of herpes zoster is a clinical one, based on its characteristic appearance and the distribution of vesicles. In some cases, however, reactivation may also result in “zoster sine herpete,” a syndrome of undefined local pain that is sometimes also associated with CNS infection that occurs in the absence of a
vesicular rash. The diagnosis of “zoster sine herpete” can be provided only by virological investigation. It may occur more commonly than previously thought. Approximately 25% of cases with CNS complications due to virologically confirmed VZV reactivation occurred in the context of zoster sine herpete (21).

In the immunosuppressed host, primary infection and reactivation can lead to severe and possibly life-threatening generalized infection. In the prevaccine era, severe disseminated primary infection associated with high mortality was a particular concern in immunosuppressed children. This remains an important entity in undervaccinated populations. After bone marrow or solid-organ transplantation, patients frequently exhibit episodes of VZV reactivation, which sometimes proceed to severe disseminated infection and to the development of visceral zoster, a clinical picture characterized by severe abdominal pain and associated with the involvement of internal organs, such as the liver, colon, or lung (22–25). Among solid-organ transplant recipients, lung transplant patients especially have an increased risk for VZV complications (26), but VZV can also cause substantial problems in patients with hematological malignancies or after hematopoietic stem cell transplantation (27). HIV-infected individuals may also undergo severe episodes of VZV reactivation and dissemination, especially during AIDS, and they may exhibit an unusual clinical presentation (28–30). VZV can also play a role in the development of immune reconstitution inflammatory syndrome, and mucocutaneous zoster may occur within 4 weeks after the initiation of highly active antiretroviral therapy (HAART) (31). Disease caused by VZV can be prevented by vaccination. A live attenuated varicella vaccine derived from the Japanese Oka strain was developed in the early 1970s. It was approved in the United States in 1995 for persons who are susceptible to chicken pox and is currently also recommended in various European countries (32). The childhood vaccination policy in the United States has led to a substantial decrease in varicella incidence (33), disease severity, and associated complications (34). An Oka-derived vaccine has also been developed to boost T-cell immunity against VZV in older patients in order to prevent zoster reactivation (35).

Varicella-zoster immunoglobulin may prevent severe varicella and is thus given to high-risk patient populations to avoid the development of disease. Seronegative women during the first 21 weeks of pregnancy receive the commercially available VZV immunoglobulin up to 72 hours after VZV exposure, to avoid the development of congenital varicella syndrome in the fetus (8). In immunosuppressed VZV-seronegative patients, such as hematopoietic cell transplant patients, application of VZV immunoglobulin has been recommended up to 96 hours postexposure to inhibit the development of severe generalized infections (36).

Early and rapid diagnosis of VZV infection is important. Different detection methods are available (summarized in Table 1). Due to its sensitivity, PCR has largely supplanted culture and become the preferred method in many instances. Antigen detection is still useful, as it can be performed rapidly and in a random-access format. Serology is most useful to ascertain immunity.

Specific antiviral treatment of VZV infection and reactivation is possible. If treatment is necessary, it is usually performed with nucleoside analogues such as acyclovir or penciclovir or with the better orally bioavailable prodrugs valacyclovir and famciclovir (37, 38). Brivudine is another nucleoside analogue that has proven effective against VZV (39). Anti-VZV treatment is applied in immunosuppressed hosts and in immunocompetent patients when clinical complications arise. In addition, herpes zoster reactivation is also treated to limit the development of postherpetic neuralgia and to prevent ocular involvement.

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

Various specimens can be used for diagnosis (Table 1), depending on the clinical presentation and test method. Vesicular fluid contains cell-free virus, mostly at high concentration. Since nearly all patients with varicella and many patients with herpes zoster show a vesicular rash, and because collection of vesicular fluid is very convenient, laboratory diagnosis from vesicular fluid is a major diagnostic tool for detection or confirmation of VZV infection.

</table>
or reactivation. The vesicular fluid can be collected using capillary pipettes or syringes. For PCR analysis, vesicular fluid can also be collected on swabs and submitted to the laboratory in physiological saline or in viral transport medium. If further virus culture is planned, it should be kept in mind that virus collected on swabs is less stable and is also further diluted in the medium, which may decrease the efficiency of virus culture.

VZV DNA is detectable by PCR in plasma, serum, whole blood, and peripheral blood mononuclear cells (PBMCs). Plasma or serum is conventionally used due to ease of preparation. Whole-blood specimens should be submitted in anticoagulants other than heparin if PCR testing is to be performed, as heparin can inhibit Taq polymerases. Virus can be recovered from PBMCs early in disease; however, this is a method used primarily in research. Cerebrospinal fluid (CSF) should be submitted in a sterile container. Usually, uncentrifuged CSF is used for detection of VZV DNA, but virus can also be detected in the cellular fraction or in supernatant.

Tissue is tested primarily at autopsy. In disseminated disease, tissue testing has now largely been replaced by PCR of blood specimens due to test sensitivity and ease of specimen procurement. Cells from tissue can be stained by immunofluorescence. Touch preparations of cells are prepared by pressing tissue (typically 10 to 15 mm in size) against the clean surface of a glass slide multiple times, over a length of 30 to 40 mm. Slides are air dried, fixed in cold acetone, and stained with reagents used in antigen detection (see below). Tissue homogenates can be prepared as described in chapter 79 and tested by culture or PCR.

Generally, VZV DNA, which is ultimately amplified by PCR methods, is quite stable during collection, transport, and storage. VZV virions, however, are quite labile; therefore, specimens should be placed into culture as quickly as possible after collection if isolation is required. Samples for PCR can be stored at −20°C. Virus isolation from frozen samples is largely ineffective unless cellular fractions are stored in cryoprotectant medium at −80°C.

**DIRECT EXAMINATION**

**Microscopy**

One of the oldest and simplest direct detection methods is the Tzanck test. In this assay, cellular material is scraped from the base of vesicular lesion and put onto glass slides. These smears are then stained, examined under a microscope, and screened for multinucleated giant cells, which contain multiple eosinophilic intranuclear inclusions representing viral capsids (Fig. 3). However, since the presence of these cells is characteristic both of herpes simplex and of varicella-zoster virus infections, a specific diagnosis of VZV cannot be made with this test. VZV can be visualized by electron microscopy, but this method also does not allow a clear differentiation between the different herpesviruses (Fig. 1).

**Antigen Detection**

VZV antigen detection from cell-containing vesicle material by direct fluorescent-antibody assay (DFA) is sometimes still used as a first front-line diagnostic test for rapid detection of VZV infection in hospitalized patients. Cell suspensions obtained by skin scrapings from the base of the vesicle are applied onto glass slides, fixed with cold acetone, and dried. Then, cells are stained with fluorescently labeled monoclonal antibodies (MAbs) for 30 min at 37°C in a humidified chamber. After a washing step, cells are covered with a coverslip and stained. VZV-specific antibodies are commercially available (Merifluor, Meridian Diagnostics, Meridian Bioscience Inc., Cincinnati, OH; Light Diagnostics, Chemicon/Millipore, Billerica, MA). Tissue homogenates are then stained, examined under a microscope, and stained with reagents used in antigen detection (see below). Tissue homogenates can be prepared as described in chapter 79 and tested by culture or PCR.

**Nucleic Acid Detection**

Over the last decade, nucleic acid (NA) amplification-based techniques, especially PCR assays, have become standard tools for the diagnosis of VZV disease. These techniques have revolutionized the diagnosis of VZV disease of the CNS and of disseminated VZV infection in immunocompromised patients and the identification of herpes zoster in patients who do not develop the typical rash. The advantages of these molecular techniques are that they require only small volumes of input material and are highly sensitive and rapid. Since the detection of the first detection of VZV DNA in CSF by conventional PCR (42), the PCR techniques have changed substantially. Real-time PCR methods (reviewed in chapter 6) that are more sensitive and can be quantitative have replaced older PCR techniques and are now routinely performed in many diagnostic laboratories. Numerous in-house PCR tests have been published for amplifying various gene segments of the VZV genome (Table 1). There is no generally preferred target sequence, and the genetic variability between virus strains is low. An increasing number of commercially available VZV nucleic acid test kits are being developed, for instance, VZV tracer (affigene; Cepheid), the VZV PCR kit (Abbott Laboratories), the LightCycler VZV Qual kit (Roche Diagnostics), or the Iam VZV Q-LAMP Qualitative assay (DiaSorin). Protocols have also been designed for simultaneous amplification of VZV together with various other viruses causing similar clinical pictures. Commercially available tests include the artus HSV LC-PCR kits (Qiagen; CE marked for in vitro diagnostic use in Europe, research use only in Canada, and not available in the United States) or HSV1 HSV2 VZV R-gene (Argene Inc.; CE marked for in vitro diagnostic use in Europe, research use only in the United States).

![FIGURE 3](image-url) Giemsa-stained preparation of material from the base of a vesicular lesion. Magnification, ×102. The arrow indicates a giant cell with a folded nucleus characteristic of VZV or HSV. doi:10.1128/9781555817381.ch99.f3
These multiplex PCRs are able to identify a variety of diagnostically important viruses simultaneously, either within one tube or by parallel detection in a single PCR run (43, 44). VZV detection and quantification by PCR can be performed in various clinical materials (for an overview, see Table 2). Quantified VZV DNA for use as nucleic acid detection and quantification test controls is provided by various manufacturers, for instance, Advanced Biotechnologies, Inc. (Columbia, MD), ZeptoMetrix Corp. (Buffalo, NY), or NIBSC (Hertfordshire, United Kingdom). VZV DNA from vesicular fluid and skin scrapings can be detected easily by PCR. This helps to discriminate quickly between vesicular lesions caused by VZV and those due to various other causes, especially HSV-1 or HSV-2 infection.

*Abbreviations: co, copies; GC, ganglion cells.*
PCR is more sensitive than virus isolation or direct immuno-
fluorescence for the detection of VZV in vesicular lesions
(45, 46). The benefits of VZV PCR were also shown for
the diagnosis of vaccine-modified varicella disease (41).
VZV DNA can be detected by PCR in crusting lesions (47)
and in skin scrapings in VZV-associated facial palsy even
in the absence of visible vesicular lesions (48). The easy
access and the high virus detection rates make dermal lesions
an ideal material to be used not only for diagnosis but also
for further genotyping of vaccine and wild-type (WT) strains
using genotype-specific PCR strategies (49, 50).

Analysis of CSF using nucleic acid amplification has
become the method of choice for diagnosis of neurological
disease associated with VZV, such as cerebellitis, aseptic
meningitis, and encephalitis. Using PCR, it was found that
neurological disease is an important and not infrequent
complication in immunocompetent as well as immunosup-
pressed patients. VZV DNA was detected in CSF of up to
10% of patients presenting with clinical symptoms of aseptic
meningitis and (meningo-) encephalitis (51–54). PCR anal-
ysis is also useful for the diagnosis of VZV-induced neurological
symptoms in cases where the characteristic vesicular rash appears only after the start of CNS infection, or even
in cases of zoster sine herpete (21, 55–58). No rash was
observed in about one-quarter of all cases of patients suffering
from VZV-associated neurological symptoms (21, 57, 58).
Higher mean VZV DNA loads were found in the CSF of
patients with herpes zoster-associated encephalitis than
with meningitis (Fig. 4A) and in patients requiring intensive
care treatment than in those who did not, although some
overlap was observed among individual patients in each of
the compared groups (Fig. 4B) (21). Virus is predominantly
detected within 1 week after the onset of clinical symptoms,
but in cases of VZV-induced neurological symptoms without
rash, virus can be detected in the second week of disease
(21, 57).

In cases of varicella-induced cerebellar ataxia, the
amount of viral DNA was shown to be generally low (42, 59, 60), supporting the theory that these symptoms might
be mediated by the antiviral immune response. After initia-
tion of antiviral therapy, CSF usually becomes negative for
VZV DNA in the follow-up in uncomplicated cases (42). In
contrast, the continuous presence of viral DNA has been found in individual HIV-infected patients in spite of
therapy, and this was associated with the death of these patients (61).

PCR testing plays an important role in the diagnosis of acute VZV-associated peripheral facial palsy occurring as a
neurological complication in the course of VZV reactiva-
tion. In cases of Ramsay Hunt syndrome, virus can be de-
tected not only in vesicles of the auricles and the oral cavity
but also in the facialis nerve sheath, middle ear mucosa,
and cerebrospinal fluid (62). As the rash is mostly hidden
in the ear or mouth and may be faint or delayed, only
sensitive testing for the presence of VZV by PCR has shown
that a considerable number of “idiopathic” peripheral facial
palsy or Bell’s palsy cases are due to VZV reactivation. Using
PCR methods, VZV was detected in saliva samples of 58%
of patients with VZV-induced facial palsy, with 64% of those
cases presenting without characteristic rash (63). Virus
was shown to be present in oropharyngeal swabs until day 12
in patients with acute peripheral facial palsy (64). VZV
DNA levels in saliva were about 10 higher, and recovery of facial function was worse in patients with facial
palsy and oropharyngeal lesions than in those with facial
palsy alone (64). VZV can be detected rarely in CSF samples
of patients with facial palsy (62, 65), and lower amounts
of virus are found in these patients than in those presenting
with meningitis and encephalitis (Fig. 4C) (21, 58, 66).

VZV DNA is also detectable in PBMCs (67–70) and in
whole blood (71–74), and although the viremia is assumed
to be cell associated, viral DNA can also be detected in
serum or plasma (68, 72, 75–77). Viremia is detected by
PCR in up to 100% of cases of acute varicella, but virus
can also be detected in the blood compartment in cases of
herpes zoster. VZV DNA was detected in 47% of serum
samples obtained within the first 8 days after the start of
herpes zoster from otherwise healthy patients (75). In
a small cohort of 9 immunocompetent patients with herpes
zoster, all were found to be VZV DNA positive when the
amount of plasma analyzed was increased to 1 ml (77).
Quantitative analysis showed that viral loads may range
from 5 to 5 × 10^5 copies/10^5 cells in PBMCs, from 20 to
10^5 copies/ml in whole blood, and from 100 to 2 × 10^5
copies/ml in plasma or serum. The virus load is higher in
patients with acute varicella than in those with herpes zoster
(72). A higher viral load correlates with a larger number
of skin lesions and more-severe disease (73) as well as with
the presence of multidermatomal zoster (72). The viral load
was lower in samples taken only a few days after the start
of varicella symptoms (69) and was found to be negative.
in convalescent-phase sera with shingles (75). When applying a highly sensitive nested-PCR assay, VZV DNA was also detected in PBMCs of patients with facial palsy without dermal lesions (78).

Virus detection in blood is important for the diagnosis of complicated or clinically unclear courses of varicella or herpes zoster, especially in cases in which the appearance of complicated or clinically unclear courses of varicella or herpes zoster without dermal lesions (78).

VZV is not detectable in the blood in the majority of healthy control patients, even with sensitive PCR methods (82), unless a very large volume of blood (50 ml) is used (74). In other studies, VZV was detectable in 2 to 3% of PBMC samples taken from immunocompetent individuals without clinical signs of VZV illness (70, 83). These findings support the assumption that asymptomatic reactivation of latent virus may occur and may be important for boosting host immunity to the virus (84). VZV PCR can be performed from aqueous humor and has been found to be helpful in confirming VZV-associated ocular disease. The viral load in the aqueous humor of patients with anterior uveitis corresponds to the extent of iris atrophy (85).

Identification of VZV by PCR in bronchoalveolar lavage specimens has been reported and seems to be useful for the successful early diagnosis of severe VZV pneumonitis (86). The detection of VZV DNA in tissue samples by PCR is also possible and has been used to confirm the association between VZV and congenital varicella syndrome (15, 87). Generally, the use of highly sensitive PCR techniques may be especially important for confirming the diagnosis of VZV-related disease in cases of less disseminated or milder disease associated with lower viral loads (48, 70) or for samples obtained later in the course of disease after the initiation of antiviral therapy.

**ISOLATION PROCEDURES**

Virus isolation by cell culture methods provides the basis for phenotypic characterization of individual VZV strains, for generating VZV-infected cells for serological tests such as fluorescent antibody to membrane antibody (FAMA), and for the phenotypic analysis of VZV drug resistance. Many laboratories use human foreskin fibroblasts for isolation of VZV from clinical samples. Other sensitive host cells include diploid human cell lines, preferably derived from fetal kidney or fetal lung, human lung carcinoma (A549), or human melanoma cell lines, and nonhuman cell lines such as primary monkey kidney cells (40, 88). A cell mixture (CV-1 and MRC-5) is commercially available for the recovery of herpesviruses including VZV (H&V Mix; Diagnostic Hybrids, Quidel Corp.). In contrast to other herpesviruses, VZV maintains a high level of genetic stability during the culturing procedure. Cell cultures are performed at 37°C under sterile conditions, and the medium used is usually Eagle’s minimal essential medium, prepared in Hanks’ or Earle’s balanced salt solution (BSS) containing neomycin and glutamine and supplemented with 10% fetal bovine serum (FBS) for the growth medium and 1 to 2% FBS for maintenance. The medium is heat inactivated at 56°C for 30 min. The need for a medium change is indicated by a drop in pH, and this is required at least once weekly. When virus culture is done for diagnostic purposes, the clinical material is adsorbed onto the cell monolayer or inoculated directly into the medium, and the cells are then incubated at 37°C and evaluated daily by microscopy. The development of a cytopathic effect (CPE) is variable but is usually visible from 4 days up to maximally 2 weeks. The CPE consists of small foci of rounded and swollen cells (Fig. 5). Confirmation of VZV infection is done by PCR or by staining monolayer cells with VZV-specific monoclonal antibodies (described below). Shell vial centrifugation cultures can provide results in 2 to 5 days and are more sensitive than conventional cultures for VZV but less sensitive than PCR.

**IDENTIFICATION**

**Virus Identification from Cell Culture**

Specific identification of VZV from clinical material in cell culture after the emergence of a CPE is necessary because it may be difficult to distinguish VZV from other herpesviruses. VZV-specific PCR analysis may be performed for identification. For this purpose, supernatant is taken from the culture, and DNA is extracted and subjected to PCR. Monolayers can also be stained with VZV-specific MAbs when approximately 50% of the monolayer demonstrates CPE suggestive of VZV. For this purpose, cell monolayers are washed with phosphate-buffered saline (PBS). Then, monolayer cells are scraped into 0.5 ml PBS. Slides are prepared by directly applying the suspension to a glass slide using a cytocentrifuge. Slides are air dried and then fixed in cold acetone for 10 minutes. Following washing with PBS, cells are stained with VZV-specific MAbs. Commercial reagents approved for use in culture confirmation include the D³ DFA VZV Detection kit (DHI) as well as the MAbs listed in “Antigen Detection” above. After a 30-min incubation at 37°C, monolayers are washed in PBS and rinsed in distilled water. Excess moisture is removed by blotting around the wells. Stained cells should not be allowed to dry, as this produces artifactual fluorescence. Mounting medium and a coverslip are applied, and the staining is visualized by fluorescence microscopy.

**Genetic Identification of VZV Strains**

Genetic identification of VZV is performed by different molecular methods, directly from clinical specimens, but primarily on a research basis. Characterization of VZV
strains is usually done by PCR assays followed by restriction fragment length polymorphism (RFLP) analysis or by sequencing of characteristic fragments and determination of single nucleotide polymorphisms (SNPs) (89). Genetic analysis of virus strains has proven that the VZV strains identified during varicella are identical within an outbreak and are also identical to those present in subsequent herpes zoster (90). It has been shown that VZV strains vary between geographic areas (3, 89).

Characterization of VZV strains may be especially important for differentiating between WT strains and Oka vaccine strains after vaccination, for determining the etiology of a postvaccination rash, for analyzing the association between vaccination and the development of herpes zoster, and also for assessing whether transmission of vaccine virus to susceptible persons has occurred. Different methods for discrimination between WT and vaccine strains have been published, and in this regard, much attention has been focused on the VZV ORF 62 because most nonsynonymous VZV vaccine mutations occur in this ORF. In particular, Small and Nael sites in ORF 62 have been shown to allow the discrimination of vaccine strains from WT strains and also from the Oka parental strain (91). RFLP analysis has also been described for other ORFs, for example, ORF 6 (92), with differences in the Alul sites, and ORFs 38 and 54 in combination, with differences in the Psrl and BglI sites (93).

Real-time PCR assays based on sequence polymorphisms, especially in ORF 62 or ORF 38, have also been established (50, 94–96). In addition, a considerable amount of sequence data for various ORFs in the VZV genome has been obtained so far in the search for SNPs that would allow further VZV strain discrimination (3).

The analysis of the Oka vaccine itself has shown that it contains a mixture of different strains that also differ in the R2 repeat region (97). The development of rash after vaccination seems to be associated with the emergence of certain strains that are closely related to the Oka parental strain (98).

**SEROLOGIC TESTS**

Antibodies against VZV develop in the course of primary infection, are directed against various proteins of the virus, and can be detected in most cases within 3 days after the appearance of the rash. Serologic testing can be used for confirmation of primary infections, where it is applied especially in clinically atypical cases. Detection of VZV-specific antibodies (Abs) is also routinely used for determining immune status. This may be required for patients who cannot remember their varicella history and is especially important in pretransplantation evaluations as well as after virus exposure to guide prophylaxis with varicella immunoglobulin in high-risk individuals such as solid-organ or bone marrow transplant patients, pregnant women, and health care workers. In addition, it may be used for monitoring a patient’s immune status after vaccination, although assessment of vaccine efficacy is not routinely performed. A variety of serologic methods that differ in specificity, sensitivity, and utility are available for detecting VZV-specific Abs.

**Specialized IgG Detection Tests**

A number of different serologic assays are performed in specialized or referral laboratories often for research purposes. One such test is the FAMA test, considered to be the “gold standard” for serologic testing (99), and which correlates best with protection against varicella (100). A flow cytometry-adapter version of the FAMA assay has also been developed (101). The FAMA titer, however, is not predictive of long-term protection after vaccination. Although high seroconversion rates have been described for vaccination, a loss of FAMA-detectable Abs is generally observed over time (102). FAMA is labor-intensive and nonautomated. A noncommercial and apparently very sensitive enzyme immunoassay (ELA) developed by Merck, based on the detection of VZV glycoprotein (gp) preparations, has been used for extended postvaccination serologic studies. ELA titers of 5 gp ELA units/ml or more are at 6 weeks after vaccination have been associated with a high degree of protection against breakthrough for the following 7 years (103). However, the fact that breakthroughs have also been observed after this Ab level has been achieved suggests that gp ELA levels correlating with long-term protection have not been adequately defined. Other IgG detection assays that are used in specialized settings include the anticomplement immunofluorescence test, the time-resolved fluorescence immunoassay (TRIFA) (104), and plaque reduction assays that detect neutralizing Abs against varicella, which are important tools for confirming that vaccine-induced Abs are in fact neutralizing circulating wild-type VZV strains (105).

**IgG Detection Tests in Routine Diagnostic Laboratories**

Clinical laboratories typically use commercial immunoassays, for which a variety of different formats are available, including ELA (colorimetric and fluorescence detection) chemiluminescence assays, and immunoassays. These tests have the advantages of being less laborious than the FAMA, not requiring any additional VZV cell culture procedures, being amenable to objective interpretation and, for many assays, to automation, and for some instruments, presenting a random-access format. The different tests use either whole VZV-infected cell lysate as the specific antigen or, in some cases, purified glycoprotein, and the test procedure is done according to the manufacturer’s protocol. In some laboratories, noncommercial, in-house ELAs have been established for routine detection of VZV-specific Abs, mostly with whole viral lysates as test antigen (104, 106–108).

Validation of commercial tests is usually done by comparison to FAMA, and the results obtained show that these assays are generally less sensitive than FAMA. Commercial immunoassays have been shown to detect Abs in 43% to 92% of naturally infected individuals identified as seropositive by FAMA or an adapted FAMA protocol (109). In their specificity, commercial immunoassays are more similar to the FAMA (106). Considering that one aim of an Ab test is usually to determine if a person is susceptible to infection and thus a candidate for vaccination, the lower sensitivity of the commercial immunoassays leads to more unnecessary vaccinations. The risks associated with this, however, are low compared to the risk of infection of a person who has been falsely declared immune. Immunoassays are typically used to determine VZV-specific Abs in blood, but they may also serve to detect Abs in CSF.

**IgG Avidity Assays**

To discriminate recent from past infections or to assess the impairment of Ab development in immunosuppressed patients, VZV IgG antibodies may be further tested for their avidity (110–112). For this purpose, an ELA is run in duplicate, and one of the runs is treated with dilutions of sodium thiocyanate or with diethylamine (110, 111). The avidity index is calculated as the ratio of the treated-sample optical density (OD) to the untreated-sample OD.
IgM Assays
Testing for IgM antibodies is usually performed by commercially available ELAs and is applied to confirm primary VZV infection, especially when the clinical picture is not typical for varicella. In addition, detection of VZV-specific IgM Abs in CSF is sometimes performed retrospectively to confirm intrathecal VZV Ab production after VZV infection of the CNS.

Cellular Immunity
It has been shown that VZV-specific cellular immunity is the key factor in keeping VZV in a latent state. T-cell-mediated immunity consists of CD4 and CD8 effector and memory cells and is detected up to 2 weeks after the rash appears (113). A decrease in cellular immunity, which is observed with increasing age or during immunosuppression, facilitates VZV reactivation and development of herpes zoster (114). Cellular immunity against VZV can be measured with a gamma interferon enzyme-linked immunospot (ELISPOT) assay or intracellular cytokine staining followed by fluorescence-activated cell sorter (FACS) analysis (115–117). The identification of VZV-stimulated cytokines may be used to assess the VZV-specific immunocompetence in transplant recipients (112, 118) or to identify protection against VZV after vaccination, in patients negative for VZV-specific Abs (111). However, these methods are so far mainly investigational.

ANTIMICROBIAL SUSCEPTIBILITIES
Most VZV strains are fully susceptible to antiviral drugs. Resistance against acyclovir or penciclovir has been observed primarily in HIV-infected individuals in the pre-HAART era, in transplant recipients, and in hematopoietic-patients.

Development of resistance may lead to uncontrolled viral dissemination, visceral complication, and death of the patient (119, 120). Data from in vitro studies and investigation of resistant wild-type isolates have shown that acyclovir resistance is associated mostly with mutations in the VZV thymidine kinase (TK) gene and only rarely due to mutations in the VZV DNA polymerase (121). Foscarnet and cidofovir can be used for treatment of acyclovir-resistant strains. Resistant VZV strains may be detected only in specific compartments, and therefore, when screening for drug-resistant VZV strains is performed, samples from all affected body sites should be investigated (122). Antiviral susceptibility of VZV strains can be determined phenotypically. Changes in virus replication in the presence of different concentrations of various drugs are measured in most cases by plaque reduction assay in human diploid lung cells. The 50% effective doses of acyclovir have been shown to range from 2.06 μM to 6.28 μM (37). Other methods that have been described include the late-antigen synthesis reduction assay (123) and phenotypic characterization of the TK gene without the need for virus isolation (124). Phenotypic analysis has several disadvantages that limit its clinical utility: time to result typically is prolonged, limiting its use in clinical decision making; it cannot easily be performed from all clinical materials; and it may be not sensitive enough for detection of minor resistant VZV populations. Therefore, genotypic resistance testing is preferred for clinical use, as it is rapid and can be performed from different clinical materials. Genotypic resistance testing is done mostly by sequencing of certain regions of the VZV TK gene that are associated with resistance to acyclovir (125) and of parts of the polymerase gene. A number of defined VZV mutations have been described so far, whose influence on resistance against different drugs has been proven by phenotypic data (126). Resistance testing is typically performed only in research settings or in specialized reference laboratories but is not applied in routine diagnostics.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS
For appropriate evaluation and interpretation of test results, knowledge about the clinical background of the individual patient is of utmost importance. The interpretation of the results is dependent on whether a primary infection with VZV is suspected or whether the patient has already had chicken pox. In addition, it is important to know whether a patient is immunosuppressed or not.

Primary infection is usually diagnosed based on clinical presentation. Virus can be detected from vesicles by PCR and antigen detection assays and from pustules and even crusts by PCR. The results of serologic tests can be suggestive but are not definitively diagnostic of primary infection. For example, IgM (alone or in the presence of IgG) or a 4-fold increase in IgG in convalescent-phase serum can be observed during primary infection; however, these serologic responses can also be detected during reactivation.

Herpes zoster can also be diagnosed clinically; however, confirmation may be necessary if vesicles are limited or otherwise indistinct in appearance from other types of infection. Detection of virus in vesicle fluid is preferred.

The presence of VZV in blood can be observed by PCR assays during chicken pox and sometimes during VZV reactivation. In most immunocompromised hosts, detection of VZV in blood by PCR is generally indicative of severe disease. It should be noted, however, that VZV DNA can also be detected in the blood of HIV patients with localized zoster. The same holds true for the detection of VZV-DNA in CSF, which is generally considered a pathological finding. Both clinical situations usually require immediate antiviral treatment.

However, highly sensitive detection of virus DNA does not always prove the causality of disease. VZV DNA may also be found due to secondary and/or subclinical reactivation but is then observed mostly at clearly lower levels than during VZV disease. In this context, the quantitative evaluation and reporting of VZV DNA levels are gaining significance. For immunocompromised patients, so far no defined VZV DNA thresholds in blood exist for distinguishing subclinical reactivation from clinically relevant and potentially fatal disease. However, severe visceral infections are clearly associated with higher virus load levels in blood (Table 2). Studies have also shown that high VZV DNA levels in CSF may be associated with the expression and severity of CNS disease (Fig. 4). It may therefore be useful to assess and report quantitative results in the setting of VZV CNS disease. In the pre-PCR era, Ab detection in CSF and quantitation in comparison to blood Ab levels were used for diagnosis of VZV infections of the CNS. The detection of IgM Abs is considered a proof for intrathecal Ab production, as is a significantly higher Ab level in CSF compared to that in blood when it is associated with an intact blood-brain barrier. The clinical significance of these tests in VZV infections of the CNS and their value for therapeutic decisions are limited, as they allow a diagnosis only late in the course of disease compared to PCR tests from CSF, which identify virus replication already at an
earlier stage of disease. Serology from CSF was, however, described to be of certain value for detection of VZV vasculopathy (127).

The major importance of Ab assays, of which commercial immunoassays are currently the most commonly used, lies in their ability to identify previously infected individuals, as indicated by anti-VZV IgG Abs in the absence of IgM. This information can be used to guide further vaccination decisions. However, this may result in the vaccination of seropositive individuals since these tests are not as sensitive as other gold standard formats.

Human Cytomegalovirus
RICHARD L. HODINKA

TAXONOMY
Human cytomegalovirus (CMV), formally designated human herpesvirus 5 (HHV-5) by the International Committee on Taxonomy of Viruses, is a member of the family Herpesviridae, which includes herpes simplex virus 1 (HHV-1) and 2 (HHV-2), varicella-zoster virus (HHV-3), Epstein-Barr virus (HHV-4), and human herpesviruses 6, 7, and 8. It is classified in the subfamily Betaherpesvirinae with cytomegaloviruses of other animal species based on its tropism for salivary glands, slow growth in cell culture, and strict species specificity. Human CMV is the type species of the genus Cytomegalovirus, and its name is derived from the subfamily Betaherpesvirinae with HHV-6 and HHV-7, which are now classified with CMV among the betaherpesviruses.

DESCRIPTION OF THE AGENT
Complete CMV particles have a diameter of 120 to 200 nm and consist of a core containing a large 220- to 240-kb linear double-stranded DNA genome, an icosahedral capsid with 162 capsomeres, an amorphous tegument or matrix, and a surrounding phospholipid-rich envelope. The CMV genome consists of more than 200 open reading frames (ORFs) for proteins involved in all stages of viral replication, which encode structural and regulatory proteins and proteins that function to modulate the immune system of the host. The viral envelope is formed as assembled nucleocapsids bud from the inner surface of the nuclear membrane.

Molecular and immunologic techniques have been used to study variation among CMV strains. Although it has been shown that different strains of CMV are 95% homologous to the standard laboratory reference strains AD-169 and Towne, genetically distinct CMV genotypes that display polymorphisms in multiple coding and noncoding regions of the virus genome have been identified. Strain diversity has been associated with specific differences in geographic distribution, transmission, tissue tropism, immunopathogenesis, and clinical manifestations of disease, but the exact role and importance of CMV genotypes in infection and disease are largely unknown (for a review, see reference 1).

CMV is inactivated by a number of physical and chemical treatments, including heat (56°C for 30 min), low pH, lipid solvents, UV light, and cycles of freezing and thawing.

EPIDEMIOLOGY AND TRANSMISSION
CMV has a worldwide distribution and infects humans of all ages, with no seasonal or epidemic patterns of transmission. The seroprevalence of CMV increases with age in all populations and ranges from 40 to 100%; the virus is acquired earlier in life and the prevalence is highest among lower socioeconomic groups in crowded living conditions. CMV can be transmitted vertically and horizontally, and infections are classified as being acquired before birth (congenital), at the time of delivery (perinatal), or later in life (postnatal).

Most infections are acquired by direct close personal contact with individuals who are shedding virus. Since CMV has been detected in many body fluids, including saliva, urine, breast milk, tears, stool, vaginal and cervical secretions, blood, and semen, it is clear that transmission can occur in a variety of ways. Prolonged shedding of virus after congenital or acquired CMV infection contributes to the ease of virus spread; virus may be excreted for weeks, months, or even years following a primary infection.

Transplacental infection of the fetus can occur following primary or recurrent infection of a pregnant woman, but the risk of CMV transmission to the fetus and the rate of symptomatic fetal infection are much higher with primary maternal infection. The incidence of fetal damage is highest if infection occurs during the first 12 to 16 weeks of pregnancy. Maternal illness may be mild, with fever and nonspecific symptoms, but is not clinically apparent in most pregnant women. Newborns can also acquire infection at the time of delivery by contact with virus in the birth canal. Nearly 10% of women shed CMV in the genital tract at or near the time of delivery, and virus is transmitted to approximately 50% of the newborns. Such infants begin to excrete virus at 3 to 12 weeks of age but usually remain asymptomatic. Mother-to-infant transmission of CMV through breast milk is very common; low-birth-weight preterm infants are at greatest risk for developing disease. Of children who attend day care centers and enter as toddlers, 20 to 70% experience CMV infection over a 1- to 2-year period.

doi:10.1128/9781555817381.ch100

1718
period. Infection is usually asymptomatic, but the children may transmit CMV to their parents and other caregivers, posing a risk to an unborn fetus if a woman is pregnant at the time. Susceptible health care workers and employees of day care centers are at risk of occupational exposure. In adolescents and adults, sexual transmission of CMV may occur and is an important route of CMV spread. Similar to infections with other herpesviruses, primary infection with CMV results in the establishment of a persistent or latent infection. The sites of latent infection are thought to include various tissues, endothelial cells, and leukocytes. Therefore, CMV can be transmitted through transfusion of blood products and by exposure to tissue and hematopoietic stem cells during transplantation. Reactivation of the virus can occur in response to different stimuli, particularly immunosuppression.

**CLINICAL SIGNIFICANCE**

CMV infections are common and usually asymptomatic in otherwise healthy children and adults; however, the incidence and spectrum of disease in newborns and in immunocompromised hosts establish this virus as an important human pathogen (for a review, see references 2 and 3).

**Immunocompetent Host**

The vast majority of immunocompetent children and adults who acquire CMV infection postnatally remain asymptomatic. Symptoms in young adults can mimic the infectious mononucleosis syndrome caused by Epstein-Barr virus and include prolonged fever (persisting for 2 to 3 weeks), malaise, an atypical lymphocytosis, and mild hepatitis without the production of heterophile antibody. Exudative pharyngitis is frequently absent, and lymphadenopathy and splenomegaly are less common with CMV-associated infectious mononucleosis. Organ-specific diseases, including colitis, hepatitis, encephalitis, pneumonia, and anterior uveitis, have also been described in the immunocompetent host but are rare. A link between CMV infection in the immunocompetent host and atherosclerosis has been suggested, and there is growing evidence that CMV is a contributing factor to vascular disease in certain individuals (for a review, see reference 4). More recently, there has been an increase in the number of reports of severe CMV infection associated with poor outcomes in hospitalized, critically ill immunocompetent patients (5, 6). Reactivation of CMV is common in these patients and is linked to increased length of stay in the hospital and/or intensive care unit, increased duration of mechanical ventilation, severe sepsis, high disease severity, and mortality (7).

**Fetus and Newborn Infant**

CMV infection has been detected in 0.2 to 2.5% of newborns and is the most common identified cause of congenital infection. Approximately 10 to 15% of congenitally infected infants develop symptoms during the newborn period; possible manifestations range from severe disease with any combination of intranuclear growth retardation, jaundice, hepatosplenomegaly, petechiae, thrombocytopenic purpura, myocarditis, pneumonitis, central nervous system abnormalities, deafness, and chorioretinitis to more limited involvement. Symptomatic infants may die of complications within the first months of life; more commonly, they survive but are neurologically damaged. It is now recognized that even congenitally infected infants who are asymptomatic at birth may develop progressive sensorineural hearing loss, visual impairment, or psychomotor and/or intellectual disabilities later in life. Perinatal or postnatal infection with CMV may occur in term and preterm infants as a result of exposure to maternal cervicovaginal secretions during delivery, ingestion of breast milk after delivery, and blood transfusions. In high-risk preterm newborns, morbidity and mortality can be significant, and hepatosplenomegaly, neutropenia, thrombocytopenia, atypical lymphocytosis, hemolytic anemia, pneumonitis, and necrotizing enterocolitis have been described. Although a large proportion of congenital CMV infections are attributed to primary maternal infection in the developing world, recent studies in resource-poor settings have shown similar rates of sequelae, especially hearing loss, following primary or reactivated maternal infection (see reference 3 for a review). Therefore, contrary to past beliefs, preexisting infection and development of CMV antibody in the mother may not eliminate the risk for significant infection in the infant. Thus far, it appears that perinatally or postnatally infected infants do not develop late neurologic sequelae of infection.

**Immunocompromised Host**

CMV infections are frequent and occasionally severe in children or adults with congenital or acquired defects of cellular immunity, such as patients with AIDS, cancer patients (particularly those with leukemia and lymphoma receiving chemotherapy), and recipients of solid organ and hematopoietic stem cell transplants. Infections in these patients may be due to reactivation of latent virus or primary infection or reinfection with exogenous virus, which may be introduced by blood transfusion or by the grafted organ. Symptoms tend to be most severe after primary infection; however, reactivation infection or reinfection in a severely immunocompromised host may also cause serious illness. Active infection usually occurs between 1 and 4 months after transplantation, when patients are at the height of their immunosuppression, or when CD4+ lymphocyte counts drop below 50 to 100 cells/μL for an individual infected with HIV. The widespread use of antiviral drugs for prophylaxis or preemptive therapy following transplantation has resulted in the emergence of late-onset (>90 days posttransplant) CMV disease (for a review, see reference 8). The frequency and severity of CMV infection in organ transplant recipients are variable and depend on the type of transplant, the source of the donated organ, the immune status of the recipient, and the duration of the immunosuppressive therapy. Major symptoms in these patients represent a nonspecific "viral syndrome" and usually include fever, malaise, leucolysis, myalgia or arthralgia, leukopenia, thrombocytopenia, and hepatitis. Specific organ damage may lead to pneumonitis in recipients of lung or heart-lung transplants; the development of myocarditis, retinitis, or accelerated vascular damage and atherosclerosis after cardiac transplantation; pneumonitis and pancreatitis in liver and pancreas transplant recipients, respectively; and gastrointestinal disease. CMV infection in transplant recipients has also been associated with delayed or failed bone marrow engraftment, an increased incidence or severity of graft-versus-host disease, and an increased risk of graft rejection in solid organ transplants. Death may occur as a result of various complications, including bacterial and fungal superinfections. CMV infection, particularly when associated with pneumonitis, is an important cause of morbidity and mortality after hematopoietic stem cell transplantation. In patients infected with HIV, CMV is an important cause of fever, sight-threatening retinits, encephalitis, polyradiculomyelopathy, and gastrointestinal infections including esophagitis, gastritis, and ulcerative colitis. However, there has been a significant decline
in severe CMV disease in AIDS patients with the introduction of highly active antiretroviral therapy.

Treatment and Prevention

Antiviral drugs, including ganciclovir, valganciclovir, foscamet, cidovir, and fomiviren, have been licensed by the U.S. Food and Drug Administration (FDA) for treatment of CMV reinitis in immunocompromised hosts, particularly in patients with AIDS. Ganciclovir, valganciclovir, valacyclovir, cidovir, and foscamet have been used with or without immunoglobulin products containing CMV-specific antibodies in various strategies as universal prophylaxis, preemptive therapy, and treatment for CMV disease in transplant recipients (for a review, see references 9 and 10). Newborns with congenital or perinatal CMV disease may benefit from treatment with ganciclovir or valganciclovir, but experience is limited and additional clinical trials are warranted. Use of antiviral drugs to treat CMV infections in immunocompetent adults is seldom indicated, and further studies are needed in hospitalized, critically ill immunocompetent patients with CMV to determine if treatment is beneficial. Several experimental CMV antiviral drugs are being studied and include brincidofovir (an orally bioavailable derivative of cidovir formerly called CMX001), maribavir (an oral inhibitor of the CMV UL97 kinase), letermovir (a CMV UL56 terminase inhibitor), and leflunomide (an arthritus drug that inhibits CMV virion assembly). There are currently no licensed vaccines available for prevention of CMV disease. A number of candidate vaccines have been developed and are in various stages of preclinical and clinical evaluation (for a review, see reference 11). These include a live attenuated whole-virus vaccine and DNA plasmid subunit, and recombinant vaccines.

Asymptomatic excretion with CMV is common, and standard precautions and good personal hygiene practices (e.g., careful hand washing) can help decrease the possibility of transmission. Common disinfectants containing alcohol, detergents, and chlorine are effective in inactivating the virus. Transmission of CMV by blood transfusion or through breast milk can be minimized by using CMV antibody-negative donors or treating the products to remove or kill the virus prior to use.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

At present, a variety of methods are available for use in the diagnosis and management of patients infected with CMV. These include isolation of the virus in cell culture, histologic and cytologic techniques, assays for the direct detection and/or quantification of viral proteins or nucleic acids, serologic tests, phenotypic and genotypic assays to screen for antiviral drug resistance, and tests to measure cellular immune function of the host and control of CMV infection. The selection of assays to perform and the choice of specimen(s) to be tested depend on the patient population and clinical situation and the intended use of the individual tests. The details of specimen collection and processing are given in chapter 79.

Specimens for Direct Detection

Tissue specimens, respiratory secretions, urine sediment, cerebrospinal fluid (CSF), umbilical cord blood, amniotic fluid, aqueous humor and vitreous fluid, and peripheral blood leukocytes have been used for the direct detection of CMV antigens or nucleic acids from various patient populations. Blood specimens have proven most useful for identification and monitoring of CMV disease in immunocompromised hosts. Purified blood leukocytes are used when performing the CMV antigenemia assay, while whole blood, plasma obtained from anticoagulated whole blood, serum obtained from clotted blood, or purified peripheral blood leukocytes have all been used to quantitate CMV DNA in molecular amplification assays (12, 13, 14, 15). EDTA is currently the preferred anticoagulant for molecular testing since it is considered to be the most effective stabilizer of nucleic acids in blood. The optimal frequency of blood collection remains to be established for surveillance of different patient groups, although it is common practice to submit blood specimens once a week while monitoring viral loads during preemptive antiviral therapy (9, 10). The first specimen should be collected at the start of therapy to establish a baseline viral load (16). There is considerable debate about which blood compartment is best suited for the detection of CMV DNA (14, 17, 18). Although peripheral blood leukocytes were commonly used in the past, whole blood and plasma are now considered the specimens of choice (19). Whole blood has been shown to yield the highest levels and most frequent and earliest detection of CMV DNA of all blood compartments examined (14) and may represent the most practical specimen for laboratories to process for use in the diagnosis and monitoring of CMV disease, since it requires little processing prior to extraction of the DNA and both cell-associated and extracellular viruses can be detected. Also, delays in sample preparation can result in lysis of leukocytes after blood collection which may result in inaccurate quantitation of CMV DNA if either purified leukocytes or plasma is used as a specimen source (20). A potential limitation for the use of whole blood is the possibility of variation in leukocyte counts from patient to patient; this may lead to erroneous quantitative measurements if fluctuations in cell numbers are not taken into consideration. Also, detection of low levels of CMV DNA in whole blood may not always correlate with active CMV disease. Plasma may be preferable in neutropenic patients who may have inadequate numbers of leukocytes for testing and may be a better specimen source for predicting CMV disease. When monitoring patients over time, the same specimen type should be used to minimize the variations observed between different blood compartments. For the CMV antigenemia assay, a total of 4 to 7 ml of whole blood is usually recommended for collection, but at least 10 ml of blood may be required for patients with severe neutropenia (e.g., absolute neutrophil counts of less than 200/mm³). Any type of anticoagulated blood can be used, including blood collected in heparin, EDTA, sodium citrate, or acid citrate dextrose, although the most extensive experience has been with using heparin or EDTA. The blood should be kept at 4°C during storage and transport and should be processed within 6 to 8 h of collection for accurate and reliable quantitation of the viral load and within 24 h and no later than 48 h for qualitative testing (21). A decrease in quantitative antigenemia levels after storage of blood specimens for 24 h to 48 h has been described, although most positive specimens remain positive after this time when held at 4°C (21, 22). As a general rule, specimens for molecular amplification should be stored at 4°C immediately after collection and then promptly transported to the laboratory for processing. CMV DNA has been shown to be stable in whole blood for up to 5 days when stored at 4°C, for 3 to 4 days when stored at room temperature, and for 14 days at 4°C when plasma is separated from whole blood (23, 24). Single-use aliquots of processed specimens should be placed in multiple cryovials for testing and storage.
By processing in this manner, specimens are not frozen and thawed repeatedly and are never returned to the original specimen cryovial, thereby avoiding possible degradation of the DNA and cross-contamination of specimens, respectively. If not tested immediately, specimens should be promptly frozen and stored at −70°C. Impression smears, frozen sections, or formaldehyde-fixed and paraffin-embedded material can be used for in situ hybridization or histopathologic examination of tissue specimens obtained from patients with pneumonia, gastrointestinal disease, hepatitis, myocarditis, retinitis, pancreatitis, nephritis, cystitis, or central nervous system disease. For prenatal diagnosis of congenital CMV infection, collection of amniotic fluid has largely replaced chorionic villus sampling or cordocentesis to collect fetal blood. Amniotic fluid should be collected after 21 to 23 weeks of fetal gestation for best sensitivity (25). Neonatal blood collected at birth and dried on paper (e.g., Guthrie cards) as blood spots has been described for neonatal screening and for retrospective diagnosis in patients beyond the neonatal period with a clinical suspicion of congenital CMV infection (for a review, see references 26 and 27). However, dried blood spots and blood in general are not as sensitive as urine or saliva for newborn screening. Dried blood spots have also been used for rapid genotyping of CMV strains in congenitally infected newborns (28) and for quantification of CMV DNA in solid organ transplant recipients (27), and both liquid- and dried-saliva specimens have proven useful for sensitive and specific detection of CMV DNA in newborns (29).

**Specimens for Virus Isolation**

CMV can be isolated from a variety of body fluids and tissues; however, urine, respiratory secretions (e.g., saliva, throat washings, and bronchoalveolar lavage fluid), and anticoagulated whole blood (leukocytes) are most common for diagnostic purposes. Urine specimens should be cleansed voided specimens. Because excretion of CMV in urine is intermittent, increased recovery of the virus is possible by processing more than one specimen. Adjustment of urine specimens to pH 7.0 with 0.1 N NaOH or 0.1 N HCl is recommended to reduce toxicity to cell cultures. Centrifuging urine specimens to obtain sediment-enriched samples has been advocated but is usually unnecessary and may produce toxicity more frequently than do uncentrifuged urine specimens. Blood leukocytes used in the evaluation of immunocompromised patients. Detection of CMV in leukocytes is often a better indicator of symptomatic CMV infection than is shedding of virus in urine or saliva, respiratory secretions, although the sensitivity of cultures of CMV in leukocytes is often a better indicator of symptom-free viral shedding than is shedding of virus in urine or saliva, respiratory secretions. Blood leukocytes used in the evaluation of immunocompromised patients. Detection of CMV in leukocytes is often a better indicator of symptomatic CMV infection than is shedding of virus in urine or saliva, respiratory secretions, although the sensitivity of cultures of CMV in leukocytes is often a better indicator of symptom-free viral shedding than is shedding of virus in urine or saliva, respiratory secretions.

**Specimens for Serologic Testing**

Single serum specimens for immunoglobulin G (IgG) antibody are useful in screening for evidence of past infection with CMV and for identifying individuals at risk for CMV infection. This approach is especially helpful in testing sera from organ transplant donors and recipients before transplantation and from donors of blood products that are to be administered to premature infants or bone marrow transplant patients. Also, knowing the immune status of women prior to conception may be helpful in identifying those individuals who may be most susceptible to primary CMV infection following pregnancy. For serologic diagnosis of recent CMV infection, detection of IgM in a single serum specimen may be beneficial or paired sera should be obtained at least 2 weeks apart when testing for IgG antibody. The acute-phase serum sample should be collected as soon as possible after onset of illness and tested simultaneously with the convalescent-phase serum sample. If congenital infection is suspected, specimens from mother, fetus, and newborn can be submitted for the evaluation of IgG and IgM antibodies for the detection of prenatal, natal, and postnatal CMV infections. When testing for IgM, the acute-phase serum should be collected after 22 weeks of gestation since fetal synthesis of antibodies starts at 20 weeks of gestation and may not reach detectable levels for 1 to 2 more weeks. Processed serum specimens may be stored at 2 to 8°C for several days pending the completion of testing or can be stored frozen at −20°C or colder for more-extended periods of time. Repeat freezing and thawing should be avoided, and specimens should not be stored in frost-free freezers. Testing saliva or oral fluids for CMV-specific antibodies has been suggested as a noninvasive alternative to the collection of blood from children (31). In patients with CMV neurologic disease, CSF may be tested for viral antibody if paired with a serum specimen collected on or close to the same date. However, the yield of such testing is low and limited by delays in intrathecal production of virus-specific antibody and passive transfer of serum antibodies across a damaged blood-brain barrier. As a general rule, screening for CMV-specific IgG and/or IgM antibodies to diagnose congenital CMV infection and testing of CSF for the diagnosis of CMV neurologic disease have limited utility and have been largely replaced by more-direct methods like PCR.
Specimens for Measurement of Cell-Mediated Immunity

Whole blood in heparin as the anticoagulant is collected for assays that measure cell-mediated immune responses to CMV infection (32, 33). For enzyme-linked immunosorbent spot (ELISPOT) tests, a total of 15.0 ml of whole blood is typically used to purify and stimulate peripheral blood mononuclear cells using defined CMV antigens. The number of cells is adjusted to 2.0 × 10⁶/ reaction for use in the assay. For described Quantiferon assays, a total of 1.0 ml of whole blood is collected into a tube containing CMV antigens dried onto the inner wall of the tube. The blood is vigorously mixed by shaking for 5 seconds to ensure that the entire inner surface of the tube has been coated with blood and then immediately stored at 37°C for 16 to 24 hours to stimulate cells before processing by centrifugation to obtain plasma for testing. Plasma samples can be stored for up to 4 weeks at 2 to 8°C or for extended times at −20°C or below prior to testing.

DIRECT EXAMINATION

Histopathologic testing, antigenemia assays, and qualitative and quantitative molecular methods have been routinely used for the direct detection of CMV from clinical samples. Histologic or immunohistochemical staining of tissue biopsy specimens is most useful in the diagnosis of localized CMV tissue-invasive disease, while antigenemia assays and molecular amplification tests are now the standard of care for testing and monitoring patients at increased risk for severe CMV disease, diagnosing active CMV disease, and monitoring response to therapy (for a review, see references 34 to 36).

Histopathologic Testing

Characteristic large cells (cytomegalic cells) with basophilic intranuclear inclusions and, on occasion, eosinophilic cytoplasmic inclusions can be seen in routine sections of CMV-infected biopsy or autopsy material following staining with Wright-Giemsa, hematoxylin and eosin, or Papanicolaou stains (Fig. 1). The nuclear inclusion has the appearance of an “owl’s eye” because it has marginated chromatin that is typically surrounded by a clear halo that extends to the nuclear membrane. The presence of characteristic cytologic changes by histopathologic testing suggests CMV infection and, while less sensitive than molecular methods like PCR, is more predictive of disease, especially in the gastrointestinal tract, and correlates with active disease in most cases. Overall, histopathologic diagnosis of CMV disease involves time and labor and is relatively insensitive, and since CMV can infect tissues without producing morphologic changes, failure to find typical cytomegalic cells does not exclude the possibility of CMV infection; additional virologic or serologic confirmation is suggested. The sensitivity of histopathologic testing can be increased somewhat by using immunohistochemical staining to detect CMV antigens or in situ hybridization to detect CMV nucleic acids. A major obstacle to tissue diagnosis of CMV is the need to perform invasive procedures to obtain specimens for testing.

Antigen Detection

The CMV antigenemia assay is a sensitive, specific, and rapid method for the early diagnosis of CMV infection and can be used for routine monitoring of patients at high risk for severe CMV disease, including recipients of solid organ and hematopoietic stem cell transplants, HIV-infected patients, and patients treated with immunomodulating drugs.

The test is relatively simple to perform and is based on immunocytochemical detection of the 65-kDa lower-matrix phosphoprotein (pp65) in the nuclei of peripheral blood leukocytes. By using this assay, CMV can be detected before the onset of symptoms and the viral load can be quantified to assist in predicting and differentiating CMV disease from asymptomatic infection (37, 38). The procedure has also been used to evaluate the efficacy of antiviral therapy and to predict treatment failure and the development of viral resistance (39, 40), to prompt the institution of preemptive therapy (41, 42), to detect CMV in leukocytes of CSF from AIDS patients with infections of the central nervous system (43), and for diagnosis of congenital CMV infection (44), CMV gastrointestinal disease (45), and CMV infection in the immunocompetent host (5). The pp65 protein has also been found in endothelial cells circulating in the blood of immunocompromised patients, and some investigators have suggested that infection of these cells is associated with organ involvement and more-advanced disease (46, 47). The results of the antigenemia assay correlate well with the quantitative detection of CMV DNA in whole blood, leukocytes, or plasma in molecular amplification assays (17, 48–52).

In the antigenemia assay, leukocytes (mainly polymorphonuclear leukocytes) are enriched from freshly collected
whole blood by sedimentation with dextran. A method for direct lysis of erythrocytes and subsequent isolation of leukocytes from whole blood has been described (53) and is now routinely used by many laboratories. This modification allows for a shorter total assay time and the capability of processing more specimens. Following sedimentation, the remaining erythrocytes are lysed with ammonium chloride, the granulocytes are counted in a hemocytometer or automated cell-counting instrument, and a known number of cells (usually 2 × 10^5, although variations of 5 × 10^4 to 10^6 cells have been used) are cyt centrifuged onto microscope slides. The cells are fixed with formaldehyde or paraformaldehyde and then permeabilized with the nonionic detergent Nonidet P-40 and stained with suitable monoclonal antibodies directed against CMV pp65. These processes are followed by incubation of the cells with a fluorescein isothiocyanate-labeled secondary antibody diluted in a counterstain. Slides are read by microscopy at magnification of ×200 to ×400. Positive results are viewed as homogeneous yellow to apple green fluorescence within the nuclei of infected cells (Fig. 2). Quantitative results are usually expressed as the number of antigen-positive cells per total number of leukocytes evaluated. Absolute CMV antigenemia values or specific thresholds to predict symptomatic disease or prompt administration of preemptive antiviral therapy have not been fully established for interpretation of quantitative testing, and they appear to be different between patient populations. Therefore, it is more important to monitor patients and trend relative rises and/or falls in the level of antigen-positive cells in multiple blood specimens collected over time than it is to rely on a single test result. The presence of small numbers of antigen-positive cells generally indicates asymptomatic infection, whereas increasingly larger numbers are more strongly associated with clinically significant disease. In patients with severe immunosuppression (e.g., after allogeneic hematopoietic stem cell transplantation), however, even very small numbers of antigen-positive cells may be significant. For transplant recipients, the frequency and extent of monitoring vary with the institution and from one transplant population to another and depend on the medical approach taken to manage CMV infection and disease (for a review, see references 35 and 36).

The major advantages of the antigenemia assay are that it is more sensitive than either conventional tube or shell vial cultures for the detection of CMV from blood; it can be completed in 2 to 4 h, providing same-day turnaround of results; and the procedure can be readily modified for quantitative measure of the viral load. The assay has the disadvantages of being labor-intensive and time-consuming, particularly when large numbers of specimens are being processed; the blood must be processed in a timely manner for accurate results; and the test should be performed by personnel with experience in immunocytochemical techniques due to the subjective nature of the interpretation. Considerable time, effort, and expertise are needed in isolating and counting cells, adjusting the cell concentration to 10^5/ml before preparing the slides for staining, and then reading the stained slides. Also, interlaboratory variability exists with regard to the exact procedures used to perform the antigenemia assay and there is a definite need for assay standardization (54–56). Commercial kits containing monoclonal antibodies and other reagents needed to perform the antigenemia assay are available (Table 1). Several of these assays have been licensed by the FDA, and comparative studies have demonstrated equivalent performances. Because of the low throughput, the antigenemia assay is best suited for laboratories processing small numbers of specimens.

**Nucleic Acid Detection**

Over the years, molecular amplification assays have progressively replaced the antigenemia assay and other nonmolecular tests for the diagnosis and monitoring of CMV infections. PCR is currently the most preferred and widely used molecular method for the detection of CMV DNA and mRNAs, and the sensitivity and specificity of PCR for diagnosis of active CMV infection have been evaluated (63–67). Amplification has been performed with a variety of primer pairs from gene regions of the immediate early antigen (UL122-123 locus), the major immediate early antigen (UL122-123 locus), the DNA polymerase (UL54), glycoproteins B (UL55) and H (UL75), pp65 (UL83), pp67 (UL65), US17, HXFL4, the EcoRI D fragment, the HindIII X fragment, the pp150 tegument protein (UL32), the major capsid protein (UL86), and the junction between glycoprotein B and the major immediate early antigen. Based on published literature, the most common targets for CMV PCR include glycoprotein B, the immediate early antigen, the major immediate early antigen, and US17 followed by the pp65 and polymerase genes. Not all primers are equally sensitive in amplifying CMV DNA, and in several studies the sensitivity of the assay was increased by amplifying genomic regions from both the immediate early and the late CMV genes or by using nested primers to a single gene fragment. The use of both gene fragments enabled the detection of a variety of clinical isolates, indicating that

Consequently, a number of quantitative and semiquantitative molecular assays have been developed over the years, and have included target and signal amplification methods. Most laboratories now use real-time PCR, because it allows for rapid and accurate quantification of CMV DNA in blood samples, and has been shown to be highly correlated with clinical and pathological findings. However, careful consideration should be given to whether detection of CMV DNA is relevant to the clinical situation.

Also, a negative result from qualitative PCR can be used as a confirmatory test for negative results from other diagnostic methods. Qualitative PCR can be used to confirm the absence of CMV DNA in samples from patients with negative results from other diagnostic methods. Qualitative PCR can also be used to confirm the absence of CMV DNA in samples from patients with negative results from other diagnostic methods.

It is also important to note that qualitative PCR results should be interpreted with caution, as they may be influenced by technical factors such as the quality of the sample, the performance of the PCR assay, and the experience of the laboratory personnel. Qualitative PCR results should be interpreted in the context of clinical and pathological findings, and should be confirmed by other diagnostic methods when possible.
culture for detecting CMV infection and can detect CMV before the onset of clinical symptoms. It has been shown that transplant recipients and AIDS patients with active CMV disease have higher levels of CMV DNA and that a rapid rise in the CMV DNA copy number correlates with the presence of symptoms and drug failure during treatment (49, 89–91). Also, Rasmussen et al. (92) have determined that quantitation of CMV DNA from peripheral blood leukocytes can be used to identify HIV-infected patients at risk for development of symptomatic CMV retinitis. It has also been determined that immunocompromised patients with CMV disease have more CMV DNA in either whole blood, plasma, or leukocyte fractions than do patients without disease but that the level of CMV DNA in whole blood or leukocytes is higher than that in plasma (49, 93). Quantitation of CMV in plasma, therefore, may be less sensitive for monitoring CMV infection, although a positive result may correlate better with active disease. Although there is general agreement between PCR and antigenemia assays, the quantitative numerical relationship is not exact and differences should be expected since these assays measure different biological features of CMV replication and infection. PCR is extremely sensitive and may detect CMV earlier than the antigenemia assay and may continue to be positive after antigen testing is negative. Conversely, negative PCR results have been reported for patients with low numbers of positive cells in the antigenemia assay (51). Therefore, depending on the test and parameters used, these assays may be more or less sensitive when compared to one another and may have higher or lower positive predictive values for CMV disease. As in the antigenemia assay, absolute CMV DNA levels or threshold values for predicting symptomatic disease and initiating preemptive therapy have not been determined and may differ by specimen type and testing platform selected and from one laboratory and patient population to another. It is currently more important to monitor the relative changes in DNA levels from serial blood specimens collected over time and tested using the same assay and specimen type. If desired, specific cutoff levels should be prospectively determined based on the assay and specimen used and the type of patients being monitored. Because of the high sensitivity of PCR and depending upon the cutoff value selected, the positive predictive value for symptomatic CMV disease may vary and may affect clinical decision making and the length of antiviral therapy. Quantitative PCR methods for the estimation of CMV DNA levels in CSF, amniotic fluid, tissue, and urine of CMV-infected patients have been described (44, 83, 94–96), but more research is needed to assess the clinical relevance of quantitating CMV DNA from these specimens. It has been shown that the prognosis of congenital CMV infection may be directly related to the amount of CMV in the urine of an infected neonate and that quantitating CMV DNA in the CSF of AIDS patients may help determine if disorders of the central nervous system are attributed more to CMV than to the direct effects of HIV or other opportunistic pathogens. In general, real-time PCR assays for the detection and quantification of CMV DNA are sensitive, specific, and reproducible and significantly reduce the time necessary to report results that may have an impact on the care and management of patients. The method offers the distinct advantages of being less technically demanding and less expensive to perform than more conventional assays, and quality reagents and automated instruments for nucleic acid extraction and amplification and detection are readily available and greatly improve the potential for standardization and increased accuracy of results. The assays also require less specimen volume for testing and can be easily performed on neutropenic patients with low leukocyte counts, the DNA is stable during extended specimen transport and storage times, and large numbers of specimens can be efficiently processed. Furthermore, the overall risk of amplicon contamination is minimized, as real-time platforms are closed systems. Various commercial real-time and endpoint PCR assays are available as either analyte-specific reagents or packaged as complete kits (Table 2). However, most real-time PCR assays are developed in the laboratory by the end user and differ in the types of specimens used, the nucleic acid target selected, the choice and design of suitable oligonucleotide primers and probes, optimization of specimen extraction and PCR amplification conditions, the controls and calibration standards used, the method chosen to detect and/or quantify the amplified product, and the quantitative units of measure and vial loads reported from one laboratory and method to another. Many of the assays require additional validation, and there is a definite need for traceable and commutable international reference materials that include both standards and controls for institutional comparison of results, since significant variability in CMV quantification has been observed between laboratories (118–121). To this end, the first international CMV standard was developed by the World Health Organization in 2010 and is available from the National Institute of Biological Standards and Controls in the United Kingdom. Secondary material calibrated against this standard can be purchased from commercial manufacturers, and a second standard reference material has been made available from the National Institute of Standards and Technology in the United States (122). Use of these standard reference materials and the recommended reporting of viral loads in international units/ml (IU/ml) should allow for broader interassay agreement among different laboratories using different quantitative molecular assays (123) and should facilitate the establishment of defined testing algorithms and cutoff values that predict clinical disease and improve management and outcomes in CMV-infected patients. A commercial quantitative assay, the Roche COBAS AmpliPrep/COBAS TaqMan CMV Test, has been developed using this international standard and has been licensed by the FDA. Results are expressed in IU/ml, and the level of agreement has been shown to be high across different laboratories during evaluations of this system (124, 125). More recently, droplet digital PCR has been developed and has the advantages of direct quantification of CMV DNA without the requirement for standards and the use of a calibration curve to facilitate accurate measurements of viral load (126). Ultimately, the clinical utility of these assays depends on their accuracy, reproducibility, precision, ease of use, cost, availability, and predictive value. Molecular methods, however, are now considered to be invaluable additions to the analytical tools already being used to provide a rapid diagnosis of established CMV disease, identify patients at risk of developing disease, assess the progression of disease and the risk of relapse, direct the initiation of preemptive therapy, monitor the response to therapy, and predict viral resistance and treatment failure.

blast cultures include those prepared from human embryonic tissues or foreskins and serially passaged diploid human fetal lung strains such as WI-38, MRC-5, or IMR-90. Diploid fibroblast cells should be used at a low passage number, since they may become less susceptible to CMV infection with increasing cell generations. Several of these fibroblast cell lines are commercially available. Culture systems for the detection of CMV in clinical specimens include conventional tube cultures and spin amplification shell vial assays. Although still performed in many laboratories, the use and clinical utility of cultures for CMV have diminished owing to a much better overall performance and ease of use of newer and more-efficient non-culture-based detection methods.

**Conventional Tube Culture**
Specimens to be tested are added in a volume of 0.2 ml to tubes of confluent fibroblasts maintained in Eagle minimal essential medium with 2% fetal bovine serum. Alternatively, the tubes are drained of medium, the inocula are absorbed for 1 h in a stationary position or by centrifugation at 700 × g for 45 min at 30 to 33°C, and then fresh medium is added. After inoculation, the tubes can be rolled or kept stationary at 37°C. Twenty-four hours later, the medium is changed in tubes inoculated with urine or leukocyte specimens. Thereafter, and for other types of specimens, the medium is changed once a week or more frequently as the pH of the cell culture medium changes or if toxicity appears. When toxicity necessitates passage of the culture, cells rather than culture medium should be passed, since CMV remains mostly cell associated. Cells are removed by addition of 0.25% trypsin–0.1% EDTA to the monolayers and incubation at 37°C for approximately 1 min. When the cells detach, Eagle minimal essential medium with 2% fetal bovine serum is added, and the cells are used to inoculate fresh tubes. Tubes are examined for cytopathic effect (CPE) for at least 4 weeks for most specimens (6 weeks for leukocyte specimens). Control, uninoculated cultures are handled in the same manner as those inoculated with clinical specimens.

CMV isolates are normally identified solely on the basis of characteristic CPE and host cell range. The time of appearance and the extent of CPE depend on the amounts of virus present in specimens. In cultures inoculated with urine from a congenitally infected newborn, CMV may develop by 24 h and progress rapidly to involve most of the monolayer if the virus titer in the urine is extremely high. More commonly, foci of CPE, consisting of enlarged, rounded, refractile cells, appear during the first week, and progression of CPE to surrounding cells proceeds slowly (Fig. 3). In cultures inoculated with urine or respiratory specimens from older individuals, CPE usually appears within 2 weeks. Leukocyte cultures may not become positive until after 3 to 6 weeks. The usual slow progression of CPE in tube cultures inoculated with clinical specimens is due, at least in part, to limited release of virus into extracellular fluid. With strains of CMV that have been serially passaged, including laboratory-adapted strains, greater amounts of extracellular virus are released and CPE progresses more rapidly. Viruses such as adenovirus and varicella-zoster virus occasionally produce CPE indistinguishable from that of CMV, so suspected CMV isolates are best confirmed by an immunofluorescence assay (IFA) using monoclonal or polyclonal antibodies that are available from various commercial sources. The appearance of typical nuclear fluorescence of infected cells indicates the presence of CMV. PCR or other molecular amplification methods also can be used for confirmation of suspected isolates.

For storage of fresh isolates, monolayers exhibiting CPE are treated with trypsin-EDTA, and the cells obtained are suspended in Eagle minimal essential medium with 10% fetal bovine serum and 10% dimethyl sulfoxide and then frozen at −70°C. Infectivity can be better maintained for long periods by storage in liquid nitrogen.

**Spin Amplification Shell Vial Assay**
The spin amplification shell vial assay has been used extensively as a rapid culture method for the detection of CMV in clinical specimens and has largely replaced the slower conventional tube cultures in most laboratories. The technique is based on the amplification of virus in cell cultures after low-speed centrifugation and detects viral antigens produced early in the replication of CMV, before the development of CPE. Even low titers of virus present in specimens are easily amplified and rapidly detected within 24 h. Monoclonal antibodies are commercially available and are used for the detection of CMV early antigens. In situ hybridization with DNA probes to CMV has also been used.

MRC-5 fibroblast cells are grown to confluency on 12-mm-diameter round coverslips in 1-dram (3.7-ml) shell vials and inoculated with 0.2 ml of specimen. Shell vials of MRC-5 cells can be obtained commercially or prepared in the laboratory. Monolayers should be inoculated within 1 week after preparation, since older monolayers demonstrate decreased sensitivity to CMV and increased toxicity. Two vials should be inoculated for urine, tissue, and bronchoalveolar lavage fluid specimens, and three vials should be inoculated for blood specimens (127). Alternatively, disruption of purified leukocytes by sonication before their use in the shell vial assay may increase the sensitivity of CMV detection from blood (128). Increasing the frequency of blood collection and the volume of blood obtained also may enhance the diagnostic yield of the shell vial assay from this specimen (129). After inoculation, the vials are centrifuged at 700 × g for 40 min at 25°C, and then 2.0 ml of Eagle minimum essential medium containing 2% fetal bovine serum and antibiotics is added. The cultures are incubated at 37°C for 16 to 24 h, fixed with acetone, and stained. A longer incubation time may be used, but the time should be determined by each laboratory on the basis of individual experience, reagents, staining technique used, and whether monolayers are purchased or prepared in the laboratory. Uninfected and CMV-infected monolayers are included as
negative and positive controls, respectively. Mink lung (ML) cells, a nonhuman continuous cell line, are comparable to MRC-5 fibroblasts for the detection of CMV in clinical specimens by shell vial culture. A distinct advantage in using ML cells is that this cell line can be propagated and passaged in the laboratory for a long time without a decrease in susceptibility to CMV. Significantly less toxicity and an increase in the number of CMV-positive nuclei were also observed with ML cells. Coverslips are scanned at a magnification of ×200 to ×250, and specific staining is confirmed at ×400 to ×630. Positive cells contain yellow to apple green fluorescent nuclei against a red cytoplasmic background. Staining of immediate early antigen appears as an even matte yellow to green fluorescence with specks of brighter yellow to green (Fig. 4A). Viral inclusions (owl’s eyes) may be visible in the nuclei (arrows) of infected MRC-5 cells following shell vial culture and IFA staining. (A) Staining of immediate early antigen appears as an even matte yellow to green fluorescence with specks of brighter yellow to green. (B) Viral inclusions (owl’s eyes) may be visible in the nuclei. CMV (for an overview, see reference 130). In deciding which test to perform, one should consider such factors as the number of specimens to be tested, the patient population, cost, turnaround time, equipment needs, and ease of performance. The method that is chosen depends on the needs of individual laboratories. For small-volume laboratories, IFA may be more cost-effective and practical, while enzyme immunoassays (EIA) may be more suitable for laboratories with higher volumes of specimens. Overall, detection of CMV-specific IgM or determination of a seroconversion from a negative to a positive IgG antibody response can be useful for the diagnosis of primary CMV infection in certain clinical settings, and the screening of blood and organ donors and recipients plays an important role in preventing the transmission of latent CMV to patients at high risk for severe CMV disease.

**Enzyme Immunoassays**

Over the years, EIAs have largely replaced other traditional methods for detecting antibodies to CMV. The main advantages of the EIA are that it is rapid, sensitive, and specific. In addition, multiple specimens can be handled daily at a relatively low cost. Kits that detect CMV IgG and IgM are available from a number of commercial sources (Table 3). The kits are easy to use, and the manufacturers have provided detailed instructions. All the materials necessary to perform the assay are included, and the reagents are stable with time. Some companies also provide a spectrophotometer and automated plate washer, which otherwise must be purchased separately at additional expense. The development of robotics technology has led to the commercial availability of both fully automated and semiautomated EIA instruments that include sample dispensers, diluters, washers, and spectrophotometers with complete computer programming and generation of electronic and written reports. More recently, an EIA that uses the envelope glycoproteins B and H to distinguish CMV strain-specific antibody responses has been developed (131). This assay may be useful for identifying strain diversity in different patient populations and may provide a better understanding of the implications of infection with multiple CMV strains and the role of strain-specific antibody in the protective immune response against CMV.

**Immunofluorescence Assays**

Indirect and anticomplement IFAs are commonly used methods for detecting CMV antibodies. In the indirect IFA, dilutions of test serum are incubated with virus-infected cells that have been fixed to a glass microscope slide. Specific antibody-antigen complexes are detected using an antihuman antibody conjugated with fluorescein isothiocyanate and fluorescence microscopy. Anticomplement immunofluorescence is similar to the indirect IFA. It differs, however, in that the test serum is first heat inactivated to remove endogenous complement activity and then incubated with virus-infected cells on glass slides. An exogenous source of complement is added and bound by any specific antigen-antibody complexes that have formed. A fluorescein-labeled anticomplement antibody is then added; it binds to the C3 component of complement, and the slides are read using a fluorescence microscope. Anticomplement IFA amplifies the fluorescent signal above what can be seen using an indirect IFA, allowing for the detection of small amounts of antibody or antibodies of low avidity. IFAs are useful and inexpensive methods that offer the advantages of speed and simplicity for the qualitative and quantitative detection of CMV antibodies. Commercial kits are readily available, or antigen-coated slides and labeled secondary antibodies can

be purchased separately. The major disadvantages of IFA systems are that they require a fluorescence microscope and darkroom for examining slides and that extensive training is needed to read and interpret the test results.

**CMV IgM Antibody Measurements**

Commercial reagents and complete EIA and IFA diagnostic kits are available for measuring CMV IgM antibodies and are most useful in the diagnosis of CMV infection in newborns. The procedures are essentially the same as those used to detect IgG antibodies, except that anti-human IgM antibodies labeled with suitable markers are used to detect CMV-specific IgM bound to viral antigens on the solid phase. A recognized pitfall of CMV IgM assays is the occurrence of false-positive and false-negative reactions. False-positive reactions occur when sera contain unusually high levels of rheumatoid factor in the presence of specific CMV IgG. Rheumatoid factor is an immunoglobulin, usually of the IgM class, that reacts with IgG. It is produced in some rheumatologic, vasculitic, and viral diseases, including CMV infection. IgM rheumatoid factor forms a complex with IgG that may contain CMV-specific IgG. The CMV IgG binds to CMV antigen, carrying nonviral IgM with it; in this setting, a test designed to detect IgM will produce a false-positive result. False-negative reactions occur if high levels of specific IgG antibodies competitively block the binding of IgM to CMV antigen. Therefore, it is highly recommended to separate IgM and IgG fractions before testing to decrease the incidence of both false-positive and false-negative IgM test results.

Rapid and simple methods for the removal of interfering rheumatoid factor and IgG molecules from serum have been developed. These include selective absorption of IgM to a solid phase and removal of IgG by using hyperimmune antihuman IgG antibody, staphylococcal protein A, or recombinant protein G from group G streptococci. Serum pretreatment methods are now readily available and are incorporated in the procedures of commercially available IFA and EIA kits, which have resulted in more-reliable IgM tests. More recently, reverse capture solid-phase IgM assays have been used as an alternative approach to avoiding false-positive or false-negative results. This method uses a solid phase coated with an anti-human IgM antibody to capture the IgM from a serum specimen, after which competing IgG antibody and immune
complexes are removed by washing. The bound IgM antibody is then exposed to specific CMV antigen, and an enzyme-conjugated second antibody and substrate are added. The development and use of recombinantly derived CMV proteins as a source of antigenic substrate also have greatly improved the performance of IgM assays (132, 133).

Although the detection of CMV-specific IgM may be beneficial in the determination of recent or active infection, the results should be interpreted with caution. Because IgM does not cross the placenta, a positive result from a single serum specimen from an infected newborn is diagnostic. However, there may be a lack of or delay in production of IgM in the newborn. Testing for the presence of CMV-specific IgM antibody beyond the newborn period is usually not recommended since IgM antibody can appear in both primary and reactivated CMV infections and can persist for extended periods after a primary infection. This complicates the interpretation of test results, particularly for pregnant women or immunocompromised patients, and may not be predictive of recent or active infection. Like newborns, immunocompromised individuals also may have a delay in IgM production or may be unable to mount a significant IgM antibody response. Lastly, CMV patients with Epstein-Barr virus-induced infectious mononucleosis may produce heterotypic IgM responses, resulting in false-positive CMV IgM test results.

IgG Avidity Assay

Measurements of CMV-specific IgG avidity have proven useful for distinguishing primary from nonprimary infections in women suspected of having CMV during pregnancy and in solid organ transplant recipients. CMV-specific IgG of low avidity is produced during the first weeks to months following primary infection, while IgG antibody of increasingly higher avidity is produced with past or nonprimary infections. The detection of CMV-specific IgM in maternal serum is not predictive of virus transmission to the fetus, since fewer than 10% of pregnant women who are positive for CMV IgM actually give birth to a congenitally infected infant. More recently, it has been suggested that finding low-avidity CMV-specific IgG antibody in CMV-IgM positive pregnant women may improve the diagnosis of recent primary CMV infection and may have prognostic value with regard to fetal infection (134, 135). In solid organ transplant recipients, it has also been shown that a delay in the development of high-avidity CMV-specific IgG antibody correlates with prolonged antigenemia and a poor prognosis (136). Both commercial and user-developed CMV-specific IgG avidity assays are available, and the tests are performed by making simple modifications to conventional EIA protocols to effectively separate and differentiate antibodies of low and high avidity (137, 138).

Measurement of CMV-Specific Cell-Mediated Immunity

CMV-specific CD4+ and CD8+ T-cell responses are critical to the control of CMV replication and the onset of symptomatic infections. Recently, tests have been developed to assess the CMV-specific cell-mediated immune response and may have potential clinical application to identify transplant recipients at increased risk for CMV infection following transplantation, to guide decision making regarding prophylaxis and preemptive therapies, and for risk stratification of patients before transplantation (32, 33). Most assays measure the status of immune reconstitution by detecting the release of gamma interferon following stimulation of whole blood or peripheral blood mononuclear cells with CMV-specific antigens or peptides, and use of these tests has been recommended in the most recent updated international CMV consensus guidelines on the management of CMV in transplant patients. To that end, assays like the QuantiFERON-CMV (Cellestis Limited, Victoria, Australia) and T-Track CMV ELISpot (Lophius Biosciences, Regensburg, Germany) have been commercialized and have recently received CE marking in Europe (139).

ANTIVIRAL SUSCEPTIBILITY TESTING

Resistance of CMV to ganciclovir has been reported in immunocompromised patients, particularly patients with AIDS receiving long-term ganciclovir treatment for CMV retinitis. Ganciclovir-resistant clinical isolates have also been recovered from bone marrow and solid organ transplant recipients and a patient with chronic lymphocytic leukemia. Although foscarnet is the alternative therapy for ganciclovir-resistant CMV infections, clinical CMV isolates resistant to foscarnet alone or to foscarnet in combination with ganciclovir have been described. The mechanisms of resistance to ganciclovir in CMV include mutations in the catalytic domain of the UL97 phosphotransferase gene, leading to a deficiency in drug phosphorylation, and alterations in the UL54 viral DNA polymerase gene; the latter is also responsible for resistance to foscarnet (for a review, see references 140 to 142). Ganciclovir-resistant CMV isolates with mutations in the UL54 gene are generally cross-resistant to cidofovir, and isolates resistant to ganciclovir, foscarnet, and cidofovir have also been reported.

The described emergence of antiviral drug resistance has led to a definite need for in vitro antiviral susceptibility testing. Laboratory confirmation of drug resistance in the setting of rising, rebounding, or persistently high viral loads during prolonged therapy (median of 5 months) is essential for defining the mechanisms of antiviral resistance, for determining the frequency with which drug-resistant CMV mutants emerge in clinical practice, for predicting treatment failure and identifying cross-resistance to other antiviral agents, for instituting the most appropriate alternative therapy, and when evaluating new antiviral agents. A number of phenotypic and genotypic assays have been described for testing the susceptibility of CMV to antiviral agents (for an overview, see reference 143). Phenotypic assays, although considered to be the reference methods for many years, are rarely used in clinical practice today, as they are cumbersome, labor-intensive, and expensive and have turnaround times that are far too long to be clinically relevant. Genotypic assays are currently the method of choice and offer speed and efficiency in screening and analysis of whole-blood or plasma specimens or CMV isolates and allow for an earlier detection of the emergence of drug resistance than phenotypic assays. Phenotypic assays measure the ability of CMV to grow in cell culture in the presence of various concentrations of antiviral drug, and they generally require isolation and passage of the virus in cell culture before testing begins. They offer the distinct advantage of being a direct measure of CMV susceptibility to any antiviral drug and can provide data on the concentration of drug needed to inhibit viral replication. Genotypic assays have been used to screen clinical specimens or CMV isolates for the identification of mutations in the CMV UL97 phosphotransferase gene and the UL54 DNA polymerase gene that confer resistance to ganciclovir, foscarnet, and/or cidofovir (144–146). These assays normally involve using PCR for amplification of specific viral genes and sequencing of the amplified
establishing treatment failure. Serial monitoring of high-risk patients also may be beneficial with respect to aiding in the decreased use of and exposure to antivirals, leading to a more cost-effective and focused use of such agents. Interpretation should be done with caution, as not all changes in quantitative CMV DNA levels may reflect a substantial biological or clinical difference, especially if the changes are small and fall within the expected range of variability for the assay used. Also, an isolated result for CMV viremia may not be predictive of disease and the need for immediate antiviral treatment. Lastly, negative viral load results do not always exclude CMV disease in symptomatic patients; end organ involvement, particularly in the gastrointestinal tract and lungs, may occur in the absence of detectable levels of CMV viremia. Histopathologic examination and/or PCR can be useful in immunocompromised hosts for the diagnosis of specific organ invasive diseases.

However, detection of CMV in tissue specimens must be interpreted with caution, particularly when infections with more than one organism are documented, as the relative importance of each pathogen in producing clinical illness may be difficult to determine. The degree of histological involvement may help in determining the role and severity of CMV in causing disease.

The isolation of CMV from urine, respiratory secretions, or other body fluids within the first 3 weeks of life is the traditional means of confirming the diagnosis of congenital infection in newborns. Urine is the preferred specimen because it contains greater amounts of virus, and the virus therefore grows quickly in culture. PCR has also been used to find CMV DNA in urine of congenitally infected infants (150), and viremia in infants with congenital infection has been detected by the antigenemia assay and PCR. Attempts to isolate or detect virus from maternal blood leukocytes and from amniotic fluid and fetal blood and tissue by molecular and/or antigen-based tests may provide useful information for prenatal diagnosis of congenital CMV infection (for a review, see references 25 and 151). While such prenatal testing is a sensitive indicator of maternal or fetal CMV infection, positive results do not predict which infants will have disease. In this regard, quantitative measures of viral load in congenital CMV infection may prove beneficial for predicting symptomatic outcome and for guiding patient management (44). It has been demonstrated that elevated levels of CMV DNA in blood during early infancy is associated with hearing loss in newborns with symptomatic and asymptomatic congenital CMV infection (152, 153). Also, quantitative real-time PCR has been used to quantify CMV DNA from amniotic fluid samples to predict fetal and neonatal outcomes (154) and to test umbilical cord blood to screen for neonatal CMV infection at delivery (69). Infants not previously tested but found to be excreting virus after 3 weeks of age may have either congenital or acquired infection. Standard serologic or virologic tests do not differentiate between these possibilities.

In general, serologic tests for CMV-specific IgG antibody have limited value for the diagnosis of acute infection since the results are obtained retrospectively and are not predictive of disease. Also, the transplacental passage of maternal IgG antibody begins at 18 weeks gestation and confounds the diagnosis of CMV infection in the neonate, and immunocompromised hosts may not mount a normal immune response or they may have been given blood transfusions or intravenous immunoglobulins that contain detectable CMV IgG antibodies. Nonetheless, a history of seroconversion from a negative to a positive IgG antibody response to CMV is diagnostic of primary infection and may be benefi-
cial in evaluating a pregnant woman with symptoms of viral disease. For pregnant women with preexisting CMV-specific IgG and/or IgM antibody, however, IgG avidity testing may be more helpful in distinguishing primary from nonprimary infections and for predicting CMV transmission to the fetus. Use of the IgG avidity assay or tests that measure immune reconstitution in immunocompromised hosts may have value in detecting those at highest risk for CMV disease. Whenever possible, serologic diagnoses of CMV infection should be confirmed by other virologic methods. CMV-specific IgG serologic assays play a more important role in the determination of an individual's immune status to CMV. Detection of CMV-specific IgG in a single serum specimen indicates exposure to CMV, and thus may be associated with disease. Serologic testing is important in determining the presence of a seropositive donor or recipient, a seronegative recipient who receives an organ or blood products from a seropositive donor is at increased risk for developing primary CMV infection and serious disease. Knowing the serostatus of the donor and recipient is therefore important in determining the treatment or prophylaxis to be used and in considering the type of donor to be selected and the blood products to be given.

The application of virologic methods, including conventional and shell vial culture, rapid direct-detection assays, and serologic testing, should be combined with clinical assessment of the patient to provide an accurate, reliable diagnosis of CMV infection and disease and to allow subsequent prompt, appropriate patient management and timely intervention with specific antiviral therapy. There is a particular need to differentiate CMV infection from graft rejection in transplant patients, since the administration of potent immnosuppressive antirejection drugs during active CMV infection may result in life-threatening disease.

**Epstein-Barr Virus**

**BARBARA C. GÄRTNER AND JUTTA PREIKSAITIS**

**TAXONOMY**

Epstein-Barr virus (EBV) is a member of the *Herpesviridae* family and belongs to the *Gammaherpesvirinae* subfamily (1). EBV is closely related to another human pathogen, human herpesvirus 8, which also replicates in epithelial cells and establishes long-term latency in lymphocytes. However, EBV is the only human pathogen in the genus *Lympocryptovirus*; human herpesvirus 8 belongs to the genus *Rhadinovirus*.

**DESCRIPTION OF THE AGENT**

Morphologically, EBV is a typical herpesvirus with 162 capsomers in an icosahedral arrangement surrounded by a lipid-rich envelope. The virus has a double-stranded, 172-kbp DNA genome which exists in a linear form in the mature virion and in a circular episomal form in latently infected cells. The genome consists of a series of unique sequences alternating with internal repeats, all sandwiched between two terminal repeat elements which are joined during circularization. Integration of viral DNA into host chromosomal DNA occurs rarely and has been documented primarily for lymphoblastoid cell lines.

EBV primarily infects naïve B cells. This requires the binding of the major EBV outer envelope glycoprotein gp350/220 with the cellular complement receptor C3d (also known as CD21 or CR2) and gp42 with the major histocompatibility complex class II molecule. In vitro, EBV uses the highly regulated, sequentially expressed proteins described below to persist in the host and transmit infection. It is believed to do this by usurping normal B cell physiologic processes. EBV substitutes for antigen, T cell help, the B cell receptor, and other signals that result in cellular activation, proliferation, differentiation, and survival, mimicking pathways followed when naïve B cells encounter antigen with the end result of establishing latency in memory B cells (2).

In *vivo*, EBV transforms B cells into lymphoblastoid cell lines. Although CD21-negative epithelial cells of the oropharynx are the most important site of viral replication and amplification (3), monocytes may also be productively infected by EBV (4, 5). In some clinical settings, T and NK (natural killer) cells also demonstrate evidence of infection (6). EBV nuclear antigens—EBNA 1, EBNA 2, EBNA 3 (also referred to as EBNA 3a), EBNA 4 (EBNA 3b), EBNA 5 (EBNA LP), and EBNA 6 (EBNA 3c)—and latent membrane proteins (LMP 1 and 2A and B) may be expressed in B cells. Four types of B cell latency have been defined, based on various levels of expression of the latency-associated proteins (7, 8). In latency type 0, only EBV-encoded RNAs (EBERs) and rightward transcripts from the BamHIA gene are expressed. EBER 1 and EBER 2 are nonpolyadenylated RNAs, are therefore not translated to a protein, and act to inhibit antiviral effects by interferon as well as apoptosis. EBERs are present in high copy numbers (10^6 to 10^7 copies) in virtually all EBV-infected cells. This expression profile is seen in memory B cells of healthy carriers. In latency type 1, in addition to the type 0 expression profile, EBNA 1 is detectable; this is observed in Burkitt’s lymphoma. In latency type II, LMP 1 and 2 are expressed in addition to gene products of latency type I; this is observed in germinal center and memory B cells in the tonsil and malignancies, including Hodgkin’s lymphoma, nasopharyngeal carcinoma (NPC), nasal NK cell lymphoma, chronic active EBV infection, and nasopharyngeal lymphoma. Finally, in latency type III, all EBNA proteins are detectable; this is observed in naïve B cells of the tonsil during acute infection and in immunodeficiency-related lymphoproliferative disorders (2).

EBV has a highly restricted host range. Although during acute EBV infection, as many as 10% of all circulating B cells, representing 50% or more of all memory B cells, may be infected, in a healthy individual remote from infection, only about 1 to 50 B cells per million are infected (9). During lytic replication, more than 70 proteins are expressed, including the virus capsid antigens (VCA) and the early antigens (EA) used in diagnostics. This occurs primarily in epithelial cells and in B cells as they undergo plasmacytoid differentiation.

**EPIDEMIOLOGY AND TRANSMISSION**

Virtually everyone becomes infected with EBV at some time during their life. In lower socioeconomic strata and developing countries, EBV infection occurs mainly during the first years of life and is usually subclinical. However, in developed countries, particularly in upper socioeconomic strata, only about 60% are infected before puberty. In these settings, infection often occurs in adolescence and early adult life, resulting in an infectious mononucleosis (IM) syndrome or atypical symptomatic infection in 23 to 89% of cases (10). As a result, by the age of 20 years ∼90% of individuals are seropositive, and by the age of 40 almost 100% of the population have seroconverted.

Transmission of EBV occurs primary through saliva exchange (3). Some investigators also believe that sexual
contact may be important (11, 12); however, recent evidence suggests that deep kissing associated with sexual activity is the more relevant transmission route (10). Contrary to previous beliefs, recent data generated using nucleic acid detection techniques (NAT) suggest that EBV shedding in saliva is continuous, persistent, and rapid in all previously infected subjects (3, 13). Therefore, use of saliva for the diagnosis of acute infections is discouraged. Although infection via blood products is theoretically possible, the importance of blood products as a source of EBV infection is uncertain, particularly in settings where blood products are universally leukodepleted.

Among immunosuppressed transplant recipients, latently EBV-infected cells transmitted with the donor organ or hematopoietic stem cells from seropositive donors to seronegative recipients are the most important source of infection in the early posttransplantation period.

EBV strains may be classified into types 1 and 2 (sometimes referred to as types A and B, respectively) based on the polymorphism of their EBNA genes. Prototypic viruses differ mainly in their nucleotide sequences for EBNA 2 and differ to a lesser extent in other EBNA proteins not routinely used in diagnostics. Since current immune inmunosassays (EIAs) predominantly use EBNA 1 antigen, strain differences might not be relevant for routine diagnostics. Both EBV types have a worldwide distribution, though they predominate in different geographical areas. Dual infections with the two types are not uncommon. In immunosuppressed individuals, coinfection with multiple strains of EBV has also been demonstrated (14).

CLINICAL SIGNIFICANCE

EBV is associated with a variety of disease states in immunocompetent and immunosuppressed individuals. Longitudinal studies with African children with acute EBV infection suggest that asymptomatic infection at a very early age (before 6 months) may be related to higher and more persistent viral loads in peripheral blood because of age-related immune immaturity; a relationship of early infection to risk for Burkitt’s lymphoma has been postulated (15). Passive maternal antibody may provide protection against infection very early in life, although the duration of that protection is uncertain (15).

IM is believed to be an immunopathologic disease with symptoms resulting from an exaggerated T cell response of a more mature immune system to a self-limited lymphoproliferative process and perhaps high viral loads (10). In this model, peak viral loads antecede clinical symptoms. In young adults with acute symptomatic EBV infection, EBV DNA (possibly representing virions) is rapidly cleared from plasma within a week of symptom onset, but EBV DNA in whole blood (perhaps representing episomal DNA in latently infected B cells) takes up to 200 days to clear to levels seen in healthy carriers (10, 16, 17). In vitro, acyclovir, ganciclovir, and foscarnet inhibit EBV replication (18–20). However, because IM appears to be an immune-mediated rather than a directly virally mediated disease, treatment of IM with antiviral agents results in termination of viral shedding but has no or only small effects on symptoms (21–24). A meta-analysis of five randomized controlled trials showed no significant benefit associated with acyclovir use for IM treatment (22). Antiviral therapy is therefore not recommended for treatment of IM. Steroids may be useful in severe complicated disease, including tonsillar enlargement threatening airway obstruction, autoimmune hemolytic anemia, severe thrombocytopenia, and aplastic anemia. Steroids have also been used by some investigators to treat EBV-associated neurologic and cardiac disease. Uncomplicated IM is generally treated with supportive treatment only. Trauma to the spleen is avoided, and acetaminophen and/or anti-inflammatory agents are used for pain and fever relief.

Symptoms vary from mild to severe, and recent data suggest that the initial viral inoculum, viral type (type 1 versus 2), and human leukocyte antigen (HLA) class 1 polymorphisms may be risk factors for symptomatic disease (25–27). The classical symptom triad of IM is fever, sore throat, and lymphadenopathy; symptoms and signs such as pharyngitis, tonsillitis, hepatitis, splenomegaly, and lymphocytosis with atypical lymphocytes are often present. Although rash in a variety of forms is seen in approximately 5% of IM patients, a pruritic maculopapular rash occurs almost universally in IM patients treated with ampicillin or amoxicillin. This antibiotic-associated rash is not predictive of future drug intolerance. The time between infection and symptoms is relatively long, at 30 to 50 days (28), and clinical disease generally persists for 1 to 4 weeks. However, protracted illness and postinfectious fatigue and/or depression for up to a year are not uncommon (29). Atypical presentations in which hematologic features such as anemia, including autoimmune hemolytic anemia thrombocytopenia, or neurologic conditions such as meningoencephalitis, radiculitis, or mononeuritis predominate can occur. These presentations may be the only symptoms or signs of acute EBV infection. When visceral organs are affected, almost any symptom resulting from inflammation of the affected organ may be seen. Death due to IM is rare but has been described; it occurs most often as a result of splenic rupture, airway obstruction, or neurologic complications. A severe and sometimes fatal complication of primary infection is hemophagocytic lymphohistiocytosis, a hemophagocytic syndrome characterized by exaggerated macrophage activation and phagocytosis of intracellular and extracellular cells. Extremely high levels of EBV DNA are observed in both peripheral blood mononuclear cells (PBMC) and sera of these patients (6, 30, 31). Atypical presentations, including acute cholestatic hepatitis sometimes misdiagnosed as acute cholecystitis, are common in older subjects (>40 years) with acute EBV infection (32). EBV is often reactivated in healthy individuals, but reactivation has not been associated with symptoms. It should also be noted that primary EBV infections cause only approximately 50 to 90% of mononucleosis syndromes (33). Other infectious agents, such as acute cytomegalovirus, adenovirus, Toxoplasma gondii, and human immunodeficiency virus (HIV), as well as lymphoma and autoimmune diseases can cause symptoms and signs similar to those seen in EBV-associated IM.

Chronic active EBV infection is a rare, severe (often fatal) EBV-associated condition most often described to occur in Japanese children; it is believed to be a precursor state for T/NK lymphoma (34). It is characterized by a clonal expansion of EBV-infected T cells and NK cells and a high viral load in both PBMC and serum and plasma. The EBV DNA in the latter is believed to be free DNA rather than virion associated. Patients often show atypical patterns of EA antibodies (6, 35–37). There is no proven role for acyclovir or ganciclovir therapy in this condition. Although chemotherapy and immunomodulatory therapy have been attempted as treatment, most cases are chemotherapy resistant. Hematopoietic stem cell transplantation (HSCT) is currently the preferred treatment option (37). EBV is associated with a variety of tumors primarily of lymphoid and epithelial origin, not related to obvious
immunosuppression. The EBV genome has been found in tumor cells in >95% of endemic Burkitt lymphomas and NPC, <5 to 70% of cases of Hodgkin’s disease (depending on the subtype), 2 to 16% of gastric adenocarcinomas, 40 to >90% of T/NK lymphomas (depending on the subtype), and 40 to 95% of lymphoproliferative-like carcinomas. The cause is unknown, and EBV is not a proven role for antiviral agents in the management of these malignancies; standard cancer treatment is used for management. Adoptive immunotherapy targeting specific EBV proteins expressed in some EBV-associated malignancies has been successfully used for some patients and is being explored further in clinical trials (38, 39).

X-linked lymphoproliferative syndrome is a rare hereditary immunodeficiency primarily involving the inability of T cells and NK cells to engage B cells (40, 41). Affected boys become symptomatic after exposure to EBV because of EBV’s exquisite tropism for B cells, developing acute fatal IM or lymphoproliferative disorders and/or dysgammaglobulinemia. Most patients have germ line mutations in the SH2D1A gene encoding the adapter molecule signaling lymphocytic activation molecule (SLAM)-associated protein; a subset of patients carry mutations in the X-linked inhibitor of apoptosis gene (XIAP) (42). Untreated, the disease is often lethal, and patients benefit from stem cell transplantation (43). The role of antiviral therapy early during acute EBV infection in these patients is uncertain; treatment with anti-CD20 antibody has been advocated by some investigators.

In immunocompromised patients, both primary infection and EBV reactivation can result in lymphoproliferative disorders. Posttransplant lymphoproliferative disorders (PTLD) represent a spectrum of disorders varying from benign polyclonal proliferations to true malignancies containing clonal chromosomal abnormalities. They are classified based on tissue pathology using a World Health Organization (WHO) lymphoma classification system of immunodeficiency-related lymphoproliferative disorders (44). PTLD are often extranodal, can be restricted to the allograft after solid-organ transplantation (SOT), and, unlike lymphoma in immunocompetent patients, can involve the brain in isolation or as part of multisystem disease. Principal risk factors are (i) EBV primary infection after transplantation in the setting of SOT and (ii) severe T cell depletion (e.g., after administration of T cell antibodies) in both SOT and HSCT settings (45–47). Although >90% of early (first posttransplant year) PTLD lesions after SOT have demonstrable EBV, >50% of late PTLD is EBV negative (48). The role of EBV in the pathogenesis of these late EBV-negative PTLD is uncertain. In many centers, EBV viral load measurements in peripheral blood have become standard of care aiding in the prevention, diagnosis, and management of PTLD (49–52).

EBV-related lymphomas are also common malignancies seen in HIV-infected and AIDS patients. Burkitt’s lymphoma, lymphomas of the central nervous system (CNS), and smooth muscle tumors are strongly associated with EBV (>95%) (53–55); the last are also observed in transplant recipients (56). Oral hairy leukoplakia, a white nonmalignant lesion of the lateral borders of the tongue observed in HIV patients and transplant recipients, is associated with lytic EBV infection and is responsive to antiviral therapy (57).

After routine implementation of EBV DNA measurement in peripheral blood, a number of investigators observed that some SOT recipients experiencing primary EBV infection or PTLD have sustained elevation of EBV viral load after asymptomatic infection or resolution of EBV disease or PTLD. These asymptomatic patients show a chronic viral load phenotype. Although a study in pediatric thoracic SOT suggests that 45% of patients with this phenotype developed late-onset EBV-positive PTLD at a median follow-up of 7 years (58), risks appear, in part, to be organ specific, with intermediate risks observed after intestinal SOT (59) and risks after liver SOT from the same center (60). However, even among recipients of specific allograft types, such as pediatric liver transplant recipients, reported long-term risks differ among centers (60, 61). Additional studies are required to determine allograft-specific long-term risks and the usefulness of ongoing viral load monitoring in this setting. This chronic load phenotype has also been observed in children and adults with HIV infection. Specific EBV “set points” for quantitative load in individual patients as well as in EBV infection of NK and T cells have been observed in this setting (62, 63). The pathogenesis of this EBV infection state is unknown.

The prevention and management of PTLD are complex, require a multidisciplinary team that includes transplant physicians, infectious disease specialists, virologists, and hematologists/oncologists, and have been reviewed elsewhere (52, 64). Approaches used include immune reconstitution by lowering immunosuppression and adoptive immunotherapy, the reduction of tumor burden by surgery or radiotherapy, and the use of chemotherapeutic agents, particularly anti-CD20 therapy (64, 65) and cytotoxic chemotherapy (52, 64).

Although antiviral drugs such as acyclovir/valacyclovir and ganciclovir/ganciclovir with or without intravenous immunoglobulin (IVIG) have been used to treat PTLD, there is no evidence to suggest that these agents impact clinical outcome. PTLD lesions, when clinically apparent, contain almost exclusively latently infected cells. Some investigators have proposed a novel oncolytic strategy of combining antiviral agents targeting the lytic EBV cycle with drugs, such as arginine butyrate and bortezomib, that induce EBV lytic replication in latently infected PTLD cells. This approach is currently being explored in research settings (52). On theoretical grounds, antiviral drugs and IVIG might have greater efficacy in preventing or modifying the course of primary or reactivation EBV infection early after SOT and HSCT in patients at high risk of donor- or community-acquired EBV infection. However, the use of prophylactic antiviral agents in these settings remains controversial. Although many SOT centers give antiviral agents, most often ganciclovir or cidofovir with or without IVIG, to EBV-mismatched patients (seropositive donor and seronegative recipient) during the initial months after transplantation, the benefit of this approach has not been proven. Reconstitution of the EBV-specific immune response is key to the management of PTLD and often initially involves reduction of immunosuppression (66). Adoptive immunotherapy using EBV-specific cytotoxic T cell therapies (using autologous and allogeneic T cells) has demonstrated efficacy in both disease prevention and treatment in pilot studies and small clinical trials, but regulatory issues, cost, and logistics currently restrict this approach to the research setting (67).

There is no approved vaccine against EBV. Studies of two different prototype vaccines showed that these vaccines failed to prevent EBV infection but were effective in partly preventing symptomatic disease (68–70).

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

For the rare circumstance where oropharyngeal viral excretion is studied, 5 to 10 ml of throat gargle, collected in
serum-free tissue culture medium or Hanks’ balanced salt solution, can be used. Approximately 5 to 10 ml of heparinized or EDTA blood is required for cell culture and detection of EBV-transformed B cells or for antigen detection in B cells by immunostaining or immunofluorescent in situ hybridization studies (see below). Blood specimens should be processed as soon as possible, although refrigeration for up to 24 h is acceptable for antigen detection. Fresh biopsy samples or thin cryosections (5 μm) are preferable to formalin-fixed material for antigen detection in tissues.

NAT are currently most frequently used to detect EBV in (i) blood, (ii) cerebrospinal fluid (CSF), and (iii) biopsy samples. The choice of sample matrix depends on the EBV-associated disease of interest and the clinical setting in which the test is being used (Table 1). For example, investigators have proposed sampling of PBMC in chronic active EBV infection (30), CSF in AIDS-related primary CNS lymphoma (71), and whole blood or plasma after transplantation (71–73). Plasma but not whole blood has been recommended as the preferred sampling matrix in IM (71–74) and in diseases in which malignant cells do not necessarily circulate in blood, such as NPC (75), nasal T/NK cell lymphoma (76), and Hodgkin’s lymphoma (77).

The optimal sample matrix for monitoring transplant recipients has not been definitively determined. There is currently no agreement on whether leukocytes, whole blood (in EDTA; heparin may inhibit the PCR), or serum and plasma should be used for EBV DNA detection for PTLD prevention and treatment monitoring. EBV DNA detection in leukocytes and whole blood has high sensitivity but lower specificity for PTLD risk prediction or disease detection, whereas the opposite holds true for cell-free specimens like serum or plasma. When serially monitoring patients at high risk to detect early infection or reactivation events, a sensitive but less specific matrix like whole blood may be preferable. In contrast, when used as a diagnostic test (single sample) for symptomatic patients in a population with a low prevalence of disease, a cell-free sample matrix is likely to be advantageous. For serial monitoring of individual patients, it is particularly important that the sample matrix is not varied. The sample quantity required varies, but it is advisable to provide at least 1 ml. Source blood specimens for serum or plasma or PBMC should be processed as soon as possible. If transport time is less than 24 h, samples may be kept at room temperature until separated. Separated materials can thereafter be stored at 4 to 7°C for a few days or frozen. Whole blood can be stored for a few days at room temperature or frozen without further processing. For long-term storage, freezing at −70°C is recommended. For detection of EBV in peripheral blood lymphocytes by DNA hybridization, 5 to 10 ml of heparin/EDTA blood is required.

Quantitative NAT (QNAT) of CSF has been used for the diagnosis of EBV-associated CNS disease, particularly lymphoma. CSF without additives should be sent, processed, and stored as described above for blood specimens being tested for EBV DNA by NAT; at least 0.5 ml should be submitted for testing when possible. Tissues (e.g., nasopharyngeal brushings for NPC) and biopsy samples to be examined for viral nucleic acids or antigens should be collected and refrigerated in saline or balanced salt solutions. Fresh or frozen samples are preferred. For patients with NPC, endoscope-guided nasopharyngeal brushings are an important sample matrix. A brush covered by a plastic catheter should be used to prevent contamination by cells from non-nasopharyngeal sites. The brush tip could be placed in transport medium and transferred immediately to the laboratory or stored at −80°C (78).

For antibody assays detecting heterophile antibody whole blood, serum or capillary fingertip blood may be used for most point-of-care tests. For EBV-specific tests, 50 μl or even less of acute-phase serum may be sufficient; however, it is advisable to provide 1 to 5 ml. Convalescent-phase serum collected 1 to 2 months after symptom onset may occasionally be required in cases with ambiguous results on initial testing. Plasma can be used, but serum is preferable. Serum can be stored at 5°C for several months. For long-term storage, freezing at −20°C or −70°C is recommended.

DIRECT DETECTION

Electron microscopy, virus isolation, and antigen detection by immunohistochemistry are primarily research tools. EBV DNA detection by molecular methods is the most common and often only method used for routine direct detection of EBV in tissue and other specimens in most clinical diagnostic laboratories.

Microscopy

Electron microscopy is not an appropriate diagnostic technique for EBV diagnosis, since most EBV-associated disease is associated with latent infection and virions are rarely present in sufficient quantity to be detected in either infected tissues or other sample matrices such as plasma, cells, or CSF.

EBV Antigen Detection by Immunohistochemistry and EBER by In Situ Hybridization

Antibodies specific to a wide range of EBV antigens have been used to detect EBV in tissue biopsy samples using immunohistochemical techniques. Studies using antibodies targeting EBNA 1, EBNA 2, LMP 1, LMP 2, BamHI H right-frame 1 protein (BHRF 1), BamHI Z left-frame 1 protein (BZLF 1), and BamHI M right-frame 1 protein (BMRF 1) (7, 79–82) have been described previously. EBNA 1 is the only antigen expressed in all EBV-infected cells expressing EBV proteins (cells with latency state other than latency state 0). However, the sensitivity of immunohistochemistry techniques for the detection of EBV-infected cells using currently available EBNA 1 antibodies is lower than that observed using in situ hybridization targeting EBER (7). EBER is present in high copy numbers in EBV-infected cells regardless of latency state. This has made its detection using in situ hybridization techniques ideal and the “gold standard” for detecting EBV-infected cells in tissues and tumors (83). Despite this, some authors report having documented EBER-negative EBV-infected cells (84).

The cellular tropism of EBV in the peripheral blood of patients with high persistent EBV viral loads is also being studied using assays that combine immunofluorescent staining for cell surface proteins (cell phenotyping) with fluorescence in situ hybridization using nucleic acid probes for EBER (85) or other targets (86). Detection can be performed on slides by microscopy or in suspension by flow cytometry. Preliminary studies report interesting observations of EBV infection in cells other than memory B cells in these patients (85, 86). These assays are not yet available in routine diagnostic laboratories.

Nucleic Acid Amplification Techniques

Molecular techniques are important tools for the detection of EBV in clinical specimens other than tissues. The choice of method and sample matrix is dependent upon the clinical question being addressed (Table 1).

Clinical diagnostic assays for direct detection of EBV DNA can be performed on a wide range of clinical specimens following DNA extraction. A variety of primers, probes, and techniques have been used. In general, quantitative viral load assessment is superior to qualitative detection. Although commercial assays are becoming increasingly available, many laboratories continue to use laboratory-developed tests (87, 88).

Assessment of viral load can be broken down into two basic strategies, based upon the genomic region being targeted. (i) The conserved BamHI W region, coding for a long internal repeat sequence of EBNA 1, is present in multiple copies (7 to 11 copies) in EBV-infected cells. NAT targeting this region have maximal sensitivity in clinical samples. (ii) The genes for LMP 1 or thymidine kinase or other parts of the EBNA 1 gene are often targeted for quantitative PCRs since these are single-copy regions (89). Some studies comparing assays using various EBV genome regions as NAT targets in parallel observed target-specific quantitative differences in results obtained for EBV viral load upon testing the same sample (90–93).

Gene targets that result in small amplicons may be more useful when measuring viral DNA in plasma samples, since EBV DNA in plasma is often free DNA, i.e., not encapsidated, and so may be highly fragmented (94).

Quantitative real-time PCR is the most popular currently used technology for measuring EBV viral load in patients at risk for EBV-associated disorders (88, 94, 95). Proficiency panel studies have demonstrated significant variability (4 log10) in both qualitative and quantitative reporting of EBV viral load results among laboratories, limiting the validity of interinstitutional result comparison (96). Proficiency panel results in both Europe (Quality Control for Molecular Diagnostics) and North America (College of American Pathologists [CAP]) have illustrated that for analytes assayed using NAT and reported quantitatively, interlaboratory variability is significantly reduced when an international reference standard is available and commercial assays calibrated to this standard are used. In October 2011, the WHO approved the first international standard for EBV (a whole-virus preparation of EBV B95-8 with a potency of 5 × 105 IU/ml) created by the National Institute for Biological Standards and Controls (United Kingdom). Quantitative standards traceable to this international standard should be used in all EBV NAT assays. For accurate quantitation, the standards should be extracted together with the clinical samples, in a matrix resembling the clinical sample. They should not be diluted in buffer, although the international reference standard is reconstituted in nuclelease-free water. It is hoped that the international reference standard will improve result harmonization. However, until this impact has been validated, interinstitutional result comparison requires formal cross-referencing of assays between institutions. Recent analysis of CAP proficiency testing results for EBV DNA suggests that calibrators are not the only issue preventing result harmonization. Commercial reagents and gene targets used also contribute to result variability (97). For more details on preferred sample matrix and detection methods, see Table 1.

Results should be reported in international units per milliliter. Normalization of viral load by using cell number or micrograms of DNA is generally unnecessary in routine diagnostics when testing samples of whole blood or CSF. Recent studies showed a close correlation between results reported in copies per milliliter and those reported as copies per microgram of DNA when testing whole blood. Similar dynamic trending in patients using both reporting formats was also observed, suggesting that normalization to cell number or genomic DNA in cellular specimens may also be unnecessary (98, 99). There is a strong correlation between viral load measured in PBMC, B cells, and whole blood. The correlation coefficient between results reported for plasma and other blood compartments (whole blood, PBMC, or B cells) is lower. Results from biopsy samples should be reported in international units per microgram of DNA; when coamplification of a cellular single-copy gene is performed, results should be reported as international units per number of cells.
The precision of EBV NAT assays is such that changes in values should be at least 3-fold (0.5 log_{10} copies/ml) to represent biologically important changes in viral replication. QNAT variability is greatest for low viral loads; thus, for viral load values at or near the limit of quantification, QNAT viral load changes may need to be greater than 5-fold (0.7 log_{10} copies/ml) to be considered significant.

Appropriate controls for extraction, contamination, and inhibition should always be included in the assays. Participation in external quality control programs is a mandatory requirement for all clinical diagnostic laboratories (for examples, see http://www.cap.org, http://www.QCMD.org, or http://www.instandev.de).

**ISOLATION AND IDENTIFICATION PROCEDURES**

EBV isolation is currently not routinely performed in diagnostic laboratories. Freshly fractionated human cord blood lymphocytes are inoculated with cell-free, filtered saliva or throat gargle specimens and monitored for 4 weeks (100). Individual viral isolates can be characterized by molecular techniques on the basis of polymorphism of the EBNA 1 and EBNA 3 genes. In addition, the sizes of many of the EBNA proteins (EBNA 1 to 6) are strain dependent. Each isolate induces a distinctive banding profile in Western blotting, thus allowing the fingerprinting or “EBNo-typing” of each virus (14). Direct sequencing of EBV isolates using next-generation deep-sequencing techniques is also being explored for strain typing directly from clinical samples (U. Allen, P. Hu, S. Pereira, J. Beyen, D. Ho, N. Khodai-Booran, T. Nalpathamkalam, and S. Read, presented at the International Congress on Oncogenic Herpesviruses and Associated Diseases, Philadelphia, PA, 1 to 4 August 2012). EBV strain typing and strain polymorphism studies may be important for improving our understanding of the epidemiology, biology, and immunology of EBV and to study potential associations between strains and disease states. However, presently there are no data to allow clear prediction of a patient’s clinical course or treatment outcome based on EBV strain polymorphisms (reviewed in reference 102). EBV genotyping is therefore not useful in clinical practice and is currently not performed in diagnostic laboratories.

**SEROLOGIC TESTS**

**Heterophile Antibodies**

Heterophile antibodies are not EBV specific. The test relies on the detection of antibodies reacting with erythrocytes of nonhuman animals that develop as a result of polyclonal B cell stimulation occurring in the setting of IM. Historically, sheep erythrocytes were used (Paul-Bunnell test) as assay targets, but these assays lacked sensitivity (103). Later, horse erythrocytes were used, and to improve specificity, the Davidsohn differential test was added. This test discriminates between the EBV heterophile response and the heterophile response seen in serum sickness and rheumatic diseases (targets the Forssman antigen). To exclude agglutination resulting from heterophile antibodies against the non-EBV Forssman antigen, in the Davidsohn differential test, these non-EBV-related heterophile antibodies are first removed by adsorption of serum with guinea pig kidney cells that express Forssman antigen. As an additional control, serum is also adsorbed with bovine erythrocytes not expressing the IM antigen. When the two adsorbed sera are then mixed with sheep or horse erythrocytes, stronger agglutination in the guinea pig-adsorbed serum indicates a positive result.

Latex agglutination tests using erythrocyte antigens are currently used for heterophile antibody detection and show a high degree of sensitivity (103). Although they are all intended for laboratory and point-of-care use, the agglutination assays may not be suitable for use by persons without laboratory training. Evaluation of a true positive agglutination result requires experience, since spontaneous agglutination will inevitably develop after some time. Immunochromatographic methods may therefore be easier to read and perform better than agglutination assays in point-of-care settings (103).

**EBV-Specific Antibodies**

Serologic testing using EBV-specific assays remains the method of choice for the diagnosis or exclusion of EBV infection (Table 2) (104, 105). The tests differ in (i) methods, (ii) antigens, and (iii) antibody isotypes tested for. Although immunofluorescence assays (IFAs) and blot techniques are more reliable, EIAs and chemiluminescence assays (CLIA) are used most frequently. At present, flow cytometry-based assays are used in some laboratories to detect EBV antibodies to different antigens (e.g., VCA, EA, and EBNA 1) at the same time, in a multiplex approach. In the case of unclear results, any of these methods may be supplemented by antibody testing. Traditionally, antibodies to three antigen complexes have been measured, including VCA, EA, and EBNA. In addition, different immunoglobulin isotypes (IgG, IgM, and sometimes IgA) can be detected. The large numbers of assays can lead to complex antibody patterns, making results difficult to interpret. When possible, kits from the same manufacturer should be used for detecting different markers in an individual patient. The antibody profile in a patient with suspected mononucleosis is presented in Fig. 1.

Immunofluorescence is still the gold standard for EBV serology, but it is labor-intensive and interpretation is subjective. On the whole, IFAs have fairly uniform performance characteristics, principally because suppliers use the same cell substrates. The performance of EIAs is much more variable, due to the plethora of antigen preparations used in the different kits. They range from cell extracts to recombinant or fusion proteins and synthetic peptides (104). This means that reference criteria established for interpretation of IFAs may not apply to all EIAs, even when the antigens are referred to by the same name. For example, EBNA is a complex of several large, native proteins detected in Raji cells by anticomplement immunofluorescence (ACIF); in EIAs, the same designation may be given to a single oligopeptide derived from EBNA 1 or an EBNA 1 recombinant protein. Recombinant proteins and peptides, however, are easier to standardize than cell-grown antigens, and assays using synthetic antigens will likely be more widely used in the future.

Recently, flow cytometry-based microparticle assays have become more popular since they allow parallel detection of different antigens. In theory, up to 100 uniquely identifiable fluorescently labeled microspheres can be detected with this technique, each particle coated with a different antigen (106–108). This approach combines the advantages of a complete antibody profile, like that of a blot, with a turn-around time of 1 to 2 h as well as a random-access feature. In addition to EBV-specific antigens, some assays also include heterophile antibodies or non-EBV antigens. However, specialized instruments are necessary for signal detection (e.g., xMAP system; Luminex, Austin, TX).
Moreover, rapid tests using immunochromatography (e.g., on strips) have been developed for EBV, enabling a fast diagnosis (less than 5 min up to ~20 min) from a single sample. These tests are particularly suited to point-of-care use (109).

Avidity testing, measuring the strength of antibody-antigen binding, is available for all methods, not only for EIA. It can be applied to differentiate between a primary infection (low avidity) and a past infection (high avidity). Avidity is calculated as the percentage of signal loss resulting from pretreatment of the serum with urea compared with a regular assay. These tests are used more often in Europe than in North America.

The main VCA is a 150-kDa protein, but the p18 and p23 proteins are also included in the VCA complex of proteins expressed in P3HR1 cells, and all three are used for serology. VCA EIAs using antigens from infected cells have been available for a long time, and assays using affinity-purified antigen still perform better than EIAs using recombinant or synthetic antigens (110). EIAs and line blots using recombinant VCA proteins (p23–p18) and peptide p18 reportedly give mixed results compared with IFA (110–113).

Moreover, rapid tests using immunochromatography (e.g., on strips) have been developed for EBV, enabling a fast diagnosis (less than 5 min up to ~20 min) from a single sample. These tests are particularly suited to point-of-care use (109).

Avidity testing, measuring the strength of antibody-antigen binding, is available for all methods, not only for EIA. It can be applied to differentiate between a primary infection (low avidity) and a past infection (high avidity). Avidity is calculated as the percentage of signal loss resulting from pretreatment of the serum with urea compared with a regular assay. These tests are used more often in Europe than in North America.

The main VCA is a 150-kDa protein, but the p18 and p23 proteins are also included in the VCA complex of proteins expressed in P3HR1 cells, and all three are used for serology. VCA EIAs using antigens from infected cells have been available for a long time, and assays using affinity-purified antigen still perform better than EIAs using recombinant or synthetic antigens (110). EIAs and line blots using recombinant VCA proteins (p23–p18) and peptide p18 reportedly give mixed results compared with IFA (110–113).

Anti-EA/D (diffuse distribution in cells) and anti-EA/R (restricted to cytoplasm) are antibodies traditionally measured with Raji cells activated to enter the lytic phase by phorbol ester or sodium butyrate. Ethanol fixation eliminates the EA/R complex; cells fixed in ethanol are used for studies of EA/D antibodies. Currently, separation of EA antibodies is rarely used for diagnostic applications. Tests using cell-derived and recombinant EA proteins are available but often lack both specificity and sensitivity (103, 114). Because of their high heterogeneity with respect to specific protein targeted and consequently their low comparability, EA assays are only rarely useful for the diagnosis of acute EBV infection. Furthermore, EA antibodies are present in a significant proportion of healthy blood donors and may thus be more problematic than helpful for diagnosis of acute EBV infection (115).

ACIF detecting not only EBNA 1 but also EBNA 2 is no longer used in routine diagnostics, since commercial EIAs
containing cell-derived EBNA or, even better, recombinant EBNA 1 (p72) are available and demonstrate high sensitivity (≥95%).

For the serologic diagnosis of EBV infection in the United States, EBV antibody panels of two, three, or four markers are commonly performed using EIA; IFA is less frequently used. Antibody panels can include VCA IgG and VCA IgM only; VCA IgG, VCA IgM, and EBNA IgG; or the last 3 antibodies plus antibody to EA. If an atypical pattern is observed (Table 3), repeating the EIA, testing by IFA, or repeat testing of a second follow-up blood sample in 1 to 2 weeks is recommended.

An alternative algorithm frequently used in Europe for serologic diagnosis is provided in Fig. 2. This cost-effective approach, stepwise analysis and data interpretation feature testing for EBNA in serum as the key initial step. This schema is feasible for assays with short incubation times and random access (e.g., microparticle multiplex assays). EBNA 1 IgG antibodies normally appear between 6 weeks and 7 months after onset of IM and should be negative in acute IM. They are maintained for life and are therefore a good marker of prior infection. However, in about 5 to 10% of patients, EBNA 1 IgG may be present in low titers or even undetectable (116). Increasing age, severe immunosuppression, or rheumatic disorders are often a reason for reduced or loss of EBNA 1 IgG titers. Diagnosis of primary EBV infections should not rely solely on the detection of VCA IgM, since both false-positive and false-negative results are possible. False positives result mainly from the presence of rheumatoid factor cross-reacting with other herpesvirus infections and antinuclear factors (117). False negatives may result from specimen collection in the window period prior to antibody development or insufficiently sensitive assays. False-negative results may also occur when the

| Table 3 | Typical EBV serological profiles using the most frequently employed antigens and Ig isotypes* |

| NPC | +++ | − | +++ | ++ | + | +/− |
| X-linked lymphoproliferative syndrome | +/− | − | − | − | − | − |

*+/−, antibodies absent or present; +, antibodies present; ++, antibodies present in elevated titers; ++++, antibodies present in strongly elevated titers. Antiprobative patterns include VCA IgM positive only, EBNA positive only, and VCA IgM and EBNA positive but VCA IgG negative. Antiprobative patterns merit repeat testing, testing of a follow-up sample, or testing by alternate methods.

*Primary infection with early detection of EBNA 1 IgG or primary infection with a prolonged detection of VCA IgM. The antibody titer might help to distinguish primary from past infection; e.g., a high IgM titer combined with a very low EBNA 1 IgG might be an primary infection, whereas a past infection might be more likely if EBNA 1 IgG is present at a high titer and VCA IgG has a low positive value. Additional methods are available to distinguish the two infections (see text).

bPrimary infection without VCA IgM or past infection with loss of EBNA 1 IgG. Depending on the time since exposure, VCA IgM may no longer be detectable in patients with symptoms of IM. Some patients with past infection lose EBNA 1 IgG over time.
specimen is collected late during a period after IgM has disappeared. In rare cases, immunoblotting including VCA p23, VCA p18, and EBNA 1 p72 may be performed (118). VCA p18 may be important since antibodies of the IgM class are detectable quite early during infection, whereas IgG antibodies are produced late (similar to EBNA 1 IgG) (104, 119). If EBNA 1 IgG and p18 IgG are negative, an avidity test for VCA IgG can be informative (118).

In the setting of NPC, different antibody isotypes (IgG and IgA) targeting a great variety of antigens, e.g., VCA and LMP 2 (120), LMP 1 (121), thymidine kinase (79), BamH1 Z-encoded EBV replication activator (ZEBRA) (122), EBNA 1 (123, 124), zta (123), or EA (125), have been studied for disease diagnosis and management.

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

Antibody assays are the method of choice for diagnosing acute EBV infection in immunocompetent hosts. NAT is discouraged in this setting, since EBV DNA may also be detected in healthy seropositive individuals (17, 126, 127). Recent studies suggest that EBV DNA is cleared rapidly from plasma (within 15 days of IM) (13) but persists significantly longer when measured in whole blood, with clearance from this matrix occurring in most subjects within 200 days (128). Detection of infection in young children (<12 months) in the presence of maternal antibody using serologic techniques is problematic. The use of NAT to document infection in this setting may be useful and requires further study (15).

Heterophile antibodies are a marker of IM but not necessarily of acute EBV infection. High levels of heterophile antibodies are seen during the first month of IM, normally followed by a rapid decrease. Low but persisting heterophile antibody titers can be found after primary EBV for up to 1 year, which can be misleading, and more importantly, heterophile antibodies can sometimes be found in an acute HIV infection, lymphoma, or infection with other infectious agents (e.g., cytomegalovirus, rubella virus, or Toxoplasma gondii) (129, 130). EBV-specific serology should always be performed in settings where the interpretation of a positive heterophile result is uncertain. False-negative heterophile antibody results (15 to 20%) are the rule among young children (103, 116, 131) but also occur for adolescents and adults, particularly when atypical clinical presentations are present. Thus, a negative heterophile antibody test should be supplemented with EBV-specific serology when EBV infection is suspected.

Because peak EBV viral load antedates the onset of IM symptoms, almost all IM patients have high titers of IgG to various lytic-phase EBV antigens (VCA and EA) but lack antibodies to the EBNA antigens (for details, see Fig. 1). The patient’s EBV status can generally be ascertained from a single serum sample by measuring VCA IgG, VCA IgM, and EBNA 1 IgG. In upwards of 90 to 95% of cases, the antibody profile is sufficiently distinct to determine whether the patient (i) is still susceptible to EBV, (ii) has a current primary infection, or (iii) has had a past infection (Table 3). The use of terminology such as “recent,” “convalent,” or “reactivated” infection, as suggested by some manufacturers in result reporting, is discouraged, since these diagnoses correspond to infection states in healthy individuals they are of limited clinical relevance when testing is performed for symptomatic patients. The exact antibody titers and the time needed to develop the complete antibody profile of past infection vary widely between individuals and do not correlate with severity of disease (128). Thus, quantitative measurement of antibodies is of limited usefulness in routine diagnostics (132).

In NPC serology, specifically VCA IgA, EA IgA, and EBV DNA in plasma or serum are established diagnostic and prognostic markers and are also used for screening in high-risk patients in areas of endemicity. Recently, data to support the important role of EBV viral load measurement in nasopharyngeal brushings for NPC case detection and management have been reported (78). EBV DNA in this setting acts as a tumor marker in plasma and exists as free nonencapsidated DNA (84). Viral load and serological markers are elevated in patients prior to the tumor becoming clinically apparent, during disease, and during recurrence. Reductions in viral load or antibody titers are a marker of effective therapy. In a recent analysis of long-term survival in patients treated for NPC, a higher relapse rate, a worse relapse-free survival rate, and poorer overall survival rate were observed in patients with higher pretreatment or persistently detectable posttreatment plasma viral loads (133). Viral load measurement is superior to serology in its prognostic value, especially for tumor recurrence (78, 125, 134). For example, DNA becomes rapidly undetectable within a few hours of tumor surgery (135), whereas serology follows the slower kinetics of antibody production and half-life.

In the setting of transplantation, EBV serostatus determination is required for risk stratification. Patients are considered seronegative if negative for both anti-VCA IgG and anti-EBNA IgG. Serostatus determination is problematic with young children and recently transfused patients because of passive antibody. In these settings, donors are considered seropositive and recipients seronegative for risk stratification purposes.

High viral load states often antedate symptoms and signs of EBV-associated PTLD occurring early after transplantation. Routine posttransplantation monitoring of EBV viral load has been recommended for PTLD prevention in high-risk settings such as when the donor is seropositive and the recipient is seronegative at the time of SOT (50, 52). Monitoring is combined with preemptive interventions that include reduction in immunosuppression with or without antiviral therapy after SOT (136, 137) and rituximab (CD20) therapy after HSCT (138). Reductions in the incidence of early EBV-positive PTLD have been reported by centers using this approach. However, quantitative viral loads that could be used as trigger points for intervention remain undefined at a global level because of lack of assay standardization and few natural history studies with sufficiently large patient populations. Trigger points may also vary by specimen type and patient group. Along with the absolute viral load, the kinetics of viral load increase may play an important role in defining risk.

In high-risk asymptomatic SOT recipients being serially monitored, the use of EBV viral load as a diagnostic test (i.e., levels above a specific quantitative threshold being diagnostic of PTLD) has good sensitivity for detecting EBV-positive PTLD but misses EBV-negative PTLD and some cases of localized and donor-derived PTLD. However, it has poor specificity, resulting in good negative (greater than 90%) but poor positive (as low as 28% and not greater than 65%) predictive values in these populations. Monitoring over the first year after transplantation after SOT and for the first 6 months after HSCT in high-risk populations is recommended in international guidelines (50, 52, 72, 73). There are insufficient data to support routine monitoring.
infection is lacking. The prevalence and quantitative levels of CNS involvement are seldom obtained; a gold standard for EBV detection in CSF has been extensively studied. Studies of this type are difficult to determine and have not been proposed as a marker of global immunosuppression (136, 139–141).

Formal evaluation of EBV NAT assays in peripheral blood as an adjunct diagnostic tool when used as a one-time test for patients presenting with symptoms or signs (usual mass lesions) and no history of recent or previous monitoring has not been carried out for populations at high risk for PTLD after SOT. In low-risk adult SOT recipients EBV seropositive before transplantation being investigated for signs and symptoms compatible with PTLD, high EBV QNAT lacked sensitivity, missing all cases of EBV-negative PTLD and some cases of localized EBV-positive PTLD, but was highly specific for EBV-positive PTLD (91). However, this study, carried out in an oncology practice, may have a referral bias and not reflect the broader use of these assays after SOT. Monitoring in plasma may have better specificity than whole-blood monitoring when used in this setting.

Data on the use of EBV NAT assays with peripheral blood to monitor PTLD treatment response and predict PTLD relapse are limited. A short-term fall and clearance of viral load coincident with clinical and histologic regression in response to interventions such as reduction of immunosuppression (142) and adoptive immunotherapy (143) have been observed in PTLD patients and patients with high viral load receiving preemptive therapy. In contrast, when rituximab was used, viral load measured in cellular blood components often fell dramatically and remained low even when disease progressed and relapsed (144, 145). In pediatric SOT patients, particularly those experiencing primary infection, asymptomatic intermittent or persistent viral load rebound occurs frequently with no short-term consequences (142). Adult PTLD patients have been observed to relapse in the presence of a persistently low viral load (144). There are some preliminary data to suggest that plasma may be preferable to whole blood when used to assess treatment response and predict relapse.

Testing of viral load in the CNS is often used to assist in the diagnosis of CNS lymphoma, particularly in immunodeficient populations, based on the observation that CSF EBV viral loads in patients with CNS lymphoma are higher than those seen in peripheral blood or may be detectable only in CSF (125, 146). However, the detection of EBV DNA in CSF has a poor positive predictive value for CNS lymphoma since it is has poor specificity (147–152). Use of quantitative levels may improve diagnostic specificity (150). Tissue diagnosis remains the gold standard for the diagnosis of CNS lymphoma, with the presence of EBV documented using immunohistochemistry or in situ hybridization in biopsy tissue. Although EBV detection in CSF is also used to diagnose EBV CNS disease in the setting of acute EBV infection in immunocompetent hosts, the sensitivity and specificity of both the qualitative and quantitative tests in this setting are difficult to determine and have not been extensively studied. Studies of this type are difficult to perform since brain biopsy and tissue confirmation of CNS involvement are seldom obtained; a gold standard for the diagnosis of EBV neurologic involvement during acute infection is lacking. The prevalence and quantitative levels of CSF EBV DNA observed in patients with acute EBV infection but without neurologic symptoms are also unknown since CSF is rarely collected in this setting. Low-level EBV DNA was detected in the CSF of patients without typical clinical symptoms in one study (147). At the present time, EBV neurologic disease associated with acute infection is a diagnosis of exclusion. The detection of EBV DNA in CSF can support but does not definitively confirm this diagnosis, particularly when at high levels relative to peripheral blood, in a patient with serologic evidence of acute EBV infection and self-limited neurologic symptoms or signs.

Patients with X-linked lymphoproliferative syndrome typically have high viral loads and do not develop EBNA antibodies. The definitive diagnosis of this condition requires genetic studies to detect specific associated hereditary mutations.

FUTURE PERSPECTIVES

Adjunctive laboratory testing may improve the specificity of high viral load as a predictor of PTLD. The best studied and most promising are assays measuring EBV-specific T cell responses using concomitant EBV-specific T cell enzyme-linked immunospot assay and tetramer assays (151–155). Although data suggest that the specificity and positive predictive value of EBV viral load can be significantly improved using these assays, they are complex, costly, and difficult to implement in a routine diagnostic laboratory (50, 52). Although further validation of their usefulness is required, some cytokine genetic polymorphisms have been correlated with development of PTLD in gamma interferon, interleukin-10, and transforming growth factor β genes.

A particularly interesting source of new EBV diagnostics involves the study of host and viral microRNAs (miRNAs), a class of recently identified small noncoding RNAs that are involved in gene regulation by inhibition of protein translation or mRNA degradation (156). Research with miRNAs has been particularly groundbreaking in hematologic malignancies. Several studies have confirmed that miRNAs play important roles in B cell differentiation and lymphoma pathogenesis and are prognostic for clinical outcome (157, 158). EBV encodes 44 mature miRNAs in two gene clusters, BHRF 1 and BART (BamHI A rightward transcripts), and viral and human miRNAs interact with each other in host gene regulation (159, 160). An advantage to the study of miRNAs is that due to their small size and molecular stability, they can be studied in formalin-fixed paraffin-embedded tissue used for diagnostic purposes and have been detected in plasma samples (161). Human and EBV miRNA profiles are being extensively studied in a number of EBV-associated malignancies to understand pathogenesis, develop new therapeutic targets, and tailor therapy and as prognostic markers (101, 162–165).

The viruses discussed in this chapter are human herpesviruses 6A and 6B (HHV-6A and HHV-6B), human herpesvirus 7 (HHV-7), and human herpesvirus 8 (HHV-8; also called Kaposi’s sarcoma [KS]-associated herpesvirus). These viruses cause diseases that are clinically significant primarily in small children and in immunocompromised patients (Table 1).

HHV-6

Taxonomy
HHV-6A, HHV-6B, and HHV-7 represent virus species in the Roseolovirus genus of the betaherpesvirus subfamily (1). Roseoloviruses share many features of their genomic architecture and genetic content, the ability to replicate and establish latent infections in lymphocytes, associations with febrile rash illnesses in young children and with a variety of neurologic disorders, and the ability to act as opportunistic pathogens in immunocompromised patients. For convenience, we frequently refer to HHV-6A and HHV-6B collectively as HHV-6.

Description of the Agent
HHV-6 virions consist of four concentrically arranged major components: a double-stranded DNA genome (160 to 170 kb) within the core of an icosahedral capsid surrounded by a proteinaceous tegument, all of which is surrounded by a lipid bilayer envelope that is studded with a variety of viral and cellular proteins. The viral genomes carry approximately 100 unique genes.

Epidemiology and Transmission
Epidemiology
Collectively, HHV-6A and HHV-6B are highly prevalent (>90% seroprevalence) (2). Most individuals become infected by the age of 2 to 3 years (3). In the United States, Japan, and Europe, HHV-6B is the main source of nearly universal early childhood HHV-6 infections, and HHV-6A prevalence in these areas may exceed 50% by adulthood. In Zambia, HHV-6A was detected in >85% of asymptomatic infants, suggesting significant international differences in the epidemiology of the HHV-6 variants (4).

Tissue Distribution
The cell surface receptor for HHV-6A is CD46, and that for HHV-6B is CD134 (5). HHV-6B DNA has been detected in as many as 90% of peripheral blood mononuclear cell (PBMC) specimens, >80% of brains, >90% of tonsils (in epithelial cells of tonsillar crypts), and 40 to 90% of oral fluid and nasal mucus specimens; it has been detected less frequently in skin, lungs, endomyocardial biopsy specimens, goblet cells and histiocytes of the large intestine, cervical fluids, and ocular aqueous humor. During primary infection in young children in the United States, HHV-6A was found by PCR in 2.5% of PBMC and 17% of cerebrospinal fluid (CSF) specimens, while HHV-6B was found in 99% of PBMC and 86% of CSF specimens (some specimens were coinfected) (6). The median salivary viral level of HHV-6 increased from approximately 10^3 copies of HHV-6/ml at 1 week postinfection to 10^5 copies of HHV-6/ml by 8 weeks postinfection (3). HHV-6A DNA has been detected in over half of lung and skin specimens, mostly in conjunction with HHV-6B. HHV-6 can use the olfactory pathway for entry into the central nervous system (7). Among adult brains, 28% were positive for HHV-6A and 75% for HHV-6B (some were dually positive) (8). For bone marrow transplant recipients, HHV-6A and HHV-6B were both detected in plasma, while HHV-6B was the variant detected in PBMC (9).

Latency, Persistence, and Transmission
Other than during the acute phase of roseola, HHV-6 can seldom be detected by culture, even though its DNA can be detected intermittently in PBMC from most children by PCR, and transcripts can occasionally be detected in asymptomatic children (~1% of specimens) (10). This suggests that a true latent infection is established in PBMC. Latent HHV-6 has been detected in monocytes, their CD34+ bone marrow progenitors, and PBMC-derived dendritic cells. HHV-6 DNA is more frequently detected in salivary glands than in saliva, in contrast with HHV-7, which is frequently detected in both the gland and the fluid. HHV-6B primary infection typically occurs within a matter of months of the waning of maternal antibody, with transmission likely being via saliva (11). Breast milk is not a significant vehicle for transmission. Little is known of HHV-6A transmission.

A small percentage of individuals (0.5 to 1%) harbor germline chromosomally integrated HHV-6A or HHV-6B genomes (ciHHV-6) at a chromosomal telomere, so all of their cells are positive for viral DNA (12), which may be a source for the occasionally detected persistence of high
levels of HHV-6 DNA in serum (13) as well as for congenital transmission of HHV-6 (14, 15).

**Clinical Significance**

While infections with HHV-6 are generally mild or subclinical in immunocompetent individuals, they can be severe in immunocompromised persons. Many of the more severe presentations have neurologic components.

**Primary Infection**

HHV-6 primary infection causes roseola (also called roseola infantum, sixth disease, and exanthem subitum) in approximately a quarter of children. While HHV-6B is the predominant etiologic agent of roseola, rare cases of HHV-6A-associated roseola or febrile illness have been reported. About 90% of children are symptomatic at the time of primary infection, with specifically associated symptoms including fever (58%), fussiness (70%), rhinorrhea (66%), diarrhea (26%), rash (31%), and roseola (24%) (3).

Classic roseola symptoms include an abrupt rise in temperature (39 to 40°C), which persists for 2 to 5 days. Fever abatement coincides with onset of a maculopapular rash (only rarely vesicular) (Fig. 1) which resolves in 1 to 3 days. Initial appearance of the rash is on the neck, behind the ears, and on the back, followed by spread to the rest of the body, usually excluding the face and distal extremities. The illness lasts 2 to 7 days, usually with no sequelae. Other clinical symptoms may include palpebral edema and suboccipital, postauricular, and cervical lymphadenopathy prior to rash onset.

Primary HHV-6 infection may also present as fever without rash or rash without fever. Less common but more severe forms of primary HHV-6 infection may include fever of >40°C, respiratory tract distress, tachypnea, inflammation, diarrhea, and convulsions. Although seizures are rare for HHV-6 primary infections, such infections, with or without clinical roseola, account for a significant proportion of febrile seizures in young children (16, 17). Other serious but rare complications reported for HHV-6 primary infections include hepatosplenomegaly, Gianatti-Crosti syndrome (an acrodermatitis of childhood that has also been associated with hepatitis B virus and Epstein-Barr virus [EBV] infections), bulging fontanels, aseptic meningitis, encephalitis (perhaps 1% of meningitis and encephalitis cases) (16), seizures and poor neurologic outcomes following congenital infection, and disseminated fatal infection.

Primary HHV-6 infection in adults is rare but can be severe. Clinical presentation in these cases may include a mononucleosis-like illness, prolonged lymphadenopathy, and fulminant hepatitis.

Immunocompromised Patients
In immunocompromised patients, such as transplant recipients or AIDS patients, HHV-6 can reactivate, sometimes causing disease. HHV-6 reactivation along with human cytomegalovirus (HCMV) reactivation can potentially exacerbate the severity of disease (18).

Transplant Recipients
HHV-6 reactivation occurs in approximately half of hematopoietic stem cell transplant (HSCT) recipients and a third of solid organ transplant (SOT) recipients (2, 19, 20). There appears to be a temporal pattern of HHV-6, HHV-7, and HCMV reactivation for SOT recipients, with the median times posttransplantation being 20 days, 27 days, and 36 days, respectively (2). Coinfections with these viruses do not affect the HCMV response to ganciclovir or valganciclovir (21).

HHV-6 is a consistent, low- to moderate-frequency contributor to posttransplant illness that can sometimes be severe, and its activity might be both a marker of and contributor to immune suppression (22). In HSCT and stem cell transplant (SCT) recipients, HHV-6 has been associated with encephalitis/encephalopathy, pneumonitis, delayed engraftment, erythematous papular rash, fever, CMV-like disease, graft-versus-host disease, seizures, hepatitis, diarrhea, and bone marrow suppression (reviewed in references 2, 23, and 24). In SOT patients, HHV-6 has been associated with encephalitis, pneumonitis, graft-versus-host disease, fungal disease, and bone marrow suppression. HHV-6B is detected more frequently than HHV-6A in transplant patients. However, HHV-6A viremia was more frequent than HHV-6B viremia in Hungarian renal transplant recipients (25). In one study, HHV-6A partitioned into plasma and HHV-6B into both plasma and circulating lymphocytes (9), suggesting that studies focused on one or the other of these compartments may have missed part of the story.

ciHHV-6 may contribute to clinical outcomes in transplant patients, but further study is required (26).

HIV-Infected Patients
Although HHV-6 infects and replicates in CD4+ T cells and there is evidence for possible pathogenic interactions, no specific role has been established for HHV-6 in AIDS pathogenesis.

Infections in the Brain
HHV-6 can grow in neuronal cells, and neurological symptoms are clearly associated with primary infection. HHV-6 encephalitis occurs during primary infection and reactivation, with slightly different disease characteristics (27). HHV-6 activity is associated with post-HSCT acute limbic encephalitis (PALE) (20), epileptic encephalopathy following PALE (28), and delirium and cognitive decline (29).

The involvement of HHV-6 in multiple sclerosis is not conclusive (30). However, the more precisely linked the specimens have been to diseased tissue (e.g., microdissected lesions versus cerebrospinal fluid versus serum), the stronger the associations have been.

There are conflicting data with respect to the association of HHV-6 with progressive multifocal leukoencephalopathy (31, 32).

Other
DIHS
Exposure to various drugs occasionally results in a severe and sometimes fatal reaction variously known as drug-induced hypersensitivity syndrome (DIHS), drug rash with eosinophilia and systemic symptoms (DRESS), and anticonvulsant hypersensitivity syndrome (33). HHV-6 reactivations have been identified in a number of DRESS cases, but it remains to be seen whether HHV-6 contributes to either initiation or exacerbation of the events.

Rosai-Dorfman Disease
Rosai-Dorfman disease (histiocytosis with massive lymphadenopathy) patients have had increased HHV-6 antibody titers, HHV-6 DNA detected by in situ hybridization, and strong immunohistochemical (IHC) staining for HHV-6 antigen in abnormal histiocytes.

HT
Hashimoto’s thyroiditis (HT) is an autoimmune disease mainly affecting women. A statistically significantly higher prevalence and viral load of HHV-6A in thyroid fine-needle aspirates was found for HT patients than for controls, along with higher natural killer cell activity and T-cell responses to HHV-6-infected thyroid cells (34). In addition, natural killer cells from HT patients had increased activity toward HHV-6-infected thyroid cells, and HT patients showed enhanced T-cell responses to HHV-6 antigen compared with controls.

Cardiomyopathy
HHV-6B antigens and DNA have been detected in damaged cardiac tissues of patients with acute and chronic cardiomyopathies (35).

Other Diseases
There is no conclusive evidence for causal associations between HHV-6 and malignancy or chronic fatigue syndrome.

Therapy
Antiviral treatment of HHV-6 has been reviewed in depth (2). No antivirals are licensed for treatment of HHV-6, but approaches such as those for HCMV have been used. In a study of HHV-6 and HHV-7 coinfections, antiviral therapy for HCMV had no discernible effect on HHV-6 or HHV-7 DNA loads (21). The clinical circumstances in which antiviral intervention for HHV-6 might be appropriate include HHV-6 reactivation in immunocompromised individuals (20). It is important to distinguish ciHHV-6 from HHV-6 reactivation for consideration of antiviral therapy in patients with clinical symptoms compatible with HHV-6 activity (12). Artesunate has anti-HHV-6 activity in vitro and was reported to effectively treat a case of HHV-6B-associated myocarditis (35).

Collection, Transport, and Storage of Specimens
Saliva specimens can be collected for virus detection by various methods, including filter paper strips (36), oral swabs, throat swabs, and expectorated saliva collection. Plasma should be separated from cells shortly after collection to avoid false-positive results for individuals with ciHHV-6 due to release of cellular DNA. Serum, plasma, and cells intended for PCR can be shipped frozen.

Direct Examination
Direct detection of HHV-6 can be done by IHC (37, 38), in situ hybridization, and in situ PCR (39, 40) (Tables 2 through 4). While those methods have their niches, the most common method of direct detection is PCR. The sensitivity of PCR is of particular value for the detection

Isolation Procedures

HHV-6 can be isolated from patient PBMC by cocultivation with stimulated human umbilical cord blood lymphocytes (47–49), but virus culture is not used for routine clinical diagnostics.

Identification

HHV-6 virions have typical herpesvirus morphology by electron microscopy, i.e., approximately 200-nm spherical enveloped virions containing a 90- to 110-nm icosahedral capsid with an electron-dense core surrounded by an amorphous tegument (1). Numerous monoclonal antibodies (MAbs) are available (both commercially and from research laboratories) that react with HHV-6A and/or HHV-6B (50).

Typing Systems

HHV-6A and HHV-6B can be typed through the use of species-specific MAbs and species-specific PCR assays (Table 2). For purposes of patient management and treatment, differentiation of HHV-6A and HHV-6B is not essential, but use of assays that discriminate between HHV-6A and HHV-6B serves the purpose of better understanding the clinical manifestations of these viruses. Typing systems are typically based on primer binding regions that are highly conserved between HHV-6A and HHV-6B, with an intervening region that can be targeted by probes specific for one or the other virus.

Serologic Tests

Numerous serological methods for detecting HHV-6 antibodies have been described, and commercial reagents are
available. These serological methods are useful for diagnosis of primary infections but are of very limited utility for identifying HHV-6 reactivations. Recent versus past infections can be discriminated through the use of immunofluorescence-based antibody avidity tests (51). Maturation from low- to high-avidity HHV-6 antibody following primary HHV-6 infection takes approximately 5 months. Antibody avidity testing can also be used to differentiate between HHV-6 and HHV-7 primary infections. Neutralizing antibodies typically become detectable 3 to 8 days following the onset of fever during primary infection.

Specificity issues for HHV-6 serological methods involve cross-reactivity between HHV-6A, HHV-6B, HHV-7, and CMV (23, 51). A recently described assay appears to distinguish between HHV-6A and HHV-6B antibodies (52). The simultaneous rise in antibodies to both HHV-6 and HCMV seen in some patients may be due to various combinations of simultaneous activity of both viruses and responses to cross-reactive antigens. There is some cross-reactivity between HHV-6 and HHV-7 antibody responses; adsorption methods and antibody avidity tests can be used for differentiation (51).

Antiviral Susceptibilities

The highest in vitro antiviral sensitivities and selectivities have consistently been seen for foscarnet, cidofovir, and ganciclovir. Mutations in the HHV-6 U69-encoded protein kinase or the HHV-6 DNA polymerase gene (U38) can cause HHV-6 resistance to these drugs (53, 54). HHV-6 antiviral susceptibility testing is not generally available, but molecular genotyping can be accomplished by PCR-based methods (55). Ganciclovir-resistant HHV-6 has been reported in posttransplantation cases, but it is rare (56).

Evaluation, Interpretation, and Reporting of Results

Laboratory diagnosis of HHV-6 is challenging given the many biological and molecular similarities among HHV-6A, HHV-6B, and HHV-7, the association between CMV and HHV-6 reactivation, the need to differentiate between primary and reactivation diseases, and the issue of chromosomal integration of HHV-6 (12, 51). In the absence of a simple “gold standard,” clinical virology laboratory methods for these viruses must be evaluated thoroughly in the relevant clinical context (e.g., febrile and/or rash illness in children under 3 years of age and specific forms of disease in immunocompromised individuals, such as transplantation patients) to assess sensitivity, specificity, and positive and negative predictive values.

For routine testing, serology has value only for the diagnosis of primary HHV-6 infections in children under 3 years of age with symptoms characteristic of roseola. In such situations, (i) IgM-positive serology, (ii) low-avidity IgG serology, or (iii) IgG seroconversion or a significant rise in titer between acute- and convalescent-phase sera can be considered confirmatory for primary HHV-6 infections (51). Quantitative PCR-based approaches can be used for detection of both primary infections and reactivation of HHV-6.

HHV-6 PCR diagnostics are confounded by the presence of cHHV-6 in 1% of individuals, which results in exceptionally high HHV-6 DNA loads in their PBMC (~1 copy per cell equivalent of DNA). Individuals with cHHV-6 can harbor 5 log_{10} HHV-6 genomes/ml in serum and >6 log_{10} HHV-6 genomes/ml in whole blood, whereas much lower viral loads are seen in non-cHHV-6 active and reactivated HHV-6 scenarios (57, 58). Quantitative PCR-based assays can help to differentiate between latent or reactivated HHV-6 and cHHV-6. HHV-6 DNA levels of >5.5 log_{10} genomes/ml in whole blood should be evaluated further for cHHV-6 (12). Droplet digital PCR is well suited for this purpose because it enables precise ratiometric comparison between HHV-6 and cellular genomes, with ratios of 1.0 (most common), 2.0, and sometimes 3.0 indicating cHHV-6 (59). Whole blood or PBMC are recommended for quantitative PCR because HHV-6 DNA in plasmas of individuals with cHHV-6 may be a product of lysed PBMC rather than circulating HHV-6 virus indicative of active infection (60).

Confirmation of HHV-6 in encephalitis cases requires detection of HHV-6 in the CSF and low levels of viral DNA in serum or whole blood. Simultaneous detection of HHV-6 in CSF and high levels of viral DNA in serum or whole blood is indicative of cHHV-6 and is not diagnostic for HHV-6 encephalitis (51).

Clinical testing for HHV-6 should be limited to circumstances for which there has been a well-characterized association between the disease and HHV-6 infection and when the results of a given test will be diagnostically informative. Such scenarios include primary infection in children under 3 years of age, primary infection or reactivation in immunocompromised individuals, such as AIDS patients or transplantation patients, mononucleosis-like syndromes, and meningitis/encephalitis cases. Ljungman et al. (61) provided useful recommendations for HHV-6 diagnostics post-SCT, including for HHV-6 encephalitis. It is still relevant that in some patients the HHV-6 infection has been identified as the cause of rash illness incorrectly diagnosed as measles virus infection. The possibility of primary HHV-6 or HHV-

7 infection should be considered when febrile and/or neurologic illness occurs shortly following routine immunizations; such illness may be incorrectly attributed to the vaccine (51). Further studies are needed to improve our understanding of the associations between HHV-6 and disease and to improve the quality of HHV-6 diagnostic testing.

HHV-7

Taxonomy and Description of the Agent

Because of the relative similarities of its nucleotide sequences, genomic architecture, and biology to those of HHV-6A and HHV-6B, HHV-7 is included as a member of the Roseolovirus genus of the betaherpesvirus subfamily (1). HHV-7 virions consist of four concentrically arranged major components: a double-stranded DNA genome (145 kb) contained in the core of an icosahedral capsid surrounded by a proteinaceous tegument, all of which is surrounded by a lipid bilayer envelope that is studded with several cellular proteins. HHV-7 genomes carry approximately 100 unique genes.

Epidemiology and Transmission

Epidemiology

HHV-7 seroprevalences in healthy adults in Europe, Japan, and the United States range from 60 to 90%. Following waning of maternal antibody, HHV-7 seroprevalence rapidly increases to over 50% by 2 years of age and then progresses toward the adult level over the remaining years of childhood.

Tissue Distribution

Although the in vitro host range of HHV-7 is restricted to lymphocytes, the virus has a broad cellular host range in vivo. One of its cellular receptors is the lymphocyte antigen, CD4; other receptors must be involved in the infection of other cell types. HHV-7 lytic antigens have been detected in salivary gland acini, lungs, skin, and mammary glands and, more sporadically, in the liver, kidneys, and tonsils (62). HHV-7 DNA has been detected by PCR in PBMC, salivary glands, gastric mucosa, skin, cervical swabs, and bronchoalveolar lavage samples. The virus has seldom been detected in brain tissues. Infectious HHV-7 has occasionally been isolated from PBMC during roseola and is easily isolated from the saliva of healthy adults. The ability to detect HHV-7 DNA in uncultured lymphocytes by PCR, along with the inability to detect infectious virus in the absence of T-cell activation, suggests that the virus is latent in PBMC. Macrophages represent another potential reservoir (63).

Transmission

HHV-7 can be cultured from the saliva of ~75% of healthy adults, with viral loads frequently exceeding 6 log10 genomes per ml. While the most plausible route of transmission is via saliva, HHV-7 has also been detected in breast milk, urine, and cervical secretions. In contrast to the case of HHV-6, congenital transmission of HHV-7 has not been documented (64).

Clinical Significance

Primary Infection

HHV-7 causes perhaps 5% of roseola cases, as well as other febrile illnesses in children. In one small study, HHV-7 appeared to cause milder roseola than that with HHV-6 in terms of mean and maximum fever, fever duration, and duration of rash. However, other studies suggested an equal or higher rate of central nervous system complications during HHV-7 primary infections than during HHV-6 infections (16). HHV-7 neurologic involvement includes hemiplegia and febrile seizures, including prolonged seizures that manifest as febrile status epilepticus (17).

Immunocompromised Patients

HHV-7 becomes latent in lymphocytes following primary infection and can reactivate in immunocompromised hosts, such as transplant recipients and AIDS patients. In bone marrow, liver, and renal transplant patients, simultaneous CMV and HHV-7 activities have sometimes been associated with clinical events (see corresponding HHV-6 section above), and a case of fatal HHV-7-associated encephalitis has been reported, but overall, HHV-7 infections are not frequent contributors to posttransplantation illness.

Like HIV, HHV-7 uses CD4 as its major cellular receptor. In vitro, HHV-7 can inhibit HIV infection, possibly due to receptor interference. There is no clear evidence of a role for HHV-7 in AIDS progression.

Other HHV-7 DNA was detected more frequently and at higher loads in affected tissues from nonimmunocompromised patients with intestinal pneumonia (65, 66). Further study will be required to fully evaluate the significance of this observation.

Data for an association between HHV-7 and pityriasis rosea are inconclusive (67, 68).

HHV-7 DNA was detected in CSF from a neurosarcoidosis patient, in a lymph node from a Kikuchi’s disease patient, and in Grave’s disease patients, with uncertain clinical significance.

Therapy

HHV-7 antiviral sensitivities are similar to those for HHV-6 and CMV, with ganciclovir, foscarnet, and cidofovir being more much inhibitory than acyclovir (69). Drug-resistant HHV-7 has not been identified, but given the widespread use of ganciclovir for therapy of CMV and “CMV disease,” it will likely occasionally emerge. Therapeutic regimens have not been defined; for transplant recipients, they may ultimately be linked to strategies for dealing generically with betaherpesvirus activity.

Collection, Transport, and Storage of Specimens

The methods described above for HHV-6 are appropriate.

Direct Examination

By electron microscopy, HHV-7 virions have appearances typical of herpesviruses. MAbs are available upon request from some research laboratories (70). The most widely used qualitative PCR primer set for HHV-7 was described by Berneman et al. (71); others have also been described, but their performances have not been compared. Real-time PCR methods for HHV-7 have been described (42, 72), including multiplex assays for detection of multiple herpesviruses (41, 42) (Tables 2 to 4).

Isolation Procedures

HHV-7 isolation can be accomplished by using methods similar to those for HHV-6. HHV-7 isolates initially propagated in primary cell culture or previously adapted
HHV-7 strains (e.g., strain SB) can be grown in SupT1 cells in a manner similar to propagation of HHV-6 in continuous cells. Although culture of HHV-7 is possible, it is not of practical utility for clinical diagnostics (48).

**Identification**

The PCR methods described above provide sensitive, specific, and rapid ways to unambiguously identify the virus. MAbs can be useful for IHC analysis of tissues.

**Typing Systems**

Biologically meaningful subtypes of HHV-7 have not been identified.

**Serologic Tests**

HHV-7 serologic assays include neutralization tests, immunofluorescence, immunoprecipitation, immunofluorescence assay (IFA) (using commercially available reagents), and enzyme-linked immunosorbent assay (ELISA) (reviewed in reference 70) (Tables 2 to 4). In one comparison of IFA, immunoblots, and ELISA, the overall performances of the three assays were quite similar, with a small sensitivity advantage for the ELISA and a specificity advantage for the immunoblot assay (73). As described above, antibody avidity testing for both HHV-6 and HHV-7 allows differentiation between HHV-6 and HHV-7 primary infections as well as recent and past HHV-7 infections (51).

**Antiviral Susceptibilities**

Antiviral susceptibilities have been evaluated by measuring inhibition of viral replication by immunofluorescence, by use of antigen slot blots, and by inhibition of virus-induced cytopathicity (69), but these tests are not available for routine clinical application.

**Evaluation, Interpretation, and Reporting of Results**

There are no circumstances that warrant routine single-agent monitoring for HHV-7 activity, but its inclusion in multiplex assays may prove to be of value for monitoring children with suspected encephalitis and/or febrile convulsions (especially in association with recent vaccination) (16) and for monitoring transplant recipients. As for HHV-6, there is no universal “gold standard” for diagnosing HHV-7 infection. The main issues for HHV-7 diagnostic testing are distinguishing HHV-6 from HHV-7, differentiation of primary HHV-7 infection from reactivation, and distinguishing latent and active infections. Differentiating HHV-6 from HHV-7 can be done both by molecular diagnostics (e.g., PCR) and through the use of specific antibodies.

### HHV-8

**Taxonomy**

HHV-8 is a member of the Rhadinovirus genus of the gamma-herpesvirus subfamily. Gammaherpesviruses, which include EBV, are characterized by being able to replicate and establish latency in lymphoblastoid cells.

**Description of the Agent**

HHV-8 virions consist of four concentrically arranged major components: a double-stranded DNA genome of 165 kb that is contained in the core of an icosahedral capsid surrounded by a proteinaceous tegument, all of which is surrounded by a lipid bilayer envelope that is studded with virally encoded proteins and some cellular proteins. HHV-8 genomes encode ~80 proteins and 12 microRNAs (74).

**Epidemiology and Transmission**

Epidemiology

HHV-8 seroprevalences range from <10% in most of Europe, the United States, and Japan to >50% in much of Africa (75). Seroprevalences are ~30% to 50% in men who have sex with men (MSM) in the United States and Europe. At least four major HHV-8 genotypes are in global circulation (76).

Tissue Distribution

In the absence of KS, HHV-8 DNA or antigens are seldom detected in seropositive immunocompetent individuals, most frequently in the saliva of HIV-negative MSM (77). In HIV-positive MSM, viral DNA can be detected in essentially all KS lesions, >50% of saliva or oral fluid specimens, ~30% of PBMC specimens, ~10% of semen specimens, and less frequently in other types of specimens. The virus is capable of replicating in many cell types, including CD19-positive B cells in AIDS patients, placental tissues (78), and circulating endothelial progenitors during classic KS (79).

Latency and Persistence

Evidence for persistence of HHV-8 in immunocompetent individuals comes from seropositive organ transplant recipients who subsequently developed KS (80). The virus is relatively quiet in immunocompetent individuals, inducing low antibody titers, producing low viral loads, and infrequently causing disease. In vivo, the virus can establish latency in CD34+ and CD19+ cells. HHV-8 latency has been studied extensively in cell culture systems that employ primary effusion lymphoma (PEL) cells, in which most cells harbor the virus in a latent state. Lytic replication can be induced by agents such as phorbol esters or the HHV-8 ORF50 lytic inducer gene. A subset of HHV-8 genes are transcribed during latency, including the ORF73 gene (encoding the major latency-associated nuclear antigen 1 [LANA-1]), v-cyclin, and the highly expressed K12 gene (74).

Transmission

Most HHV-8 transmission is probably via oral fluids but may also occur via breast milk and semen. In Africa, the virus is typically acquired in a maternally linked manner early in life. Although not the major route, HHV-8 seropositivity is linked to sexual risk factors among adolescents with high-risk sexual behaviors and among MSM (81, 82). The virus can be transmitted via injection drug use and by blood transfusion (83, 84).

**Clinical Significance**

Primary Infection

Little is known of primary HHV-8 infection. HHV-8 DNA has been detected in febrile children in areas where the virus is endemic. Among HIV-negative MSM, diarrhea, fatigue, localized rash, and lymphadenopathy were sometimes noted in association with primary infection (85). In immunocompromised patients, HHV-8 primary infection was associated with KS, fever, arthralgia, lymphadenopathy, splenomegaly, and cytopenia (86, 87).

KS

All four major forms of KS are associated with HHV-8: (i) African endemic KS, which primarily affects children; (ii)
Mediterranean or classic KS, which affects older men from Mediterranean Europe who have no known immunologic dysfunction; (iii) transplant-associated or idiopathic KS, which affects approximately 1% of SOT recipients in the United States; and (iv) AIDS-associated KS, which is the most aggressive form of KS. The importance of immune deficiency in KS is indicated by the >1,000-fold higher KS incidence in HHV-8-seropositive individuals who are immunocompromised. KS incidence has declined but has not been eliminated since the advent of highly active antiretroviral therapy.

KS is a reactive angio proliferative disease characterized by reddish brown plaque or nodular lesions on the skin of the trunk or the extremities, in the oral cavity, and on internal organs. The disease can be disfiguring, disabling, and life-threatening and has elevated mortality in HIV-infected patients when accompanied by immune reconstitution inflammatory syndrome. KS lesions are characterized by networks of vascular slits, spindle-shaped cells of endothelial origin, extravasated red blood cells, and purplish deposits of hemosiderin. HHV-8 is present in the spindle cells, lyrically in a small percentage and latently in the remainder.

PEL

PELs are a rare (approximately 3% of AIDS-related non-Hodgkin’s lymphomas) but frequently aggressive subset of body cavity-based lymphomas with a median survival of <6 months (88, 89); they are most common in HIV-infected young or middle-aged men. PELs are lymphomatous effusions in body cavities, occasionally disseminate beyond the cavity of origin, and have cell morphologies between those of large-cell immunoblastic lymphoma and anaplastic lymphoma. PEL cells express CD45 and associated antigens and have clonal immunoglobulin rearrangements suggesting a B-cell origin, but they seldom express B-cell antigens. PEL cells harbor HHV-8 in every cell, express LANA-1, and are frequently infected with EBV.

MCD

Multicentric Castleman’s disease (MCD) is a multicentric angiofollicular expansion of plasmablastic cells in germinal centers of lymph nodes (90, 91). Systemic manifestations include fever, fatigue, recurrent lymphadenopathy, hepatosplenomegaly, bone marrow plasmacytosis, and polyclonal hypergammaglobulinemia. HHV-8-associated MCD occurs predominantly in HIV-infected individuals and has a poor prognosis. HHV-8 is present in scattered B cells in the mantle zone of germinal centers, interleukin-6 is activated, and EBV coinfection is uncommon.

Disease in Transplant Recipients

Organ transplant recipients are at risk for developing KS (92), with the risk being highest in regions with a high HHV-8 seroprevalence. In most cases, the disease is from reactivated prior infection, but graft-derived infections are common. In renal transplant recipients, parenchymal KS infiltration has led directly to marrow aplasia with plasmacytosis, fever, splenomegaly, cytopenia, marrow failure, graft failure, and disseminated KS (93). PELs have been reported following cardiac transplants, as has donor-derived fatal disseminated KS in liver transplant recipients.

Other Diseases

Multiple HHV-8-associated cellular proliferations can occur simultaneously in the same individual (e.g., KS plus MCD plus PEL), even in the same lymph node. HHV-8 has been associated with several other diseases, including angioimmunoblastic lymphoproliferative disease, oral plasmablastic lymphomas, prostate cancer in some populations, and some cutaneous disease.

Therapy

An important form of KS therapy in immunocompromised patients is immune reconstitution, i.e., highly active antiretroviral therapy for patients infected with HIV and tapering of immunosuppressive regimens (for example, by changing from calcineurin inhibitors to inhibitors of mammalian target of rapamycin) for organ transplant recipients. When such approaches are not possible or are ineffective, surgical removal, cytotoxic and tissue-destructive regimens, and immune enhancement by alpha interferon can be attempted (93–95). In cell culture, HHV-8 is exquisitely sensitive to cidovir and is also sensitive to ganciclovir and foscarnet. Although oral ganciclovir can suppress oral ulcers induced by the therapeutic effects of these agents have been equivocal in small trials. Nonetheless, in large retrospective analyses, foscarnet or ganciclovir used for controlling other herpesvirus infections has been associated with a lower KS risk, possibly due to these agents being more effective for prevention than for treatment of KS.

PEL and MCD are rare, and there have been no controlled therapeutic trials. Anti-CD20 MAb (rituximab), ganciclovir, and high-dose dexamethasone therapies have improved survival for MCD patients (90). PEL is refractory to conventional systemic cytotoxic chemotherapy, but responses have been seen to bortezomib, rituximab, and combined treatment with pleurodesis and bleomycin (74, 89).

Collection, Transport, and Storage of Specimens

Conventional methods can be used for collection and storage of serum or plasma for serology and for preparation of lymphocyte DNA for PCR. Oral fluids can be collected for PCR by the methods described above for HHV-6. Biopsy specimens are used for pathologic analyses that may include hematoxylin-and-eosin-stained cytopathic examination, PCR for total DNA extracted from a section, in situ PCR, or IHC. Standard methods can be used for the preparation of such specimens.

Direct Detection

KS can readily be distinguished from its mimickers, such as benign vasculoproliferative lesions and tumors that have a prominent spindle cell component, by IHC employing a MAB to HHV-8 LANA-1 (encoded by ORF73) and by heat-based antigen retrieval methods (96) (Tables 2 to 4).

Numerous systems have been described for quantitative PCR, which is used for epidemiology, monitoring of virus loads, and diagnosis of unusual cases and has possible applications in clinical trials (Table 2). Because of the low frequency of circulating HHV-8-infected lymphocytes and the low viral copy number in latently infected cells, important variables for PCR amplification from blood specimens include the number of cells in the initial lysis sample and the total quantity of resulting DNA included in the PCR mixture (44). Plasma and serum are both suitable for evaluating viremia in patients with HHV-8-associated lymphoproliferative diseases (97). A kit for simultaneous detection and quantification of HCMV, HHV-6, HHV-7, and HHV-8 (Argene 69-102B; bioMérieux, Verniolle, France) had a sensitivity of 96% in comparison to in-house assays (41).
Isolation Procedures
Reliable systems have not been developed for primary culture of HHV-8 from KS lesions. Ascitic fluids from PEL patients have been used to derive PEL cell lines.

Identification
HHV-8 is readily identified by PCR, hybridization with nucleic acid probes that target abundant transcripts, and use of MAbs. By electron microscopy, HHV-8 virions have a morphology similar to that of other herpesviruses (Table 2).

Typing Systems
HHV-8 genotyping is based predominantly on the sequence of the highly variable K1 gene sequence (76). HHV-8 genotypes have been associated with the global migration of the virus in association with human migration but have not been associated specifically with any of the major forms of the disease or conclusively associated with pathogenic variation.

Serologic Tests
Serologic testing is the best way to identify HHV-8-infected individuals from single specimens. It has potential application in matching organ donors and recipients in areas where HHV-8 is endemic, as well as for enrolling HHV-8-seropositive individuals in studies of KS prevention.

Latent versus Lytic Antigens
EBV and HHV-8 share the following two biologic properties relevant to their serodiagnosis: (i) in vitro, they maintain their latent state in circulating lymphocytes; and (ii) in vitro, they are propagated in cell lines in which the virus is present in a latent form in >95% of cells but in which the lytic cycle can be induced by treatment with an inducer, such as a phorbol ester. In addition to LANA-1, useful serologic antigens include the latently expressed viral cyclin, encoded by ORF72, and the lyrically expressed antigens encoded by ORF65 and K8.1.

Serologic Assays
IFAs can be sensitive and specific but have a low throughput. ELISAs can have a high throughput but have not been as sensitive for detecting serologic responses in immunocompetent individuals.

The two main varieties of IFA in use for detection of HHV-8 antibodies are based on (i) uninduced PEL cell lines that target LANA-1 and (ii) lytically induced PEL cell lines. LANA-1 fluorescence is restricted to the nucleus, while lytic fluorescence is predominantly cytoplasmic. Most laboratories use serum dilutions in the range of 1:40 to 1:100 for IFA. In addition to PEL cell lines that express complex mixtures of HHV-8 antigens, IFAs have been developed based on single defined antigens expressed via recombinant Semliki Forest viruses, as well as multiple defined antigens expressed via baculoviruses (98). The most widely used HHV-8 ELISAs are based on purified virions, purified baculoviral ORF65, and synthetic peptides based on ORF65 and K8.1 sequences (99, 100). These assays enable high-throughput and objective evaluation of individual specimens relative to a defined cutoff but are less sensitive than lytic IFA. A system has been described that employs transfection of mammalian cells with luciferase-linked antigens, with detection based on chemiluminescence from immunoprecipitates (101). A neutralizing antibody assay based on inhibiting infectivity of a recombinant HHV-8 strain that has been engineered to express green fluorescent protein in infected cells was used to demonstrate the potential importance of neutralizing antibody titers in preventing KS (102). Little attention has been paid to serologic methods for identifying and discriminating recent from past infections, such as detection of IgM or antibody avidity.

Sensitivity, Specificity, and Interassay Agreement
Established assay cutoffs and assessing the specificity and sensitivity of HHV-8 serologic assays have been complicated by several issues that revolve around the problem of unambiguously identifying individuals who are truly positive or negative for the virus. Healthy blood donors are often defined as HHV-8 negative, although some of them are likely to be positive for the virus, and KS patients are frequently regarded as truly positive, even though some may be seronegative. Most tests identify >95% of specimens from KS patients as being positive, and most identify >90% of European and U.S. blood donors as being negative. In-house assays have often performed well in comparison to commercial tests, and there has been little agreement about which blood donor specimens are positive (100, 103).

Antiviral Susceptibilities
Antiviral susceptibilities of HHV-8 are commonly measured as a function of the extent of DNA replication inhibition, for example, through the use of quantitative PCR (104).

Evaluation, Interpretation, and Reporting of Results
We anticipate an expanded role for clinical microbiology and pathology laboratories in the management of HHV-8-related illness. Many individuals at risk for HHV-8 infection and associated disease are under ongoing clinical scrutiny as part of managing their HIV infection, and our understanding of the utility of various virologic and immunologic markers as prognostic indicators is expanding. In addition, consideration is being given to whether donors and recipients should be matched with respect to HHV-8 status or whether the HHV-8 status of transplant recipients should be monitored to allow for heightened surveillance for KS and other HHV-8-associated diseases.

KS
While KS is often diagnosed on the basis of clinical or histologic presentation, as mentioned above, LANA-1-based IHC is important for establishing a definitive diagnosis of KS. An area of active research is identification of markers for progression to KS. The major risk identified thus far is being dually positive for HHV-8 and HIV.

PEL and MCD
PCR can be useful for initial screening of suspected cases. More definitive diagnosis requires analysis of biopsy specimens or cell smears with a method such as virus-specific IHC (74).

FUTURE DIRECTIONS
HHV-6, HHV-7, and HHV-8 cause clinically relevant infections that require accurate clinical and laboratory diagnosis. However, this need is generally confined to restricted populations, such as organ transplant recipients or individuals infected with HIV, and these infections occur at frequencies that have limited the development of convenient licensed commercial assays. Thus, we anticipate continued use of in-house assays that are available only from reference laboratories or in research settings. In such environments,
standardization can be improved through the use of shared reference materials and interlaboratory comparisons. Multiplex PCR systems that include testing for these viruses are coming into wider use. This places an additional responsibility on clinical virologists to ensure that test interpretation is done in the context of what is known of the biology of these viruses.

Adenoviruses
MARCELA ECHAVARRIA, CHRISTINE ROBINSON, AND RANDALL T. HAYDEN

In 1953, Rowe and colleagues described an "adenoid degeneration agent" that induced spontaneous deterioration of tissue cultures prepared from adenoids of children (1). In 1954, Hilleman and Werner cultivated a similar agent from military recruits with respiratory illnesses and called it RJ-67 (2). The two viruses were subsequently shown to be related, and in 1956 the term "adenovirus" (AdV) was proposed to acknowledge their initial source. Epidemiologic studies soon identified the virus as a major cause of acute respiratory disease (ARD) and ocular and gastrointestinal disease. In the mid-1960s, adenoviruses were found to cause tumors in rodents, prompting studies that revealed fundamental processes of molecular biology but failed to link the virus convincingly to human cancer. More recently, adenoviruses have generated considerable interest as vectors for gene delivery and as emerging human pathogens.

TAXONOMY

Human adenoviruses belong to the Adenoviridae family, Mastadenovirus genus. Seven species (A through G) have been recognized by the International Committee on Taxonomy of Viruses (ICTV) based on immunologic, biologic, and genetic properties (3) (Table 1). Species B is further subdivided into species B1 and B2. Within each species, there are many serotypes, which are defined by neutralization and hemagglutination (HA) assays using specific antisera. To date, 51 serotypes are widely accepted, while it is still controversial whether AdV serotype 52 is a simian or human strain (4). Recently, additional new "putative types" have been described by means of sequencing and genomic data analysis. Some of these new types (AdV 53, 55, and 56) are intertypic recombinants (5). Whether the latter represent truly new viruses that should be given their own type designations or rather simply result in different serologic properties (6). Genome types are designed with lowercase letters after the numbered serotype (e.g., adenovirus serotype 7h or 7p). The reference prototype is denoted by the letter "p." Intrasppecies recombination resulting in intermediate strains with hexon sequences of one serotype and fiber sequences of another serotype has been described (7).

DESCRIPTION OF THE AGENT

Adenoviruses are large, nonenveloped, icosahedral viruses 70 to 90 nm in diameter (Fig. 1). Each particle consists of a single, linear, double-stranded DNA molecule of about 36 kb that encodes approximately 40 genes. The DNA is covalently attached to a terminal protein at both 5' ends and encased by core proteins. A viral protease is also present. Seven structural proteins form the capsid. The major capsid proteins are the hexon, penton base, and fiber. The capsid is formed primarily by 252 capsomeres consisting of the 240 hexons that form the 20 triangular faces and 12 pentons, one at each of the 12 vertices. Each penton consists of a base and a fiber, a rod-like projection of variable length with a terminal knob which interacts with cellular receptors. The hexon has antigenic sites common to all human adenoviruses, but these sites reside within the capsid, so neutralizing antibodies are not induced. Hexons also contain the ε determinant, which induces serotype-specific neutralizing antibodies. The fiber has mostly serotype-specific antigenic determinants and some species specificity. The knob region of the fiber includes the γ determinant, which is responsible for HA in vitro.

Productive infection begins by attachment of the viral fiber knobs to cell surface molecules, such as the coxsackie adenovirus receptor, although most species B viruses and certain species D viruses use CD46 or sialic acid. The specificity of this interaction is an important determinant of tissue tropism. Following secondary interaction of capsids with integrins, particles are internalized by endocytosis and are transported to the nucleus, where viral transcription and DNA replication initiate. Viral structural proteins synthesized in the cytoplasm likewise migrate to the nucleus, where the particles assemble and aggregate, forming large crystalline arrays (Fig. 2A). Productive infection results in 10,000 to over a million viral particles per cell, only 1 to 5% of which are infectious.

Latent infection is not well understood. Early studies showed latency mostly associated with species C adenoviruses in the mucosal T lymphocytes of tonsils and adenoids of asymptomatic young children. More-recent work has

Evidence of a wider spectrum of viral species and has demonstrated viral genomic material in gastrointestinal-associated lymphoid cells (8). Similar reservoirs may exist elsewhere in the body. The highest quantities of viral DNA are detectable in the tissues of young children, suggesting that virus stores may decline with age (9). In contrast, little or no viral DNA is detectable in the circulating white blood cells of healthy individuals (10, 11).

EPIDEMIOL了Y AND TRANSMISSION
Adenovirus infections are common and ubiquitous. About half of the known serotypes cause disease. Adenoviruses are responsible for 1 to 5% of respiratory infections overall but induce 2 to 24% of all respiratory infections and 5 to 15% of all acute diarrheal illnesses in children and 30 to 70% of all respiratory illnesses in unvaccinated new military recruits.
Most infections occur in the first few years of life, and about half are asymptomatic. By the age of 10, most children have been infected with one or more serotypes. Coinfection with different serotypes and different species is documented, especially when different body sites are sampled (12). The incidence of infection is highest in crowded closed settings, such as day care centers, boarding schools, geriatric facilities, military training camps, and hospitals. Intrafamilial infections are common. There is no obvious difference in susceptibility by gender or ethnic group. Infections occur worldwide, with some differences in serotypes associated with various syndromes in other parts of the world.

Adenovirus infections can be epidemic, endemic, or sporadic, with the pattern of circulation, specific syndrome, and severity varying by serotype, population, and route of exposure. Sporadic infections occur year-round. Respiratory infections are most often associated with species B, C, and E, with serotypes 1, 2, 5, and 6 causing endemic infections and serotypes 4, 7, 14, and 21 causing small epidemics mostly in winter to early summer. A survey of U.S. isolates conducted in 2004 to 2006 identified the most common serotypes as 3, 2, 1, and 5, with an increasing amount of serotype 21 (13). Epidemics of severe respiratory disease in U.S. military recruits typically occur in the winter and spring. Historically, serotypes 4 and 7 were the most common cause. Serotype 4 now predominates, with lesser amounts of species B serotypes 7 and 21 detected. The emerging serotype 14 was also identified (13, 14). Serotype 14 has also caused clusters of severe disease and fatalities among civilians in several states. A novel genome type (serotype 14α) is the apparent cause (15). Large epidemics of keratoconjunctivitis are caused mostly by serotypes 8, 9, and 37. Smaller outbreaks of serotypes 3, 4, and 7 occur in the summertime and are associated with contaminated swimming pool water. Adenovirus-associated gastroenteritis is caused primarily by serotypes 40 and 41, which are also known as the “enteric adenoviruses.” These infections are endemic globally and occur year-round.

Adenovirus infections in persons with primary or acquired immunodeficiencies, but the most frequent and severe infections are associated with hematopoietic cell transplantation (HCT) and solid-organ transplantation (SOT). HCT recipients have the highest incidence of infection (up to 30%) and highest morality rates (exceeding 80% in some studies) (17). Risk factors for serious disease in this population include young age, allogeneic transplantation, T-cell depletion, graft mismatch, cord blood transplantation, and severe graft-versus-host disease (18). Infections with species A to F (mostly species C and A) are described, and mixed or sequential infections with different serotypes are common (19). Data for SOT recipients are more limited (20), but this group generally experiences fewer and milder infections than HCT recipients. The lowest incidence is for renal transplant patients, who tend to acquire species B adenoviruses of serotypes 7, 11, 34, and 35. Adenovirus infections can be problematic in lung, small bowel, or liver transplant recipients and lead to graft dysfunction (or loss) and fatalities. In the pantrivial era, mortality rates as high as 53% were reported for young liver transplant patients with adenovirus disease. Most infections are with species C viruses, and serotypes 1, 2, and 5 are the most common. Transplant patients can acquire adenovirus as a result of endogenous reactivation of the virus from recipient or donor tissue, as well as from the community or hospital (21). Transplantation of adenovirus-positive donor tissue into a negative recipient confers a higher risk than if both parties are either negative or positive. Adenoviruses once caused many serious infections in human immunodeficiency virus/AIDS patients, mostly with species D serotypes rarely identified or problematic in other settings (22). The introduction of highly active antiretroviral therapy has dramatically reduced the incidence of such infections in this population.

Transmission is primarily by the respiratory or fecal-oral route. Airborne transmission occurs by small droplets and, to a lesser extent, large-droplet aerosols. Fecal-oral spread probably accounts for the majority of enteric adenovirus infections. Adenoviruses are also spread by contaminated fomites, fingers, and liquids, such as aphthous ulcers and sewage. Preceding eye trauma facilitates infection and the spread of keratoconjunctivitis in environments with high levels of airborne particulates. The infection’s spread among new military recruits may involve direct contact as well as aerosol exposure via ventilation systems. Stress and fatigue may be contributory host factors in this setting. The mean incubation period for most respiratory tract infections is 5-6 days, and that for gastroenteritis is 3 to 10 days (23).

Transmission is facilitated by adenoviral resistance to chemical decontaminants and physical treatments. Stability of particles in gastric secretions, bile, and pancreatic proteases also permits passage through the stomach, followed by replication in the intestine. The prolonged period of virus shedding from various body sites aids transmission as well. Length of shedding varies by serotype, body site, patient age, and immune status. In general, nonenteric adenoviruses are shed for several days by adults with upper respiratory tract infections, for a few weeks after ocular infections, and for 3 to 6 weeks from the throat or stool of children with respiratory or generalized illness. Infected children may excrete the virus initially from the respiratory tract and later from the gastrointestinal tract. Excretion in stool can be intermittent and prolonged for 18 months or longer after recovery (24) (although the possibility of serial reinfection cannot be ruled out in all cases). In contrast, enteric adenoviruses are shed for only a few days after recovery. Immunocompromised individuals shed adenovirus longer than immunocompetent individuals.

**CLINICAL SIGNIFICANCE**

The spectrum of adenovirus-associated disease is broad due to the many serotypes and their tissue tropisms (Table 2). Clinical manifestations also depend on the age and immune status of the infected person. Most infections affect the respiratory tract, eye, and gastrointestinal tract, with lesser involvement of the urinary tract, heart, central nervous system, liver, pancreas, and genital tract. Solid-organ involvement and disseminated disease are seen primarily in immunocompromised patients.

Most respiratory tract infections occur early in life and are self-limited and mild. usual signs and symptoms are fever, nasal congestion, coryza, pharyngitis, cervical adenopathy, and cough, with or without otitis media. An exudative tonsillitis clinically indistinguishable from infection with group A streptococcus has been described. A pertussis-like syndrome has been reported, although adenoviruses are more likely to be copathogens or to reactivate in this syndrome than to be a significant cause. The role of adenoviruses in asthma remains controversial (25). Adenoviral lower respiratory tract infections, such as bronchiolitis, bronchitis, croup, and pneumonia, can be severe and sometimes fatal, particularly in young children less than 2 years of age. Long-term sequelae of these lower respiratory tract

Infections are frequent in some populations (26). Higher morbidity is reported for serotypes 5 and 21 and other genome types, such as 4a and 7h, and when extrapulmonary manifestations occur (13, 27).

Frequent outbreaks of adenovirus-associated ARD in young military recruits were noted beginning in 1953. Symptoms included febrile cold-like illness, pharyngitis with tonsillitis, bronchitis, and pneumonia. Hospitalization rates were as high as 50%, and some fatalities occurred. Live, oral adenovirus vaccines directed against serotypes 4 and 7, the most common serotypes involved at the time, were introduced for this population in 1980 and significantly reduced disease. In 1996, vaccine production lapsed, and outbreaks occurred in civilians. Reintroduction of vaccine (again to serotypes 4 and 7) has been problematic and involves a broader array of serotypes (13). In particular, serotype 14 has been associated with numerous outbreaks in recent years among both military recruits and the general population. Interestingly, serotype 4 has been an uncommon cause of respiratory disease in civilians. Reintroduction of vaccine (again to serotypes 4 and 7) to the military occurred in 2011.

Ocular adenovirus infections are common. The most frequent manifestation is acute follicular conjunctivitis, which is usually superficial and resolves without consequence in a few weeks. Pharyngoconjunctival fever is a follicular conjunctivitis accompanied by upper respiratory tract symptoms, fever, and occasionally lymphadenopathy, pharyngitis, and malaise. Epidemic keratoconjunctivitis is a more serious infection that starts with conjunctivitis but progresses to painful edema of the eyelids, sometimes followed by corneal erosions and infiltrates. Symptoms may resolve in 2 weeks, although reduced vision, photophobia, and foreign-body sensation may persist for months to years. Epidemics of acute hemorrhagic conjunctivitis similar to those caused by enterovirus are also described.

The enteric adenoviruses 40 and 41 are a common cause of viral gastroenteritis in children less than 2 years old (Table 2). Diarrhea is usually watery and nonbloody, lacks fecal leukocytosis, and lasts a mean of 10 days, which is somewhat longer than diarrhea due to rotavirus (28). Mild fever, vomiting, and abdominal pain can occur, and respiratory symptoms are sometimes present. Most immunocompetent patients recover uneventfully, although infants with ileostomies or colostomies can have prolonged symptoms, and rare fatalities have been reported for immunocompetent patients. Gastrointestinal syndromes associated with nonenteric adenovirus infections include intussusception, acute mesenteric lymphadenitis, and appendicitis.

Clinical manifestations of adenovirus in immunocompromised patients depend on the individual’s underlying disease or transplanted organ, patient age, and serotype involved (16). Infections in transplant patients can involve the graft or other organ systems. Presentations in HCT patients most often include hemorrhagic cystitis, pneumonia, hepatitis, enteritis, and disseminated disease. Fatalities are most frequent in patients with pneumonia or disseminated disease. In liver transplant patients, infections are most often associated with jaundice, hepatomegaly, and hepatitis, with pneumonia and diarrhea in some patients. Enterocolitis, with occasional spread to the liver, occurs in intestinal transplant recipients. The major clinical presentation in renal transplant patients is acute hemorrhagic cystitis and, to a lesser extent, pneumonia. However, recent work
has reported systemic involvement with graft dysfunction (29). Infections of the graft in lung transplant recipients can result in necrotizing pneumonitis, leading to respiratory failure and progressive graft loss. Bronchiolitis obliterans can be a late consequence. In the post-highly active antiretroviral therapy era, clinical manifestations in patients with human immunodeficiency virus/AIDS are uncommon until the immune system deteriorates. AIDS patients have presented with adenovirus-associated pneumonia, meningoencephalitis, and hepatitis as well as generalized disease. Symptoms of hemorrhagic cystitis in immunocompromised patients can be especially severe and may signal the start of disseminated disease (30).

Less common clinical manifestations include exanthems, neonatal disease, which can be severe and frequently fatal, neurologic manifestations, such as meningoencephalitis and encephalitis, acute myocarditis in otherwise healthy persons or associated with graft rejection in cardiac transplant patients, macrophage activation syndrome, and genitourinary disease, including genital lesions and urethritis. The role of adenoviruses in fetal demise remains unclear. Adenovirus type 36 has recently been linked to obesity (31), although this association remains controversial. Some adenovirus infections resemble Kawasaki disease, but adenovirus has also been described concomitantly with Kawasaki disease, and so one should be cautious when making these diagnoses (32).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS
Adenoviruses are best detected from affected sites early in the course of illness. Suitable specimens vary with the clinical syndrome and test requirements (Table 2). Collection of cell-rich specimens usually results in the highest sensitivity. Flocked nylon swabs (Copan Diagnostics, Murrieta, CA) have shown excellent yield compared to those from cotton swabs or nasopharyngeal aspirates for the detection of respiratory viruses, including adenovirus (33–35). When a deep-seated infection is suspected and tissue from the affected site is unavailable, collection from multiple sites (e.g., respiratory, stool, and urine) or blood is recommended.

Recovery is best if specimens are kept cold (2 to 8°C), transported, and processed as described in earlier chapters. Suitable viral transport media can be laboratory prepared or purchased from commercial sources. Some commercial formulations, such as MicroTest multimicrobe medium M4RT (Remel, Lenexa, KS) or universal transport medium UTM (Copan), preserve infectivity for prolonged periods at room temperature and are also suitable for detection of viral antigen or DNA (36). If plasma or serum samples are being tested, they should be separated within several hours of collection. Specimens, virus isolates, or DNA extracts can be frozen at −70°C indefinitely, with minimal loss of activity. Long-term storage in self-defrosting freezers and repeated freeze-thaw cycles ultimately reduce infectivity and degrade adenovirus DNA. Such conditions are not recommended for storage of any clinical specimens.

Adenoviruses are highly resistant to inactivation by chemical and physical treatment. Most serotypes are stable for a week at 36°C, for several weeks at room temperature, and for several months at 4°C. Infectivity is retained for several weeks on paper or in saline and for over a month on nonporous surfaces. Strict adherence to conventional safety practices, such as the use of personal protective equipment and biologic safety cabinets, disinfection of work surfaces, and hand washing, minimizes laboratory infections. Avoid hand-to-eye or hand-to-mouth contact due to the affinity of adenoviruses for mucosal and ocular tissue. Treatments that eliminate infectivity include a 1:10 dilution of household bleach (0.5% sodium hypochlorite) for 30 min, heating surfaces to 56°C for 30 min or 60°C for 2 min, and autoclaving. Serotype 4 is especially heat resistant. Alcohol-based hand gels can destroy infectivity, although several minutes of contact may be required for some products. Variable disinfection is achieved with povidone-iodine, formaldehyde, and UV light. Viral DNA can be detected long after loss of infectivity.

DIRECT DETECTION
Microscopy
Adenovirus-infected cells can be visualized by light microscopy as “smudge cells” in hematoxylin-and-eosin- or Wright-Giemsa-stained tissues, fluid sediments, or cultures. Smudge cells are large late-stage-infected cells containing solitary, central, basophilic nuclear inclusions composed of adenoviral particles (Fig. 2A). Other types of inclusions have been described as well (37). Adenoviral inclusions can be mistaken for those of cytomegalovirus, herpes simplex virus, or polyomavirus. Further identification by immunohistochemistry or in situ hybridization is recommended to avoid misdiagnosis (38, 39). The characteristic morphology of adenovirus particles permits their detection by electron microscopy (EM) without need for further identification. Particles, often in large crystalline arrays, can be visualized in the infected cells by transmission EM (Fig. 2A). The large quantity of virus (10⁶ to 10⁹ particles/ml) in the stools of children with acute diarrhea (Fig. 2B) also permits detection by direct EM (40). The sensitivity of direct EM can be increased by ultracentrifugation, by immunoelectron microscopy using antihexon antibodies, or by a special ultracentrifuge rotor (Airfuge; Beckman Coulter, Inc., Fullerton, CA) that permits concentration of virus onto grids prior to examination (41). Few clinical laboratories have access to EM facilities, so other methods are typically used.

Antigen Detection
Antigen detection can be used for the rapid detection of adenoviruses in respiratory, ocular, and gastrointestinal tract specimens. Sensitivity is often poor, particularly when adults or immunocompromised patients are tested, and particularly compared to the sensitivities of molecular methods (42). However, some series focused on detection of adenoviral conjunctivitis have shown improved sensitivity with more recently available assays (43). Most antigen assays target conserved regions of the adenovirus hexon protein and utilize monoclonal antibodies (MAbs). Immunofluorescence (IF), enzyme immunoassay (EIA), and lateral-flow immunochromatography (IC) are the most common formats.

IF can be used for definitive identification of culture isolates and for primary detection of respiratory tract infections. Suitable specimens for direct detection are washes, aspirates, or swabs containing exfoliated ciliated columnar epithelial cells from the posterior nasopharynx or midturbinate. Touch preparations of fresh tissue or frozen or formalin-fixed tissue sections can be tested as well. However, these may not be approved applications for a given commercial reagent and as such would require further validation prior to routine clinical use. General techniques for IF are described in chapter 80. Positive cells usually display con-
densed nuclear or granular cytoplasmic staining (Fig. 3). Although indirect IF is highly sensitive and specific, direct IF can provide satisfactory and rapid results (44). Labeled MAb s directed solely against adenovirus or pools of MAbs labeled with different fluorochromes directed against adenoviruses and other respiratory viruses can be used. Pools may be most economical for laboratories with a low prevalence of adenovirus. The reported sensitivity of IF for adenovirus detection in respiratory specimens is 40 to 60% of that of culture, which is lower than the detection rate of most other respiratory viruses. A sensitivity higher (60 to 80%) than that of culture is achievable using cytocentrifugation (44) and specimens from pediatric patients. The specificity of IF for adenovirus is excellent (>99%) in most studies.

Antigen detection can also be performed by EIA, IC, or latex agglutination (LA). These technologies are fully described in other chapters. Two types of EIA are available, a serotype 40- and 41-specific EIA and a generic EIA to detect all serotypes (45, 46). Both assays utilize microtiter plates and adenovirus-specific MAbs as capture and detector reagents. This format is most economical for large laboratories which usually test in batch mode. The sensitivity of the serotype 40/41 assay compared to that of 293 cell culture or EM is >90% in most studies, although sensitivity can be lower with some variants (47). Specificity is >97%. The generic EIA detects species F and other species in a single reaction. Some have shown high sensitivity (>95%) when stool is tested, but the sensitivity is only 65 to 75% when other specimen types are tested. Urine may give the lowest value, and occasional false-positive reactions occur (45, 48), although others have had better results. Other formats used less frequently include time-resolved fluoroimmunoassay and radioimmunomassay.

The IC format is attractive for smaller laboratories because tests can be run individually, and results are usually available in less than 30 min. The SAS rapid adenovirus test (SA Scientific, San Antonio, TX) is a commercial assay for testing of eye swabs, nasopharyngeal secretions, and fecal material. Initial reports suggested good sensitivity (84 to 95%) compared to those of culture and PCR on nasopharyngeal specimens, but sensitivity was only 55% when a broader array of specimen types was evaluated (42, 49). Performance is best with specimens from young children. The RPS adenovirus detector (Rapid Pathogen Screening Inc., South Williamsport, PA) is available for testing of eye swabs. The sensitivity and specificity were 89% and 94%, respectively, compared to those for PCR in a recent study (50). The assay is insensitive if swabs are placed in viral transport medium prior to testing (51). A generic LA assay for stool specimens is available but infrequently used. Its sensitivity is only moderate, and false positives have been reported with control latex particles coated with non-adenovirus-reactive antibodies (52).

**Nucleic Acid Detection**

Nucleic acid detection has become commonplace for sensitive and rapid viral detection and quantification. Although this methodology was initially used primarily for specimens (for example, blood) that were not amenable to antigen detection or culture, more recently, molecular amplification has become a primary detection modality for respiratory tract specimens. In fact, adenovirus has been detected by PCR or similar methods in virtually all specimen types, so the appropriate specimen depends largely on the associated disease (Table 2). Amplification is necessary for detection in most sample types, although viral DNA can be directly detected in some stools by gel electrophoresis and viral DNA can be demonstrated without PCR in infected tissues by in situ hybridization.

Both endpoint PCR and real-time amplification methods are in current use. Degenerate or nondegenerate primers and probes for the hexon or fiber gene or the viral-associated (VA) RNA I and II regions are usually selected due to the extensive homology of these regions among serotypes. Assays that utilize multiple primer and probe sets are preferred by many laboratories for uniform detection or quantification of all serotypes (53–58). Over the years, a variety of laboratory-developed tests (LDTs) have been described in the literature, their development increasingly facilitated by the availability of well-defined control material and reference strains of a number of serotypes of adenovirus. Commercial reagents were initially limited to those labeled for research use only (RUO) and analyte-specific reagents (ASRs). More recently, tests that are cleared or approved for in vitro diagnostics (Table 3) have been marketed (59–61). While these have largely been approved only for detection of respiratory tract viruses, their availability represents a marked advance in our ability to rapidly and accurately detect adenoviral infections.

Detection formats described for endpoint PCR methods have included gel electrophoresis, Southern blotting or liquid hybridization and capture onto microtiter plates, and fluidic or solid-phase microarrays (62). Conventional assays that detect all adenoviruses as well as multiplex PCRs for adenoviruses, herpesviruses, and other respiratory viruses have been reported (12, 63, 64). Increasingly, widely multiplexed methods that detect a full range of respiratory viruses have been developed and marketed (59–61). The sensitivities of such systems for adenovirus and the spectra of viral serotypes detected are widely varied among platforms and test versions. Early versions of some systems have shown marked weakness in the detection of adenovirus, compared to other pathogens. While the trend has been for manufacturers to ameliorate such issues in subsequent test versions,
this weakness points to the need for critically assessing the sensitivity of such tests prior to implementation. Real-time PCR is most often used when targeting adenovirus alone, rather than in a panel approach, as it is more rapid and less prone to contamination than endpoint PCR and can provide quantitative results. Many real-time LDTs have been described (41, 53–55, 57, 58). In almost all reports, irrespective of the specific method used, the sensitivity of PCR has approached or exceeded that of antigen detection or culture (65). The major application of quantitative real-time PCR is the detection and quantification of adenoviremia to predict current or incipient localized or disseminated adenovirus disease in immunocompromised patients (66, 67). Quantitative tests have increasingly been applied to other sample types, such as stool, in an effort to improve the clinical predictive value of positive results (68). Detection and quantification of viremia can be performed using plasma, peripheral blood mononuclear cells (PBMCs), or whole blood. No significant differences in qualitative sensitivity have been observed among these specimen types, although viral load values were slightly higher for whole blood and plasma than for PBMCs in one recent report (69).

Detection of all adenoviral serotypes and genome types represents a tremendous challenge in test design. It is therefore incumbent on both the developer and the user of such tests to verify the sensitivity of a given assay for the whole range of adenoviral species and serotypes of clinical importance in the population being tested. Clinical specificity should also be determined whenever possible because adenovirus DNA can be found in some specimens from healthy control subjects. On average, fewer than 2% of specimens from healthy individuals contain detectable adenovirus DNA, although values can vary significantly depending on the patient population and specimen type (10, 11, 57, 70). Somewhat higher detection rates have been reported for chronic conditions (such as asthma), for tonsil and adenoid tissue, and for gastrointestinal biopsy specimens with negative pathology (9, 25, 71). Each laboratory should therefore define the clinical significance of positive PCR results in its patient population and sample types. Where quantitative tests are used, quantitative linearity should be assessed across detectable viral types to ensure accuracy when a non-type-specific calibration curve is used.

Many transplant centers now assess viremia with such quantitative tests on a weekly basis for several months after transplantation or when symptoms appear. Routine screening has become especially commonplace for pediatric HCT patients. Screening of asymptomatic patients can be used to trigger preemptive therapy (18). In patients with diagnosed adenoviral infection, changing viral load values can be used to assess the clinical response to antivirals and predict outcomes (72). Due to differences in assay characteristics and patient populations and the lack of universal calibration standards, there is also no single threshold value of viremia that can be recommended to initiate antiviral treatment or preemptive therapy in these patients. Some experts follow in vivo dynamic changes by repeat testing in 2 or 3 days after a single low viral load to identify patients with a rapid increase before initiating treatment.

**ISOLATION PROCEDURES**

Although historically considered the reference standard, viral isolation is now used with decreasing frequency. Viral culture is slower than antigen or DNA assays and, with some specimen types, can be less sensitive than PCR, yet it remains useful to detect serotypes that might be missed by direct methods and yields infectious progeny for further identification and serotyping. Most specimens are suitable for culture (Table 2). Exceptions are blood and cerebrospinal fluid (CSF), which may contain insufficient virus to be cultivated or may contain virus neutralized by antibodies. For these specimens, DNA amplification is typically preferred.

Adenoviruses grow best in human epithelial cells. Primary human embryo or neonatal kidney cells are the most sensitive but are rarely available, so human epithelial cell lines, such as A549, Hep2, or sometimes HeLa or KB, are used. Human fibroblasts and nonhuman cells, such as Vero and primary monkey kidney cells that contain endogenous simian virus 40, may support adenovirus replication, but the yield is low. Enteric adenoviruses are often termed “fastidious” because they are noncultivatable or grow slowly in routine cell lines. Cultivation of enteric adenoviruses is most successful in Graham 293 cells (28).

Adenoviruses can be isolated by conventional tube culture or shell vial centrifugation culture (SVCC). These methods are detailed in earlier chapters. Although SVCC is popular because it produces rapid results, tube culture remains useful (among culture techniques) to detect low concentrations of virus or slow-growing serotypes, particularly of species A or D, which may not be evident for 3 or 4 weeks. Holding tubes for 2 weeks is customary for routine diagnostic work. If tubes are held for longer periods, cells should be subpassaged at least once to maintain the health of the monolayer. Typical cytopathic effects (CPE) consist of grape-like aggregates of swollen, refractile cells (Fig. 4B). Aggregates may not develop with species D, and a web-like flattening is described for serotypes 3 and 7 (73). CPE is usually evident in 2 to 7 days in A549 cells but may be less characteristic and slower to appear in other cell types. As infection progresses, cells can become highly granular and detach completely from the surface. Most infectious virus remains cell associated so that high-titer preparations can be produced by several freeze-thaw cycles of harvested cells. CPE that develops within hours after inoculation with concentrated preparations is known as “lysis from without” and is due to a free penton base. It can be prevented by using a lower concentration of the inoculum.

A significant proportion of culture-positive specimens can be detected in A549 or Hep2 SVCC after 1 to 5 days of incubation and should be confirmed using fluorophore-conjugated MAbs directed against the adenovirus hexon protein. Often the MAb preparations used to identify viral antigen in direct specimens can be used in SVCC. Maximum detection of fluorescent foci requires at least 30 min of centrifugation at 700 × g (20). The sensitivity of SVCC compared to that of tube culture under these conditions is approximately 50% at 24 h, increases somewhat at 2 days, and can approach 100% by 5 days (45, 74–77). Similar results can be achieved using 24-well microtiter plates. Lower detection rates are reported if human fibroblast or monkey cells are used (78). Dexamethasone, which enhances the identification of some viruses in SVCC, can improve adenovirus detection in SVCC after 1 to 5 days (79). Recovery of adenoviruses from respiratory sources in R-Mix (Diagnostic Hybrids Inc., Athens, OH), a mixture of A549 and mink lung cells, is lower than that for parainfluenza or influenza viruses (80). Enteric adenoviruses can be detected in SVCC if appropriate cells lines are used (81), but other approaches are more sensitive and convenient.

IDENTIFICATION

Culture isolates should be definitively identified before a report is generated. For diagnostic work, genus-specific identification is usually sufficient. Most immunologic or molecular methods for direct detection of adenoviruses are suitable for this purpose. Identification by IF is most often used for culture isolates because the technique is simple and rapid. For IF, cells that appear to contain adenovirus should be harvested when at least 20% of the monolayer shows CPE. Other methods that can be used for identification are LA, IC, or PCR. On occasion, CPE-positive variants or new serotypes that cannot be identified by these methods emerge. Under these circumstances, EM of infected cells, HA of the isolate, or DNA sequence-based methods may aid identification.

TYPING SYSTEMS

Typing of adenoviruses into species or serotypes is used primarily for epidemiology or studies of pathogenesis or to reveal the cause of an unusual or especially severe infection. Traditional and molecular typing methods are available. Traditional typing requires a viral isolate and detects serologically recognized differences in fiber and hexon epitopes. Molecular typing can be performed with isolates or directly on PCR-positive specimens. The most valuable regions for sequencing are in the fiber and hexon genes, but whole-genome sequencing has been used as well. Typing by serology or molecular methods is usually in agreement, although discrepant results can be obtained on occasion. The two approaches are different in that serology measures a phenotypic property, whereas genotyping queries DNA.

Traditional typing is performed by provisionally determining the species of an isolate by HA (Table 1) or, if the isolate is from stools, by a species F (serotype 40/41) EIA. Serotyping by HA inhibition (HAI) or serum neutralization (SN) is then performed, utilizing specific antisera that define the serotypes of that species. HAI is the easier assay, but SN is the primary arbiter of serotype. Modified SN procedures are preferred for speed and simplicity over the conventional 7-day test with human epithelial cells (or 293 cells for stool isolates). Intersecting pools of antibody mixtures reduce the number of individual reactions. Modified SN tests include a 3-day test with monkey kidney cells and a 5-day microneutralization test with Vero cells (105). Interpretation of traditional typing is not always straightforward, especially with intermediate strains, but it remains the gold standard to validate new systems and classify novel viruses.

Molecular typing has increasingly replaced serology as the method of choice for routine strain typing and epidemiologic studies. Direct methods use extracted viral DNA from an isolate or specimen. Restriction endonuclease analysis (REA) is the classic direct typing method (82), but some genome types in current circulation do not retain the cleavage patterns of the prototypes, so interpretation can be challenging. REA is still used, however, for presumptive identification of new serotypes, for identification of new genome types associated with severe disease, or to confirm results obtained by other means. Single-stranded confirmation polymorphism and heteroduplex mobility assays are other direct approaches. Sequence-based typing is rapid and highly accurate. Some assays can be performed directly with clinical material, but isolates are often preferred because of their larger amount of viral DNA. Amplification is then performed by generic or multiplex PCR, or sometimes by nested PCR, to obtain sufficient DNA for analysis (83). Methods of analysis can include measurement of product length, REA, DNA sequencing, REA followed by DNA sequencing, or mass spectrometry (84–87). In addition, probe-based methods include reverse line blotting, in-well hybridization, type-specific real-time PCR, and solid-phase microarrays (88–90). Common regions for sequence interro-
tain are hypervariable regions 1 to 6 or 7 of the hexon gene or the fiber gene, although other regions, such as E3, can be analyzed. The presence of intermediate strains or coinfections can often be detected by sequence analysis (91). Sequence analysis of polymorphisms in long nucleotide repeats (microsatellites) is proposed to track strains (92). Some molecular typing systems identify only the species or serotypes recovered from a single body site, whereas others are more comprehensive (62, 83, 93).

SEROLOGIC TESTS
Most primary adenovirus infections (in immunocompetent patients) are accompanied by a diagnostic rise in virus-specific immunoglobulin G (IgG), a less-predictable IgA response, and an IgM response in 20 to 50% of cases. Neutralizing antibodies can persist a decade or more in a relatively undiminished titer, probably maintained by periodic reinfection, reactivation, and heterotypic anamnestic antibody responses. The IgG response can be delayed in many children for months after infection and may not appear in immunocompromised individuals. An IgM response occasionally occurs when virus reactivates.

In recent years, serodiagnosis of adenovirus infections has largely been superseded by other methods of virus detection. Its current use is for epidemiologic investigations, to confirm associations between virus detection and unusual clinical outcome, and to study the immune response. The value of serology for patient care is limited due to the retrospective nature of demonstrating seroconversion, false-negative results due to the delay of the IgG response in children, the insensitivity of IgM assays, persistent infections, and the lack of antibody responses in immunocompromised individuals. False positives also occur due to heterotypic responses or late antibody rises in children unrelated to their current problem.

Serology is typically performed by documenting at least a 4-fold rise in virus-specific IgG (seroconversion) or by detecting an IgM response in the right setting. For clinical work, it is usually sufficient to know that adenovirus caused the infection, so a genus-specific EIA to detect IgG or IgM antibodies against the hexon protein is adequate. Formats with a viral antigen preparation or a “capture” immunoglobulin on the solid phase are commercially available and sensitive. Serotype-specific antibody tests are infrequently used for diagnosis but can pinpoint serotypes responsible for a cluster of infections when other specimens are unavailable. HAI and SN are the serotype-specific assays of choice. SN is the standard, with the 3-day monkey kidney test or microneutralization preferred. Complement fixation, indirect IF, LA, and radioimmunoassay are rarely used. Assays utilizing genetically modified cells and fluorescent reporter molecules as surrogates for SN activity are increasingly used for serosurveys (94).

Treatment
Antivirals have been used to treat some adenovirus-associated clinical entities. Several antivirals, including ganciclovir, ribavirin, and cidofovir, as well as the antiretroviral drugs zalcitabine, abacavir, and stavudine, have in vitro activities against adenovirus. Ribavirin was initially reported to have in vitro activity only against species C serotypes but is now said to be active against most isolates of species A, B, and D and all isolates of species C (95). In vitro studies suggest that cidofovir may be effective against severe lower respiratory tract infection caused by the emerging adenovirus serotype 14a, whereas ribavirin may not (96).

The most common drugs utilized in patient care have been ganciclovir, ribavirin, or cidofovir. Ganciclovir has only a moderate effect in vivo and is no longer recommended for clinical use. Ribavirin has been used with somewhat greater success, but many failures and fatalities are reported. Ribavirin may be somewhat effective against hemorrhagic cystitis, probably due to the high drug concentrations achievable in urine.

The mainstay of antiviral treatment to date has been cidofovir, an acyclic nucleoside phosphonate analogue and broad-spectrum antiviral agent. All adenovirus serotypes are susceptible to cidofovir in vitro. Although resistance can develop with serial passage, little resistance has so far been detected in isolates from cidofovir-treated patients (95). Despite its significant side effects of nephrotoxicity, myelosuppression, and uveitis, cidofovir is increasingly used to treat a variety of clinical presentations, mostly in immunocompromised patients. In HCT patients, efficacies up to 98% are reported, and regimens with acceptable levels of toxicity have been developed (97). Some transplant centers now advocate weekly surveillance of viremia for their high-risk patients in the first few months posttransplantation, followed by preemptive cidofovir treatment if results are positive or rising. This strategy still does not completely eliminate adenovirus disease, however, and some pediatric patients clear their viremia spontaneously without treatment (97). A clinical algorithm that recommends treatment only of HCT patients at high risk (as defined by host factors, transplant type, and viremia) was evaluated in a small retrospective series (98). All six low-risk patients cleared their adenovirus infection without treatment, whereas 1 of 10 high-risk patients died. Several other retrospective and prospective studies have since been published, without a clear consensus. However, recent guidelines from the European Conference on Infections in Leukemia include recommendations for preemptive therapy with cidofovir in high-risk patients (18).

A lipophilic conjugate of cidofovir, Brincidofovir (CMX001-hexadecyloxypropyl cidofovir) has shown promise in early studies for the treatment of adenoviral infections (99) and is currently in advanced-stage clinical trials. Brincidofovir can be administered orally, with good absorption, and reaches higher intracellular concentrations than cidofovir. It has shown potent in vitro antiviral activity against a wide range of double-stranded DNA viruses, and evidence points to less toxicity than that of cidofovir.

Other promising strategies include reduction of immuno-suppressive therapy or immunotherapy using donor lymphocyte infusion (100). Both approaches, with or without concomitantly administered antivirals, have improved outcomes for HCT patients in some studies. To avoid inducing graft-versus-host disease with donor lymphocyte infusion, adenovirus-specific cytotoxic lymphocytes have been produced in vitro. A strategy to expand naive cord blood T cells in vitro with efficacy against adenovirus, Epstein-Barr virus, and cytomegalovirus infections has shown promise (101). Combination approaches using intravenous immunoglobulin, antivirals, and reduced immunosuppression have also met with some success.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS
The clinical spectrum of adenoviral disease is broad, so laboratory testing is usually required for accurate diagnosis.
Selection of tests should be guided by the patient’s symptoms and immune status, the interval between disease onset and specimen collection, and laboratory expertise. In the last few years, testing has shifted primarily toward molecular methods, such that most adenovirus infections can now be detected within hours when automated “sample-to-answer” systems are used or within 1 to 2 days when quantitative LDT-based assays are used. The use of culture (centrifugation or tube culture) continues to diminish. Antigen testing has found limited application, and serologic testing rarely provides clinically actionable data. Testing can be aimed at systemic detection in blood samples (primarily in immunocompromised patients) or at detection in sites of end-organ involvement. In the latter instance, histopathology and adjunctive immunohistochemical and in situ hybridization continue to play an important role.

Interpretation of positive results can be challenging since many adenovirus infections are asymptomatic or due to reactivation of endogenous virus. Accurate interpretation should consider patient and specimen characteristics, test method and, under some circumstances, the viral serotype or quantity detected. This requires close communication between the laboratory and the clinician. In general, detection of virus from the involved organ or in large quantities in a patient with an illness that is epidemiologically associated with adenovirus is evidence that adenovirus is the actual cause of the disease.

PCR-based methodology has now displaced culture and antigen detection as the method of choice for rapid detection of adenoviral respiratory tract infection. These assays typically have a high degree of sensitivity, but like antigen tests, one can expect higher rates of detection in samples from children, as virus is typically shed at higher titers and for longer periods in children than in adults. Caution is advised in the selection of test methods, as the complex phylogeny of adenoviruses can present a daunting assay design challenge. A given test, though claiming broad detection capabilities, may have significantly reduced sensitivity for specific adenoviral serotypes or species. Nonetheless, both sensitivity and speed of detection have markedly improved over time, and the rapid reporting of such results can have a positive impact on patient and fiscal outcomes (102, 103). The sensitivity advantage of PCR over those of other methods is such that confirmatory reflex testing for samples testing negative by other methods should be considered in critically ill or high-risk populations. Although typically utilized for immunocompromised patients, assessment of viremia may be a useful adjunct for the diagnosis of severe adenoviral disease in immunocompetent children (71). The exquisite sensitivity of PCR can also present challenges, however. Low viral DNA loads can be detected in specimens from asymptomatic subjects. Results of tissue PCR may be particularly hard to interpret in the absence of correlative viral inclusions that are positive by immunohistochemistry or in situ hybridization. Furthermore, the clinical significance of continued shedding of adenovirus after resolution of symptomatology is an unresolved issue.

Adenovirus gastroenteritis in immunocompetent patients is best detected by a serotype 40/41-specific immunoassay or PCR of stools. Interpretation is usually straightforward, because these infections are usually mild and self-limited in such hosts, with viral shedding infrequent past the symptomatic period. In contrast, nonenteric adenoviruses can be detected in stools of asymptomatic immunocompetent and immunocompromised patients for prolonged periods. In the latter group, severe or fatal gastrointestinal disease can result, and detection in the stool can presage disseminated infection. High viral loads in excess of 10^6 genome copies/ml of stool have been shown to be predictive of subsequent viremia in allogeneic stem cell transplant recipients (104). Detection of nonenteric adenoviruses in stools of immunocompromised patients may be achieved by EIA, PCR, or culture. Viral load is typically determined by PCR. It should be noted that many assays are designed to detect only enteric adenovirus (types 40/41), and any assay should be validated for detection across all species or serotypes of presumed import in a given patient population. Detection of adenovirus in the stools of transplant recipients does not rule out graft-versus-host disease or graft rejection.

Detection of adenovirus in urine has also been associated with hemorrhagic cystitis. Among immunocompetent patients, this picture is typically seen in pediatric patients, with a male predominance, in association with adenovirus serotypes 11 and 21. In HCT patients, hemorrhagic cystitis may be severe and might be the initial site of severe disease or dissemination (30). However, as in other organ systems, adenovirus may be shed asymptomatically in the urine, and the predictive value of routine testing for this sample type is unclear, with some investigators failing to show an association between adenoviruria and hemorrhagic cystitis in HSCT patients.

In contrast, ocular adenoviral detection by EIA, IC, culture, or PCR may be considered diagnostic. Adenovirus encephalitis and meningitis occur infrequently, so studies comparing traditional and newer methods of detection are lacking, although PCR of CSF is likely to be the optimum approach.

Diagnosis of adenovirus disease in immunocompromised patients is challenging due to the many copathogens, the high rates of asymptomatic virus shedding, and the protein manifestations of adenovirus infections in this population. HCT and SOT recipients are at highest risk of severe disease and are the usual focus of testing. Some centers utilize surveillance cultures or PCR studies of multiple body sites to detect virus in temporal association with the onset of new symptoms. Involvement is then classified as infection, probable disease, or definite disease, depending on the number of virus-positive sites, symptoms, or histologic confirmation. Detection of adenovirus viremia by PCR is increasingly used instead of culture for surveillance. Viremia is usually present during severe or fatal adenovirus infection and often precedes the development of disease, although not all PCR-positive patients become symptomatic. Values then decline following successful treatment. Therefore, many centers now monitor weekly viremia in high-risk transplant patients, treat preemptively based on single high-positivity results or dynamic increases from low baselines, and reevaluate viremia to assess response to treatment. Similar approaches may be useful to assess the clinical effectiveness of new treatment modalities for adenoviral disease. However, caution is warranted in adapting universal or consensus breakpoints for institution of therapy. The lack of international quantitative standards, together with wide variations in methodology, and the potential for inaccuracies in quantification across different serotypes for individual assays mean that treatment thresholds must continue to be verified based on the test in use and the population being assessed in any given institution.

Human Papillomaviruses

CHRISTINE C. GINOCCHIO, PATTI E. GRAVITT, AND JENNIFER S. SMITH

104

TAXONOMY
Papillomaviruses (PVs) are small (55 nm in diameter), non-enveloped DNA viruses. PVs are classified according to nucleic acid (NA) sequence homology into genus, species, type, subtype, and variant (1). Members of the same genus share at least 60% NA sequence homology. Species are defined by sequence homology of 60 to 70%, with types in the same species having 71 to 89% homology. Subtypes are rare, exhibiting 90 to 98% homology, while variants are more common and show >98% homology. The genus and species groupings based on genotypic variation reflect key phenotypic differences, including species specificity, epithelial tropism (e.g., cutaneous versus mucosal), and oncogenic potential. Human PVs (HPVs) are clustered in five genera: Alphapapillomavirus, Betapapillomavirus, Gammapapillomavirus, Muapapillomavirus, and Nupapillomavirus. The majority of identified HPVs with clinical significance are found in the genus Alphapapillomavirus, which includes types infecting the genital and nongenital mucosa and genital cutaneous surfaces as well as the genotypes associated with human cancers. Table 1 summarizes the clinical manifestations of the genotypes, including oncogenic potential, in the alpha species group. The beta, gamma, mu, and nu types tend to infect nongenital epithelium.

DESCRIPTION OF THE AGENT
PVs contain a circular (or episomal) double-stranded genome and an icosahedral capsid structure consisting of 72 pentamers. The ~8,000-bp viral DNA has eight open reading frames encoding six early (E) proteins and two late structural capsid proteins, L1 and L2. L1 serves as a ligand for virion attachment to the basal cell layer of the epithelium. DNA transcription is controlled by the long control region (also known as the upstream regulatory region), which contains binding sites for many human transcription factors and regulatory elements, including steroid hormones reviewed in reference 2. Viral gene expression is dependent on the differentiation state of the infected epithelium, with early gene expression occurring predominantly in the suprabasal epithelial cells, while late gene expression is limited to the terminally differentiated keratinocytes. The precise mechanisms of differentiation-dependent viral gene expression have not been elucidated, though recent data suggest a potential role for epigenetic mechanisms, including viral DNA methylation (3–5). The early viral proteins have pleiotropic roles which generally involve viral replication and transcription (E1 and E2) and an interaction with key host regulator proteins (E6 and E7) resulting in the loss of a major tumor suppressor function. Specifically, the E6 protein from high-risk (HR) genotypes interacts with the human E6-associated protein (E6AP) to target p53 for ubiquitination and proteosomal degradation (6, 7), thereby impairing appropriate cell cycle arrest in response to genomic damage. The E7 protein from HR genotypes binds with pRB (the retinoblastoma protein) (8, 9) to uncouple cyclin-dependent cell division, allowing for dysregulated cell cycle progression. In self-limiting HPV infections, the expression of E6/E7 is tightly regulated and limited to the middle layers of the epithelium to facilitate viral replication in quiescent cells but is downregulated upon terminal differentiation. The dedifferentiation of the epithelium characteristic of high-grade neoplasia is associated with dysregulated expression of E6/E7 in the upper layers of the epithelium (10). Dysregulated E6/E7 expression can occur via loss of E2 regulatory protein expression due to integration of the HPV DNA into the host genome. While integration occurs in high-grade lesions and cancers, it is not a necessary prerequisite and varies by genotype (11). Data remain conflicting as to whether integration is a cause or a consequence of the tumorigenic process (12, 13).

EPIDEMIOLOGY AND TRANSMISSION
PVs are strictly species specific, with no animal reservoir. HPVs have been shown to infect both cutaneous and mucosal epithelia of the skin, oral cavity, conjunctiva, anus, and lower genital tracts of men and women, with no systemic, or blood-borne, phase. Consequently, transmission occurs via direct epithelium-to-epithelium contact and not exposure to bodily fluids, as in the cases of hepatitis and human immunodeficiency virus (HIV) infections. Infection is thought to occur in basal epithelial cells, which are presumably accessed through microtrauma incurred during sexual activity through both penetrative and nonpenetrative epithelial abrasive contact. Infection of the skin with the Betapapillomavirus species is thought to be nearly ubiquitous (reviewed in reference 14).

Transmission of anogenital HPV in both men and women is largely and predominantly sexual (15, 16); however, some evidence also supports the possibility of autoinoculation between sites and digital/fomite transmission (17, 18). Condoms, which do not cover external epithelial sites harboring...
HPV, offer partial protection from infection, particularly with consistent and correct use (19–21). Sexually active individuals are exposed to and can acquire any one or more of the >40 HPV types known to infect the anogenital tract. Concurrent, multiple-type HPV infections at the same anogenital site are common, particularly among young individuals and those with a compromised immune system (e.g., HIV-positive individuals and organ transplant recipients). Having multiple HPV infections may be a marker of high-sexual-risk behavior or a marker of a woman’s immune status. While multiple infections may be a marker of compromised immune response to HPV infection and thus increased risk of neoplastic progression, associations between multiple concurrent HPV infections and the risk of cervical intraepithelial neoplasia of grade 2 or higher (CIN2+) have been inconsistently reported (22).

Because of an inability to differentiate new from reactivated infections, per sex act and per partnership transmission rates have been difficult to estimate (15, 16, 23). Transmission rates observed in the HPV Infection and Transmission among Couples through Heterosexual Activity study were 3 to 4/person-month (16), which corresponds to a per partnership transmission probability of 0.20 (95% confidence interval [CII], 0.16 to 0.24), lower than previous model estimates derived from natural history data suggesting 40% transmission in a single sex act (24). Because of the difficulty in the conduct and interpretation of transmission studies, estimates for per partnership or per sex act HPV transmission rates vary from 20 to 40%. It is estimated that at least 80% of sexually active adults will have acquired at least one anogenital HPV infection in their lifetimes (25), further emphasizing the ease of HPV transmission. Studies of college-age men and women observed a 24-month cumulative incidence of any HPV infection of 38.8% in women (26) and 62.4% in men (17). Importantly, nearly 50% of newly sexually active women were found to acquire HPV within 3 years of sexual debut with their first male sexual partner (27). These data highlight the difficulty of any risk stratification to select individuals at high risk of HPV infection.

The average duration of HPV infection in women is 6 to 12 months (28), with approximately 90% of women becoming HPV DNA negative within 24 months of infection. In a recent systematic review, the median duration of any HPV detection was 9.8 months, and HR HPV (9.3 months) persisted longer than low-risk (LR) HPV (8.4 months); HPV type 16 (HPV-16) (12.4 months) persisted longer than HPV-18 (9.8 months) (28). From a natural history perspective, it is not clear whether the loss of HPV DNA detection represents viral eradication, reduction of viral load below detectable limits, or establishment of viral latency (23), though suppression of HPV viral load to undetectable levels and reemergence of replicative virus upon immunosuppression have been well documented for other animal PVs (29). From a clinical standpoint, however, persistently detectable HR-HPV DNA confers a very high risk of progression to cervical precancer (30, 31).

Approximately two-thirds of women with detectable HPV DNA and up to 36% of men with detectable HPV DNA are found to develop a natural type-specific antibody response to infection (32, 33). Recent data have shown that women having naturally produced HPV serum antibodies are likely at a lower risk of future acquisition of HPV infection (34), but the same does not necessarily appear to be true for men (35, 36). These results in women do support the hypothesis that prior HPV infection induces type-specific immunity and is generally consistent with epidemiological data which do not fully support repeated reinfections from dually infected partners. Further studies are indicated for men.

The prevalence and natural history of penile HPV in men are becoming more understood (37, 38). A large international cohort examining male genital HPV infection (combined exfoliated glans/coronal sulcus, shaft, and scrotum epithelial samples) reported an overall HPV prevalence of 65.1% for any type of infection and a prevalence of 29.7% for carcinogenic HPV infection (39). These estimates did not differ significantly by age, in contrast to age-specific patterns of HPV infection observed in women from the same countries. Several studies have recently been published.

*HPVs were recently reclassified by the International Committee on Taxonomy of Viruses (ICTV). Both the new classification (species, ICTV) and the historical classification (species, common use) are represented. MMPV1, Macaca mulatta PV 1. Species are listed by type; e.g., HPV-32 is HPV type 32.*
on the natural history of penile HPV infections in men (40). Among 1,159 men enrolled in the HPV Infection in Men (HIM) study from Brazil, Mexico, and the United States, HPV incidence was estimated at 38.4 per 1,000 person-months (40). Studies of the natural histories of men have consistently shown that rates of HPV clearance appear to be higher among men than among women and lower among HIV-seropositive participants than HIV-seronegative ones (41). Smaller studies of incident HPV infection in young men have similarly observed a higher risk than that for women of the same age, with a 2-year cumulative incidence of 62.4%, which was significantly associated with a new sex partner in the previous 8 months and a history of cigarette smoking (17). Circumcised men appear more likely to clear penile HPV infection (42), and data from randomized controlled trials in Uganda, South Africa, and Kenya have demonstrated that adult male circumcision reduced the point prevalence, incidence, and persistence of HPV infection at the glans/coronal sulcus (43–45).

In contrast, relatively few studies are yet available concerning the natural history of anal HPV infections, particularly among women (37). In a cohort study of young women in San Francisco, CA, HPV-16 was less likely to clear than other HPV infections, although the majority of anal HPV infections cleared within 3 years (37). Some studies of anal HPV infection have been conducted among men, particularly among men at higher risk of anal neoplasia, i.e., men having sex with men (MSM), and HIV-seropositive men (38, 46–48). Relatively few oral HPV natural history studies have been conducted, though it is clear that HR-HPV infection (particularly with HPV-16) is associated with a subset of head and neck squamous cell cancers (49). The prevalence of oral HPV infection in the general population is substantially lower than the genital HPV prevalence in men and women (50). Risk factors for oral HPV infection include increasing age (unlike with female cervical HPV infection, for which young age is a risk factor), male gender, HIV infection, immunosuppression, a history of a sexually transmitted infection, and a number of oral sex partners (25). The HIM study found that among over 1,500 men aged 18 to 73 years, 4.4% acquired an oral HPV infection within the first year (51). Risk factors for acquisition of oral HPV included smoking and not being married or cohabiting. The median duration of oral HPV infections was 6.9 months for overall HPV, 6.3 months for high-risk HPV, and 7.3 months for HPV-16. Another study of over 400 HIV-seropositive participants found that HPV infection was less likely to occur or be persistent in the oral than in the anal canal (52).

CLINICAL SIGNIFICANCE
The vast majority of HPV infections at all sites are subclinical and asymptomatic. These infections are characterized by noninflammatory; therefore, most individuals who acquire HPV never know that they have been infected. Because the viruses utilize natural cell death in terminally differentiated keratinocytes to complete their viral life cycle, no tissue destruction or ulceration results from HPV infections. However, despite the abundance of subclinical and self-limited infections, both HR- and LR-HPV infections can cause clinical disease in their hosts.

Clinical Manifestations of Female Anogenital Infection
LR-HPV infection of the anus, cervix, vagina, and vulva can result in benign warts caused predominantly by HPV types 6 and 11. All LR-HPV types can also result in the diagnosis of low-grade squamous intraepithelial lesions (LSILs) on Pap smears. These lesions are characterized by high nucleus/cytoplasm ratios and the presence of koilocytic atypia (KA). KA is defined as the presence of nuclear atypia as well as a clearly defined perinuclear halo in cervical epithelial cells (Fig. 1). KA is considered the hallmark of HPV infection.

HR-HPV infection can cause both high-grade squamous intraepithelial lesions (HSILs) and invasive cancer at all female anogenital sites, though HR-HPV cancers occur at a much higher frequency at the cervix than at the other sites. An HSIL is considered a true cancer precursor lesion, in contrast to a low-grade SIL (LSIL), which is generally thought to represent nothing more than viral infection. HSILs are differentiated from LSILs by diminished differentiation, with basoloid cells with a high nucleus/cytoplasm ratio present close to the epithelial surface. HSILs have been found to contain a higher frequency of genomic abnormalities and are therefore at high risk of progression to invasive cancer. Cervical cancers occur predominantly at the transformation zone, or squamocolumnar junction. The most common treatment for preinvasive neoplasia (CIN2 or CIN3) is the loop electrosurgical excision procedure (LEEP) or cold knife cone, which removes the entire cervical transformation zone. Other treatments include laser therapy or cryotherapy; however, LEEP and cone procedures have the advantage of presenting intact tissue specimens for histopathological review for determining lesion margins and have been shown to result in lower recurrence rates (53). A residual presence of HR-HPV following excisional therapy is a predictor of disease recurrence (54).

Clinical Manifestations of Male Anogenital Infection
HPV infection in the anogenital tracts of men is more likely to remain undetected, since routine screening for detection of subclinical lesions is not performed in men. Benign warts and flat lesions can occur in all areas of the male lower genital tract, and HR-HPV infection may rarely result in the development of anal and penile cancers. Men who have sex with men and HIV-positive men are at a particularly high risk of anal cancer, and anal HPV infection in these men is nearly ubiquitous (55).

Clinical Manifestations of Male and Female Oral Infection

Oral infection is also rarely symptomatic. A very rare syndrome, recurrent respiratory papillomatosis, is caused by infection with LR-HPV types that are typically found in genital warts (e.g., HPV types 6 and 11). The juvenile-onset form of recurrent respiratory papillomatosis is likely the result of laryngeal HPV acquired from the birth canal of the infected mother. HR HPV, particularly type 16, is also associated with a subset of head and neck cancers, especially cancers of the larynx and oropharynx. Diagnosis of HPV in head and neck tumors yields important prognostic information, as the survival rate for patients with HPV-positive tumors is significantly higher than that for patients with HPV-negative tumors (56).

Primary Prevention

Primary prevention of up to 90% of genital warts and 70% of invasive cervical cancers is now theoretically possible with the introduction of a highly efficacious vaccine. Gardasil (Merck, West Point, PA) targets HPV types 6, 11, 16, and 18 and prevents external genital lesions and CIN associated with these HPV types in both men (57) and women (58, 59). An alternative vaccine, Cervarix (GlaxoSmithKline, Research Triangle Park, NC), targets HPV types 16 and 18 and has demonstrated a similar efficacy (60). Both are approved in the United States for use in females aged 9 to 26 years, and Gardasil is approved for prevention of genital warts in males aged 9 to 26 years. Both vaccines are based on a recombinant construct of the major capsid protein which is expressed and self-assembled in yeast or insect cell systems into a virus-like particle, which is both morphologically and immunologically indistinguishable from the native virus. The virus-like particle, however, carries no viral nucleic acid and therefore confers no risk of inadvertent HPV infection in vaccine recipients. While these vaccines are nearly 100% efficacious in preventing lesions due to the vaccine types, they offer absolutely no therapeutic benefit to women already exposed to or infected with these types. Therefore, Gardasil and Cervarix are most beneficial when offered prior to sexual debut.

Recommendations on Cervical Cancer Screening

The United States Preventive Services Task Force (USPSTF) released new cervical cancer screening recommendations in March 2012 (Table 2) (61). The most important changes from USPSTF’s previous recommendations include the following. The USPSTF recommends screening for cervical cancer in women ages 21 to 65 years with cytology (Pap smear) every 3 years or, for women ages 30 to 65 years who want to lengthen the screening interval, screening with a combination of cytology and HPV testing (detection of HPV DNA or HPV E6/E7 mRNA) every 5 years. The USPSTF recommends against screening for cervical cancer in women younger than 21 years. There are important policy implications associated with the USPSTF recommendations. The USPSTF states that their A- or B-rated recommendations are “relevant for implementing the Affordable Care Act.” This is the first time that HPV cotesting has been included in federal recommendations, thus potentially facilitating coverage for millions of women in the United States. The American Cancer Society (ACS), the American Society for Colposcopy and Cervical Pathology (ASCCP), and the American Society of Clinical Pathology (ASCP) have published screening guidelines for the prevention and early detection of cervical cancer (62). The ACS-ASCCP-ASCP guidelines are consistent with the USPSTF recommendations and will have an immediate impact on clinical practice in order to improve cervical cancer screening in the United States. The full description of the guidelines is available through the Journal of Lower Genital Tract Disease (63). The most significant changes include the following. For women 21 to 29 years of age, screening with cytology alone every 3 years is recommended. HPV testing should not be used to screen women in this age group. Women ages 30 to 65 years should be screened with cytology and HPV testing (‘cotesting’) every 5 years (preferred) or cytology alone every 3 years (acceptable).

bFDA approval for the Roche cobas assay was obtained in April 2014.
samples (Hologic, Bedford, MA). Exfoliated cell samples are collected from the endo- and ectocervix using a cervical brush or spatula-endocervical brush combination and rinsed into the LBC media. Additionally, Qiagen supplies a specimen transport medium (STM) tube with both brush and Dacron swab collection devices that are approved for use with the hc2 assay. Specimens are transported at room temperature and stored at 2 to 30°C until tested. The validated stabilities of STM and the residual ThinPrep sample vary by manufacturer (Table 3).

The use of non-FDA-cleared collection and transport media, including alternative LBC media, such as BD SurePath (Becton, Dickinson-TriPath, Burlington, NC), viral transport medium (M4), Tris-EDTA buffer, and phosphate-buffered saline, would require rigorous validation before these alternatives are considered comparable to manufacturer-determined performance standards established for the FDA-approved collection and transport media (68, 69). Additionally, alternative processing methods, such as glacial acetic acid treatment of grossly bloody LBC specimens to remove excess blood and mucus, thereby facilitating improved cytological analysis, require comprehensive validation (70).

HPV tests from oral, penile, and anal swab samples are not standard clinical tests, and none of the commercial HPV tests are FDA approved for testing samples from these anatomical sites. Penile and anal swab samples are collected using a saline-moistened Dacron swab, can be placed in the same buffers (e.g., ThinPrep LBC medium and STM) as cervical swabs, and likely have similar levels of stability. Exfoliated oral cells are best sampled using a 30-s oral rinse and gargle with saline or Scope mouthwash. These samples should be stored at −80°C.

Self-Collection for HPV Infection

In order to increase access to cervical cancer screening among harder-to-reach populations and those who may be reluctant to obtain a physician-based Pap smear, a number of recent research studies have focused on the validity, feasibility, and acceptability of self-collected samples for cervical cancer screening. Self-collection refers to a technique by which women use a collection brush to obtain cervical (cervico-vaginal) cell samples that are later tested for HPV infection and potentially other biomarkers. The self-collection kit is present in a kit with simple instructions. Several recent studies have investigated the use of self-collected samples for HPV screening (71–73). Research suggests that self-collection methods show promise in populations with limited resources and low cervical cancer screening uptake (71, 72). Investigations of acceptance of self-collection for detection of HPV infection in both developed and less developed countries have found that self-collection is well accepted (66% to 94% acceptance) (71, 74, 75). A recent systematic literature review and meta-analysis examined the performance of self-collection to detect high-grade cervical neoplasia of CIN2 or worse (CIN2+) (73, 75). HPV testing by self-collection was shown to be at least as sensitive as cytology for high-grade CIN2+ detection. Most studies found HPV testing via self-collection to be as sensitive for detection of CIN2+ as physician-based sampling, especially when more analytically sensitive PCR-based tests were used. In terms of specificity, HPV testing by self-collection has been shown to be less specific than cytology and as specific as HPV testing by physician-based collection. Additionally, a prototype Trovagene HPV test (San Diego, CA), developed for use with urine samples, has demonstrated sensitivity estimates for detection of CIN2+ comparable to those of the Roche Linear Array (Roche Molecular Systems, Pleasanton, CA) (76). Trovagene HPV assay specificity was lower, presumably due to the inclusion of LR-HPV types 53 and 70, which will not be included in the commercial version of the assay. A home self-collection method has the potential to overcome many barriers to traditional screening and may help motivate women overdue for screening to follow up with a health care provider-collected Pap test (77).

HPV Diagnostic Applications

HPV testing from diagnostic tissue specimens is not routine in cervical cancer screening applications, as it is assumed that all CINs are HPV positive. However, it has been found to be useful in the differentiation of primary and metastatic tumors and in HPV type attribution in vaccine trials. In contrast, HPV testing from oropharyngeal cancers provides important prognostic information, as survival is significantly improved in HPV-positive cancers (36). Fresh biopsy tissue or resected tissue snap-frozen in liquid nitrogen is ideal and allows for the flexibility in detection of DNA, mRNA, and protein. Paraffin-embedded tissue can be used, although the risk of DNA degradation, and especially RNA degradation, with increasing time in fixation is high. Fixation with 10% buffered neutral formalin is recommended for future PCR testing.

DIRECT DETECTION

Microscopy

Direct visualization of HPV infectious particles is not possible using standard light microscopy. The morphological cellular changes characteristic of HPV infection and associated neoplasia are the basis for standard cervical cytology and are classified based on the Bethesda system (78). Conventional cytology, in which exfoliated cells are smeared onto a glass slide and fixed, has been criticized as suffering from inaccurate readings resulting from obscuring blood and inflammatory cells and poor fixation or air drying. LBC alternatives were developed to prevent these problems and offer the added benefit of residual material for DNA- and RNA-based tests. A large randomized trial compared conventional cytology and LBC and found a modest reduction in smear inadequacy using LBC methods (79) but no benefit in disease detection or positive predictive value (PPV) (80).

Antigen Detection

At present, immunohistochemical detection of HPV proteins has not been validated for clinically relevant diagnostic applications. However, immunohistochemical or immuno-cytological detection of cellular proteins, such as p16INK tumor suppressor protein, MCM2, and Ki-67, have been evaluated as molecular markers of anal cancer precursors (81) and CIN2+ (82–85) (Table 4). Of these, p16 immunohistochemistry is recommended as an adjunctive test to increase accuracy and reproducibility in specific cases of diagnostic uncertainty (86). p16INK is a good biomarker of HR-HPV infection and oncogene expression, since there is measurable upregulation of p16INK expression in cells expressing HPV E7. p16 staining is also used for differentiating HPV-positive and HPV-negative oropharyngeal samples.

NA-Based Detection and Typing Methods

HPV is not culturable, and therefore, the detection and genotyping of HPV are predominantly dependent on molecular tests that target either HPV DNA or mRNA (87–89). DNA-based tests screen for the absence or presence of the HPV genome (integrated or episomal), while the RNA-based tests screen for the expression of E6/E7 mRNA genes. Although DNA-based tests are highly sensitive for the detection of HPV, clinical specificity is low due to the frequent transient nature of most HPV infections. Therefore, E6/E7 mRNA tests have been developed and evaluated as an alternative test method to increase the clinical specificity of HPV testing and thereby improve the positive predictive value of the result (88). Fewer positive tests in women without disease would improve the management of women with cervical screening abnormalities and theoretically decrease the burden of overtreatment.

All four FDA-approved tests are applicable for the clinical indications for HPV testing listed in Table 2. Currently, only the Roche cobas assay is approved for primary screening in the United States. Standardized protocols are provided with the assay; therefore, details are omitted here. While modifications to these protocols may be warranted, laboratories should understand that performance standards are inextricably linked to the use of the validated protocol. Deviations from the recommended protocol run the risk of compromising performance. Therefore, if deviations are warranted, parallel comparisons are essential to confirm that the deviations do not affect the established performance standards. Reference documents that discuss how to appropriately validate and assess an HR-HPV assay have been published (90–92).

The number of additional commercially available assays for HPV detection has increased dramatically in recent years, many of which are Conformité Européenne (CE) marked for clinical use in Europe. In this section, only assays designed to detect the presence or absence of HR-HPV

Infection are discussed, with preference given to those having FDA approval at press time (Table 3). Other non-FDA-approved commercial assays for HPV screening and genotyping are listed in Tables 5 and 6.

**NA Isolation and Purification**

The appropriate method for HPV NA isolation is a function of the sample type (e.g., fresh tissue, formalin-fixed paraffin-embedded [FFPE] tissue, and exfoliated cells), the collection medium (e.g., STM, PreservCyt LBC medium, or SurePath LBC medium), the type of NA target (e.g., mRNA or DNA), the HPV detection assay used, and the reason for testing.

**Fresh Frozen Tissue**

NA purification from human tissue samples requires standard methods using organic solvents (e.g., phenol, chloroform, or isooamyl alcohol). Generally, extraction with phenol, chloroform, or isooamyl alcohol and ethanol precipitation can be used. Utilization of commercially available phase-separating microcentrifuge tubes (e.g., Qiagen MaXtract) may help in reproducible recovery of HPV DNA by minimizing operator error. If mRNA is the target of the HPV assay, NA isolation should begin with a standard TRIzol method.

**FFPE Tissue**

HPV DNA tests are typically performed on one to three 10-μm sections of FFPE tissue. Extreme caution must be used in preparation of sections to avoid specimen-to-specimen contamination, particularly for use in PCR assays. Precautions include the use of disposable microtome blades, thorough cleaning of the microtome between specimens with 70% ethanol, and changing of gloves between each specimen. HPV-negative tissues (e.g., fallopian tubes) should be sectioned periodically as a negative control. Sections are deparaffinized with octane and digested with a buffer containing proteinase K and a nonionic detergent. Large sections can be further purified with organic extraction and ethanol precipitation. DNA from very small tissue biopsy specimens can be lost during organic purification; HPV amplification directly from a crude lysate (after it is heated at 95°C for 10 min to inactivate the protease) has been demonstrated to be sufficient (93).

**Exfoliated Cells**

LBC samples are likely to be the most frequently encountered sample type for HPV testing in clinical laboratories. Manufacturers of most commercial HPV assays provide validated methods for DNA/RNA purification. Most samples in transport media do not require organic purification, and NA extraction is based on precipitation methods. A sample conversion step, provided by the manufacturer, is required for LBC samples to render them compatible with the hc2 test (64). The Cervista test recommends purification of DNA from PreservCyt samples using the Genfind DNA extraction kit (Hologic) (65). NA extraction using the

coxsackievirus B19 (Coxsackievirus B19) and the Acanthamoeba castellanii (Acanthamoeba castellanii) are included in the automated test procedures. When possible, the recommended protocol should be utilized to ensure that test performance is consistent with that validated by the manufacturers.

### Alternative Methods
Numerous NA isolation systems are commercially available, several with high-throughput biorobotic capabilities. Laboratory validation of these methods against the manufacturer’s method is necessary before claims of performance equivalent to that reported in the assay trials can be made (90–93). Sample transport medium composition will determine what level of purification is required, particularly for enzyme-dependent assays. Additionally, test sensitivity will reflect the volume of the original sample used for purification, any concentration or dilution steps, and the fraction of purified material used in the final assay. To claim performance comparable with that of an alternative procedure, the final proportion of sample tested should be similar to that used in the manufacturer’s performance validation. Finally, it is critical to note that the validation of NA purification methods has been conducted primarily using uterine cervix samples and that comparable performance when other specimen types are used cannot be guaranteed.

### FDA-Approved Molecular Assays for Detection of HPV

**hc2 Tests**
The Hybrid Capture 2 (hc2) HPV tests (Qiagen, GmbH, Hilden, Germany) are based on hybrid capture signal amplification technology, where full-length RNA probes against 13 HR-HPV genotypes (hc2 HPV and hc2 HR-HPV tests) and 5 LR-HPV types (hc2 HPV test) are hybridized to denatured target DNA (Table 3) (64). HPV RNA/DNA hybrids are detected using a sandwich enzyme-linked immunosorbent assay (ELISA)-type reaction. Hybrids are initially captured onto a solid-surface microwell by anti-RNA/DNA hybrid antibodies to the captured target hybrid. Addition of substrate produces light, which is measured by a manufacturer-supplied luminometer. The readout of the assay is in relative light units (RLU), and patient sample results are compared to values for the internal positive-control calibrator. For samples collected in STM, the sample RLU/positive-control RLU ratio of ≥1.0 is considered positive for the detection of the HR-HPV types included in the assay. LBC samples with a ratio of ≥2.5 are considered positive. Samples with RLU ratios between 1.0 and 2.5 are recommended for repeat testing, though reproducibility will be inherently poor due to stochastic sampling error in samples with low concentrations of HPV DNA. A positive result is indicative of ≥5,000 HPV copies/ml in the original sample. hc2 can be performed manually or using the automated Rapid Capture system (Qiagen).

The hc2 test has been extensively evaluated in multiple population-based screening studies and randomized clinical trials (94) and has been shown to have a very high sensitivity (pooled sensitivity = 99.9% [94]). While the hc2 test targets only 13 HR-HPV types, the probe pool cross-reacts with several LR-HPV genotypes (95, 96) and HR type 66. The cross-reactivity affects analytic specificity (97) but has only a modest impact on the clinical specificity and may increase the sensitivity compared to those of less cross-reactive tests, specifically if cases are defined as CIN2 or more severe (97). The hc2 test does not contain an internal control for specimen adequacy, increasing the risk for false-negative results. However, the rate of false negatives in cervical samples tested by assays which include a human DNA control is usually reported as <1%. In FDA clinical trials, hc2 results were compared to those of colposcopy and consensus histology. hc2 sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) for the detection of CIN2+ were 93%, 61.1%, 17.2%, and 99.9%, respectively (64).

**Cervista HPV-HPV Test**
The Cervista HPV-HPV test (Hologic, Madison, WI) detects but does not distinguish the DNA from 14 HR-HPV types (Table 3) (65). The Cervista HPV-HPV test is based on
signal amplification with the use of Invader chemistry. The test can be performed manually or using the Cervista high-throughput automation (HTA) platform (Hologic). The test includes an internal control for human histone DNA. In clinical trial studies for FDA approval, results obtained with the Cervista HR-HPV test were compared to those of colposcopy and consensus histology for the detection of CIN2+ and CIN3+. Assay sensitivity, specificity, PPV, and NPV for the detection of CIN2+ were 92.8%, 44.2%, 8.3%, and 99.1%, respectively, and for the detection of CIN3+ were 100%, 43.0%, 2.9%, and 100%, respectively (65, 98).

Analytical positive percent agreement (PPA) and negative percent agreement (NPA) with the results of a composite comparator (hc2 testing and PCR sequencing) for a population with atypical squamous cells of undetermined significance (ASC-US) were 95.5% and 89.4%, respectively, and for a population with cytology results negative for intraepithelial lesion or malignancy in women 30 years or older (NILM 30+) were 94.4% and 84.2%, respectively. Several additional studies have demonstrated that the analytic performances and clinical performance are comparable to those of hc2 (99, 100).

Aptima HPV Assay

The Aptima HPV assay (Hologic/Gen-Probe, San Diego, CA) detects E6/E7 mRNA from 14 HR types (Table 3) (67). The assay is fully automated on the Tigris and Panther platforms (Hologic). The three-step test process takes place in a single-tube format. E6/E7 mRNA is isolated using an HPV-specific target capture process, the mRNA is amplified by transcription-mediated amplification (TMA), and detection of the amplification products is performed using the hybridization protection assay (HPA). The assay incorporates an internal control to monitor nucleic acid capture, amplification, and detection. The internal control and target mRNA are distinguished using a dual-kinetics assay. In clinical trial studies for FDA approval, results obtained with the Aptima HPV assay were compared to those of colposcopy and consensus histology for the detection of CIN2+ and CIN3+ (106). Assay sensitivity, specificity, PPV, and NPV for the detection of CIN2+ were 86.8%, 62.9%, 20.1%, and 97.8%, respectively, and for the detection of CIN3+ were 90.2%, 60.2%, 9.4%, and 99.3%, respectively (67). Analytical PPA and NPA with the results of a composite comparator (hc2 testing and reverse transcription RT-PCR sequencing) for an ASC-US population were 97.8% and 199%, respectively, and for a population with cytology NILM 30+ results were 93.2% and 85.8%, respectively. Overall, the Aptima HPV assay demonstrated sensitivity comparable to those of DNA-based assays with slightly more specificity for detection of clinically relevant disease (107–114).

Comparison of HPV Assays for the Detection of CIN2+ and CIN3+

Numerous clinical studies have compared the performances of the various HPV assays to that of hc2 in a variety of clinical populations and in regions of varying disease prevalence. Detailed review is beyond the scope of this chapter. However, two large studies compared the performances of multiple tests (FDA approved and for research use only [in the United States]) in women with abnormal cytology (112, 113) and in one study of a screening population (112). The Predictors 1 study compared the performances of 7 tests (hc2, Amplicor [Roche], PreTect HPV-Proofer, Aptima HPV, Abbott Real-Time HPV [Abbott Molecular GmbH & Co., Wiesbaden, Germany], BD HPV [BD Diagnostics, Sparks, MD, USA], and CINtec p16) using samples in PreservCyt transport medium. The Predictors 2 study evaluated seven tests (hc2, cobas HPV, PreTect HPV-Proofer, Aptima HPV, Abbott Real-Time HPV [Abbott Molecular GmbH & Co., Wiesbaden, Germany], BD HPV [BD Diagnostics, Sparks, MD, USA], and CINtec p16) using samples in PreservCyt transport medium collected from 1,099 women referred for colposcopy (113). A recent study by Cuzick et al. compared the performances of six HPV tests, including four DNA-based tests (Abbott RealTime, hc2, cobas HPV, BD HPV) and two RNA-based detection assays (Aptima and PreTect HPV-Proofer), in a screening population (114). Residual PreservCyt samples were tested according to each manufacturer’s protocol. Each study evaluated the clinical sensitivity, clinical specificity, PPV, and NPV of each assay for the identification of high-grade CIN. Overall, in all three studies, the mRNA-based Aptima assay and the DNA-based assays, with the exception of Genomica clinical arrays, demonstrated high sensitivity for the detection of CIN2+ and CIN3+. In all three studies, the PreTect HPV-Proofer assay demonstrated significantly lower clinical sensitivity, since the assay detects only E6/ E7 mRNA of 5 of the most common 14 HR-HPV types associated with CIN2+. Conversely, the PreTect HPV-Proofer demonstrated the highest specificity and PPV, followed by the CINtec p16 and Aptima assays. Using the data from the Predictors 1 and 2 studies, Mesher et al. (84) evaluated triage testing for the detection of CIN2+ and CIN3+ in women with borderline or single mildly dyskaryotic cytology smears. Four HPV DNA assays (hc2, Abbott RealTime PCR, BD HPV test, cobas 4800) and one HPV RNA assay (Aptima) had sensitivities of 99% to 100% for the detection of CIN3+ and despite a lower specificity could reduce referrals to colposcopy by 20 to 30% (84). Specificity could be improved by another 20 to 30% if only women positive for HPV-16 or p16INK4a were referred for colposcopy, although sensitivity for CIN2+ was slightly decreased. Less sensitive triage tests, such as PreTect HPV-Proofer and CINtec p16, could reduce the number of unnec-
necessary referrals further by 15 to 25% but miss 15 to 30% of CIN3+ women. These studies confirm that both the DNA-based and the Aptima RNA-based assay can provide high sensitivity for detection of high-grade disease and that the use of RNA-based assays and CIStec p16 can improve the specificity of the HPV testing.

FDA-Approved HPV Genotyping Systems
One of the most characteristic features of HPV infection is the multiplicity of genotypes known to infect the anogenital tract and oral cavity. Complete genotyping has been incredibly useful as a research tool to evaluate the natural history of all genotypes in epidemiological studies; however, the clinical utility is limited. Early natural history studies of HPV utilized quite successfully laboratory-developed versions of the now commercially available assays, as well as alternative primer systems, such as MY09/11 and GP5+/6+. Because of the high degree of similarity among the HPV genotypes, assays utilizing target-specific probes are likely to be more specific than those based on SYBR green dye intercalation. Performance comparable to that of the commercial tests has been demonstrated in only a few highly experienced laboratories. Due to the complexity of HPV genotyping, the use of laboratory-developed assays is strongly discouraged unless there is adequate demonstration of quality control for each genotype targeted.

Direct sequencing of consensus primer PCR products is limited in utility to samples with a single type of infection. Discrimination of HPV sequences from infections with multiple HPV types, which are common, is not possible by standard sequencing technologies. However, deep sequencing, next-generation sequencing, and also mass spectrometry have the potential to provide the means for more-comprehensive genotyping.

Presently, the American Society for Colposcopy and Cervical Pathology provides recommendations for specifically identifying only HPV-16 and HPV-18 (Fig. 2) (115). The utility of discriminating HPV-16 and HPV-18 stems from long-term population-based screening studies which have found that HPV type 16 or 18 detection confers a significant increased risk for progression to CIN2+ within the 2 to 3 years subsequent to detection compared to risks after detection of the other carcinogenic HPV types (116). In addition, HPV types 16, 18, and also type 45 account for the majority of adenocarcinomas (AdCa), which are located internally and often missed by cytologic screening, whereas HPV DNA is frequently detected years prior to the AdCa diagnosis. These data led to the current guidelines for reflex HPV type 16/18 genotyping of HR-HPV DNA test results among cytologically normal women (Fig. 2).

The Cervista HPV genotyping assay (Hologic) identifies and differentiates HPV-16 and -18 (98, 117, 118). The Aptima HPV genotyping assay (Hologic) detects HPV-16, -18, and -45 and differentiates type 16 from types 18 and 45 (119). Both assays are FDA approved for clinical use as a reflex test for samples HR-HPV positive by the Cervista HR-HPV test and the Aptima HPV assay, respectively. The cobas 4800 system tests simultaneously for a pool of the 12 HR-HPV types and separately for HPV-16 and HPV-18 (66, 101, 102, 120).

Use of HPV Genotyping to Manage HPV HR* Positive / Cytology negative
Women 30 years and Older

Research-Use-Only HPV Genotyping Assays

Numerous research-use-only genotyping systems that utilize a variety of methodologies (Table 6) are available for the detection of HR HPV, LR HPV, and types of yet-undetermined significance. The systems are generally based on consensus L1 or E1 PCR amplification of a broad spectrum of HPV genotypes in a single reaction mixture using a pooled HPV primer cocktail and genotype discrimination by reverse hybridization of labeled PCR products to a spectrum of strip-immobilized type-specific probes (e.g., Linear Array [Roche], INNO-LiPA, Innogenetics/Fujirebio Europe, Ghent, Belgium). DNA arrays (e.g., PapillCheck [Greiner Bio-One GmbH, Frickenhausen, Germany]), bead-based arrays (e.g., GeneFinder [Innomeditech, Seoul, South Korea]), and multiplex PCR using matrix-assisted laser desorption ionization--time of flight mass spectrometry (MALDI-TOF MS) (PCR-M5) (e.g., MassARRAY [Sequenom, San Diego, CA]) (121, 122). Many include an internal control that targets a human housekeeping gene, such as β-globin.

Some type-specific differences in amplification efficiency have been noted for several tests. Because ~30% of HPV-positive women will have two or more genotypes present in a single sample, assays that detect a wide range of genotypes may provide more-realistic type-specific prevalence estimates for population-based surveys and post-HPV vaccine surveillance. Additionally, the selection of a genotyping test is dependent on the source material. For example, the large fragment amplified by the Linear Array test (450 bp) prohibits its utility for HPV typing from fragmented DNA, such as that found in FFPE tissues. The small fragments amplified using the INNO-LiPA SPFl0 primers are ideally suited for typing from the fixed tissues.

Alternative Molecular Markers and Methylation of Viral DNA

Testing for HPV infection is very sensitive, although not very specific for the detection of high-grade cervical neoplasia, compared with cytology. New research has been focused on examining the role of human gene methylation as a biomarker for the triage of women testing positive for HR-HPV infection. A recent literature review in 2012 provided evidence of the potential utility of the detection of methylated viral DNA to ascertain a woman’s increased risk of high-grade cervical intraepithelial neoplasia of grade 2 or higher (CIN2+) and to differentiate HR-HPV-positive women with and without clinical CIN2+ (123). A recent study in Tanzania found that a 5% increase in DNA methylation of paternally expressed gene 3 (PEG3) was associated with a 1.6-fold-higher risk of invasive cervical cancer. Overall, data have been relatively consistent in showing a higher risk of CIN2+ among women with methylation of CpG sites of the L1 gene and less consistent in showing methylation of CpG sites in the upstream regulatory region (123). Predictors 1 and 2 analyzed DNA methylation levels in the L1 and L2 regions of HPV-16, HPV-18, and HPV-31 and in the EPB4L3 and DPVS human genes among 1,711 women and 582 CIN2+ cases (124, 125). There will be an emerging literature on the role of epigenetics as potential diagnostic tools that merit further observation.

ISOLATION PROCEDURES

HPV is not culturable, and therefore, the detection and genotyping of HPV are predominantly dependent on molecular tests that target either HPV DNA or mRNA.

SEROLOGIC TESTS

Serologic detection of HPV antibodies is a marker of cumulative exposure and thus cannot determine the site of infection or time of infection. Research-use-only assays demonstrated limited sensitivity, detecting antibodies in only ~60% of women with DNA from the same type of HPV (126). Therefore, the utility of serologic detection of HPV in clinical practice is extremely limited. With the availability of type-specific prophylactic HPV vaccines and the lack of therapeutic benefit, both patients and some providers may wish to use antibody testing to evaluate susceptibility prior to making a choice to vaccinate. Because of the described problems with HPV serology, particularly in the context of low-titer antibodies produced during natural infection, this practice is strongly discouraged.

There are currently no commercially available serologic tests for the detection of HPV-specific antibodies. However, the use of prophylactic HPV vaccines has precipitated standardization of serologic assays for immunogenicity testing by the vaccine manufacturers. The relative strengths and weaknesses of the three most common assays used to measure serum HPV antibodies (i.e., ELISA, competitive Luminex immunoassay, and neutralization) have been recently reviewed (127).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

The goal of HPV testing is to identify individuals at high risk of CIN2+ lesions as part of either routine cervical cancer screening or posttreatment management for prevention of recurrent disease. At present, the four FDA-approved assays have been widely applied, showing reproducibly high sensitivity and negative predictive value when used for the detection and treatment of CIN2+ disease in cervical cancer screening. Detection of the presence or absence of a pool of HR-HPV genotypes is sufficient for the currently approved clinical indications (61, 62, 63). The exception is the possible added positive predictive value in identifying the presence of HPV types 16, 18, and 45 from other HR-HPV types. Broad-spectrum genotyping assays are useful primarily for research purposes, including postvaccination genotype distribution surveillance. The detection and reporting of LR-HPV genotypes have no clinical value. Laboratorians should encourage following the current testing guidelines with respect to patient age, cotesting, reflex testing, and testing frequency.

The Future of HPV Testing

The question that remains is “can HPV testing replace cytology as a primary cervical screening method for the detection of CIN2+ and CIN3+ in women 30 years and older?” In 2009, international guidelines for HPV DNA test requirements for primary cervical cancer screening in women 30 years and older stated that candidate HPV tests must offer an optimal balance between clinical sensitivity (not less than 90% of the clinical sensitivity of hc2) and specificity (not less than 98% of the specificity of hc2) for CIN2+ or higher CIN (90). Assays must be robust and highly reliable and should display inter- and intralaboratory reproducibility. A recent study by Ronco et al. using follow-up data from four European randomized controlled trials determined that HPV-based screening provided 60 to 70% greater protection against cervical cancer than cytology (128). Additionally, the data confirmed that screening intervals can be extended to at least 5 years. In April 2014, based on the data from the ATHENA HPV study and a...
recommendation from the U.S. FDA advisory panel, the cobas HPV test, not cytology, was approved as a primary screening tool for cervical cancer in women 25 years and older.

Human Papillomaviruses

Human Polyomaviruses
RICHARD S. BULLER

105

TAXONOMY
Because of the discovery of a significant number of new human polyomaviruses (HPyVs), the taxonomy of these viruses has been in flux since the last edition of this Manual. The polyomaviruses were formerly members of the Papovaviridae family but have been reclassified into the family Polyomaviridae, which has a single genus, Polyomavirus. The Polyomaviridae Study Group has proposed that the family now be divided into three genera, i.e., Orthopolyomavirus, Wukipolyomavirus, and Avipolyomavirus, with mammalian and human viruses found in the first two genera and bird viruses in the third (1). The recognized human species BK polyomavirus (BKPyV), JC polyomavirus (JCPyV), Merkel cell polyomavirus (MCPyV), Human polyomavirus 9 (HPyV9), and Trichodysplasia spinulosa-associated polyomavirus (TSPyV) would reside in the genus Orthopolyomavirus, along with the type species for the genus, the primate virus Simian virus 40. The proposed genus Wukipolyomavirus would contain the human type species KI polyomavirus (KIPyV) and the HPyVs WU polyomavirus (WUPyV), Human polyomavirus 6 (HPyV6), and Human polyomavirus 7 (HPyV7). Characteristics of other recently discovered HPyVs, including Malawi polyomavirus (MWPyV) (2), St. Louis polyomavirus (STLPyV) (3), and Human polyomavirus 12 (HPyV12) (4), suggest that recombination events have generated these viruses, as well as some of the other HPyVs, making their placement in the proposed taxonomy problematic (3). It is likely that changes to the proposed polyomavirus taxonomy will be forthcoming.

Because some of the novel HPyVs were discovered nearly simultaneously in more than one laboratory, different names for what appear to be the same virus, or strains of the same virus, can be found in the literature. For example, the novel viruses MxPyV and HPyV10 (5, 6) appear to be the same species as MWPyV (2), with current usage favoring the name “MWPyV,” as it was the first reported. Additionally, in the previous edition of this Manual, Lymphotropic polyomavirus (LPyV), a strain of African green monkey polyomavirus, was listed here because antibodies to that virus were reported in humans, suggesting infection by LPyV or a closely related virus. It now appears that HPyV9 is likely the closely related virus responsible for those findings (7).

From a diagnostic perspective, further subclassification of polyomaviruses is primarily important for BKPyV. BKPyV was originally divided into six subtypes based on VP1 gene sequences. However, whole-genome sequence data support the existence of four subtypes (I to IV), with two subtypes reclassified as subgroups of subtype I (8). Subtypes vary in prevalence and geographic distribution (9). Subtype I is most prevalent and is found worldwide; subtype IV is second most prevalent and is found mostly in Asia and Europe. Subtypes II and III are uncommon and are found throughout the world. Subtype-dependent quantification bias has been observed and can contribute to interassay differences in quantification (see “Nucleic Acid Amplification Methods” below).

DESCRIPTION OF THE AGENTS
The polyomaviruses are small (40- to 45-nm diameter), icosahedral, nonenveloped viruses with a circular double-stranded DNA genome. The size of the genome is relatively small, with all of the human viruses, including the newly identified members and SV40, falling within the range of 4,900 to 5,400 bp. JCPyV, BKPyV, and SV40 have been extensively characterized. The newly characterized viruses have been less well studied.

The genome is organized into an early region that is transcribed prior to DNA replication and a late region transcribed after DNA replication. The noncoding control region (NCCR) separates the early and late regions and includes the origin of replication (10).

Early region transcripts code for the large and small T antigens, nonstructural proteins that regulate viral replication, control of viral transcription, induction of host cell division, and transformation. Late gene transcripts code for viral capsid proteins VP1, VP2, and VP3, of which VP1 is the major capsid protein, comprising ~80% of the capsid and being the only surface-exposed protein (10). The late regions of JCPyV, BKPyV, and SV40 also code for a fourth late protein termed the agnoprotein, the function of which is incompletely understood, but which appears to be a nonstructural protein involved in viral assembly and release from infected cells (10).

The genomic organization of the newly identified polyomaviruses appears to be similar to those previously described, with open reading frames identified for the T antigens and VP1, VP2, and VP3 (2–4, 11). These viruses appear to differ from JCPyV and BKPyV in that there is no agnoprotein open reading frame (2–4, 11).

The NCCRs of the human viruses BKPyV and JCPyV are hypervariable sequences of ~300 to ~500 bp in length. The NCCR contains the origin of replication and promoters

doi:10.1128/9781555817381.ch105

1803
for early and late gene transcription. The variable nature of the NCCR is apparent when sequences of this region are compared between viruses obtained from different anatomical sites. The NCCR sequence from kidney and urine isolates is referred to as the archetype. Viruses with archetype NCCR sequences do not replicate well in cell cultures and may be the infectious form of the virus.

**EPIDEMIOLOGY AND TRANSMISSION**

Both BKPyV and JCPyV appear to infect the majority of humans by adulthood. Seroepidemiology studies reveal that 50% of children acquire anti-BKPyV antibodies by the age of 3 years, with the 50% prevalence for JCPyV being reached by age 6 years (12). For all age groups, the seroprevalence for BKPyV ranges from 55 to 85%, with similar numbers for JCPyV, although there is more variability in the age of seroconversion for JCPyV relative to BKPyV (13). The mechanism of BKPyV and JCPyV transmission is largely speculative, in part because primary infection does not appear to cause clinical illness, although there are reports of signs and symptoms such as fever or respiratory illness accompanying seroconversion (13). Respiratory and oral transmission has been hypothesized, since JCPyV can infect tonsillar cells (14) and has been detected in tonsillar tissue (15). However, studies of oral and respiratory specimens have failed to detect BKPyV and JCPyV (16, 17). Uro-oral transmission has been hypothesized, and circumstantial evidence consists of intermittent BKPyV and JCPyV excretion in urine of immunocompetent and immunocompromised individuals (13, 18), detection of BKPyV and JCPyV in sewage samples (19-21), and the stability of these nonenveloped viruses. Even less is known about the epidemiology and transmission of the newly identified HPyVs. WUPyV and KIPyV are found in respiratory secretions and are widely distributed around the globe (22-30). WUPyV has been detected in respiratory secretions of a 1-day-old infant, raising the possibility of *in utero* or intrapartum infection (28). Studies have also detected WUPyV in small numbers of serum and stool specimens (31, 32). MCPyV is also found in respiratory specimens (33, 34), and seroprevalences of 50 and 80% in children and adults have been documented, suggesting that infection is common (35).

Epidemiological studies of the more recently identified HPyVs are in their infancy, with initial seroepidemiological studies suggesting that infection with these viruses is also common, with seroprevalence low in children and rising in adulthood to 35 to 75% depending on the virus (36). Caution must be exercised in the interpretation of these findings, as cross-reactions are possible among the polyomaviruses and it is likely that unidentified HPyVs exist that could confound the interpretation of seroprevalence studies (36).

Humans were exposed to the nonhuman primate polyomavirus SV40 between 1955 and 1963 when some incompletely formalin-inactivated lots of polio vaccine were found to be contaminated. Monkey kidney cell cultures used to prepare the vaccine were found to be the source of contamination. About 200 cases of paralytic polio occurred due to the presence of infectious poliovirus in the vaccine. Although ~100 million Americans were vaccinated during this period, it is not known how many of the lots contained infectious SV40 or how many people became infected with SV40 as the result of this accident (37).

**CLINICAL SIGNIFICANCE**

Polyomaviruses cause a number of diseases in different patient populations (Table 1). Progressive multifocal leuкоencephalopathy (PML) is a rare disease of the central nervous system (CNS) caused by infection and destruction of myelin-producing oligodendrocytes by JCPyV. Focal demyelination in white matter can be visualized by neuroimaging studies such as magnetic resonance (MR) imaging (Fig. 1). Neurological signs and symptoms include gait or other motor disturbances and cognitive abnormalities (38). Prognosis is poor, with long-term survival defined as >12 months (10). Prior to the development of highly active antiretroviral therapy (HAART), PML was primarily seen in severely immunocompromised HIV-infected individuals. With the advent of HAART, PML has become less common in the HIV-infected patient population but has now appeared in patients treated with immunomodulatory agents, in particular multiple sclerosis patients treated with natalizumab. PML is still uncommon in this group (incidence, ~2/1,000 patients treated), but three risk factors are recognized: duration of natalizumab treatment, prior use of immunosuppressives, and positive JCPyV antibody status (39, 40). Prior to effective anti-HIV therapy, mortality from PML was nearly 100%, but it has now fallen to about 50%. Mortality for PML induced by immunomodulatory agents is lower, although there can be severe neurological sequelae (41). Other CNS diseases such as cerebral atrophy and granule cell neuronopathy appear to be rare forms of JCPyV infection (41).

BKPyV has tropism for uroepithelial cells and can cause a spectrum of presentations. Asymptomatic shedding can occur in urine of normal individuals (especially during pregnancy and in the elderly) and immunocompromised patients. Polyomavirus-associated nephropathy (PVAN) occurs in immunocompromised patients and is the result of BKPyV replication in, and the destruction of, renal tubular epithelial cells. It occurs most commonly in renal transplant recipients (42). BKPyV has also been described as a rare cause of nephropathy in other settings of immunocompromise such as HIV, hematologic malignancy, hematopoietic stem cell transplant, transplant of organs other than kidney, and congenital immunodeficiency (43).

In PVAN, increasing levels of virus are initially found in urine, followed by viremia and then development of the disease (44). Without clinical intervention, PVAN can result in renal graft dysfunction and, ultimately, graft loss (45). In a prospective study of 78 renal transplant recipients, the probability of developing PVAN was 8% (46). Renal transplant patients may have a propensity to develop PVAN due to the use of more-aggressive immunosuppression regimens (45). BKPyV acquisition from the donor kidney, or HLA-mediated predisposition (47, 48). PVAN is treated by reducing immunosuppression; certain antiviral compounds have also been used (44, 49, 50). JCPyV has also been reported to rarely cause PVAN (51, 52).

Other pathological conditions associated with BKPyV include hematuria, ureteral stenosis, and hemorrhagic cystitis. Hemorrhagic cystitis is due to BKPyV infection of the bladder epithelium. It occurs most commonly in the setting of stem cell transplantation and is seen less frequently in other immunocompromised states, including HIV infection. Allogeneic stem cell recipients are at particular risk, and disease occurs several weeks after transplant, differentiating it from chemotherapy-associated disease, which generally occurs immediately. Hemorrhagic cystitis is associated with significant morbidity but is rarely fatal (53). The risk of developing the disease has been shown to correlate with increased levels of BKPyV viremia (54) and viremia (55).

</table>

Treatment is supportive, although the use of select antiviral drugs has been attempted (53). Rarer examples of BKPyV diseases in immunocompromised patients, including HIV infection and posttransplant immunosuppression, include disseminated disease, CNS infections, retinitis, colitis, vasculitis, and pneumonia (43).

Attempts to link the newly identified HPyVs with specific human diseases are in their infancy. KIPyV and WUPyV have not been firmly associated with human disease (56). WUPyV DNA and antigens were found in a 2-year-old bone marrow transplant (BMT) patient who died of multiorgan disease (57); a definitive link between virus infection and disease awaits further study.

Merkel cell carcinoma is a rare, highly aggressive human neuroepithelial tumor of the skin noted for its high mortality. In 2008, using molecular viral discovery techniques, a novel polyomavirus, subsequently named MCPyV, was identified in specimens from this cancer (58) (Table 1). Subsequent studies have demonstrated MCPyV in ~80% of Merkel cell carcinoma samples examined (59, 60), although MCPyV has also been detected in skin samples from healthy individuals (60), with one report indicating that MCPyV is chronically shed from the skin of healthy individuals as intact virions, suggesting a mode of transmission (61). The fact that MCPyV infection appears to be ubiquitous and Merkel cell carcinoma is uncommon suggests that other factors, such as immune suppression, sun exposure, female sex, and age >60 years, contribute to the development of this cancer (60, 62).

Trichodysplasia spinulosa is a rare skin disease that occurs only in immunocompromised individuals (60). In 2010, a novel HPyV, subsequently named TSPyV, was identified in specimens from a heart transplant recipient with the disease (63), confirming an earlier report of polyomavirus-like particles seen in electron micrographs (64). High viral loads and the presence of viral proteins in trichodysplasia spinulosa lesions suggest that active TSPyV replication is taking place in diseased tissues (65). As with some of the other HPyVs, TSPyV infection appears to be ubiquitous, with seroepidemiological studies indicating a low seroprevalence in children that rises to ~70% in adults (66, 67). Currently, there is no clear clinical significance that can be ascribed to the remaining novel HPyVs (Table 1), although it is intriguing that many HPyVs, including the
PCR of 64 days and a 90% of the viral concentration as measured by quantitative direct microscopic examination of tissue is performed less commonly for PML than for PVAN due to the risks involved in obtaining brain biopsy material. In brain biopsy specimens, PML appears as foci of demyelination containing macrophages, enlarged oligodendrocytes with basophilic or eosinophilic nuclear inclusions, and enlarged bizarre astrocytes with pleomorphic nuclei, typically in the subcortical white matter (Fig. 3) (78, 79).

Electron microscopy (EM) can be used in the diagnosis of PVAN and PML. Intracellularly, polyomaviruses appear as 40-nm-diameter virions packed in paracrystalline arrays or so-called “stick and ball” or “spaghetti and meatballs” structures (Fig. 2 and 3) (80–82). Extracellular BKPyV virions are found by EM in aggregates called “Haufen” in urine of BMT patients (83) and PVAN patients (84). EM may be useful in the diagnosis of Merkel cell carcinoma, as polyomavirus particles have been observed in some cases (85). EM has also been used to demonstrate typical polyomavirus virions in tissue from trichodysplasia spinulosa patients (65).

**Antigen Detection**

Immunohistochirochemical staining of tissue sections using antibodies reactive with polyomavirus antigens has been employed as an adjunct to histopathological examination of tissue for the diagnosis of PVAN (42, 81, 86, 87) and PML (82, 88) (Fig. 2 and 3). In the case of PVAN, the demonstration of polyomavirus antigen can help in determining whether PVAN or rejection is the cause of renal pathology. Commercially available antibodies raised against the SV40 large T antigen are most commonly used for this purpose (see http://www.biocompare.com for suppliers). These antibodies are cross-reactive with JCPyV and BKPyV antigens and can be used to detect polyomaviruses but cannot be used to definitively identify which virus is present.

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

Although systematic studies of clinical specimens have not been reported for polyomaviruses, as one would expect for these nonenveloped DNA viruses, polyomaviruses appear to be quite stable. A study of JCPyV stability in sewage at 20°C found a t90 value (time required for a reduction of 90% of the viral concentration as measured by quantitative PCR) of 64 days and a t99 of 127 days, with a greater t90 value obtained when the virus was suspended in phosphate-buffered saline (111 days) (72). These data suggest that standard guidelines for the collection, transport, and storage of specimens for viral diagnostics (see chapter 79) should be sufficient for polyomaviruses.

Specimens commonly submitted for the detection of polyomaviruses include blood, cerebrospinal fluid (CSF), urine, respiratory specimens, and tissue. Polyomaviruses can be recovered from peripheral blood mononuclear cells, usually for research purposes. Guidelines for collection and transport of specimens are generally those that apply to molecular testing (see chapter 79 and reference 73). When available, manufacturers’ directions for collection, transport, and storage of specimens should be followed. Since nucleic acid detection methods are the primary means by which polyomaviruses are detected in clinical specimens, extracted DNA should be stored in tightly sealed low-binding plastic tubes to prevent evaporation and binding of DNA to the walls of the tubes (73). DNA can be stored in Tris-EDTA buffer for up to 1 year at 2 to 8°C, at −20°C for up to 7 years, or at −70°C or lower for at least 7 years (73).

**DIRECT EXAMINATION**

**Microscopy**

Histologic assessment of renal biopsy material is the gold standard for the diagnosis of PVAN (44). PVAN is a tubulointerstitial nephritis that resembles the pathology associated with rejection (42, 74–76). In contrast to rejection, characteristic basophilic, intranuclear viral inclusions are observed in PVAN (Fig. 2) (42, 74, 76). At least two tissue biopsy specimens should be examined prior to ruling out PVAN due to its patchy nature (44, 75). Papainicolau stain of urine sediment from patients with PVAN reveals abnormal inclusion-bearing cells referred to as “decoy cells” due to their resemblance to malignant cancer cells (Fig. 2) (77).

Antemortem direct microscopic examination of tissue is performed less commonly for PML than for PVAN due to the risks involved in obtaining brain biopsy material. In brain biopsy specimens, PML appears as foci of demyelination containing macrophages, enlarged oligodendrocytes with basophilic or eosinophilic nuclear inclusions, and enlarged bizarre astrocytes with pleomorphic nuclei, typically in the subcortical white matter (Fig. 3) (78, 79).

Electron microscopy (EM) can be used in the diagnosis of PVAN and PML. Intracellularly, polyomaviruses appear as 40-nm-diameter virions packed in paracrystalline arrays or so-called “stick and ball” or “spaghetti and meatballs” structures (Fig. 2 and 3) (80–82). Extracellular BKPyV virions are found by EM in aggregates called “Haufen” in urine of BMT patients (83) and PVAN patients (84). EM may be useful in the diagnosis of Merkel cell carcinoma, as polyomavirus particles have been observed in some cases (85). EM has also been used to demonstrate typical polyomavirus virions in tissue from trichodysplasia spinulosa patients (65).

**Antigen Detection**

Immunohistochirochemical staining of tissue sections using antibodies reactive with polyomavirus antigens has been employed as an adjunct to histopathological examination of tissue for the diagnosis of PVAN (42, 81, 86, 87) and PML (82, 88) (Fig. 2 and 3). In the case of PVAN, the demonstration of polyomavirus antigen can help in determining whether PVAN or rejection is the cause of renal pathology. Commercially available antibodies raised against the SV40 large T antigen are most commonly used for this purpose (see http://www.biocompare.com for suppliers). These antibodies are cross-reactive with JCPyV and BKPyV antigens and can be used to detect polyomaviruses but cannot be used to definitively identify which virus is present.

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

Although systematic studies of clinical specimens have not been reported for polyomaviruses, as one would expect for these nonenveloped DNA viruses, polyomaviruses appear to be quite stable. A study of JCPyV stability in sewage at 20°C found a t90 value (time required for a reduction of 90% of the viral concentration as measured by quantitative PCR) of 64 days and a t99 of 127 days, with a greater t90 value obtained when the virus was suspended in phosphate-buffered saline (111 days) (72). These data suggest that standard guidelines for the collection, transport, and storage of specimens for viral diagnostics (see chapter 79) should be sufficient for polyomaviruses.

Specimens commonly submitted for the detection of polyomaviruses include blood, cerebrospinal fluid (CSF), urine, respiratory specimens, and tissue. Polyomaviruses can be recovered from peripheral blood mononuclear cells, usually for research purposes. Guidelines for collection and transport of specimens are generally those that apply to molecular testing (see chapter 79 and reference 73). When available, manufacturers’ directions for collection, transport, and storage of specimens should be followed. Since nucleic acid detection methods are the primary means by which polyomaviruses are detected in clinical specimens, extracted DNA should be stored in tightly sealed low-binding plastic tubes to prevent evaporation and binding of DNA to the walls of the tubes (73). DNA can be stored in Tris-EDTA buffer for up to 1 year at 2 to 8°C, at −20°C for up to 7 years, or at −70°C or lower for at least 7 years (73).

**DIRECT EXAMINATION**

**Microscopy**

Histologic assessment of renal biopsy material is the gold standard for the diagnosis of PVAN (44). PVAN is a tubulointerstitial nephritis that resembles the pathology associated with rejection (42, 74–76). In contrast to rejection, characteristic basophilic, intranuclear viral inclusions are observed in PVAN (Fig. 2) (42, 74, 76). At least two tissue biopsy specimens should be examined prior to ruling out PVAN due to its patchy nature (44, 75). Papainicolau stain of urine sediment from patients with PVAN reveals abnormal inclusion-bearing cells referred to as “decoy cells” due to their resemblance to malignant cancer cells (Fig. 2) (77).

Antemortem direct microscopic examination of tissue is performed less commonly for PML than for PVAN due to the risks involved in obtaining brain biopsy material. In brain biopsy specimens, PML appears as foci of demyelination containing macrophages, enlarged oligodendrocytes with basophilic or eosinophilic nuclear inclusions, and enlarged bizarre astrocytes with pleomorphic nuclei, typically in the subcortical white matter (Fig. 3) (78, 79).

Electron microscopy (EM) can be used in the diagnosis of PVAN and PML. Intracellularly, polyomaviruses appear as 40-nm-diameter virions packed in paracrystalline arrays or so-called “stick and ball” or “spaghetti and meatballs” structures (Fig. 2 and 3) (80–82). Extracellular BKPyV virions are found by EM in aggregates called “Haufen” in urine of BMT patients (83) and PVAN patients (84). EM may be useful in the diagnosis of Merkel cell carcinoma, as polyomavirus particles have been observed in some cases (85). EM has also been used to demonstrate typical polyomavirus virions in tissue from trichodysplasia spinulosa patients (65).

**Antigen Detection**

Immunohistochirochemical staining of tissue sections using antibodies reactive with polyomavirus antigens has been employed as an adjunct to histopathological examination of tissue for the diagnosis of PVAN (42, 81, 86, 87) and PML (82, 88) (Fig. 2 and 3). In the case of PVAN, the demonstration of polyomavirus antigen can help in determining whether PVAN or rejection is the cause of renal pathology. Commercially available antibodies raised against the SV40 large T antigen are most commonly used for this purpose (see http://www.biocompare.com for suppliers). These antibodies are cross-reactive with JCPyV and BKPyV antigens and can be used to detect polyomaviruses but cannot be used to definitively identify which virus is present.
JCPyV- and BKPyV-specific monoclonal antibodies against respective VP1 proteins are available and can be used for this purpose. For trichodysplasia spinulosa, a lab-developed, noncommercial immunofluorescence assay has been used to detect VP1 proteins of TSPyV in affected tissues (65).

**Nucleic Acid Detection**

**ISH**

*In situ* hybridization (ISH) using probes specific for BKPyV or JCPyV is an adjunct histopathologic method sometimes employed for the laboratory diagnosis of PVAN and PML (Fig. 3) (49, 86, 89–91). The addition of a PCR step may increase sensitivity (90). In the case of PVAN, as is the case for immunohistochemical staining, ISH can aid in discriminating PVAN from rejection by, in this case, localizing the presence of BKPyV nucleic acid to the site of pathology. Biotin- and digoxigenin-labeled BKPyV and JCPyV probes suitable for ISH are commercially available (Enzo Life Sciences, Farmingdale, NY).

**Southern Blotting**

Although Southern blotting is primarily a research tool, the monoclonal integration of MCPyV in Merkel cell tumors can be demonstrated in genomic DNA extracted from Merkel cell tumors using standard Southern blotting techniques followed by hybridization with MCPyV probes (58, 92).

**NAATs**

Although there are analyte-specific reagents and research use only reagents, there are currently no Food and Drug Administration (FDA)-approved assays for the detection or quantification of polyomaviruses. Laboratories are therefore left to develop their own tests and confront various issues, including selecting suitable extraction methods, controlling for various biochemical steps in testing, and choosing an amplification method and reagents. Information specific to polyomavirus nucleic acid amplification tests (NAATs) addressing these issues is provided below.

**Template Extraction**

The ideal performance characteristics for BKPyV and JCPyV NAATs are different. Monitoring for PVAN is usually performed with quantitative NAATs for BKPyV that must be reproducible (yielding results with low coefficients of variation) but not necessarily exquisitely sensitive, as low virus concentrations are not considered significant in most instances. In contrast, extremely sensitive assays for the detection of JCPyV in CSF are desirable for use in the
FIGURE 3  PML pathology (A) Gross section of the brain from a patient with PML demonstrating asymmetric focal patches of involvement mostly confined to the white matter. (B) Photomicrograph of hematoxylin and eosin-stained section of brain from a patient with PML showing plum-colored oligodendroglial nuclei (arrows), some with margined chromatin and inclusions. Infected oligodendrocytes are markedly enlarged compared to more normal-sized oligodendroglia (arrowheads) (magnification, ×400). (C) Electron micrograph of brain from a patient with PML showing the "stick and ball" or "spaghetti and meatballs" (arrows) appearance of JCPyV in an oligodendrocyte (magnification, ×58,000). (D) Photomicrograph of an immunostained brain section demonstrating JCPyV proteins in enlarged immunoreactive oligodendroglial nuclei (arrowhead) but little involvement of atypical astrocytes (arrow) (magnification, ×600). (E) Photomicrograph of ISH using a labeled JCPyV probe showing a positive signal in oligodendrocytes (arrowheads) and an atypical labeled astrocyte (arrow) (magnification, ×1,000). diagnosis of PML. The nucleic acid extraction method should be selected to help meet these different performance criteria.

There exist in the peer-reviewed literature several evaluations of extraction methods that examine the ability of different methods to extract and purify BKPyV DNA from clinical specimens (93–97). In general, there were minimal differences between the automated and manual methods examined for BKPyV-containing specimens, although one study noted a difference in the ability to remove PCR inhibitors from urine between two automated platforms (98) and differences were observed in the relative amounts of hands-on or turnaround time for the different methods.

Cross-contamination between specimens due to the extremely high levels of viruria that can occur is a major concern in BKPyV DNA extraction. No evidence of cross-contamination was observed with an automated extractor, suggesting that instrumentation is a viable option (99). Extraction may not be necessary if small sample volumes can be used in NAATs. Two microliters of unprocessed urine added to a 20-μl PCR reaction produced qualitative and quantitative BKPyV results that were not significantly different from those with samples extracted using a manual spin column method (100). A larger sample volume (5 μl) resulted in inhibition.

**Internal Controls**

Internal controls are particularly important when testing urine specimens for polyomaviruses. Such controls can be used to detect, but cannot distinguish between, problems that arise during extraction, such as incomplete elimination of amplification inhibitors (the primary concern with urine specimens) or poor nucleic acid extraction efficiency. Chemically modified noninfectious BKPyV virions that can be used as extraction controls are commercially available (ZeptoMetrix, Buffalo, NY). A seven-member inhibition panel consisting of quantified substances recognized as being NAAT inhibitors of reactions is also available (AcroMetrix, Benicia, CA) and can be used during test validation to assess assay robustness in the presence of known inhibitors.

**Positive Controls and Standards**

All NAAT reactions require the use of positive and negative controls, while quantitative NAATs require an additional set of quantitated standards for use in constructing a standard curve. There are several options available for laboratories seeking controls and standards for use in NAATs for polyomaviruses. There are no commercially available materials for the newly identified polyomaviruses. For these viruses, laboratories can either identify positive specimens that can be used to clone viral DNA and produce controls and standards or contact researchers in the field for materials. BKPyV and JCPyV control materials are commercially available (whole virus and plasmids encoding entire virus genomes [American Type Culture Collection, Manassas, VA], quantified viral DNA [Advanced Biotechnologies, Inc., Columbia, MD], and quantitated inactivated BKPyV virions [ZeptoMetrix]). There are currently no international reference quantitation standards for any of the HPyVs.

**Nucleic Acid Amplification Methods**

Conventional laboratory methods for viral diagnosis such as cell culture, rapid antigen detection, and serology have significant drawbacks for the laboratory diagnosis of HPyVs, while other methods such as immunohistochemical stains, EM, and ISH are traditionally not performed in microbiology laboratories. Therefore, for the majority of diagnostic microbiology laboratories, nucleic acid amplification will be the method of choice for the detection and/or quantitation of HPyVs in clinical specimens.

PCR has been used almost exclusively as a NAAT for the amplification of HPyVs from clinical specimens, although alternative amplification formats have been described. PCR methods can be classified as having either conventional or real-time formats. With conventional PCR assays, oligonucleotide primers amplify a specific DNA sequence, the products of which are then resolved by agarose gel electrophoresis, Southern hybridization, or microplate hybridization. In the case of real-time PCR, the assay usually includes some type of dye-labeled oligonucleotide that emits a characteristic fluorescence upon binding to the specifically amplified amplicon. Although both conventional and real-time PCR methods are capable of producing qualitative or quantitative results, real-time methods are much better suited for performing quantitative assays through the use of quantitation standards and instrument software. This feature, along with other advantages such as rapidity of results, less hands-on time, and a closed system less prone to contamination issues, has made real-time PCR the method of choice for many laboratories.

PCR assays detecting BKPyV and/or JCPyV using different formats have been described in the literature, including conventional assays with either gel detection (101, 102) or microplate colorimetric hybridization detection (103) of amplified products. Real-time PCR assays performed on the Roche LightCycler platform (104–107) as well as TaqMan probe-based assays (108–110) have also been described. A novel NAAT employing loop-mediated isothermal amplification has also been described for BKPyV (111). In the United States at this time, there are still relatively few commercial NAAT products available for the detection of BKPyV and JCPyV (Table 2).

NAATs for BKPyV and JCPyV are challenging to design due in part to species-specific sequence variation. A recent study of seven different assays employing two different calibrators reported significant variability in quantification related to the calibrators employed and, more importantly, to primer and probe designs. The most important cause of error was nucleotide mismatch between viruses and amplification/detection oligonucleotides, particularly in the case of BKPyV subtypes III and IV (112). An assay using two modified primer/probe sets was better able to accurately quantify all subtypes detected in the study. Another study found significant nucleotide mismatches in up to 31% of the BKPyV strains when primers and probes from five published real-time PCR assays were aligned against 716 sequences, with subtypes IVa, IVb, and IVc being most problematic (113). Another report detailed the use of primers and probes with degenerate bases to improve detection of BKPyV sequence variants (114). Sequence variability may also affect JCPyV NAATs. False-negative NAAT results (proved by amplification of an alternate target) have been reported in an individual with progressive CNS illness and polyomavirus-like particles by EM in brain biopsy material (115). Attention to this issue in the assay design phase is important; broadly reactive real-time PCR reagents and less-variable target sequences have been described (106, 112–114). Additionally, laboratories should align their primers and probes against new sequences at regular intervals to ensure detection of these viruses.

PCR methods have also been published for the newly identified HPyVs, although due to the novelty of these

Agents relative to JCPyV and BKPyV, much less information is available regarding sequence variation. Conventional PCR methods are available (24, 27, 116), and real-time PCR assays employing TaqMan probes (28, 31, 117, 118) have been reported for WUPyV and KIPyV. Conventional PCR assays (58) and real-time PCR assays employing TaqMan probes have also been published (33, 34) for MCPyV. PCR assays for the more recently discovered HPyVs are also available, including HPyV6 and -7 (61), TSPyV (63, 65), MWPyV (2, 6), STLPyV (3), HPyV9 (7, 119), and HPyV12 (4).

ISOLATION AND CULTURE PROCEDURES

JCPyV and BKPyV can be isolated and propagated in cell culture (120–122), although currently there is no role for these methods in the laboratory diagnosis of HPyV infections. JCPyV demonstrates restricted host range (human cells only) and can be grown in primary embryonic cells, human brain-derived cells (particularly astrocytes and oligodendrocyte precursors), and the permanent cell line SVG. BKPyV has an expanded host range compared to JCPyV and can grow in similar primary cell cultures, primary human embryonic kidney and lung cells, human foreskin fibroblasts, and continuous cell lines (HeLa and monkey cell lines such as CV-1 and Vero). The cytopathic effect of both viruses includes cellular translucency, nuclear enlargement, and gradual loss of the monolayer. Successful propagation often requires weeks and multiple rounds of blind passage. Most virus remains cell associated.

SEROLOGIC TESTS

Sero logic tests for HPyV are primarily investigational tools with little role in the routine diagnosis of HPyV disease. The majority of assays are laboratory developed. For JCPyV and BKPyV, two types of serologic tests have been described, including hemagglutination inhibition (HAI) and enzyme immunoassays (EIAs) employing either crude antigens or the use of virus-like particles (VLPs). Detection of an antibody response by HAI is based on the capacity of specific antiviral antibodies to inhibit the agglutination of human erythrocytes mediated by the viral structural VP1 proteins of JCPyV and BKPyV (122). The development of EIAs for the detection of antibodies to both BKPyV and JCPyV was made possible when engineered cell lines capable of producing adequate amounts of JCPyV antigen were developed (123). A comparison of HAI and EIA demonstrated that antibody titers measured by the two assay formats were statistically significantly correlated, although EIA titers were higher (124). VLPs have also been used as antigens in EIAs for the detection of antibodies. VLPs are empty particles that retain the full antigenicity of intact virions. They form spontaneously when viral capsid proteins are expressed in certain systems and are preferred as antigen sources for EIAs because they contain native conformational epitopes that may be missing when other forms of viral antigens are employed (125).

Sero logic tests for HPyV are used primarily for seroepidemiological studies and not for diagnosis of infection, although a study has demonstrated a correlation between kidney donor BKPyV antibody titers and infection in the transplant recipient (47). An exception to this is the FDA-approved, commercially available Stratify JCV test offered by Focus Diagnostics (Cypress, CA). The purpose of the assay is to determine the JCPyV serostatus of patients undergoing natalizumab therapy as part of a strategy to determine the risk for the development of PML (126–128). Despite the fact that JCPyV and BKPyV are closely related, it appears that the antigenic epitopes responsible for the human antibody response are not cross-reactive and antibody tests can discriminate between infection by these two viruses (124). In contrast, it appears that seroreactivity to SV40 is due largely to cross-reactivity with BKPyV (125, 129, 130). The identification of novel HPyVs in recent years has complicated polyomavirus serology and highlighted issues associated with the interpretation of some polyomavirus serologic assays. Further complicating matters, it appears that human sera contain antibodies that can react with animal polyomaviruses, suggesting possible transmission from animal to human. This and the likelihood that more HPyVs will be discovered suggest that caution should be employed when interpreting the results of some HPyV assays. These and other issues concerning HPyV serology are covered in depth in a recent review (36).
ANTIVIRAL SUSCEPTIBILITIES

For PML, a number of antiviral agents have been examined, including cidofovir, an acyclic nucleoside phosphonate; topectacin, an inhibitor of DNA topoisomerase I; iflunomide, an immunosuppressive agent with antiviral properties; vidarabine (ara-A) and cytarabine (ara-C), synthetic nucleosides that inhibit viral DNA polymerases; and alpha interferon (131). Following evidence that JCPyV uses the serotonin 2A receptor to infect cells in the CNS, interest has been shown in investigating drugs, such as risperidone, that bind to this receptor and are approved for treatment of certain neuropsychiatric diseases (132), although another study reported that infection of cells by JCPyV was independent of the serotonin receptor (133). A study that examined a collection of 2,000 currently approved drugs found evidence that the antimalarial drug mefloquine had activity against JCPyV in vitro (134). Unfortunately, a clinical trial of mefloquine treatment for PML was stopped early when interim data indicated that the drug offered no benefit (135). For some of these agents, antiviral activity against JCPyV has been demonstrated in vitro, and encouraging results have at times been reported in case reports. However, studies have been hampered by the fact that PML is a rare disease and the majority of patients are HIV infected and receiving potentially confounding anti-HIV therapy, making it difficult to evaluate the effect of the drug being studied. Unfortunately, most clinical studies of antiviral treatments for PML have failed to demonstrate a consistent benefit (136–140) and there are no currently FDA-approved drugs for the treatment of this devastating disease. Current approaches to therapy include optimal HAART for HIV-infected patients, with the aim of increasing CD4 cell counts and decreasing HIV RNA level (38). For non-HIV-infected individuals, reversal or amelioration of the immunosuppressed state ultimately responsible for the disease is recommended (136). While not an antiviral therapy, removal of immunomodulatory agents such as natalizumab can be achieved with plasma exchange. This in turn can trigger an immune reconstitution inflammatory syndrome, a condition that, while itself dangerous, can improve survival, although sequelae are common (41).

Many of the same agents studied as possible antiviral treatments for PML have also been investigated for the treatment of BKPyV PVAN and, less commonly, hemorrhagic cystitis. In addition to these compounds, fluoroquinolone antibiotics and intravenous immunoglobulin have also been studied. Similar to the situation with the development of antiviral drugs for the treatment of PML, there are currently no FDA-approved agents for the treatment of BKPyV diseases. The lack of antivirals can be attributed to several factors, including the need for prospective randomized controlled studies, the nephrotoxicity exhibited by a number of the drugs, and the confounding variable of the near universal approach of improving immune function in transplant recipients showing signs of BKPyV disease by some form of reduction in the level of immunosuppression. A review of the literature on antiviral treatment of PVAN found a total of only 184 patients in 27 published studies examining the use of cidofovir, 189 patients in 18 studies of the use of iflunomide, and 14 patients in 2 studies of the use of fluoroquinolones, with the authors concluding that there was no consensus on the use of antivirals for PVAN (141). Currently, there is an ongoing phase 1/2 study of the use of nucleoside analogs for treating BKPyV infection (142), but until this or potential future studies can demonstrate a benefit for a particular antiviral, the mainstay of current therapy for PVAN is the reduction of immunosuppression, although in cases where a patient is in danger of losing a graft to PVAN, a course of an antiviral may be of use (143–145).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

The current trend in laboratory testing for PVAN is to monitor levels of the BKPyV in urine and blood and to reduce immunosuppression when viruria or viremia reaches levels that predict progression to disease. A management algorithm published in 2005 for monitoring BKPyV viruria and viremia in renal transplant recipients recommended that patients be screened for viruria every 3 months for the first 2 years after the transplant; if viruria is detected, then a quantitative NAAT should be employed for monitoring of urine or plasma, with sustained high levels of viruria (>10^7 copies/ml) triggering a renal biopsy (86). Testing for BKPyV viruria has a high negative predictive value and a variable positive predictive value for the development of PVAN, with sustained high levels of viruria (>10^7 copies/ml) having a positive predictive value of up to 67% (145). Sustained high levels of BKPyV viruria are frequently followed by the appearance of viremia. The majority of individuals with PVAN have been found to have BKPyV viremia, with the positive predictive value for viremia being ~60% for the development of PVAN (145). A recent review indicates that these guidelines have yet to be superseded and goes into more detail than is possible here on other testing modalities, such as the detection of BKPyV mRNA, which appears to have no advantages over the detection of viral DNA (142).

These recommendations are helpful in directing NAAT use and interpretation of NAAT results. However, implementing them is complicated by interlaboratory variability in BKPyV quantification due to the lack of internationally recognized standards that can serve as calibrators and by the use of assays that may not optimally detect and quantify all BKPyV strains. For example, in 2008, the College of American Pathologists sent four proficiency samples to laboratories performing quantitative BKPyV assays to compare results among the different assays. All 48 laboratories (38 using user-developed assays and 10 using commercial tests) that tested a sample that did not contain BKPyV DNA reported a negative result. When BKPyV-positive specimens were tested, the results were less encouraging. The sample producing the most variation was tested by 41 laboratories with the following results: mean, 700,946 copies/ml; standard deviation (SD), 1,729,692 copies/ml; coefficient of variation (CV), 246.8%; and range, 129 to 10,400,000 copies/ml. For 35 laboratories that also reported log-transformed data on this specimen, the results were as follows: mean, 4,806; SD, 1,231; and range, 1.02 to 6.51. The BKPyV-positive specimen with the lowest CV produced the following results: mean, 277,288 copies/ml; SD, 284,990; CV, 102.8%; and range, 7,800 to 943,000 copies/ml (All data used with the permission of the College of American Pathologists.) Obviously, there is a significant amount of interlaboratory variation in quantitative BKPyV results.

Until the problems of assay variation are resolved, laboratories should work toward the consistent intralaboratory performance of their own assays. Careful coordination between physicians and the laboratory can result in the establishment of in-house viruria and viremia thresholds for adjusting immunosuppression regimens. The additional effort this requires is clearly worthwhile, since successful implementation...
of testing algorithms has been shown to significantly reduce PVAN incidence (143, 146). To draw accurate conclusions regarding the course of infection, patients should be monitored at one site if possible. Sequential measurements by different laboratories are difficult to interpret given the likelihood of interlaboratory differences in BKYPV quantification. The laboratory should educate physicians and transplant coordinators about this issue.

In cases where PVAN is suspected and BKYPV titers are negative or low, the possibility of a false negative should be considered, due potentially to sequence mismatches between the virus and real-time PCR primers or probe. Alternatively, it may be possible that JCPyV is responsible, in which case it may be best to try to identify this virus either in biopsy material by histological methods or in plasma. Shedding of this virus is common in the urine and may not indicate the presence of a causative organism. Unfortunately, guidelines for interpreting JCPyV levels in peripheral blood are not available.

Quantitative NAATs of urine from BMT recipients to early predict the development of or diagnose hemorrhagic cystitis may be useful. High levels of viruria (>1 × 10^9/ml) can be seen in hemorrhagic cystitis due to BKYPV (54, 147); a negative result suggests another cause of this condition. The interpretation of BKYPV viruria is complicated by the fact that BMT recipients frequently excrete BKYPV in their urine and by the lack of guidelines for thresholds that can be applied to predicting or diagnosing disease. Studies have yielded variable data. One report suggested that viruria of >10^9 to 10^10 copies/ml or an increase of ≥3 log_10 relative to baseline levels may help implicate BKYPV as the cause (53). Another found that levels of BKYPV viremia of >10^4 copies/ml were associated with hemorrhagic cystitis (53); however, this relationship was not observed in a similar study (54).

Serology and culture have little role in the diagnosis of PML. A majority of individuals are seropositive for JCPyV by adulthood; culture requires special cells and prolonged incubation and is insensitive. Therefore, the preferred diagnostic test for PML is a JCPyV-specific NAAT. The detection of JCPyV DNA in CSF is distinctly abnormal. In combination with appropriate imaging studies and patient history, it is strongly suggestive of PML. JCPyV NAAT sensitivities in CSF range from 42 to 100%, with most between 70 and 80%; specificities range from 92 to 100% (148). False-negative JCPyV PCR results in patients with PML, possibly due to mismatches between primers and probes and target sequences (115, 149), have been observed. Additionally, decreased PCR sensitivity has been reported in the HAART era (89.5% pre-HAART versus 75.5% HAART, with the negative predictive value falling from 98 to 89%) (150). These findings underscore the fact that a negative JCPyV result cannot rule out the presence of PML. It may be advantageous to retest CSF with a different NAAT if the initial result is negative in a presumptive case of PML. It should be noted that in patients with natalizumab-induced PML who are treated with plasma exchange to remove the drug, JCPyV DNA has been reported to persist in the CSF for periods ranging from months to years (151).

Because of the devastating nature of PML, laboratory testing methods have been explored to either help identify patients at increased risk for developing PML or to provide a prognosis for those patients who have already been diagnosed. A single qualitative test for JCPyV DNA in urine and blood does not appear to be useful for the identification of patients at risk of PML, as demonstrated by studies of individuals with HIV and those with immunosuppression unrelated to HIV (including immunomodulatory therapy with natalizumab) (152, 153), and is therefore not recommended. Persistent viruria and rising urine viral loads have been found to be associated with the development of PML in HIV-positive patients (154). However, a large study that tested >12,000 urine and blood specimens from 1,397 natalizumab-treated multiple sclerosis patients for the presence of JCPyV DNA reported the following: (i) the prevalence of JCPyV viremia was very low in treated patients (<1%) and similar to that seen in untreated healthy controls; (ii) the detection of JCPyV viremia did not correlate with the development of PML; and (iii) the prevalence of JCPyV viruria was high (~25%) at both baseline and after 48 weeks of treatment, leading the authors to conclude that detection of viremia or viruria was not useful in determining the risk of development of PML in this population (155).

Quantitative PCR for the determination of the JCPyV load in the CSF of PML patients has been reported to be potentially useful as a prognostic measure for disease progression. However, because of small study sizes and the lack of standardized quantitative JCPyV NAATs, it has been difficult to formulate guidelines for threshold CSF viral loads. Different reports have indicated, roughly, that JCPyV CSF viral loads of between 10^4 and 10^5 copies/ml separate those PML patients whose disease progresses quickly from those whose illness is stable or progressing more slowly (153, 156–158).

The commercial Stratify JCv offered by Focus Diagnostics is used to determine the JCPyV serostatus of multiple sclerosis patients undergoing natalizumab therapy. Data in support of using this test to determine risk for development of PML come from a study that revealed that 54% of 831 multiple sclerosis patients were seropositive for JCPyV and that the 17 patients who subsequently developed PML were all JCPyV seropositive (126). In the same study, it was reported that the JCPyV false-seronegative rate was 2.5%, as determined by the detection of viruria in 5 of 204 seronegative patients. However, another study of natalizumab-treated patients found a much higher false-seronegative rate of 35% in 17 patients with JCPyV viremia, suggesting that, while the determination of JCPyV serostatus may be useful in helping to evaluate the risk of development of PML, other measures of risk need to be developed and employed to supplement serology and that JCPyV serology needs to be interpreted with caution (159).

Laboratory testing for the newly identified HPVs is considered investigational at this time, so it is not possible to offer meaningful interpretations for test results for these agents.

Parvovirus B19 and Bocaviruses

KEVIN E. BROWN

TAXONOMY
Parvoviruses are small (~22-nm-diameter), nonenveloped, icosahedral viruses with a linear, single-stranded DNA genome. They take their name from parvum, the Latin for "small," and Parvoviridae are among the smallest known DNA-containing viruses that infect mammalian cells. The Parvoviridae are divided into two subfamilies, Parvovirinae and Densovirus. The virus of the basis of their ability to infect vertebrate or invertebrate cells, respectively. The vertebrate viruses (Parvovirinae) are currently subdivided into five genera on the basis of their number of open reading frames (ORFs), their transcription map, their ability to replicate efficiently either autonomously or with helper virus, and their sequence homology. The eight genera are Dependoparvovirus, Depen- poparvovirus, Erythroparvovirus, Bocaparvovirus, Aveparvovirus, Copiparvovirus, Tetraparvovirus, and Amdovirus (1).

At least four different parvoviruses are known to infect humans. Parvovirus B19 (B19V) is the best characterized and is classified as the type member of the Erythroparvovirus genus. The other human viruses are the human bocaviruses (Bocaparvovirus); parvovirus 4 (PARV4) (Tetraparvovirus), and the nonpathogenic adeno-associated viruses (Depen- doparvovirus).

PARVOVIRUS B19

Description of the Agent
B19V has the typical features of a member of the Parvoviridae: the virions are nonenveloped, 15 to 28 nm in diameter, and show icosahedral symmetry (Fig. 1). The virions hemagglutinate, and this is through the primary viral receptor, blood group P, also known as globoside (2–4).

The genome consists of a single strand of DNA of 5,596 nucleotides, with long inverted terminal repeat sequences at each end. The genome has two large ORFs, with the left ORF encoding the nonstructural (NS) protein and the right ORF encoding the two capsid proteins, VP1 and VP2, by alternative splicing. The B19V virion consists of 60 copies of the capsid proteins, of which 95% are VP2, with 5% or less of the larger VP1 protein (5). VP2 capsid proteins self-assemble to form virus-like particles (VLPs) in the absence of B19V DNA; VP1 is not required for capsid formation (6, 7). Although three different genotypes have been described, there is serologic cross-reactivity, and thus only one sero- type.

In 1985, the virus was officially recognized as a member of the Parvoviridae, and the International Committee on Taxonomy of Viruses recommended the name B19V to prevent confusion with other viruses (e.g., human papillo- mavirus). It is classified as a member of the Erythrovirus genus with the name parvovirus B19 (official abbreviation, B19V) (1).

Epidemiology and Transmission
B19V is a common infection in humans, and although there is some variation in different countries (8), 50% of 15-year-olds and 80% of the elderly have detectable IgG (9, 10). Infections in temperate climates are more common in late winter, spring, and early summer months. Rates of infection may also increase every 3 to 5 years, and this is reflected by corresponding increases in the major clinical manifestations of B19V infection, mainly transient aplastic crisis (TAC) and erythema infectiosum (11).

The virus can be readily transmitted by close contact through the respiratory route. In one study, the secondary attack rate from symptomatic patients to susceptible (IgG-negative) household contacts was ~50%. (12). The highest secondary attack rates and also seroprevalence and annual seroconversion rates are seen among workers with close contact with young children, e.g., daycare providers and school personnel (10, 13).

Infectious virus can also be found in serum, and infection can be transmitted by blood and blood products. Although ~1% of blood donations have low-level B19V DNA detectable (14), reports of transmission of B19V infection by individual units of blood or platelets are rare. However, transmission from pooled products is more common, and recommendations in Europe and North America now require all plasma pools for fractionation to be screened for high-titer parvovirus DNA to try to minimize the transmission of B19V by blood products.

Currently there is no vaccine for B19V, although B19V VLPs expressed in either insect or yeast cells are highly immunogenic (15, 16), and the results of the first phase 1 trial looked very promising. However, a more recent, larger trial was stopped due to the development of unexplained skin rashes in three recipients (17).

Clinical Significance
B19V primarily infects erythroid progenitor cells, inducing cell death through apoptosis and cessation of red cell production. Thus, the presentation of infection depends on the significance of the drop in red cell production and/or the immune response to infection, and unlike many virus
Infections, the disease manifestation of infection with B19V varies widely with the immunologic and hematologic status of the host (Table 1).

Healthy Individuals—Normal Immune Response
Although a significant number of infections are asymptomatic, the major manifestation of B19V infection is erythema infectiosum, also known as fifth disease or slapped-cheek disease due to the characteristic facial rash. After a 2- to 5-day nonspecific prodromal illness (fever, chills, and myalgia) (Fig. 2A), the classic slapped-cheek rash appears, followed 1 to 4 days later by an erythematous maculopapular exanthema on the trunk and limbs. This rash is almost certainly immune mediated, and the timing correlates to detection of an antibody response. As the rash on the trunk and limbs fades, it takes on a typical lacy appearance. There may be great variation in the appearance of the rash, and rarely B19V may present as a petechial rash or papulo-purpuric “gloves and socks” syndrome (although this is more often at the viremic stage of the infection, and not primarily immune mediated). The classic slapped-cheek rash is more common in children than adults, and the second-stage eruption may vary from a very faint erythema that is easily missed to a florid exanthema and may be transient or recurrent over 1 to 3 weeks.

In children, B19V infection is usually mild and of short duration. However, in adults and especially in women, there may be a symmetrical arthropathy primarily affecting the small joints of the hands and feet in ~30% of patients (18). Joint symptoms often last 1 to 3 weeks, although in 20% of affected women, arthralgia or frank arthritis may persist or recur for >2 months or even years. In the absence of a history of rash, the symptoms may be mistaken for acute rheumatoid arthritis, especially as B19V infection can be associated with transient rheumatoid factor production (19).

It has been postulated that B19V is involved in the initiation and perpetuation of rheumatoid arthritis, leading to joint lesions (20), but these results have not been reproducible by other groups. In contrast, B19V DNA is frequently found in synovial tissue of patients with rheumatoid arthritis, chronic arthropathy, and control subjects, and it seems unlikely that B19V plays a role in classic erosive rheumatoid arthritis. The association between B19V and juvenile rheumatic disease is more convincing (21), but whether B19V is the cause of the disease or one of many potential triggers is less clear.

Patients with Increased Erythropoiesis
TAC, the abrupt cessation of red cell production (Fig. 2B), due to B19V has been described in a wide range of patients with underlying hemolytic disorders, including hereditary spherocytosis, thalassemia, and red cell enzymopathies such as pyruvate kinase deficiency and autoimmune hemolytic anemia (22). Even in hematologically normal individuals, acute anemia or a drop in red cell count has been described (23, 24). Other blood lineages may also be affected, and there may be varying degrees of neutropenia, thrombocytopenia, and transient pancytopenia (22). Rarely the patient may present with a petechial or purpuric rash, and some cases of idiopathic thrombocytopenia purpura (25) and Henoch-Schönlein purpura (26) have also been linked to B19V infection.

Although it is a self-limiting disease, patients with aplastic crisis can be severely ill, with dyspnea, lassitude, and even confusion due to the worsening anemia. Congestive heart failure and severe bone marrow necrosis may develop (27, 28), and the illness can be fatal (29). TAC is readily treated by blood transfusion.

Infection during Pregnancy and Congenital Infection

B19V is a known cause of fetal hydrops and miscarriage. Studies have estimated an increased fetal loss of 9% in women with confirmed B19V infection in the first 20 weeks of pregnancy (30–32). Many cases of B19V-induced hydrops fetalis are now treated with intrauterine blood transfusion.

Rare cases of congenital anemia after a history of maternal B19V exposure have been reported (33). In these cases, the virus load is generally low and the anemia does not respond to immunoglobulin therapy. The B19V infection may mimic Diamond-Blackfan anemia (34), and the role of in utero B19V infection in inducing constitutional bone marrow failure such as that in Diamond-Blackfan anemia is still not clear.

Immunosuppressed and Immunocompromised Patients

In patients with a compromised immune system, there may be a failure to induce a neutralizing antibody response, leading to chronic infection of erythroid progenitors and, as a consequence, prolonged failure of red cell production and development of chronic anemia (Fig 2C). Persistent B19V infection resulting in pure red cell aplasia has been reported in a wide variety of immunosuppressed patients, ranging from patients with congenital immunodeficiency, AIDS, and lymphoproliferative disorders to transplant patients (35). The stereotypical presentation is persistent anemia rather than the immune-mediated symptoms of rash or arthropathy. Often there is a pure red cell aplasia, but invariably other lineages may also be affected. Treatment is by reduction of the immunosuppression, if this is feasible, or more often, administration of immunoglobulin (36).

Other Presentations

B19V infection has been associated with a wide range of other manifestations including vasculitis, hepatitis, myocarditis (and cardiomyopathies), glomerulonephritis, Kawasaki disease, and virus-associated hemophagocytic syndrome.

Treatment

Treatment for all presentations of B19V infection is symptomatic only. None of the currently available antivirals is known to have antiparvovirus activity. B19V does not encode either a DNA polymerase or viral proteases, so targets for antivirals are limited.

Collection, Transport, and Storage of Specimens

Due to its small DNA genome and lack of a lipid envelope, B19V is resistant to most types of physical inactivation and is heat stable. Therefore, no special precautions are needed for transportation and storage of most clinical specimens, although repeated freeze-thaw cycles should be prevented where possible. Serum (or plasma) samples should be obtained if possible, and permit measurement of both viral load and B19V-specific IgM and IgG levels. Additional samples may include cerebrospinal fluid (for investigation of neurologic infection), amniotic fluid (investigations in pregnancy), and bone marrow samples (hematologic dis-
ease), but these should always be in addition to serum samples where possible, as interpretation may be difficult without a concurrent serum sample. For investigation of fetal deaths, fetal tissues can be used, either frozen or fixed, although frozen material is preferable for DNA analysis. Samples can usually be transported at room temperature, with the exception of tissue samples (and especially fetal liver samples), which, if not fixed, should be frozen as soon as possible after collection and kept frozen until processed (due to the large amount of proteases and DNase activity often present in such samples).

**Direct Examination**

**Microscopy**

Infected cells are characterized both in vivo and in vitro by the presence of giant pronormoblasts, or “lantern cells” (37). These are early erythroid cells, 25 to 32 μm in diameter, with cytoplasmic vacuolization, immature chromatin, and large eosinophilic nuclear inclusion bodies (Fig. 3). Electron microscopy of such cells shows that the inclusion is made up of large viral arrays, which can be confirmed by monoclonal antibody staining. These cells can be found in the bone marrow of infected individuals at the time of their peak viremia, and occasionally in the peripheral circulation (38). Although they have been said to be pathognomonic of B19V infection, similar cells can be seen in the bone marrow of patients with other infections, including HIV, and so should not be used for diagnosis of B19V infection without other confirmation.

When seen as a large viral array within a cell, B19V can be readily identified. However, often the infected cells do not have inclusions, and in these cases, electron microscopy cannot always distinguish intracellular virus from ribosomes, limiting its practicalities apart from as a research tool.

High viral loads (>10^6 IU/ml) can be detected in serum samples (after concentration) by electron microscopy, in which the characteristic 22-nm-diameter, icosahedral virions can be seen (Fig. 1). Immune electron microscopy using polyclonal serum to clump the virions together can increase the sensitivity and make the virions easier to identify.

**Antigen Detection**

Antigen detection, generally using monoclonal antibodies, can be used with standard histochemistry (Fig. 4) to identify infected cells in blood samples, tissues, or cell culture. It is relatively insensitive and can be useful for identifying infected cells in cases where the significance of low levels of B19V DNA is unknown. Its role in clinical microbiology is limited.

B19V antigen-based assays are relatively insensitive (>10^6 virus particles/ml), but antigen detection can be used for detecting high concentrations of virus in serum or plasma samples. It has been suggested as a screening method for detecting high-titer virus in blood and plasma samples (39). The Japanese Red Cross has also used a modified hemagglutination assay for detection of high-titer virus in plasma samples (receptor-mediated hemagglutination) (40).

**Nucleic Acid Detection**

Detection of B19V DNA is the preferred method for identifying B19V in samples. Although in situ hybridization can be used to identify B19V DNA within specific cells, and direct hybridization was used for many years to detect B19V DNA in serum samples, more commonly these days DNA detection is by PCR. Due to the exquisite sensitivity of PCR, B19V DNA can then remain detectable for months or even years at low levels even following complete recovery, and thus quantitative PCR is required to distinguish recent infection from previous infection with the virus. All assays should be calibrated against the World Health Organization (WHO) B19V nucleic acid amplification technology standard (41) and the results reported as international units per milliliter.

A large number of different PCR primers (and probes) have been described in the literature (42–44), and commercial assays are available from a number of different companies, including Abbott Diagnostics (Abbott Park, IL), altona Diagnostics (Hamburg, Germany), bioMérieux (Marcy l’Etoile, France), Qiagen (Hilden, Germany), Fast-track Diagnostics (Sliema, Malta), Focus Diagnostics (Cypress, CA), Ingenetix (Vienna, Austria), and Roche Diagnostics (Indianapolis, IN). When choosing an assay, primers should be designed from the more conserved parts of the virus genome, such as the region in NS where there is a second ORF (45), and should be chosen to specifically detect all three genotypes. Although the genome is relatively conserved, a single nucleotide difference may markedly alter the sensitivity of the assay (46). There is now a 1st WHO International Reference Panel available comprising the different genotypes so that assays can be checked to make sure that all three genotypes are detectable in an assay (47).
Detection of viral RNA can be very useful for confirming the presence of replicating virus and active infection. Often this is achieved through amplification across a spliced junction, so that there is distinction between the spliced RNA and viral DNA (48). This generally is used only as a research tool.

Isolation Procedures

B19V, like all autonomous parvoviruses, is dependent on mitotically active cells for its own replication. B19V also has a very narrow target cell range and can only be efficiently propagated in human erythroid progenitor cells. For erythroid progenitors from bone marrow, susceptibility to B19V increases with differentiation; the pluripotent stem cell appears to be spared and the main target cells are CD34-positive erythroid colony-forming cells and erythroblasts (49, 50). Thus, B19V cannot be grown in standard tissue culture.

A number of semipermissive cell lines have been described, including UT7/Epo (51, 52) and KU812Ep6 cells (53). However, more efficient replication is obtained using primary cultures from bone marrow or fetal liver (37, 54). Methods for enhancing erythroid differentiation have been developed, so that efficient B19V replication can be achieved in the research laboratory (44). Routine culture is not recommended for investigation of B19V infection.

Typing Systems

B19V is now recognized to have three different genotypes, with ~10% variability at the DNA level between genotypes (45, 55, 56). Most of the B19V identified is genotype 1 (55), the original B19V genotype, which is distributed worldwide. Genotype 3 seems to be the predominant B19V genotype in Ghana, representing >90% of the sequences identified (57). Genotype 2 has been identified primarily in tissues of older patients (born before 1973), suggesting that it may have circulated more frequently prior to the 1970s (58), although blood donations containing high-titer genotype 2 are occasionally identified. Genotype 2 and 3 sequences have been identified in blood and tissues from many different parts of the world (59–61), suggesting a more widespread distribution than originally assumed.

Despite the differences in the DNA sequences, the capsid protein sequence is conserved between the different genotypes, and there is evidence for both serological cross-reactivity and cross-neutralization (62). There is no evidence that the different genotypes show any differences in virological or disease characteristics (63, 64).

Serologic Tests

Serologic surveys were originally performed using the relatively insensitive counterimmune electrophoresis but were superseded first by radioimmunoassays and now almost universally by either enzyme or chemiluminescence immunoassays. Due to the inability to grow B19V in standard cell culture systems, early serology assays were based on the use of synthetic peptides (65) or fusion proteins in Esherichia coli (66) as antigen. However, the epitopes presented by these products do not accurately reproduce the epitopes of the native capsids, and the sensitivity and specificity were disappointing. The production of B19V capsid proteins as VLPs using baculovirus (67, 68) or yeast (69) expression systems appears to have overcome these problems, and results based on these antigens show good correlation with assays based on native virus. The antigens are relatively easy to mass-produce and are noninfectious.

Immuoassays using VLPs as antigen are generally both sensitive and specific. Although B19V IgM can be detected by both IgM capture assays and indirect assays, capture assays appear to be more sensitive and less prone to false-positive results due to rheumatoid factor. In contrast, IgG assays are probably more sensitive in an indirect (or sandwich) format, especially for seroconversion studies. Commercial immunoassays for both B19V IgM and IgG are available from a number of different companies, including Biokit (Barcelona, Spain), DiaSorin (previously Biotrin) (Saluggia, Italy), DRG International (Springfield, NJ), Euroimmun (Lubeck, Germany), Focus Diagnostics, Mikrogen (Neuried, Germany), MyBioSource (San Diego, CA), and Virion/Serion (Wurzburg, Germany), but several of these are designated for research use only, and in the United States only the DiaSorin assays are approved by the Food and Drug Administration for diagnostic use.

Antibody to B19V is usually present by day 7 of illness (aplastic crisis) or a day after the onset of erythema infectiosum rash, and probably is lifelong thereafter, although some waning of antibody has been suggested (70). In immunocompetent individuals, the early antibody response is to the major capsid protein, VP2, but as the immune response matures, reactivity to the minor capsid protein, VP1, dominates (71, 72). Sera from patients with persistent B19V infection typically have antibody to VP2 but not to VP1 (73). Thus, a number of other formats for assays have been described, including epitope-specific assays, Western blot, and avidity tests for B19V infection (71, 74). Apart from a commercial immunoblot assay (Mikrogen), these assays are all in-house assays and are not available outside research laboratories. In specialist settings, and in combination with B19V DNA viral load, epitope-specific assays may be useful, especially for confirming the timing of recent infection, e.g., during pregnancy (75).

Although assays to detect neutralizing antibodies have been described (48), they are very time-consuming and not used outside the research setting.

Evaluation, Interpretation, and Reporting of Results

The diagnosis of B19V infection is very dependent on the host characteristics and the presentation of the illness, with serology and/or quantitative PCR being the most appropriate assay depending on the circumstances (Table 1; Fig. 2). For otherwise healthy children or adults presenting with the immune-mediated rash illness consistent with B19V (i.e., slapped-cheek or rash of erythema infectiosum), appropriate testing is for the detection of B19V IgM, as the high-titer viremic stage correlates with the time of the prodrome (Fig. 2A). The IgM remains detectable for several months following infection. B19V IgG is also detectable within a day of onset of the rash, and then remains detectable lifelong. Patients with fifth disease do have detectable B19V DNA in blood, with titers of >10^8 IU/ml. At 2 to 3 months following infection, B19V DNA titers fall to <10^4 IU/ml, and low-level B19V DNA may remain detectable in blood and tissues for the rest of life. False-positive B19 IgM serology can occur with other acute rash infections, including measles and rubella, and may mislead clinicians. In addition, B19V infection may be associated with production of rheumatoid factor and produce false-positive serology in other assays. Measurement of the B19V viral load can then be useful in determining the specificity of the IgM result.

Patients with increased red cell turnover and presenting with TAC often have between 10^8 and 10^14 genome copies/ml (IU/ml) of virus DNA detectable in their blood
(Fig. 2B), and diagnosis should be by quantitative PCR. IgM and IgG are not initially detectable, and the diagnosis can be missed if these assays are not combined with detection of B19V DNA. Assays for detection of B19V antigen in serum or plasma are not recommended, as they can give false negatives due to immune complex formation.

Similar high viral loads and undetectable IgM (and IgG) in the serum at the time of presentation are also seen in the rare patients who present with a petechial or purpuric rash. In these patients, B19V infection cannot be excluded on the basis of a negative IgM test alone.

Immunosuppressed or immunocompromised patients with persistent parvovirus infection often have a low or absent antibody response but high titers (>10^6 IU/ml) of B19V DNA in blood or serum (Fig. 2C). Diagnosis should be made using quantitative PCR.

B19V infection in the fetus is usually suspected following confirmation of maternal infection. However, infection of the fetus follows maternal infection, and it can be that the mother’s B19V IgM response is negative at the time of the fetal hydrops. In these cases, B19V IgG avidity (if available) or B19V DNA titer may be useful in determining the time of maternal infection (75).

As low levels of B19V DNA remain detectable in serum or tissues of otherwise healthy, immunocompetent individuals lifelong following an acute infection, the finding of low-titer B19V DNA alone should not be interpreted as an indicator of recent infection or the causal agent of pathology.

HUMAN BOCAVIRUSES

Human bocavirus (HBoV) was discovered in 2005 as part of a virus discovery program to identify the causes of lower respiratory tract infections in children (76). This respiratory virus is now classified as HBoV1. Related viruses have subsequently been detected in fecal samples: HBoV2 to -4 (77–79).

Description of the Agent

HBoV1 has the typical structure of a member of the Paroviridae. The full-length genome of HBoV1 is 5,543 nucleotides, with dissimilar hairpin sequences at the 5’ and 3’ ends. The genome has three large ORFs (as seen in other members of the Bocavirus genus) encoding the nonstructural protein (NS1), the capsid proteins (VP1 and VP2), and a second nonstructural protein (NP1) (80).

The major capsid protein, VP2, has been expressed in insect cells, and it self-assembles to form VLPs (Fig. 5) that are the basis of most serology assays. The coding sequences for the other HBoVs (HBoV2 [77], HBoV3 [81], and HBoV4 [79]) have been determined. The different HBoV species show between 10 and 30% divergence, with increased genetic variation and evidence for recombination (79).

Epidemiology and Transmission

HBoVs have a worldwide distribution and have been identified in all countries that have looked for it. HBoV1 is found predominantly in respiratory secretions, including in 2 to 20% of samples from children with upper or lower respiratory tract disease (82). Although HBoV1 DNA can be detected throughout the year, primary infection occurs predominantly in the winter and spring months (76, 83, 84), as for other respiratory infections. Based on serologic studies using HBoV1 as antigen, most, if not all, individuals are infected in early childhood before the age of 6 (85).

HBoV2, HBoV3, and HBoV4 are identified predominantly in fecal samples, both in patients (children and adults) with gastroenteritis and in healthy controls (79, 82). HBoV2 appears to be the most commonly identified species, followed by HBoV3 and then HBoV4 (82, 85). This is also reflected in the seroepidemiology, with increased seroprevalence in the order HBoV1 > HBoV2 > HBoV3 > HBoV4.

HBoV1 appears to be transmitted predominantly by the respiratory route, although HBoV1 DNA has been detected in urine and fecal samples (86, 87), suggesting that it may also be spread by the fecal-oral route. HBoV2–4 are found mainly in fecal samples and appear to be spread by the fecal route.

Clinical Significance

Although HBoV1 DNA is commonly found in respiratory secretions of hospitalized children with respiratory symptoms (82), in many cases HBoV1 is found with other pathogens, raising questions as to whether it is the main cause of symptoms. It is now clear that there can be prolonged persistence of bocavirus DNA in respiratory secretions (and fecal) samples, and if a stricter definition for diagnosing HBoV1 infection is used (high viral load in respiratory secretions, DNA in serum, and/or a serologic response), several groups have shown that HBoV1 infection is associated with both upper and lower respiratory tract infection and specifically with wheezing (88–90).

Similar criteria for the diagnosis of infection due to the fecal bocaviruses have not been identified, and although HBoV2–4 can be found in patients with acute gastroenteritis, in controlled studies they are found in healthy controls at similar rates (91, 92).

Direct Examination

Microscopy and Antigen Detection

Although parvovirus-like particles had been observed in fecal samples by electron microscopy, it is only with the identification of the nucleic acid sequence that their true identity has been confirmed. Microscopy and antigen detection do not have a role in the diagnosis and management of bocavirus infection.
Nucleic Acid Detection
The mainstay of bocavirus diagnosis is by nucleic acid detection, preferably by quantitative PCR. A number of different primers and probes have been described (93–103), but there have been virtually no studies comparing the relative specificity or sensitivity of the different assays. The NS1 and NPI regions are the most conserved regions of the virus, and therefore the preferred targets. Commercial assays have also been produced (by, e.g., bioMérieux, Fast-track Diagnostics, and Gentaur [Kampenhout, Belgium]), often as part of a multiplex combined with other respiratory targets.

Isolation Procedures
HBoV1 can be grown in human airway epithelia (104), and cells in the respiratory tract are presumed to be the main site of replication during infection. Although HBoV1 can also be grown in vitro in well-differentiated airway epithelia cells (105, 106), replication is relatively inefficient, and this is a research tool only. For clinical purposes, virus detection is generally by identification and quantitation of viral DNA by PCR.

Typing Systems
At least four different HBoVs have been described, and they can be readily distinguished based on the DNA using specific primers (95). The viruses are also serologically distinct, although antigenic differences are used more to characterize the serologic response than to identify the viruses (107).

Serologic Tests
As with B19V, several groups have expressed the major capsid protein of HBoV capsids in insect cells (Fig. 5) and developed serologic assays to detect both IgM and IgG (108). In addition, bocavirus IgG avidity assays have been described (109). However, most assays probably measure cross-reacting antibodies to any of the four HBoVs, and there have only been few studies to try to distinguish between the antibody responses (107). None of these assays is commercially available.

Evaluation, Interpretation, and Reporting of Results
It is now recognized that diagnosis of HBoV infection should not be based on detection of bocavirus DNA in respiratory or fecal samples alone, because of the persistence of DNA at these sites. For HBoV1, detection should be based on the detection of viral DNA in the serum and evidence by serology of recent infection. This is generally by evidence of IgG seroconversion or by detection of IgM or low-avidity antibody. If serum is not available for serology and PCR, then high-titer (>10⁶ genome copies/ml) HBoV1 DNA in respiratory secretions should be used (82).

Similar viral load criteria have not been developed for HBoV2–4 infections.

HUMAN PARVOVIRUS 4
PARV4 was also discovered in 2005 as part of a virus discovery program looking for new viruses in plasma samples using sequence-independent single primer amplification. The initial sample was from a daily-injecting intravenous drug user (110). Very little information is available on the clinical features of acute infection with PARV4, with only very limited studies on cohorts at high risk of acquiring infection through parenteral exposure (114).

The PARV4 sequences can be divided into three main groups or genotypes. Genotypes 1 and 2 are found predominantly in North America and Europe, and genotype 3 in Africa, and although there may be differences in transmission (this has not been confirmed), it is not known if there are any other differences in virology or pathogenicity between the genotypes.

Testing of pooled plasma products from Europe and North America showed that PARV4 DNA can be readily detected in plasma pools (4 to 5%), with viral loads varying from <100 copies/ml to 4 × 10⁴ copies/ml (111). The prevalence may be significantly higher in other parts of the world.

PARV4 has not been grown in culture, but several groups have expressed capsid protein in insect cells. Serologic studies suggest that infection is unusual in the general population but observed higher seroprevalence in those who participate in needle-sharing activities or receive blood products (112) and in some parts of Africa (113). Although the main route of transmission in Europe and North America appears to be parenteral, transmission via the fecal-oral route cannot be dismissed.

Very little information is available on the clinical features of acute infection with PARV4, with only very limited studies on cohorts at high risk of acquiring infection through parenteral exposure (114).

Diagnosis is generally by the detection of PARV4 viral DNA by PCR. Patients with acute infection appear to have transient high levels of PARV4 DNA in serum. However, the duration of the high-level viremia before the development of an IgM and IgG response is not known. No commercial assays are available for PARV4, and testing for PARV4 is currently a research tool only.

Poxviruses

LAURA HUGHES, VICTORIA A. OLSON, AND INGER K. DAMON

TAXONOMY

All poxviruses described in this chapter belong to the family Poxviridae and subfamily Chordopoxvirinae (see chapter 78). The genera and species of the viruses discussed in this chapter are shown in Table 1. DNA-based assays, including DNA sequencing, are the most precise methods for poxvirus genus, species, strain, and variant identification and differentiation. The G+C contents of orthopoxviruses, yatapoxviruses, molluscum contagiosum virus (MCV), and parapoxviruses are ∼33, ∼32, ∼60, and ∼63%, respectively.

DESCRIPTION OF THE AGENTS

Virions are large and brick shaped (orthopoxviruses, yatapoxviruses, and molluscipoxvirus) or ovoid (parapoxviruses). Virions range in length from 220 to 450 nm and in width and depth from 140 to 260 nm. The appearances of virions under an electron microscope vary somewhat with sample preparation. By cryo electron microscopy, in unstained, unfixed vitrified specimens, vaccinia virus appears as smooth, rounded rectangles; a uniform core is surrounded by a 30-nm-thick membrane. In conventional negatively stained thin sections, the core appears dumbbell shaped and is surrounded by a complex series of membranes. Lateral bodies of undefined function occupy the space between the outer membrane and the bar of the dumbbell. This feature may be a dehydration effect of negative staining.

Virus particles contain about half of the ∼200 potential virus genome-encoded proteins. Virions consist of structural proteins and enzymes, including a virtually complete RNA polymerase system for primary transcription of viral genes (1). The genome is a 130- to 375-kbp (depending on the genus) double-stranded DNA molecule that is encapsidated in a nucleoprotein complex (nucleosome) inside the core. The genome is covalently closed at each end, and its ends are hairpin-like telomeres. Complete genome DNA sequences have been reported for several different poxviruses. GenBank entries are compiled at a dedicated website (http://www.poxvirus.org).

During virus replication (1), virion morphogenesis begins in the cytoplasm in areas known as cytoplasmic viral factories, where cellular organelles are largely absent. Thin-section electron microscopy observations of cells early after infection show crescent-shaped membrane structures, which progress to ovoid structures, called immature virions, which enclose a dense nucleoprotein complex. Primary transcription precedes the production of the crescents (cup-shaped in three dimensions) and the immature virions. Brick-shaped, membrane-covered mature virions (MVs; also known as intracellular MVs [IMVs]) form as the viral core condenses. These are features that aid the electron microscopist in the identification of poxviruses in clinical materials (2).

A small portion of IMVs may be further transported on microtubules from the viral factory and processed to acquire a bilayer tegument (envelope) of Golgi intermediate compartment membrane that contains specific viral proteins. The intracellular enveloped MV then moves along cellular microtubules to the cell surface, where the outermost membrane fuses with the cellular membrane to reveal a cell-associated enveloped virus on the cell surface. The cell-associated enveloped virus can prompt actin polymerization behind the virion, which may facilitate cell-to-cell infection with virus. Enveloped virions can also exit the cell to spread more distantly.

A virus receptor has not been identified. Enveloped and nonenveloped forms attach to cells differently; however, studies suggest that the nonenveloped particle (IMV) is the particle that enters, via fusion, into the host cell. A complex of viral proteins is believed to act as a fusion complex. The common result of entry is uncoating of the particle, release of viral contents into the cell, and initiation of virus-controlled transcription of early-class proteins. Reviews of virion entry, morphogenesis, and exiting processes have been published (3–6).

EPIDEMIOLOGY AND TRANSMISSION

All current, naturally occurring poxviruses that infect humans are sporadic zoonotic agents, except the Molluscipoxvirus species Molluscum contagiosum virus, which is transmitted strictly between humans. The zoonotic poxviruses include members of the genera Orthopoxvirus (monkeypox virus, cowpox virus, and the vaccinia virus subspecies including buffalopox virus), Parapoxvirus (orf, pseudocowpox, sealpox, and papulosa stomatitis viruses), and Yatapoxvirus (tanapox virus [TPV], Yaba monkey tumor virus [YMTV], and Yaba-like disease virus [YLDV]). Orf virus and MCV infections are the most common poxvirus infections worldwide. These dermatologic lesions often can be readily identified, and laboratory confirmation of clinical diagnosis is often not utilized (7–9).

*Causes milker's nodule in humans.

Orthopoxviruses

The Vaccinia Virus

Vaccinia virus, the cause of smallpox, had a strict human host range and no known animal reservoir. The virus was most often transmitted between humans by large-droplet respiratory particles inhaled by susceptible persons who had close, face-to-face contact with an infected person. It was spread less commonly by aerosol, by direct contact with the rash lesion, or by sloughed crust material from a scab (10).

Monkeypox Virus

Human monkeypox was first reported in 1970 in the Democratic Republic of the Congo (DRC). Since 1970, the disease has been seen in Liberia, the Ivory Coast, Sierra Leone, Nigeria, Benin, Cameroon, and Gabon, but most cases have been in the DRC. In the 1980s, serosurveys and virologic investigations in the DRC by the World Health Organization (WHO) indicated that (i) monkeys are sporadically infected, as are humans; (ii) three-fourths of cases, mainly those in children <15 years of age, were from animal contact; (iii) the protective efficacy of vaccinia vaccination is ~85%; (iv) monkeypox virus has a broad host range, including squirrels (Funisciurus spp. and Heliosciurus spp.); and (v) human monkeypox has a secondary attack rate of 9% among unvaccinated contacts within households (i.e., it is much less transmissible than smallpox). In an outbreak in the DRC, ~250 serosubstantiated cases of monkeypox occurred among 0.5 million people in 78 villages from February 1996 to October 1997. Unlike those in the earlier outbreak, about three-fourths of the cases appeared to result from human-to-human transmission; however, the secondary attack rate of 8% among unvaccinated contacts within households appeared to be about the same as that found in the 1981-to-1986 surveillance (11–14). More-recent case series have been reported from the DRC (15, 16), and disease with a sustained chain of human-to-human transmission was reported in the Republic of the Congo in 2003 (17).

The emergence of monkeypox in the United States provides another example of the ability of this zoonotic disease to exploit new ecological niches. The North American prairie dog, infected with a vaccinia virus variant, and its close relative the prairie vole are potential natural reservoirs for the virus. Vaccinia and other monkeypox viruses have been used as recombinant vectors for the expression of a variety of proteins, including vaccine immunogens. Infection can be transmitted to laboratory workers by accidental exposure, and significant pathologic changes have been observed in vaccinated individuals (22). Vaccination is therefore currently recommended for personnel working with live, replicative orthopoxviruses, including vaccinia virus.

The origin of vaccinia virus is uncertain. (For insights on the origins of vaccinia and cowpox viruses, see reference 23). Vaccinia virus infections are not generally regarded as naturally occurring, although vaccinee-to-cattle and cattle-to-human transmissions occurred on farms during the smallpox eradication campaign. Sporadic outbreaks of infection caused by the vaccinia virus subspecies Buffaloopox virus that involve transmission between milking buffalo, cattle, and people have been reported, mainly in India but also in Egypt, Bangladesh, Pakistan, and Indonesia. Vaccinia-like lesions have been observed on the animals’ teats and the milkers’ hands; milk is infectious. Biological data and limited DNA analyses of isolates from an outbreak in India in 1985 suggest that buffaloopox virus may be derived from vaccinia virus strains transmitted from humans to livestock during the smallpox vaccination era (24).

Quite interestingly, multiple distinct vaccinia viruses, possibly related to the vaccine strain used during smallpox eradication in Brazil, were described in cattle and their farm worker handlers in rural Rio de Janeiro (25, 26) as well as various locales within the Minas Gerais state (25, 27–29). Historic collections, when reevaluated with additional techniques, suggest that vaccinia-like viruses were previously isolated in the 1960s and 1970s (30). Inadvertent exposure to a vaccinia virus-vectorated recombinant rabies virus vaccine dispersed to control rabies in wildlife has resulted in at least two instances of human infection; in both cases the bait was encountered via the family dog (31, 32).

Cowpox Virus

Cowpox, sometimes a rare occupational infection of humans, can be acquired by contact with infected cows. Other animals, e.g., infected rats, pet cats, and zoo and circus elephants, have more often been sources of the disease. Cowpox virus is a rather diverse species and has been isolated from humans and a variety of animals in Europe and adjoining regions of Asia (33, 34). An outbreak of human disease in Europe was associated with contact with pet rats (35). A serosurvey of wild animals in Great Britain found orthopoxvirus antibodies in a portion of bank and field voles and wood mice, which is consistent with small rodents being reservoir hosts (36).

Yatapoxviruses

The epidemiology and natural history of yatapoxviruses are poorly understood. YMTV and YLDV infections have occurred in animal handlers (37); however, TPV is the main naturally occurring human pathogen in the Yatapoxvirus genus (38). Tanapox is an endemic zoonosis of equatorial Africa that is thought to be transmitted mechanically to humans by biting insects, especially during the rainy season (39). Reports have demonstrated that travelers to regions where the disease is endemic can be infected (40, 41).

Parapoxviruses

Many different parapoxvirus diseases occur in humans (38, 42), generally as occupational infections: milker’s nodule (in dairy cattle, the disease is termed pseudocowpox or paravaccinia), orf (in sheep and goats, the disease has been...
referred to as orf, contagious ecthyma, contagious pustular dermatitis, contagious pustular stomatitis, and sore mouth), and papulosa stomatitis (in calves and beef cattle, the disease is termed bovine papular stomatitis). Parapoxvirus infections are transmitted to humans by direct contact with infected livestock through abraded skin on the hands and fingers, and ocular autoinoculation sometimes occurs (38, 42). Sealpox virus infections have been transmitted to humans from pinnipeds (43).

Molluscipoxvirus

MCV is the sole member of the genus Molluscipoxvirus. MCV appears to have a human-restricted host range, and it does not grow readily in culture. Molluscum contagiosum occurs worldwide. In children, it is transmitted by direct skin contact, and sexual transmission occurs in adults (38).

CLINICAL SIGNIFICANCE

Orthopoxviruses

A global commission of the WHO declared smallpox eradicated in December 1979, and the declaration was sanctioned by the World Health Assembly in May 1980 (10). Human monkeypox, an emerging zoonotic smallpox-like disease caused by monkeypox virus, with recurrent (and likely endemic) disease in the Congo Basin countries of Africa, is now regarded as the most serious naturally occurring human poxvirus infection (11, 15, 19, 44). The emergence of monkeypox virus as a human pathogen in the United States in 2003 is a classic example of a pathogen’s exploitation of new ecologic niches and hosts.

Variola Virus

Variola major virus strains produced “variola major,” a syndrome consisting of a severe prodrome, fever, prostration, and a rash. Toxicemia or other forms of systemic shock led to case fatality rates of up to 30%, with secondary attack rates of 30 to 80% among unvaccinated contacts within households. Variola minor virus strains (alastrim, amass, and kaffir viruses) produced “variola minor,” a less severe infection with case fatality rates of <1%, although secondary attack rates among unvaccinated contacts were as high as those observed with variola major virus infections. DNA and biological data have indicated that alastrim variola minor viruses obtained from Europe and South America are similar to each other but distinct from the so-called African variola minor viruses, which appear to be variola major virus variants (7). Epidemiologically, the disease syndromes were discriminated by case fatality rates; current sequence data indicate that the genetic distinctions between strains causing major or minor disease manifestations are multiple and varied. The last naturally occurring smallpox case occurred in Somalia in October 1977, although a fatal laboratory-associated infection with variola major virus occurred at the University of Birmingham, Birmingham, United Kingdom, in August 1978 (10).

Naturaly acquired variola virus infection caused a systemic febrile rash illness. For ordinary smallpox, the most common clinical presentation, after an asymptomatic incubation period of 10 to 14 days (range, 7 to 17 days), was fever, quickly rising to about 103°F, sometimes with dermal petechiae. Associated constitutional symptoms included backache, headache, vomiting, and prostration. Within a day or two after incubation, a systemic rash appeared that was characteristically centrifugally distributed (i.e., lesions were present in greater numbers on the oral mucosa, face, and extremities than on the trunk). Initially, the rash lesions appeared macular and then papular, enlarging and progressing to a vesicle by day 4 to 5 and a pustule by day 7; lesions were encrusted and scabby by day 14 and sloughed off. Skin lesions were deep seated and were in the same stage of development on any one area of the body. Milder and more severe forms of the rash were also documented. Less-severe manifestations (modified smallpox or variola sine eruptione) occurred in some vaccinated individuals, whereas hemorrhagic or flat-pox types of smallpox occurred in patients with impaired immune responses.

Variola major smallpox was differentiated into four main clinical types: (i) ordinary smallpox (~90% of cases) produced viremia, fever, prostration, and rash; (ii) modified smallpox (5% of cases) produced a mild prodrome with few skin lesions in previously vaccinated people; (iii) flat smallpox (3% of cases) produced slowly developing focal lesions with generalized infection and an ~50% fatality rate; and (iv) hemorrhagic smallpox (<1% of cases) induced bleeding into the skin and the mucous membranes and was invariably fatal within a week of onset. A discrete type of the ordinary form resulted from alastrim variola minor infection (10).

Prior to its eradication, smallpox as a clinical entity was relatively easy to recognize, but other exanthematous illnesses were mistaken for this disease (10). For example, the rash of severe chicken pox, caused by varicella-zoster virus, was often misdiagnosed as that of smallpox. However, chicken pox produces a centripetally distributed rash and rarely appears on the palms and soles. In addition, in the case of chicken pox, prodromal fever and systemic manifestations are mild, if present at all. Chicken pox lesions are superficial in nature, and lesions in different developmental stages may be present on the same area of the body. Other diseases confused with vesicular-stage smallpox included monkeypox, generalized vaccinia, disseminated herpes zoster, disseminated herpes simplex virus infection, drug reactions (eruptions), erythema multiforme, enteroviral infections, scabies, insect bites, impetigo, and molluscum contagiosum. Diseases confused with hemorrhagic smallpox included acute leukemia, meningococcemia, and idiopathic thrombocytopenic purpura. The Centers for Disease Control and Prevention (CDC), in collaboration with numerous professional organizations, has developed an algorithm for evaluating patients for smallpox. The algorithm and additional information are available at http://www.bt.cdc.gov/agent/smallpox/ and at www.bt.cdc.gov/EmContact/index.asp. Experience with the algorithm has been summarized previously (45).

Monkeypox Virus

Reviews of human monkeypox infection are available (11, 44). Monkeypox was first recognized by Von Magnus in Copenhagen in 1958 as an exanthem of primates in captivity. Later, the disease was seen in other captive animals, including primates in zoos and animal import centers. The clinical appearance of human monkeypox, typified by the Congo Basin variant, is much like that of smallpox, with fever, a centrifugally distributed vesiculopustular rash (appearing also on the palms and soles), respiratory distress, and, in some cases, death from systemic shock. Like variola virus, monkeypox virus appears to enter through skin abrasions or the mucosa of the upper respiratory tract, where it produces an enanthem and cough. During the primary viremia, the virus then migrates to regional lymph nodes, and during secondary viremia, it is disseminated throughout the body and the skin rash appears. During the prodrome, ly-
phadenopathy (generally inguinal) with fever and headache is common. Individual skin lesions develop through stages of macule, papule, vesicle, and pustule. Sequelae involve secondary infections, permanent scarring and pitting at the sites of the lesions, and sometimes alopecia and corneal opacities. Acute illness in the United States in 2003, caused by the “West African” variant, appeared generally more mild (19, 20); genomic sequence analyses and comparative epidemiologic and clinical data support the existence of two distinct clades of monkeypox virus. Additional information on clinical manifestations of disease (46) is also available.

Vaccinia Virus

Humans have historically encountered vaccinia virus most commonly in the form of smallpox vaccine (now called vaccinia vaccine), a live-virus preparation that is cross-protective against other orthopoxvirus infections. The most recent recommendations of the Advisory Committee on Immunization Practices (ACIP) on vaccinia vaccination are available at http://www.cdc.gov/mmwr/preview/mmwr html/rr5010a1.htm (47). The ACIP recommends vaccination as a safeguard for laboratory and health care workers who are at high risk of orthopoxvirus infection. In the United States, the CDC Drug Service provides the vaccine after CDC approval of a formal request for this purpose by the administering physician. Vaccinia immunoglobulin is available to treat possible postvaccination complications, which can be severe.

Vaccination is done by using a multiple-puncture technique that causes a local lesion, which develops and recedes in a distinctive manner in primary vaccinees during a 3-week period. At the site of percutaneous vaccination, a papule forms within 2 to 5 days, and the lesion reaches maximum size (~1 cm in diameter) by 8 to 10 days postvaccination after evolving through vesicle and pustule stages; an areola may encircle the site. The pustule dries into a scab, which usually separates by 14 to 21 days after vaccination. In some vaccinated children, fevers with temperatures as high as about 100°F have occurred, though these have been uncommon in adults, and a regional lymphadenopathy has been observed.

Because of an increased risk for serious adverse events, such as eczema vaccinatum or vaccinia necrosum, the ACIP has stated that the vaccine is contraindicated for persons with eczema or immunocompromising conditions. The possible complications of vaccinia vaccination are described in the ACIP report (47). Despite attempts to prescreen potential vaccinees for contraindications, instances of generalized vaccinia rash, which may arise 10 to 14 days postvaccination, continue to be reported (48). On a clinical basis alone, it is often difficult to distinguish between generalized vaccinia, which represents virus presumably spread hematogenously, and a form of erythema multiforme, which may be immunologically mediated. Laboratory identification of virus within the disseminated rash may differentiate these conditions (48).

Cowpox Virus

In humans, cowpox lesions occur mainly on the fingers, with reddening and swelling. Autoinoculation of other parts of the body may occur, and severe systemic infections have been reported. Skin lesions are likened to those from a primary vaccinia vaccination. The site becomes papular, and a vesicle develops in 4 to 5 days. Healing takes about 3 weeks (33).

Yatapoxviruses

The three members of the genus Yatapoxvirus, TPV, YLDV of monkeys, and YMTV, are serologically related (37). DNA maps of TPV and YLDV are extremely similar, suggesting that they are the same agent. However, these DNA maps are markedly different from YMTV DNA maps, even though the DNA from the three viruses cross-hybridizes extensively (49).

TPV and YLDV infections in humans consist of a brief fever, followed by development of firm, elevated, round, maculopapular nodules that become necrotic and are distinct from the vesiculopustular lesions of orthopoxvirus infections. Generally, few lesions develop, and these occur primarily on the skin of the upper arms, face, neck, or trunk (50). Symptoms that occur prior to the appearance of lesions include fever, backache, and headache. Lesions umbilicate without pustulation during recovery from infection. They usually heal in 2 to 4 weeks. YMTV produces epidermal histiocytomas, tumor-like masses of histiocytic polygonal mononuclear cell infiltrates that advance to suppurative inflammation.

Parapoxviruses

Milker’s nodule occurs as a reddened hemispheric papule that matures into a purplish, smooth, firm nodule varying up to 2 cm in diameter. The lesions usually are not painful and can persist for about 6 weeks. Human orf virus infection is usually found on the fingers, hands, and arms but may also be found on the face and neck. Fever and swelling of draining lymph nodes may be present, and the lesions often ulcerate and are painful. Autoinoculation of the eye may lead to serious sequelae (8). Contact with (e.g., skinnning of) certain wild animals, including deer, reindeer, chamois, and Japanese serow, has also been a source of human parapoxvirus infection. Technicians handling gray seals have contracted sealpox virus (42, 43).

Molluscipoxvirus

In children and teenagers, molluscum contagiosum lesions generally appear on the trunk, limbs (except the palms and soles), and face, where there may be ocular involvement. Infection is usually transmitted by direct skin contact. When MCV infection is transmitted sexually among teenagers and adults, the lesions are mostly on the lower abdomen, pubis, inner thighs, and genitalia. Lesions are pearly, flesh-colored, raised, firm, umbilicated nodules, ~3 mm in diameter. The lesions tend to disseminate by autoinoculation. Prior to highly active antiretroviral therapy, MCV was an opportunistic pathogen in ~15% of patients with AIDS in the United States. Restriction endonuclease mapping of isolates suggests that there are at least three MCV subtypes (9). Two predominant MCV subtypes, MCV1 and MCV2, have been detected in a limited number of samples examined by restriction pattern and base sequence analyses, but no correlation of subtype with disease syndrome or geographic distribution has been confirmed (8, 9). A rapid PCR and restriction fragment length polymorphism analysis using skin lesion material has been described previously for differentiating the MCV subtypes (51).

Antiviral Therapy

Currently there are no drugs approved for use in the treatment of poxvirus infections; this is an area of active research and development (52). The experimental drug ST-246, an inhibitor of poxvirus egress, appears to be effective against orthopoxviruses including variola virus and monkeypox.
viroid infections of nonhuman primates (53), and has been used
investigationally in the treatment of human smallpox
(vaccinia) vaccine adverse events (54). The DNA polymer-
ase inhibitor cidofovir and its orally bioavailable derivative
CMX-001 similarly have in vitro and in vivo data to support
anti-orthopoxvirus activity and have been used as investiga-
tional agents in the treatment of vaccine adverse events
(55). Vaccinia immune globulin is licensed for use as a
treatment for severe adverse events associated with vaccina-
tion and can be obtained from the CDC.

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

A suspected case of smallpox should be immediately re-
ported to the appropriate local or state health department.
After review by the health department, the case should be
immediately reported to the CDC if the diagnosis of small-
pox is still suspected. Current international recommenda-
tions advise that work with variola virus be done using
WHO-sanctioned biosafety level 4 laboratories. Two WHO
collaborating centers (WHOCCs) currently have the capa-
bility to handle smallpox specimens: one at the CDC in
Atlanta and the other at the State Center for Virology and
Biotechnology, Koltsovo, Russia. The WHOCC at the CDC
also has containment facilities appropriate to work with
monkeypox virus and other exotic poxviruses (e.g., TPV).
Generally, clinical specimens suspected of containing other
poxviruses (e.g., parapoxviruses and MCV) can be tested by
experienced local staff using biosafety level 2 containment
facilities and equipment. Additionally, laboratories testing
samples from laboratory workers with potential occupational
exposures to vaccinia virus may wish to consider vaccination
of staff, in addition to the use of biosafety level 3 contain-
ment facilities, equipment, and work practices.

Suitable specimens for laboratory testing of most sus-
ppected poxvirus infections are at least two to four scabs and/or
material from vesicular lesions. Scabs can be separated
from the underlying intact skin with a scalpel or a 26-gauge
needle, and each specimen should be stored in a separate
container to avoid cross-contamination. Coexistent infec-
tious rash illnesses, including simultaneous chicken pox and
monkeypox infections, have been noted (14).

Lesions should be sampled so that both the vesicle fluid
and the overlying skin are collected. Once the overlying
skin is lifted off and placed in a specimen container, the
base of the vesicle should be vigorously swabbed with a
wooden applicator or polyester or cotton swab. The viscous
material can be applied onto a clean glass microscope slide
and air dried. A "touch prep" can be prepared by pressing
a clean slide onto the opened lesion by using a gradual
pressing motion. If available, three electron microscope grids
can be applied in succession (shiny side to the unroofed
vesicle) to the lesion by using minimal, moderate, and mod-
erate pressure. The glass slides and electron microscope grids
should be allowed to air dry for about 10 min and then
placed in a slide holder or a grid carrier box for transport
to a laboratory.

Alternative lesion sampling processes, including storing
material on appropriate filter paper types, are being evalu-
at ed. Sample storage in transport medium (as done, for
example, with herpesviruses) is discouraged, since specimen
dilution decreases the sensitivity of direct evaluation by
electron microscopy. Specific recommendations for electron
microscopy sampling and specimen processing can be found
on the Internet (http://www.bt.cdc.gov/agent/smallpox/lab-
testing/pdf/em-rash-protocol.pdf). A biopsy of lesions may
also provide material suitable for direct viral evaluation or
immunohistochemistry. A 3- to 4-mm punch biopsy speci-
men can be made, and the specimen can be bisected, with
half placed in formalin for immunohistochemical testing
and the remainder placed in a specimen collection con-
tainer. Blood and throat swabs obtained from suspected
smallpox patients during the prodromal febrile phase and
early in the rash phase were also a potential source of virus
during the smallpox era (56).

Patient serum can also be obtained for serology to sub-
stantiate viral infection diagnoses or to infer a retrospective
diagnosis. Paired acute- and convalescent-phase serum spec-
imens can be of great value for diagnosis of infection. In
this case, serum should be obtained as early as possible in
the disease course and then 3 to 4 weeks later.

Most virus-containing specimens should be stored frozen
at ~20°C or on dry ice until samples reach their transport
destination. Storage at standard refrigeration temperatures
is acceptable for <7 days. Electron microscopy grids and
formalin-fixed tissues should be kept at room temperature.

**CLINICAL UTILITY OF LABORATORY TESTS FOR POXVIRUS DIAGNOSIS**

Poxvirus infections can often be distinguished by the appear-
ces of rashes and associated dermatopathologies (57). In
addition, multiple different clinical laboratory tests can be
useful for identifying and differentiating poxviruses, includ-
ing electron microscopy, antigenic testing, nucleic acid detec-
tion, determination of virus growth features, and serol-
y. The utility of these test methods for the diagnosis of
poxvirus infections is shown in **Table 2**.

**DIRECT DETECTION**

**Microscopy**

Electron microscopy is a first-line method for laboratory
diagnosis of poxvirus infections. Negative-stain electron
microscopy of lesion samples was widely used during the
smallpox eradication era. Because the clinical diagnosis of

*Abbreviations: EM, electron microscopy; HA, hemagglutination; HP, histopathology; NAT, nucleic acid test. X’s indicate the utility of the tests for the specified viruses.

*Pack formation on CAM and tissue culture isolation are useful.

*Isolation in tissue culture only; viruses do not produce pocks on CAM.
Poxviruses produce inclusions that have characteristic appearances when stained with May-Grunwald Giemsa and hematoxylin-eosin stains. Perinuclear basophilic or B-type cytoplasmic inclusions (virus factories or viroplasm) are observed in cells infected with any of the poxviruses and represent sites of virus replication. Certain species (e.g., the Orthopoxvirus Cowpox virus) produce acidophilic inclusions or A-type inclusions. Depending on the strain, A-type inclusions may (V⁺) or may not (V⁻) contain virions.

Antigen Detection
Orthopoxvirus is the only genus whose members produce a hemagglutinin (HA) antigen, which is detectable by hemadsorption or hemagglutination assays using chicken erythrocytes that are pretested to be suitable for such tests. Orthopoxvirus antigen can also be rapidly detected by the Orthopox BioThreat Alert assay (Tetracore, Rockville, MD), which uses a lateral flow system to rapidly detect the presence of virus in clinical specimens. It has been shown to recognize vaccinia and monkeypox viruses at levels that may be found in rash lesions (62). Direct detection of poxvirus antigens in clinical specimens is not routinely performed in many laboratories as a diagnostic assay.

Nucleic Acid Detection
PCR analysis is used by the WHOCC at the CDC to detect poxviruses DNA in samples. A recent development is the validation of a pan-poxvirus PCR assay, which can screen specimens for the presence of poxviruses other than avipoxviruses (63). Multiple single-gene PCR assays, followed by restriction fragment length polymorphism analysis or sequence analysis of the amplicon, permits species identification of orthopoxviruses. A number of different targets are used, including the HA gene, which is unique for the genus Orthopoxvirus; the gene for the B cytokine response modifier (CrmB, one of several different tumor necrosis factor receptor homologs produced by orthopoxviruses); and the gene for the A-type inclusion body protein. In these assays, DNA that is present in any orthopoxivirus is amplified (Table 3). The amplicon is digested with the appropriate restriction endonuclease, and digested fragments are electrophoresed. Fragment sizes are compared to reference restriction fragment length polymorphism profiles to discriminate species. Conventional PCR tests for other poxvirus genera have also been reported (64). Other nucleic acid diagnostic approaches include random amplified polymorphic DNA fragment length polymorphism for orthopoxvirus species and strain discrimination (65, 66). Microchips have also been utilized to identify poxvirus species by discernment of PCR-amplified, fluorescence-labeled DNA fragments by hybridization to orthopoxvirus species-specific immobilized DNA. The high sensitivity of and rapid results from real-time PCR assays make them attractive for laboratory diagnostic use (67). In the United States, many national reference laboratories, as well as the Laboratory Response Network laboratories, use this format of nucleic acid testing for rapid response to diagnose suspected orthopoxvirus infections and/or to rule out smallpox infections. The use of a probe or probes in this type of assay allows for the specificity; however, the extreme sensitivity of the assays can lead to false-positive contaminants from specimen carryover. Many of these methods for detection of orthopoxviruses and other poxviruses are summarized in Table 4. These types of assays are performed primarily at specific reference centers, including the CDC Poxvirus Program/WHOCC for Smallpox and Other Poxvirus Infections.

### Isolation and Identification

Orthopoxviruses can be grown in a variety of established cell culture lines, including Vero, BS-C-1, CV-1, LLCMK-2 monkey kidney cells, human embryonic lung fibroblast cells, HeLa cells, chicken embryo fibroblast cells, and MRC-5 human diploid fibroblast cells, as well as in fetal rhesus monkey kidney (FHRK-4) cells. Cytopathic effects (CPEs) appear as cell rounding with long cytoplasmic extensions (Fig. 2 and 3). In some cases, syncytium formation can also be seen; in Fig. 3B, this is seen in the monkeypox virus-induced CPE. The timing of CPEs is dependent on the infectious inoculum. Most laboratories confirm the presence of a specific orthopoxvirus via PCR (see above). Methods for growing and discriminating the morphologies of orthopoxviruses on the chorioallantoic membranes (CAMs) of 12-day-old chicken embryos have been described previously (58, 59, 68, 69). Orthopoxviruses are the only human poxviruses that produce pocks in the CAMs of fertile chicken eggs; pock morphology is useful for biologic species and variant differentiation. Parapoxviruses, yatapoxviruses, and MCV do not form pocks on the CAM, although avipoxviruses, leporipoxviruses, and capripoxviruses do so. Poxvirus genera can usually be identified and differentiated by virus neutralization testing with hyperimmune reference sera (24, 38, 58, 59, 70). However, it can be difficult to identify the infecting species since poxviruses are antigenically closely related within a given genus.

### Serologic Tests

**Orthopoxviruses**

When virus-containing clinical specimens are not available, antibody detection may be the only way to define the etiology of the disease. Serologic methods currently used to detect antibodies against human orthopoxviruses include enzyme-linked immunosorbent assays (ELISAs), the virus neutralization test, Western blotting, and hemagglutination inhibition. Various protocols for poxvirus serologic testing used at the CDC are detailed elsewhere (39).
The description of an orthopoxvirus IgM assay offers great promise to enhance investigations of orthopoxvirus infection outbreaks, often semiretrospective in nature (39). This technique offers the advantage of measuring recent infection or illness with an orthopoxvirus. It is useful for evaluating disease incidence in epidemiologic surveillance studies. For example, during the 2003 U.S. monkeypox outbreak, the IgM capture assay demonstrated ~95% sensitivity and ~95% specificity for epidemiologically linked and laboratory test-confirmed patients when sera were obtained between days 4 and 56 post-rash onset. A low-grade response, termed “equivocal,” awaits further research. This assay was also used to detect anti-orthopoxvirus IgM in the cerebrospinal fluid of an encephalitic patient with monkeypox (71). A peptide-based ELISA for the identification of monkeypox virus-specific antibodies has been reported (72, 73). It was capable of differentiating between monkeypox virus and vaccinia virus. However, this ELISA is known to cross-react with variola virus and, due to sequence conservation across the orthopoxviruses, is also likely to cross-react with many strains of cowpox viruses. It remains an investigational tool rather than a clinical test since its clinical utility has not been further established. A monkeypox virus-specific antibody has been isolated, and characterization of the epitope has provided insight into the design of peptides to be used in a monkeypox-specific serologic assay (74, 75).

In the current state of bioterrorism response awareness, tests to evaluate residual protection from previous vaccination are being requested. It is important to note that there is no one routine immunologic test that defines a person’s degree of protection against a poxvirus infection. Protection is genetically defined and requires a concert of cell-mediated and humoral immune responses. Studies (76) suggest that humoral responses may be the critical component of recovery from and survival of a systemic orthopoxvirus infection. The presence of neutralizing antibodies generally indicates recovery from an infection, not always protracted protection from future infection. Neutralizing antibodies against variola, monkeypox, cowpox, or vaccinia viruses may be detectable as early as 6 days after infection or vaccination. Neutralizing antibodies have been detected as long as 20 years
after vaccinia vaccination or natural infection with other human orthopoxviruses.

The orthopoxvirus neutralization test has been traditionally performed by looking for a reduction in plaque number. This was improved upon using a green fluorescent protein-tagged vaccinia virus and measuring viral entry into tissue culture cells (77, 78). In the virus neutralization assay, a 4-fold rise in antibody titer between serum samples drawn during the acute and convalescent phases is usually considered diagnostic of poxvirus infection. When only one serum specimen is available from one phase of infection, confirmation of a clinical diagnosis may be difficult to impossible. Because orthopoxviruses are closely related, serum cross-absorption tests, such as those performed in immunofluorescent-antibody or immunodiffusion methods, have been used with variable success with patient and animal sera. Orthopoxvirus antigen cross-absorption assays have been performed using hyperimmune animal sera and have been utilized in serosurveys for animal or human monkeypox infection (58, 59). False-positive results should be ruled out by using appropriate control sets of sera of known provenance.

The Western blot assay is performed essentially as described by Towbin et al. (79) and uses various antigens, including purified virus and sometimes the concentrate of culture fluid from infected cells maintained under medium that contains 1% or no serum supplement. Few laboratories are using this method, as reliable standardization has not been achieved.

**Pseudocowpox, Orf, Tanapox, and Molluscum Contagiosum Viruses**

Serologic methods used to help confirm parapoxvirus infections (milker’s nodule and orf) have included ELISAs (80) and Western blot assays that use various antigen preparations. Serologic testing for TPV infection by standard ELISA (80) with antigens obtained from concentrates of infected cell culture, by an indirect immunofluorescent-antibody test, and by neutralization test has been moderately effective. Optimally, sera should be collected at the time of actual disease and 3 to 5 weeks or later after the presumed onset date. Because MCV cannot be readily grown in culture, no routine serologic test is available. Molluscum contagiosum is readily diagnosed clinically, often with the aid of electron microscopy and histopathologic testing performed by a local diagnostic facility.

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

For confirmation of an infectious agent, cell culture or other mechanism for demonstrating viable virus should be regarded as the gold standard. Absent readily available or feasible tissue culture methods, the use of multiple diagnostic assays or techniques improves the specificity of a diagnosis. Nucleic acid amplification tests, while sensitive, can result in false-positive results. A proficiency survey of nucleic acid amplification tests performed by 33 labs spanning three geographic areas (Europe, Australasia, and the United States) found a substantial rate of false-positive results (~12%), highlighting the need for sound molecular practices, which becomes even more critical when testing for potential biothreat agents (81). The use of multiple nucleic acid tests, with different detection targets, can improve the specificity of a diagnosis. Electron microscopy can be used to evaluate generically for the presence of a poxvirus and can be used to infer viable agent if multiple virus forms are present but cannot be used to make a specific genus diagnosis except in the case of parapoxvirus infections. Serologic assays are available at a few reference laboratories worldwide but only rarely can be used to make a specific species diagnosis. Histochemistry, combined with immunologic analysis, can be used to identify poxvirus genera in a few reference centers worldwide. A combination of nucleic acid amplification, growth of agent in culture, serology, electron microscopy, and/or immunohistochemistry techniques improves the sensitivity and specificity of a diagnosis.

**REFERENCES**

HEPATITIS B VIRUS

Introduction

Epidemic hepatitis was first described in the 5th century B.C. The earliest documented blood-borne outbreak of hepatitis occurred in Bremen, Germany, in 1883 among shipyard workers who received a smallpox vaccine stabilized with human serum. In 1950, Bauer and Wyman referred to viral hepatitis as either infectious hepatitis (hepatitis A) or serum hepatitis (hepatitis B) based on the different epidemiologic characteristics of the diseases (1). This terminology was adapted by the World Health Organization (WHO) in 1973 to distinguish the two agents of hepatitis.

Subsequently, Blumberg and colleagues in 1965 discovered the "Australia" antigen, now known as hepatitis B virus (HBV) surface antigen (HBsAg), in blood specimens from Australian aborigines (2, 3). A few years later, in 1968, Prince (103) and Okochi and Murakami (104) isolated the Australia antigen in patients with HBV infection, which led to the first HBV vaccine in 1981. There is now abundant information on the natural history of HBV, including the pathogenesis and epidemiology. This has led to more accurate diagnostic assays as well as successful antiviral treatment and safe and effective vaccines. Due to the tremendous burden of this disease, laboratory tests used to diagnose and monitor disease as well as the effectiveness of the vaccine are keys to the control of this disease.

Taxonomy

HBV is an enveloped DNA virus in the Hepadnaviridae family and has a narrow host range. HBV infects only species closely related to humans, such as gibbons and several monkey species (4). As with other viruses in this family, the HBV genome is partially double stranded. It has a circular DNA molecule that replicates via an RNA intermediate. The replication of HBV DNA by reverse transcription is unique for human DNA viruses (4).

Description of the Agent

HBV is a 42-nm, partially double-stranded DNA virus that replicates in the nucleus of the host cell. HBV-infected cells have no cytopathic features because the virus causes little damage to the host cell (5). The virion is composed of HBsAg embedded in a lipid membrane surrounding a viral nucleocapsid core. The complete virus particle is known as the Dane particle, after its discoverer (6). The viral nucleocapsid core is surrounded by a specific viral core protein (HBcAg) and encloses a single molecule of partially double-stranded DNA, hepatitis B e antigen (HBeAg), and a DNA-dependent polymerase (Fig. 1A). The terminology used to describe the various antigens and antibodies associated with HBV as they appear at different stages of infection is given in Table 1.

HBV particles found in the sera of patients with active HBV infection reveal three distinct morphologic entities in varying proportions (Fig. 1A and B). The most abundant forms (by a factor of 10⁴ to 10⁵) are the small, pleomorphic, spherical, noninfectious particles (17 to 25 nm in diameter). These noninfectious particles have a low buoyant density, reflecting the presence of lipids from the host cell membrane (7). Less numerous are the tubular or filamentous forms, which have diameters similar to those of the small particles. The third and least numerous particle is the complete HBV virion, with a diameter of approximately 42 to 47 nm (6). At present there is no cell culture system that supports the growth of HBV.

The HBV genome is approximately 3,200 bases and contains overlapping genes (Fig. 1C). There are four open reading frames (ORFs) in the complete, minus strand. These genes encode the structural proteins (HBsAg and HBcAg), replicative proteins (polymerase and X protein), and regulatory proteins. The genome is compact, and most sequences are essential for productive infection (4).

After binding to hepatocytes, the HBV virion is taken up and uncoated. The partially double-stranded, relaxed circular DNA is converted by the host polymerase to a covalently closed circular DNA (cccDNA) template in the cell nucleus. The cccDNA form is used as a template for transcription of the pregenomic RNA (pgRNA) and mRNA (4). The pgRNA is transcribed from the cccDNA in the nucleus and then moves into the cytoplasm of the host cell. In the cytoplasm, the pgRNA serves as the template for the HBV reverse transcriptase enzyme as well as the core protein. At the same time, the polymerase converts the pgRNA to a new circular DNA molecule. Early in infection, some newly synthesized genomes from the cytoplasm circulate back to the nucleus to build up and maintain the pool of cccDNA (8).
FIGURE 1  (A) The intact infectious HBV virion and the empty particles are shown. The two HBV particles (right) comprised of HBsAg are shown as elongated or tubular particle and as spherical particles. These particles vastly outnumber the virions. (Designed by the University of Kansas Graphic Design Department, 2009.) (B) Electron micrograph of serum showing the presence of three distinct morphologic entities: 17- to 25-nm-diameter pleomorphic, spherical particles (a); tubular or filamentous forms with diameters similar to those of the small particles (b); and 42- to 47-nm-diameter double-shelled spherical particles representing the HBV virion (Dane particle) (c). Magnification, ×10³. (C) Diagrammatic representation of HBV coding regions. The functioning genome is a double-stranded circular DNA molecule, shown in the middle. RNA transcripts (arrows) are generated using both the plus-strand [(+)-Strand] and minus-strand [(-)-Strand] DNA templates. The largest transcript codes for the viral polymerase shown around the genome as the P transcript. The transcript for surface antigen (S) is produced as three separate transcripts, pre-S1, pre-S2, and S. The core protein is translated from the C transcript. HBeAg is encoded within the HB core gene. The transactivating protein is coded by the X transcript. (Designed by the University of Kansas Graphic Design Department, 2009.) doi:10.1128/9781555817381.ch108.f1
The HBV genome is highly efficient in that every nucleotide in the genome is in at least one coding region. More than half of the genome is transcribed into more than one ORF. Four viral mRNA transcripts are translated into HBV proteins. These viral mRNAs are transcribed from different promoter regions on the cccDNA template (Fig. 1C). The longest mRNA acts as the template for genome replication (pgRNA) and also the translation of precore, core (HBcAg), and polymerase proteins (4). The second transcript encodes the pre-S1 protein (39 kb), pre-S2 protein (33 kDa), and S protein (24 kDa, also known as HBsAg). A third transcript encodes the pre-S2 protein and the S protein. The smallest mRNA codes for the X protein, which is responsible for transcriptional regulation. Mature virions are produced by transcription of RNA into a circular DNA molecule. The long RNA transcript and the polymerase protein are packaged into mature core particles, and the reverse transcriptase enzyme synthesizes a new viral DNA genome. These particles are then transported to the HBsAg in the endoplasmic reticulum (ER) of the host cell and exported from the cell. The unused HBsAg is also released from infected cells as spherical and tubular particles devoid of HBV genomes or core proteins. Thus, these HBsAg particles are used as a diagnostic marker in serum to detect active viral replication (5, 9).

The envelope proteins of HBsAg are made up of three polypeptides encoded by the S/pre-S region of the HBV genome (Fig. 1C). The major protein is the smallest peptide. It is encoded by the S region and is a glycosylated polypeptide. The middle protein, encoded by the S and the pre-S2 regions, has an additional glycosylation site. The large S protein consists of 389 to 400 amino acids encoded by the pre-S1, pre-S2, and S regions of the genome. The production of HBsAg exceeds what is needed for virion production, and this excess antigen circulates in the blood of infected individuals as spherical and tubular particles and can be detected in clinical assays to detect active HBV infection (Fig. 1A and B) (10). This antigen may persist in the serum for variable periods after initial infection and in some patients can be as high as 10¹¹ per ml.

Two additional HBV-specific proteins play a key role in diagnostic testing. HBcAg and HBeAg have different antigenic specificities, and both can be distinguished from HBsAg. The HBeAg is a polypeptide encoded by the C gene of HBV and is translated from the pregenomic mRNA (Fig. 1C). The precore sequence within the C gene contains the start codon for HBeAg translation (10). Because of the different start codons the two proteins, HBcAg and HBeAg, are antigenically unrelated. HBeAg lacks the viral DNA-binding domain found on HBcAg. The first 29 amino acid residues of the HBeAg are encoded in the precore region of the C gene. This part of the HBeAg directs the protein to the host ER. In the ER this “homing” portion of the protein is cleaved off, and HBeAg is released from the host cell to the blood. In the blood HBeAg is a soluble protein or is bound to albumin, α-1-antitrypsin, or immunoglobulin. It is a dependable marker for the presence of intact virions indicating high infectivity. In some HBV strains, a mutation at the end of the precore region of the C gene results in a stop codon which prevents the translation of HBeAg. These precore mutants contribute to the pathogenesis of chronic HBV disease, leading to acute exacerbation of disease (11, 12). Other HBV gene mutations have been observed in the core, core promoter, envelope, and polymerase regions. The envelope protein variants become relevant, as some of them lead to antigenic changes that are not recognized by the HBV vaccine. These viruses are called escape HBV mutants, and infected patients do not have detectable antibody to HBsAg and do not respond to hepatitis B immunoglobulin (HBIG) therapy (13–15).

**Epidemiology and Transmission**

According to the WHO, HBV is 50 to 100 times more infectious than HIV-1 (http://www.who.int/csr/disease/hepatitis/whoecsrisrlyo20022/EN/index3.html#transmission). HBV infections are prevalent around the world and represent a global public health problem. The WHO estimates that 2 billion people are infected with HBV, and approximately 600,000 people die each year as a result of acute or chronic HBV (16, 17).
The majority of these HBV-infected individuals live in Asia or Africa (Fig. 2). Approximately one-fourth of adults who were infected with HBV as children experience serious complications from liver cirrhosis and/or hepatocellular carcinoma (HCC) linked to chronic HBV (18). The Centers for Disease Control and Prevention (CDC) estimates that 800,000 to 1.4 million individuals in the United States are chronically infected with HBV despite a decline of new infections during the last 20 years (http://www.cdc.gov/hepatitis/Statistics/2010Surveillance/Commentary.htm, accessed February 2015). In the United States, most infections are in adults, in whom the risk of chronic infection is lower. In contrast, outside the United States, perinatal exposure is more common and leads to chronic HBV infections (18, 19).

The most common modes of HBV transmission are vertical transmission (mother to child perinatally), early childhood infections from close contact with infected individuals, sexual activity (both heterosexual and male homosexual), and injection drug use or other physical contact with infected body fluids (occupational exposure, contaminated blood products, etc.) (4). HBV is not transmitted by casual activities such as talking, hand holding, or hugging, by ingestion of food or water, or from a cough or sneeze.

HBV causes chronic hepatitis, cirrhosis, and HCC worldwide. In most countries HBV infections are reportable to the public health authorities. HBV is a public health concern that can be addressed by accurate diagnostic detection, infection control, and vaccinations (5).

**Clinical Significance**

HBV infects hepatocytes, leading to either an acute infection that resolves or a chronic infection lasting years. In infected individuals, subclinical hepatitis presents as a mild disease without symptoms or jaundice. It is not uncommon for many HBV-infected people to be asymptomatic early in disease. Nevertheless, some patients may have vague symptoms such as abdominal pain, nausea without jaundice (anicteric hepatitis), or nausea with jaundice (icteric hepatitis). HBV infections can result in the complete recovery of the patient, fulminant hepatitis with mortality, or a chronic viral infection. Three phases of chronic HBV disease are recognized: (i) the immune tolerant phase, (ii) the immune clearance phase, and (iii) the inactive carrier phase (20).

The incubation period of acute HBV infection ranges from 6 weeks to 6 months. During this time the infection can be symptomatic or asymptomatic. Newborns infected with HBV usually have chronic, asymptomatic infections, while older children and adults are typically symptomatic after a primary infection (4, 9, 21).

The symptoms of acute HBV infection are often mild but sometimes include physical signs such as jaundice, dark urine, clay-colored stools, and hepatomegaly (4). Some patients experience weight loss, right upper quadrant pain, and a tender, enlarged liver (21). Acute HBV infections are usually self-limited, and most patients recover completely after specific antibodies (anti-HBs) clear the virus (22).

The disease outcome of acute HBV is age dependent, and most patients with acute disease are adults. Acute liver damage is caused by the host immune response to HBV-infected hepatocytes (4). This results in massive necrosis, which can lead to permanent damage to the liver. Mortality associated with fulminant hepatic failure is high without liver transplantation. After transplantation, HBV reinfection of the “new” liver is common, resulting in injury to the new liver in some patients. HBIG and/or antiviral therapy can prevent this outcome (20). Pathologic features of acute HBV include both degenerative and regenerative liver parenchymal changes that lead to lobular disarray. Cytotoxic T lymphocytes (CTLs) play a role in facilitating viral clearance during acute infection as well as the pathogenesis of hepatocellular injury (23).

Patients with perinatally acquired HBV are usually immune tolerant to HBV antigens. This explains the absence of severe liver disease despite high levels of virus (24). Patients who continue to have detectable HBsAg or detectable HBV DNA in serum for at least 6 months after infection are considered to have chronic HBV infections (20). Chronic carriers can remain positive for HBsAg indefinitely, although some HBsAg-positive patients spontaneously convert to HBsAg negative after the appearance of anti-HBs. Many of these patients continue to have detectable HBV DNA (4, 5). Symptoms of chronic HBV are generally nonspecific and may be unrecognized for years.
The National Institutes of Health (NIH) sponsored a consensus conference in 2008 on HBV infections (20). The conference defined three phases of chronic HBV infection: the immune tolerant phase, the immune active phase, and the inactive carrier phase, as mentioned above. The immune tolerant phase usually occurs in children who are infected with HBV early in life. It is characterized by high levels of HBV DNA with little damage or inflammation in the liver (Table 1). This stage can last for a few years to several decades (4, 5, 20).

Most HBV-infected individuals progress to the immune active phase, in which a liver biopsy shows inflammation with fibrosis, thus the term “active.” This pathology results from a persistent immune response to the HBV proteins on infected hepatocytes. The last phase of chronic HBV infection is the inactive carrier phase, characterized by less inflammation as determined by liver biopsy and normal liver enzyme levels. These patients have a lower risk for HCC (9, 22).

Chronic HBV infection is associated with an increased risk for HCC (5, 9, 22). During HBV infection, the viral DNA first randomly integrates into the hepatocyte genome. Over time this results in high levels of integrated viral DNA in host cells that can persist for years. Since the viral DNA integrates randomly, the number of integration sites also increases over time (20). Some of this randomly integrated viral DNA can activate cellular proto-oncogenes or suppresses the regulation of gene expression (25). In addition, some HBV proteins, such as the X protein and the truncated pre-S/S protein, are potent transactivators of cellular genes (26). Likewise, several other factors have been associated with the development of HCC, such as smoking, alcohol consumption, infections with other hepatotropic viruses (hepatitis C), and mycotoxins (aflatoxin).

Safe and effective vaccines against HBV have been available since 1981. The efficacy of HBV vaccination has been proven worldwide and is monitored by the WHO (17). The complete HBV vaccination series is protective in >95% of infants, children, and young adults (17, 22). Vaccine-induced protection lasts at least 20 years and may be lifelong (22). Currently there are two vaccines that contain only HBsAg and three different combination vaccines that contain HBsAg along with antigens to other pathogens. The immune responses induced by vaccines made by different manufacturers are not significantly different. Individuals with a known or suspected exposure to HBV should be given HBV vaccine as soon as possible after the exposure, in addition to HBIG.

Chronic HBV infections should be treated with antiviral drugs. The primary goal of treating chronic HBV is to suppress viral replication and slow the progression of liver damage (4). At present, seven therapeutic agents have been approved for use in the United States by the FDA. These drugs are classified into two categories, the interferons and nucleoside/nucleotide analogs. The first nucleoside analog approved for treating chronic HBV infection was lamivudine (27). More recently, several new agents have become available for the treatment of chronic HBV. These include adefovir, entecavir, tenofovir, emtricitabine, and telbivudine (20, 28, 29).

**Collection, Transport, and Storage of Specimens**

HBV infection is diagnosed by serologic and molecular markers detected in serum or plasma. All FDA-approved assays have specific specimen requirements defined in their package inserts. These requirements state the specimen types acceptable as well as describe the processing and storage of the specimen. In general, HBV antigens and antibodies are stable at room temperature for days, can be stored at 4°C for months, and can be frozen at −20 to −70°C for years. Although HBV markers are stable in serum stored at −70°C, repetitive freezing and thawing can lead to their degradation. The use of hemolyzed samples should be avoided due to the potential of these specimens to interfere with the detection signals used in immunoassays.

Plasma recovered from blood collected in tubes containing EDTA (lavender-top tubes) or in tubes containing anti-coagulant citrate dextrose (ACD; yellow-top tubes) is used for nucleic acid analysis. Plasma should be separated from red cells within 6 h and stored at 4°C until tested. EDTA stabilizes the viral nucleic acid, which can then be stored at 4°C for up to 5 days without significantly affecting the results (30). For long-term storage, plasma should be kept at −70°C. Heparinized plasma is unacceptable for most nucleic acid analysis because heparin interferes with Taq polymerase-mediated PCR (30, 31). There is evidence that HBV DNA is stable and detectable without a loss of sensitivity after many freeze-thaw cycles (32, 33). Useful information about many diagnostic tests can be found by consulting the FDA website and the specific year of test approval (http://www.fda.gov/MedicalDevices/ProductsandMedicalProcedures/DeviceApprovalsandClearances/Recently-ApprovedDevices/default.htm, accessed February 2015).

The HBV virion is very hardy and remains infectious for at least 7 days outside the host (30). Thus, spills or splashes should be cleaned using absorbent material and disinfected with an appropriate disinfectant. Decontamination should be carried out while wearing gloves. Laboratory personnel should regard all specimens as potentially dangerous (34). The Occupational Safety and Health Administration (OSHA) standards for occupational exposure to blood-borne pathogens (35) are designed to protect employees exposed to blood and other potentially infectious materials. OSHA mandates that all employees whose job requirements put them at risk for blood-borne pathogens be offered HBV vaccine at no cost. OSHA standards and additional safety recommendations can be found in the literature.

**Direct Detection**

The diagnosis of HBV uses a combination of tests. These assays detect specific HBV proteins, nucleic acid, and specific antibodies in plasma or serum (Table 1).

**Microscopy**

Microscopic detection of HBV does not play a role in the diagnosis of disease. However, a liver biopsy is often used to assess the extent of histologic involvement as well as the response to therapy. Histologic examination is useful for distinguishing among acute viral hepatitis, chronic hepatitis, and cirrhosis.

**Antigen**

Several HBV-specific proteins can be detected in patient specimens during infection. These are a marker of active viral replication. The presence of HBsAg and/or HBeAg in serum occurs during primary infection and during chronic HBV infection (Table 1). HBsAg is located on the outer surface of the HBV particles, while HBeAg is translated from the precore mRNA of HBeAg (Fig. 1C). The function of HBeAg and its role in disease have not been clearly identified; however, the detection of this protein in serum indicates high viral replication. Both HBsAg and HBeAg are made in large excess by infected host cells and can be detected in serum during active infection (4).
Diagnostic assays with high sensitivity and specificity are available to detect these HBV antigens. Table 1 lists the assays used to determine the stage of HBV disease. HBV antigens are detected using solid-phase assays based on capture with a monoclonal antibody and then detected with a second antibody attached to a signal. These assays use microparticles with different compositions and sizes and are performed on automated instruments (36, 37). Antigen capture and detection reagents are specific for the major immunodominant region of HBsAg. Current detection methods use enzyme reactions, chemiluminescence, or fluorescence polarization to detect specific antigens (Table 2).

HBsAg

The detection of HBsAg in serum plays a central role in establishing the diagnosis of HBV infection. Each HBsAg assay is approved by the FDA either for diagnostic use only, for testing donors of blood, organs, and tissue only, or for both applications. The “Name and Intended Use” section of the package insert should be consulted to determine what sample types have been approved for use with each HBsAg test (Table 2).

The presence of HBsAg in the serum indicates that the patient is highly infectious. Patients who resolve an acute infection eventually produce anti-HBs (see “Serologic Tests” below). However, when HBsAg is present, anti-HBs can be negative in diagnostic tests because the antibody is bound to the HBsAg.

For all commercially available diagnostic assays, any specimens nonreactive for HBsAg are considered negative and do not require further testing. In contrast, specimens reactive for HBsAg are often repeated to verify positive results. These repeatedly HBsAg-positive results may be confirmed by a neutralization assay provided by the manufacturer consistent with FDA approval protocols (Table 2). If the HBsAg-reactive serum is neutralized by the anti-HBs, then the specimen is considered positive for HBsAg. Conversely, if the anti-HBs does not neutralize the HBsAg, the HBsAg test must be considered nonconfirmed and a new specimen should be requested and/or a recommendation that the patient be tested for other markers of HBV infection such as IgM anti-HBc or total anti-HBc should be made.

All HBsAg assays are capable of detecting subnanogram amounts of protein with no loss of specificity (38, 39). For diagnostic applications, this level of sensitivity is sufficient to detect the HBsAg in the sera of individuals with actively replicating HBV. However, a recent concern is that some assays cannot detect variants of HBsAg that have mutations within the major antigenic region of the protein. These mutant HBsAg can be missed by some diagnostic assays (14, 40, 41), so initial testing should include the detection of antibodies to both HBsAg as well as HBc core.

The major antigenic determinant on the HBsAg is designated the “a” determinant. This antigenic site is formed by a conformational structure containing a disulfide bond that results in a specific three-dimensional epitope. The region between amino acids 124 and 147 is found within the major hydrophilic loop of the protein (42, 43). There is a concern that current diagnostic assays do not detect HBsAg with alterations within this major antigenic epitope, since some HBsAg assays use monoclonal antibodies that capture the HBsAg using this immunodominant epitope. These HBV strains are known as “escape mutants.” The first escape mutant was described to occur in a child born to an HBV-positive mother who transmitted HBV to the child despite vaccination and HBIG (44). This virus had a substitution in HBsAg at amino acid position 145 of arginine for glycine. A single amino acid change altered the antigenic portion of the protein such that vaccine-induced antibody no longer recognized the antigen. This allowed the altered virus to persist in the infant. Subsequently, the patient remained positive for HBV DNA and HBsAg (with mutation) for longer than 12 years. Since that time, a number of other substitution mutants within the “a” determinant region of HBsAg have been recognized (45, 46). Recent studies have evaluated HBsAg assays to determine their ability to detect well-defined HBsAg mutants and have found that some mutations in the HBsAg may be missed by diagnostic assays (10, 40, 44, 45, 47).

In response to the concern that blood donors with an HBsAg mutant are not be identified by HBV antigen assays, most countries screen blood donors for anti-HBc in addition to screening for HBsAg. Blood donors in the United States are also tested for HBV DNA (48). Individuals with positive tests for HBV DNA and anti-HBc and/or patients with positive results for HBeAg and/or HBV DNA but negative for HBsAg could be infected with an escape mutant (49).

HBeAg

The detection of HBeAg in serum is a sign of rapid viral replication usually associated with high HBV DNA levels. HBeAg-positive patients are highly infectious. However, some HBV strains do not make the HBeAg due to a precore mutation. Patients infected with these mutant strains may have high HBV DNA levels in the absence of detectable HBeAg (42). Several commercial assays are available for the detection of HBeAg in serum and use principles similar to those of the HBsAg detection system; i.e., initially positive specimens should be retested and confirmed with neutralization (Table 2).

Nucleic Acid Detection

Molecular assays to quantitate HBV DNA are used for the initial evaluation of HBV infections and the monitoring of patients with chronic infections during treatment. In addition, as mentioned above, blood donors are routinely screened for HBV DNA using qualitative tests to identify donors in the early stage of HBV infection.

A number of quantitative assays have been developed to detect and monitor HBV DNA levels in infected patients. Monitoring of HBV DNA levels provides information on the effectiveness of antiviral treatment and can indicate when a change in the antiviral regimen is needed. Several assays are available for these purposes and use a variety of different methods (38, 50). Most of the available assays have a lower limit of detection, between 5 and 50 copies/ml, and can quantify levels up to 1 million copies/ml. This wide range of quantitation allows for monitoring HBV DNA early after infection and identifying HBV infections resistant to antiviral therapy (Table 2) (51). Recent studies have shown that the persistent suppression of HBV DNA is a primary measure of therapeutic success (20, 52, 53). A high level of HBV DNA following resolution of clinical hepatitis indicates a failure to control viral replication (4). Commercially available HBV DNA assays differ in their limits of detection, dynamic ranges, and methods used to measure DNA levels (Table 3). An international HBV DNA standard was established in 2001 by the WHO in response to the need to standardize HBV DNA quantification (32, 54). The WHO standard virus preparation is a high-titer genotype A preparation (code 97/746) which has been assigned a potency of 10^6 IU/ml. The standard has established that 1 IU of HBV is equivalent to 5.4 genome

equivalents (54). The WHO standard has allowed results for different HBV DNA assays to be reported in international units per milliliter.

However, despite the availability of this standard, the various quantitative assays usually have different conversion factors, demonstrating their variability (Table 3). Thus, the best practice is the consistent monitoring of patients using the same manufacturer’s assay in the same laboratory (51).

Some of the variability of HBV DNA quantification may occur during collection and processing of the specimen. Most assays use serum or plasma (EDTA or ACD) as the specimen of choice. Regardless of the collection tube, the specimen should be separated from the clotted blood within 4 to 6 h after collection. As with all FDA-approved diagnostic assays, the package insert should be followed for specimen type, processing, and storage. Repeated thawing and freezing (>2 times) should be avoided, as this may reduce assay sensitivity.

Most commercial assays quantitate HBV DNA and cover a 7- to 8-log10 range, which permits the accurate evaluation of HBV levels above a million down to very low levels that occur during treatment or in inactive carriers. Several studies have shown that a reduction of 2 log10 in HBV DNA levels in the first 6 months of antiviral therapy indicates treatment efficacy (38, 51, 53).

Many of these assays use oligonucleotide primers that recognize a conserved sequence within the HBV precore/core gene (51). The assays quantitate HBV DNA using a series of standards containing a known amount of the target nucleic acid. These standards provide the standardization curve used to correlate the results from each patient sample. The viral load is determined by computerized analysis of individual results, which are compared to the standard curve (51, 53).

### Isolation Procedures

Although HBV can infect hepatocytes in vitro, culture of HBV is not used as a diagnostic test.

### Identification

The methods for identification of HBV infection use a combination of molecular, antigenic, and serologic methods described in “Direct Detection” above and “Serologic Tests” below.

### Typing Systems

Antigenic variation occurs naturally in HBV due to genetic heterogeneity. These various genetic differences are used to classify HBV into eight distinct genotypes, designated A through H (Table 4). They are distinguished by a genetic divergence of 8% or more within the complete nucleotide sequence (4, 22). There are substantial data that have correlated HBV genotypes with disease outcome. The most common genotypes associated with chronic HBV infections are B and C. Patients with genotype B are more likely to spontaneously convert to anti-HBeAg and thus have less severe liver damage. Genotype C is more common in Asia and has been associated with a high risk of progression to cirrhosis. However, in European studies, genotype D has been shown to be more likely to be associated with active liver disease than other genotypes (42). It is noted that most of these patients have acquired these infections in childhood and had more exposure to HBV than other patients evaluated. It is not clear yet how the variances in HBV genotypes affect clinical outcomes. It is possible that the differences are associated with the viral expression of immune epitopes or the loss of critical control over viral replication such as precore and core promoter mutations. Thus, in spite of the intriguing studies on HBV genotypes, the role of HBV genotyping in predicting clinical and therapeutic outcomes has not been firmly established. However, with additional studies, the value of HBV genotyping to determine specific treatment will likely become apparent (18, 25, 43).

### Serologic Tests

Serologic tests for HBV-specific antibodies are used to determine the stage of HBV disease and to establish immunity after HBV vaccination. As the host mounts an immune response, the first antibodies to appear are IgM specific for Hbc (IgM anti-HBc); this is followed by the appearance of total anti-HBc, anti-HBe, and finally anti-HBs (24). Several commercial assays are available for HBV serologic testing (Table 2).

**IgM Anti-HBc**

IgM anti-HBc persists for several weeks to months after an initial infection. The detection of IgM anti-HBc indicates an infection of less than 6 months’ duration (Table 1). During this stage of disease, the patient’s liver enzymes may be elevated. A negative IgM anti-HBc excludes a recent,
acute infection but does not rule out chronic infection (22, 55). The presence of IgM anti-HBc identifies patients who are acutely infected; such patients usually have high levels of HBV DNA (55).

**Total Anti-HBc**
A negative anti-HBc test indicates that a person does not have a history of infection with HBV. A positive result can indicate either an acute infection in which the patient is also HBsAg positive and IgM anti-HBc positive or a resolved (HBsAg-negative) or chronic (HBsAg-positive) HBV infection (Table 1) (4, 55). Total anti-HBc antibodies remain after IgM anti-HBc disappears and can be detected for many years. These antibodies persist longer than anti-HBs. Thus, total anti-HBc is the best marker for documenting prior exposure to HBV infection. Vaccines do not include HBc; thus, vaccination induces only anti-HBs. Therefore, anti-HBc is not present in vaccinated individuals unless they were infected with HBV prior to vaccination (17, 56). Individuals positive for antibody to HBc without any other serologic evidence of HBV infections should be considered infected with HBV (55). This serologic pattern is consistent with a remote, past HBV infection that has resolved and in the case of which the viral DNA levels are at times negative or very low (4, 22).

Commercial kits for detection of total anti-HBc are available and use a variety of different methods and instrumentation (Table 2). All assays use recombinant HBc antigen for capture of antibody. In competitive tests, if anti-HBc is present in the sample, it competes with a known amount of added labeled human anti-HBc. Samples containing anti-HBc lead to signal suppression that is proportional over a limited range to the amount of anti-HBc present. Values generated by positive and negative kit controls are required to calculate assay cutoff and to establish validity. Each assay should be calibrated on a regular basis using the calibrators provided in each kit. All anti-HBc assays have a test algorithm that involves testing initially reactive specimens in duplicate in an independent run. If one or both duplicates are reactive, the sample can be reported as positive.

**Anti-HBs**
A negative result for anti-HBs in the absence of any other HBV specific antigen or antibody indicates that a person has not been infected with HBV, nor has the individual been vaccinated with HBV. A positive result is consistent with immunity to HBV due to an infection or from effective vaccination (Table 1).

Commercial assays for anti-HBs are solid-phase tests based on the sandwich principle. These assays provide a quantitative result to assist in determination of adequate immunity after vaccination. An initially reactive result for anti-HBs requires repeat testing in duplicate in an independent run. If one or both duplicates are reactive, the sample is positive. Anti-HBs quantitation panels are commercially available and should be used when validating anti-HBs assays.

Anti-HBs is a key serologic marker for both vaccine-induced immunity and immunity due to infection. As HBV vaccination has become more widespread, this serologic marker is used to monitor vaccine success. Both the WHO and CDC recognize a level of >10 mIU/ml of anti-HBs as an indication of protective immunity. However, it has been demonstrated that levels of anti-HBs determined by one commercial assay system cannot be compared with those detected with a different system despite the use of international standards (57).

Postvaccination testing for the presence of anti-HBs is not recommended for infants, children, or most adults. The CDC lists exceptions to this rule, which are infants born to mothers who are HBsAg positive, immunocompromised patients, dialysis patients, and to confirm successful vaccina-

*Information derived from references 38, 76, and 102.*
tion in health care workers to prevent the transmission of HBV in the health care setting (58, 59).

HBV escape mutants in which the HBsAg has mutated can result in HBV infections without detectable anti-HBsAg (42). Conformational changes in the major antigenic determinant of HBsAg result in reduced detection of the anti-HBsAg by diagnostic assays.

**Anti-HBe**

A positive test for anti-HBe indicates the resolution of acute infection and is associated with a decrease in viral replication (Table 1). During acute infection, these antibodies are bound to the HBsAg; the antibody will not be detected until the HBsAg levels decrease. This decrease is associated with a reduction of virus and thus the resolution of acute infection.

Patients who have recovered from acute HBV infection have detectable anti-HBe, anti-HBc, and anti-HBs. Interestingly, patients infected with HBsAg-negative strains of HBV still have anti-HBe (22).

Competitive binding is the basis for most anti-HBe assays. To detect anti-HBe, the patient sample and a measured amount of recombinant HBsAg are added simultaneously to the assay. If anti-HBe is present in the patient’s sample, it competes with solid-phase anti-HBe for the limited number of binding sites on the added HBsAg. Positive and negative control values are used in validity calculations.

Test algorithms for HBsAg and anti-HBe kits vary. Initial reactive samples in the anti-HBe assays are often retested. If the repeat test is reactive, the sample is reported as positive. The enzyme immunoassays (EIA) have indeterminate or gray zones around the assay cutoffs. If the samples repeatedly yield values in this zone, additional testing should be performed with a new specimen.

**Antiviral Susceptibility Testing**

Therapy for HBV usually requires long-term treatment with nucleoside or nucleotide analogs. A disadvantage of long-term therapy is the subsequent development of antiviral resistance. As noted above, HBV replicates through an RNA intermediate. The HBV RNA-dependent DNA polymerase is not precise during rapid replication cycles and does not correctly proofread the final copies, leading to frequent errors. Some of these errors create resistant mutants, which are selected in the presence of antiviral agents (38, 60). Over time the HBV strains with antiviral resistance become the major viral species (61, 62). The current recommendation is that a patient who has a 1-log$_{10}$ increase from the lowest HBV DNA level should be evaluated for the development of antiviral resistance (28, 38, 52, 63).

Recently, the nomenclature of HBV antiviral resistance was standardized in order to track nucleotide changes associated with drug resistance and to recognize new mutations (Table 5) (38). Antiviral resistance mutations can be detected by molecular methods that recognize known mutations associated with resistance (11, 38, 62, 64). Methods used to detect these mutations are available; however, the interpretation of results is not always straightforward. Some mutations predict resistance to multiple drugs. A single mutation at A181T is associated with resistance to lamivudine, adefovir, tenofovir, and telbivudine (11, 65) (Table 5). In other situations genetic sequence changes may not confer resistance when present alone but do contribute to the resistance when additional mutations are present. For example, lamivudine resistance does not occur due to a single L180M mutation, but with the addition of a second mutation, such as A181T, resistance to lamivudine occurs. Thus, the detection of an L180M, A181T double mutation, which alters the position of a critical residue in the nucleotide binding pocket, is required for resistance to be apparent (28, 29, 32). An additional concern is that patients treated with multiple drugs will have a combination of sequence changes that represent drug resistance mutations in addition to mutations that occur in order to balance the fitness of the HBV strains selected out after antiviral therapy (46). Many of these single nucleotide changes have not been recognized as a phenotype and may represent the random genetic changes found in viruses that use a reverse transcriptase during replication (28).

Commercial assays are available to detect mutations associated with antiviral resistance in HBV. One assay employs biotinylated amplicons that hybridize to membrane-bound oligonucleotides that represent mutation sequences (INNO-LiPA HBV, Innogenetics). The first generation of this assay detects several lamivudine resistance mutations at amino acids 180, 204, and 207 (66, 67). The second-generation assay detects additional resistance sequences, including those associated with lamivudine resistance at amino acids 80, 173, 180, and 204, as well as changes at amino acids 181 and 236 associated with adefovir resistance (47, 68, 69).

This version detects HBV resistance mutations in specimens that contain both wild-type HBV and mutant virus. Some disadvantages with these assays are the facts that the reading of the reaction lines on each strip can be difficult (up to 34 lines per strip), faint bands can be problematic to interpret, and at times the test results show no bands in viral preparations with known mutations (66, 68, 70).

A second assay (Trugen HBV/genotyping kit; Siemens Medical Solutions Diagnostics) is available as a research-use-only assay. This system detects antiviral mutations by direct sequencing from specimens, including specimens with low HBV levels (68, 71). Comparison between the sequence assay and the hybridization assay shows a high concordance (68, 70).

A number of individual laboratory-developed assays have been used to detect antiviral mutations in HBV. These

*Resistance is defined as virologic breakthrough confirmed by an increase on two consecutive occasions with HBV DNA levels that increased by >1 log$_{10}$ copies/ml during therapy. Data are derived from references 28, 52, 62, and 102.*
assays use a variety of different techniques for the detection of known resistance mutations in HBV (38, 72). One of these methods is to use direct DNA sequencing to detect such mutations. The advantage of DNA sequencing is that it is accurate and mutations can be identified in any part of the HBV genome (55). However, a serious disadvantage is that these methods lack sensitivity and detect mutants present in 10 to 30% of the viral population. This level of detection does not always consistently identify resistance mutants, which make up at least 10% of the virus population (73). Thus, this limits its use clinically. Additionally, testing by this method can be labor-intensive and the reagents can be costly.

However, newer technology, such as ultra-deep pyrosequencing, is now being used to detect minor viral populations that could emerge during antiviral treatment. These HBV variants are present in the patient in low numbers and can have random genetic changes that lead to antiviral drug resistance. During treatment, the HBV variants can be monitored to determine when the patient needs a different anti-HBV treatment (74, 75).

The HBV viral level is often used for monitoring and detecting the development of resistance to antiviral therapy. Resistance to antiviral agents is defined clinically by a 1-log increase in serum HBV DNA levels during antiviral therapy (53). The disadvantage of using the HBV DNA levels to detect antiviral resistance is that other factors, such as compliance and drug metabolism, may also be responsible for increasing HBV DNA levels. Therefore, the combined use of a genotyping assay for mutation detection and quantitative detection of viremia with a reproducible and sensitive assay is warranted for optimal monitoring of HBV antiviral therapy (11, 50).

Phenotypic testing is used to detect HBV antiviral resistance in research and development laboratories. These methods detect drug resistance based on the use of molecular or cellular techniques or using animal models (38, 53) and are not always applicable for clinical use. These tests are labor-intensive and required long testing periods.

**Evaluation, Interpretation, and Reporting of Results**

HBV infection leads to several different disease presentations, from acute hepatitis with fulminant hepatic failure to chronic hepatitis leading to cirrhosis and/or HCC (4, 22, 76). The initial assessment for suspected viral hepatitis should include laboratory tests that measure serum transaminases, direct and total bilirubin, albumin and total protein, a complete blood count, coagulation tests, and alpha fetoprotein. The specific laboratory tests to detect and monitor HBV infection are a mix of viral antigen detection, molecular measurements of HBV DNA, and serologic markers. The tests to diagnose new HBV infection are anti-HBc IgM, HBsAg, and HBV DNA (Table 1).

During acute HBV disease, IgM anti-HBc is usually positive when serum transaminases are elevated. At this phase, HBsAg and/or HBeAg may be detectable. In a typical acute HBV infection, HBsAg can be detected 2 to 4 weeks before the liver enzyme levels become abnormal and before symptoms appear; thus, when the patient presents with clinical signs, HBsAg may not be detected. Additionally, HBV DNA can be detected 3 to 4 weeks before HBsAg, long before the onset of symptoms; thus, it is usually not tested until serologic markers of infection are detected (56, 76). The levels of IgM anti-HBc eventually decline as the disease resolves or becomes chronic. Most patients with an active HBV infection which resolves have detectable anti-HBs shortly after the disappearance of HBsAg. Figure 3 illustrates a typical serologic pattern that occurs in patients with an acute HBV infection. Chronic HBV stages can be distinguished using a combination of laboratory tests and clinical signs (Table 1 and Fig. 4).

The immune tolerant phase usually occurs when the patient acquires HBV infection at birth or during early childhood. Infection in this case is associated with a high level of viral production and the presence of HBeAg. These markers indicate a high rate of viral replication (4). There is an absence of liver disease despite high levels of HBV replication. This is a consequence of immune tolerance; however, the underlying pathology is poorly understood (4, 20, 38).

**FIGURE 3** Typical sequence of serologic markers in patients with acute HBV infection with resolution of symptoms. doi:10.1128/9781555817381.ch108.f3

**FIGURE 4** Typical sequence of serologic markers in patients with HBV infection that progresses to chronicity. In patients with chronic HBV infection, both HBsAg and IgG anti-HBc remain persistently detectable, generally for life. HBeAg is variably present in these patients. doi:10.1128/9781555817381.ch108.f4
As the host’s immune response matures, the patient often moves to the immune active phase (also referred to as HBeAg-positive chronic hepatitis phase), during which HBV-specific epitopes are recognized by the host immune system, leading to immune-mediated injury in the liver. Individuals who acquired HBV perinatally often transition from the immune tolerant phase to the HBeAg-positive chronic hepatitis phase between 20 and 30 years of age (4, 77). The liver biopsy in this stage shows active inflammation accompanied by fibrosis. Patients who remain HBeAg positive have a higher risk of progressing to liver disease due to the induction of a chronically active immune response by high rates of HBV replication (22, 55). Such patients have high HBV DNA levels and increased levels of serum transaminases. However, as these individuals develop anti-HBe, they revert to HBeAg negativity and move to the inactive carrier phase (Table 1) (21, 55). The transition from the immune tolerant phase is often not recognized, since patients with HBeAg-positive, chronic hepatitis often remain asymptomatic (55).

The inactive carrier phase is characterized by the seroconversion to anti-HBe, and patients alternate between low and undetectable levels of HBV DNA. The seroconversion to anti-HBe is associated with a decrease in liver damage and the normalization of serum transaminase levels. Mild hepatitis may be noted on biopsy (55). Many patients remain in this phase for years. Patients in the inactive carrier phase have detectable HBV DNA in serum, at intermittent or low levels, and usually have normal serum transaminase levels.

A portion of inactive HBsAg carriers (about one-third) develop chronic hepatitis which recurs in the absence of HBeAg in their sera (HBeAg-negative chronic hepatitis). These patients are infected with an HBV variant that cannot express HBeAg due to mutations in the precore or core promoter regions of the HBV core gene (42, 44). Patients with chronic hepatitis that are HBeAg negative are more likely to have more advanced liver disease in spite of lower serum HBV DNA levels (42, 76, 78). HBsAg-positive patients can transmit HBV sexually, percutaneously, or perinatally. Individuals with detectable HBeAg pose the highest risk of transmitting HBV to others.

Patients who are negative for HBsAg, anti-HBc, and HBV DNA are not infected with HBV. In some individuals the presence of anti-HBc alone may be the only evidence of an active, occult HBV infection of remote origin. Patients infected with an HBsAg escape mutant test negative for HBsAg but are positive when tested for anti-Hbc and HBV DNA (20, 44).

Anti-HBs without anti-HBc develops in individuals who receive hepatitis B vaccine (which contains only HBsAg), and anti-HBs levels of ≥10 mIU/ml are considered protective (80). Due to the prevalence of vaccinated individuals, the detection of anti-HBc is used to evaluate past or current infection with HBV and identify individuals who should receive the HBV vaccination. Passive transfer of anti-HBs or anti-HBc may be observed in neonates of mothers with current or past HBV infections (56). However, passive antibody levels decline gradually over 3 to 6 months, while levels of antibody induced by infection are stable over many years (79, 80). Since blood donations are tested for HBsAg and total anti-HBc, passive transfer of these HBV markers following blood transfusions is unlikely.

Most individuals vaccinated for HBV have detectable levels of anti-HBs; however, some vaccinated people test negative due to waning levels of anti-HBs. They usually respond to a challenge dose of HBsAg vaccine with an anamnestic response in approximately 2 weeks (81). Studies of vaccinated individuals who no longer have detectable anti-HBs show that infection can occur but is blunted by the anamnestic anti-HBs response such that liver damage is minimal and symptoms do not occur (81). In contrast, an HBsAg-negative carrier may fail to produce detectable levels of anti-HBs after vaccination (82). Individuals who do not have a detectable response to the first series of HBV vaccine should be given a second three-dose vaccine series (19, 59). Individuals who do not respond to the second vaccination series should be considered susceptible to HBV infection and should be given HBV immunoglobulin prophylaxis after any known exposure to HBV-positive body fluid. It is important to note that some HBV vaccine nonresponders are chronically infected with HBV. Thus, individuals who do not have detectable anti-HBs after six doses of vaccine should be tested for HBsAg (34, 60).

Testing for the HBV genotype is usually not required except for selected patients from regions around the world that have variability in HBV genotypes (Table 4). Testing for mutations associated with antiviral resistance is also not useful during the initial evaluation of patients (20, 38, 83). The “gold standard” for assessing inflammatory activity (grade) and degree of fibrosis (stage) is the liver biopsy, which is a useful baseline for future follow-up (55).

Molecular assays are used to determine HBV DNA levels and contribute to establishing the stage of disease in newly diagnosed patients. They are also used to monitor patients on antiviral therapy. The reduction of HBV DNA during antiviral therapy is a measure of treatment response and predicts histologic improvement. Increasing HBV DNA levels are associated with chronic liver disease, cirrhosis, and possibly death (22, 50, 63). The WHO standard for HBV DNA has helped standardization of HBV DNA assays, and results are now reported in international units per milliliter (32, 84).

Antiviral therapy is given to patients to prevent progression of liver disease (4, 28, 38). During the course of therapy, treatment response is monitored using biochemical, virologic, serologic, and histologic results. Currently the most accurate monitor of virologic activity is the HBV DNA level using an assay with a wide dynamic range (28, 38, 50, 55). The loss of HBsAg, seroconversion to anti-HBs, and long-lasting suppression of HBV DNA indicate a successful response to therapy (50, 63). Patients who appear to have suppressed HBV DNA levels are monitored periodically because relapse due to antiviral resistance is possible. The most reliable measure of a successful long-term treatment response is the sustained suppression of HBV DNA (38, 50, 55, 63).

When HBV DNA levels increase by 1 log_{10} in a patient taking antiviral treatment, it may indicate antiviral resistance (38, 55, 63). It is not recommended that resistance testing be performed before starting therapy even if the patient has a very high viral level (20, 50). Resistance detection is useful only after a patient has been treated for several months and fails to show an HBV DNA reduction of at least 1 log_{10}. Such patients are classified as primary nonresponders. They should be tested for the presence of resistant mutants to assist in selecting a new treatment.
HEPATITIS D VIRUS

Introduction
Hepatitis D virus (HDV) is a defective RNA virus that requires the presence of HBV for its replication. HDV has a single-stranded, circular, negative-sense RNA genome that is completely nonhomologous with HBV DNA. The agent was first described in 1977 as occurring in Italian patients with chronic HBV who developed episodes of serious acute disease (85).

Taxonomy
HDV is unable to replicate without the presence of HBV, which is the host virus. Thus, it is a subviral particle rather than a true virus. The HDV particle is similar to those of plant subviral agents (86). However, there are some major differences between the plant viroids and HDV. The plant viroids do not encode a specific protein and do not utilize a host or helper virus as HDV does with HBV (87, 88).

Description of the Agent
HDV is generally spherical, with an average diameter ranging from 36 to 43 nm, which is slightly smaller than that of the HBV particle (88). The 1.7-kb RNA genome of HDV encodes only a single protein, the HDV nucleocapsid protein, known as the hepatitis delta antigen (HDAg). It is nonglycosylated and is produced in two forms: a short 214-amino-acid 27-kDa protein, known as the hepatitis delta antigen (HDAg). It is nonglycosylated and is produced in two forms: a short 214-amino-acid 27-kDa protein and a larger peptide consisting of a 195-amino-acid 24-kDa protein (89, 90). The protein cannot assemble into viral particles without the presence of HBsAg (88, 89). The HDV RNA genome is surrounded by HDAg, which is then surrounded by HBsAg. Consequently, HDAg is undetectable on the complete HDV particle. In spite of this, infected individuals produce antibody to the HDV antigen (anti-HDV). However, anti-HDV does not neutralize this particle, whereas anti-HBs does have neutralizing activity (88).

The HDV genome displays a high degree of complementarity, which creates a three-dimensional, double-stranded, stable structure that resists dry heat for long periods. The extensive internal complementarity of the HDV genome results in a rod-like structure much like that of plant RNA satellite viruses. The manner by which this virus replicates is unusual. The replication of the HDV genome uses the host RNA polymerase II rather than an HDV- or HBV-encoded RNA polymerase (88, 89). The only enzymatic activity inherent to HDV is mediated by RNA elements termed ribozymes which cleave the newly synthesized, circular RNA genomes, producing linear molecules (92). After that cleavage, replication of the HDV genome occurs via a rolling-circle mechanism with self-cleavage. Synthesis of the HDV particles suppresses HBV viral production. A unique, obligatory relationship exists between HDV and HBV (88).

Epidemiology and Transmission
Worldwide, it is estimated that approximately 15 to 20 million people are HDV carriers (85, 93). Several areas of the world have a high prevalence of HDV-infected individuals, including countries bordering the Mediterranean, the Middle East, Central Asia, West Africa, the Amazon Basin, and the South Pacific Islands (85). In these areas of endemicity, HDV appears to be transmitted by close person-to-person spread, such as household contact. Additionally, many individuals have acquired HDV through exposure to blood-contaminated needles and blood products. Persistent epidemics of severe acute HDV have been observed in these populations, which have high HBV carrier rates (85, 94).

Clinical Significance
HDV can be transmitted only to individuals who are infected with HBV already or when both viral agents are transmitted together. A coinfection occurs when a naive individual is infected simultaneously with both viruses; coinfection occurs in only 2% of the cases (Fig. 5) (88). A superinfection occurs when an individual chronically infected with HBV is infected with HDV (Fig. 6) (88). Superinfection occurs in more than 90% of infected patients (85, 94). Acute HDV superinfection has a greater risk of fulminant hepatitis and liver failure than HBV infection alone. Likewise, chronic HDV infection is associated with more rapidly progressing liver damage than infection with HBV alone (94).

Rates of fulminant hepatitis can be as high as 5% in patients with HBV and HDV coinfection (85, 88). A biphasic clinical course is sometimes observed during coinfection. HDV infection does not increase the rate of chronicity of acute HBV but may convert an asymptomatic or mild, chronic HBV infection into a rapidly progressive, fulminant or severe disease (87, 95, 96). Limited success has been achieved in treating chronic HDV patients with gamma interferon (IFN-γ). High-dose, long-term therapy is required, and relapses are common after therapy is stopped (83, 95, 97, 98). Patients with HDV who have hepatic decompensation are candidates for liver transplantation and in general have had favorable outcomes (96). Treatments with antiviral agents known to reduce HBV titers have been studied. However, it appears that therapy with IFN-α in combination with either ribavirin or lamivudine is not useful in treating chronic HDV infections (95, 97). Successful vaccination for HBV also prevents HDV infection, since HDV cannot replicate in the absence of a concurrent HBV infection.

FIGURE 5 Serologic course of HDV infection, with resolution when the virus is acquired as a coinfection with HBV. doi:10.1128/9781555817381.ch108.f5
chronic HBV, a circumstance usually leading to chronic superinfection occurs when HDV infects a patient with acute infection and usually disappears with resolution. The detection of HBsAg, HBeAg, HBV DNA, and IgM anti-HDV can be used to confirm the diagnosis of a coinfection with HBV and HDV. All serologic and molecular assays are available from reference laboratories.

Diagnosis of a coinfection with HBV and HDV is based on the detection of HBsAg, HBeAg, HBV DNA, and IgM anti-HBc in a serum sample that is positive for HDAg, anti-HDV IgM, and HDV RNA (Fig. 5). Anti-HDV appears during acute infection and usually disappears with resolution. A superinfection occurs when HDV infects a patient with chronic HBV, a circumstance usually leading to chronic HDV infection. The diagnosis of HDV superinfection is made when anti-HDV is found simultaneously with HBsAg and anti-HBc in the absence of IgM anti-HBc. Anti-HDV is present indefinitely in patients with chronic HDV infection (99, 100) (Fig. 6).

TAXONOMY

Prions

According to the generally accepted prion hypothesis, the infectious agent causing transmissible spongiform encephalopathies (TSEs) now referred to as prion diseases is the “prion” (for proteinaceous infectious particle). An essential component of prions is the scrapie-like prion protein (PrPSc), an abnormally folded, protease-resistant, beta-sheet-rich isoform of a normal cellular prion protein (PrPc) (1). According to this theory, which is consistent with a large body of experimental data and has not been disproven to date, the prion does not contain any informational nucleic acids, and its infectivity propagates simply by “autocatalytic” conformational conversion of PrPc into disease-associated PrPSc (2). Importantly, it has been possible to generate synthetic prions, consisting entirely of recombinantly expressed PrPSc, which is misfolded to a PrPSc-like state by physicochemical treatment (3). The size of the minimal infectious unit of PrPSc is still a matter of debate. Oligomeric PrPSc, consisting of 14 to 28 PrPSc molecules, seems to harbor the highest converting activity (4).

DESCRIPTION OF THE AGENT

As outlined above, the data arguing in favor of PrPSc representing an essential component of infectious prions are overwhelming. PrPSc is encoded by the PRNP gene on the short (p) arm of chromosome 20. Mutations in PRNP lead to genetic forms of prion disease (see below and Table 2). A polymorphism of codon 129 of PRNP (encoding either methionine or valine) is both a susceptibility factor for the development of a prion disease (see genetic testing) and a disease modifier (see “Epidemiology and Transmission” below) (5). The three-dimensional structure of PrPSc has been solved by structural biology (6). Similar analyses have not been possible for PrPc. Studies employing low-resolution biophysical techniques yielded conflicting data. The following structures have been proposed for PrPSc: (i) a left-handed beta-helix, (ii) a spiraling core of extended beta-sheets, or (iii) a stack of parallel beta-sheets (7).

One of the defining features of PrPSc is its relative resistance to digestion by proteinase K (see “Direct Examination” below). Recent data indicate that proteinase K-sensitive forms of infectious prions may exist (8). These data are further supported by novel studies showing that proteinase K-sensitive PrPSc may also contribute to prion infectivity (9, 10).

Epidemiology and Transmission

Human prion diseases manifest as sporadic, genetic, and acquired disorders. They are referred to as sporadic Creutzfeldt-Jakob disease (sCJD), genetic CJD (gCJD), iatrogenic CJD (iCJD), and variant CJD (vCJD). For historical reasons, kuru, a prion disease endemic to tribal regions of Papua New Guinea in the latter half of the last century, deserves to be mentioned here. This disease, which was caused by endocannibalistic funeral practices of the Fore people, appears to have come to an end with the last case reported in 2005 (11).

Sporadic CJD

sCJD is a rapidly progressive dementia, usually leading to death within 6 months of disease onset (12). The cause of sCJD remains enigmatic. To date, no obvious risk factors have been identified (13). Because of the short mean duration of this disease, incidence and mortality rates for sCJD are similar; thus, mortality rates are routinely used to describe the epidemiology of this disease (14). Mortality rates are fairly constant, both over time and between countries, oscillating around 1.5 cases per million per year with the highest incidences in patients between the ages of 65 and 75 years (http://www.eurocjd.ed.ac.uk/allcjd.htm). Recently, a novel type of sCJD has been described. This entity, termed variably protease-sensitive prionopathy (vPSp), is characterized by typical clinical signs and absence of bona fide protease-resistant PrPSc (Table 1) (8).

Genetic CJD

gCJD can be subdivided into three phenotypes: hereditary Creutzfeldt-Jakob disease, Gerstmann-Sträussler-Scheinker syndrome (GSS), and fatal familial insomnia (FFI). The mode of inheritance in all of these diseases, which cosegregate with mutations in PRNP, is autosomal dominant (15). Some mutations within PRNP (Y145stop, Y226stop, Q227stop) cause distinct disease phenotypes, i.e., an angiopathy with deposition of prion protein in vessels of the central nervous system (CNS) referred to as cerebral amyloid angiopathy (PrP-CAA) (16). Incidences of gCJD vary...

from country to country, with Slovakia reaching the highest incidences at more than 1 case per million (17, 18).

**Variant CJD**

vCJD, a relatively new member of human prion diseases, was first reported in 1996 (19). Biochemical, neuropathological, epidemiological, and transmission studies indicate that vCJD represents the transmission of bovine spongiform encephalopathy (BSE) prions to humans (22). The incidence of vCJD in the United Kingdom rose each year from 1996 to 2001, evoking fears of a large upcoming epidemic (21). Since 2001, the incidence of vCJD in the United Kingdom has dropped; however, other countries that were presumably exposed to BSE prions, such as France and Spain, have reported a significant number of vCJD cases (http://www.eurocjd.ed.ac.uk). Predictions on the future of the vCJD epidemic indicate that the total number of vCJD victims will be limited (22). vCJD has a distinct clinicopathological profile including young age of onset (median age at death, 29 years) and long disease duration (Table 1; see also Fig. 1 and 2) (19).

**Iatrogenic CJD**

iCJD is caused by accidental prion exposure during medical or neurosurgical procedures such as implantation of human dura mater or treatment with human cadaveric pituitary extracts or blood transfusion (23). Iatrogenic CJD is rare, with fewer than 300 published cases (23). The majority of cases were caused by implantation of dura mater and injection of pituitary growth hormone. Recent epidemiological data confirm the observation that iCJD affects mainly individuals younger than 39 years (14).

**Prion Mechanisms in Other Dementias**

Clinical manifestation of prion diseases requires spread of infectious prions from the periphery to the CNS, in the case of iatrogenic and variant CJD, and spread of prions within the CNS in the case of all forms of human prion disease. The mechanism by which prions spread is referred to as nucleated seeding, a process that is thought to include formation of small PrSc seeds that can act as templates to facilitate further protein aggregation. Similar mechanisms have been described for other cerebral proteopathies such as Alzheimer’s, Parkinson’s, or Lou Gehrig’s disease (24, 25).

**CLINICAL SIGNIFICANCE**

Initial symptoms of sCJD include rapid cognitive decline, sleep disturbances, and behavioral abnormalities. As the disease progresses, other clinical features such as extrapyramidal symptoms (i.e., akinnesia, which is the inability to initiate movement) and pyramidal symptoms (i.e., loss of fine motor skills), ataxia, and visual disturbances appear and patients usually develop myoclonus (involuntary twitching of a muscle) (12). Terminally affected sCJD patients typically develop a state of akinetic mutism prior to death. The disease course is usually short, the mean duration of the illness being 4 to 5 months (Table 1). VPSSPr is characterized by psychiatric signs, speech deficit, and cognitive decline in the absence of rapid course or myoclonus (8).

The clinical presentation of gCJD varies with the underlying mutation. Some mutations present with a clinical picture that is similar to that of sCJD (Table 2). The age at onset tends to be younger and the disease duration longer than that for sCJD. FFI and GSS represent exceptions. FFI has a unique clinical course that is characterized by profound disruption of the normal sleep-wake cycle, insomnia, and sympathetic overactivity such as accelerated heart rate or perspiration, whereas GSS presents with a progressive cerebellar ataxia (15).

In iCJD, the site of prion exposure seems to dictate the incubation time from exposure to onset of prion disease-related symptoms. Direct intracerebral exposure to prions and implantation of prion-contaminated dura, for example, are associated with short incubation periods (16 to 28 months), whereas exposure to prions at sites outside the central nervous system results in long incubation times ranging from 5 to 30 years (23). Furthermore, there is evidence that the route of prion exposure influences the clinical presentation. Dura mater or growth hormone-related cases of iCJD present with a predominantly ataxic phenotype, whereas dementia was the initial symptom in cases in which prions were directly introduced into the CNS.

The fact that vCJD carries a distinct clinical profile has facilitated the formulation of diagnostic criteria. vCJD victims are much younger than sCJD patients (median age at death, 29 years). Furthermore, initial features and illness duration are relatively specific, with initial psychiatric symptoms and median illness duration of 14 months (Table 1). It has been hard to estimate incubation times for vCJD due to the fact that the exact time points of prion exposure are not defined.

The diagnosis of human prion diseases is based on the evaluation of clinical signs and auxiliary examinations (26). Electroencephalography (EEG) has historically been used to substantiate the diagnosis of a human prion disease. The usefulness of EEG has been questioned due to its limited sensitivity, which ranges between 0 and 73% for sCJD (27). Recent advances in neuroimaging, especially in magnetic resonance imaging (MRI), have revealed that different human prion diseases have specific patterns. For vCJD, the "pulvinar sign," a high T2 MRI signal in the posterior thalamus, seems to be pathognomonic (28). For sCJD, a high T2 MRI signal in the striatum as well as a high MRI signal in the cortex in fluid-attenuated inversion recovery sequences (a pulse sequence used in brain imaging to suppress cerebrospinal fluid (CSF) effects on the image) are classical findings (28).

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

**Safety and Security**

Human prions are classified as biosafety level 2 (BSL2) or BSL3 depending on the source of the infectious material and the level of infectivity of the source specimen. Unfixed samples of brain or spinal cord, as well as other tissues such as lymphoid tissue specimen from vCJD–diseased individuals known to contain high amounts of infectious prions, should be handled at BSL3 (29). In clinical laboratories, personal protective clothing such as disposable gowns, gloves, and barrier protection for mucous membranes (eye protection or full face visor) is recommended when working with potentially contaminated specimens. In addition, strict adherence to standard working procedures aimed at minimizing the chance of penetrating injuries is essential. Prions are not inactivated by formalin. A procedure recommended by the College of American Pathologists (http://www.cap.org) for safe handling of tissues is adequate formalin fixation, followed by agitation in a sufficient amount of formic acid (95 to 100% [vol/vol]; the sample should be entirely immersed in formic acid) for 1 hour, and subsequent formalin fixation for 2 days prior to embedding. Formic acid inactivates formalin-treated prions...

*Abbreviations: GSS, Gerstmann-Sträussler-Scheinker syndrome; FFI, fatal familial insomnia.

but has minimal effect on the quality of histology. Disposable histologic equipment should be used whenever possible.

CSF may contain detectable amounts of infectious prions and must be handled with caution. Analysis of samples from confirmed CJD patients should not be performed in automated equipment, and any materials coming in contact with CSF should be incinerated or decontaminated according to one of the methods listed below (see also http://www.advisorybodies.doh.gov.uk/acdp/tseguidance/). Blood and bone marrow are presumed to contain low levels of infectivity (http://www.advisorybodies.doh.gov.uk/acdp/tseguidance/) and can be handled safely under BSL2 conditions by adhering to universal precautions for prevention of transmission of bloodborne pathogens. These specimens can be tested in automated analyzers found throughout clinical laboratories if instruments are enclosed and can contain spillage and if waste can be disposed of safely. Maintenance and emergency procedures that protect the user from exposure should be outlined in laboratory standard operating procedures and implemented. Manual processing (specimen decanting, for example) should be performed inside a negative-pressure laminar flow hood in a contained environment.

Prions can be substantially but not completely inactivated by physical exposure to steam or dry heat at high temperatures. Disposable laboratory equipment should be used whenever possible. Potentially contaminated laboratory waste should be autoclaved (134 to 137°C, 20 minutes) and then incinerated (http://www.advisorybodies.doh.gov.uk/acdp/tseguidance/). Blood and bone marrow are presumed to contain low levels of infectivity (http://www.advisorybodies.doh.gov.uk/acdp/tseguidance/) and can be handled safely under BSL2 conditions by adhering to universal precautions for prevention of transmission of bloodborne pathogens. These specimens can be tested in automated analyzers found throughout clinical laboratories if instruments are enclosed and can contain spillage and if waste can be disposed of safely. Maintenance and emergency procedures that protect the user from exposure should be outlined in laboratory standard operating procedures and implemented. Manual processing (specimen decanting, for example) should be performed inside a negative-pressure laminar flow hood in a contained environment.

Shipping

Shipping of infectious material must comply with the “Recommendations of the United Nations Committee of Experts on the Transport of Dangerous Goods.” In these guidelines, human prions are listed in category 6 (Toxic and Infectious Substances), division 2 (Infectious Substances). The code numbers UN 2900 apply for this type of pathogen. Certified shipping containers must be used.

DIRECT EXAMINATION

Microscopy

Histological examination of brain biopsy specimens is a diagnostically valid premortem test. Routine hematoxylin...
and eosin staining is used to interpret the vacuolization patterns, whereas immunohistochemical demonstration of PrP is necessary in order to determine PrP deposition patterns (Fig. 1). Postmortem, defined regions within the central nervous system (cerebellum and thalamus) and nonneuronal tissues can be sampled to demonstrate distinct PrP deposition patterns (33). Histologically, prion diseases are characterized by spongiform changes, astrogliosis, and neuronal loss. These changes are most evident in the cerebral cortex and in the cerebellum. The prominent cerebellar involvement is typical for prion diseases and clearly separates this group of diseases from other dementing illnesses such as Alzheimer’s disease or diffuse Lewy body disease (34). In vCJD and in about 10 to 20 percent of sCJD patients, prion plaques are a prominent feature and may be demonstrated by Congo red staining or immunohistochemistry (Fig. 1). Types of prion deposits are indicative for the type of prion disease (e.g., florid plaques surrounded by spongiform changes can be found only in vCJD [Fig. 1]). Birefringence under polarized light, a feature of proteins assuming β-pleated sheet conformation, usually a characteristic for amyloid plaques, may be absent due to formic acid pretreatment of fixed tissue.

Antigen Detection
Western blotting is performed on unfixed tissue originating from the central nervous system, usually in research settings. Biosafety measures have to be taken and material handled at BSL3. Generally, this test is undertaken with postmortem material. In rare cases, a brain biopsy specimen may be used for this test.

The basis of biochemical characterization of PrP<sup>Sc</sup> resides in the relative resistance of PrP<sup>Sc</sup> to proteolytic degradation. Whereas PrP<sup>C</sup> is entirely digested by proteinase K, identical treatment of PrP<sup>Sc</sup> leads to removal of a variable number of N-terminal amino acids. Western blotting of digested PrP<sup>Sc</sup> reveals three distinct bands, corresponding to di-, mono-, and unglycosylated forms (34). The molecular classification of PrP<sup>Sc</sup> takes three parameters into account: molecular weight of unglycosylated PrP<sup>Sc</sup>, the relative amounts of PrP<sup>Sc</sup> di-, mono-, and unglycosylated forms, and the status of a PRNP polymorphism at codon 129, where either methionine (M) or valine (V) can be encoded (see “Nucleic Acid Detection: Genetic Testing” below). Thus, defined PrP<sup>Sc</sup> types correlate with distinct disease phenotypes. The resulting information is then used to establish the “type” of PrP<sup>Sc</sup> according to proposed schemes (35, 36) (Fig. 2). Depending on the exact conditions under which the protease digestion and the Western blotting procedure are performed, between 3 and 6 different PrP<sup>Sc</sup> types can be distinguished. Distinct PrP<sup>Sc</sup> types are thought to represent the molecular correlates of distinct prion strains. The fact that the PrP<sup>Sc</sup> types found in vCJD patients and in BSE-diseased cattle are identical is one of the main arguments supporting the theory that BSE prions are responsible for the vCJD epidemic in humans (20). Novel anti-PrP antibodies are able to discriminate PrP<sup>Sc</sup> types and have thus facilitated diagnostic procedures (37).

In addition to Western blotting, sandwich enzyme-linked immunosorbent assays (ELISAs) are available to detect partially proteinase K-resistant PrP<sup>Sc</sup>. Although these tests do not give exact information on PrP<sup>Sc</sup> types, recent studies support their use in a diagnostic setting for human prion diseases (38).

Nucleic Acid Detection: Genetic Testing
For genetic testing, DNA is routinely extracted from whole blood. The extraction procedure significantly reduces the already low titers of infectious prions in blood if isolation protocols using protein denaturing steps are employed. The entire PRNP open reading frame may be amplified for sequencing using PCR.
PrP differentiates 4 principal PrP PRNP and unglycosylated forms and the genotype of codon 129 on detected band of PrP to discriminate PrP types according to two proposed schemes (36, 45), which differentiate 4 principal PrP types (1, 2a, and 2b) are proposed in the second scheme (45). doi:10.1128/9781555817381.e109.2

Sequencing of PRNP allows for the exclusion of gCJD (39). More than 30 disease-causing insertion or point mutations in PRNP have been identified to date (Table 2).

In addition, there are several PRNP polymorphisms, one of which (codon 129M/V) has a disease-modifying function (40). Homozygosity for methionine at codon 129 constitutes a risk factor for the development of prion disease: methionine homozygotes are overrepresented among sCJD patients, and all definite vCJD patients for which codon 129 status was tested were homozygous for methionine at codon 129. These analyses are available at most academic human genetic institutions.

CSF Analysis

To date, there are no serologic screening or confirmatory tests for prion diseases. Rather, several studies have evaluated the usefulness of surrogate markers, such as 14-3-3 and Tau protein, that are found in CSF. Sequecing of PRNP allows for the exclusion of gCJD (39). More than 30 disease-causing insertion or point mutations in PRNP have been identified to date (Table 2).

Antiviral Agents

AIMEE C. HODOWANEC, KENNETH D. THOMPSON, AND NELL S. LURAIN

The use of antiviral agents for the treatment of viral diseases continues to expand. Most of the agents currently approved by the Food and Drug Administration (FDA) are active against one or more of the following viruses: human immunodeficiency virus types 1 and 2 (HIV-1 and HIV-2); hepatitis viruses B and C (HBV and HCV); the human herpesviruses; and influenza A and B viruses. This chapter is organized according to these virus groups with cross-referencing for agents with activity against more than one group of viruses. The major targets of these agents are viral replication enzymes, proteases, and entry/exit pathways (1–7). In a few cases, approved drugs for the above families of viruses have also been used to treat viruses in other families. The expanded spectrum of drug usage is discussed under the individual drug sections.

AGENTS AGAINST HIV-1 AND HIV-2

There are now five classes of antiviral agents for treatment of HIV-1: (i) nucleoside/nucleotide reverse transcriptase inhibitors (NRTIs/NtRTIs); (ii) nonnucleoside reverse transcriptase inhibitors (NNRTIs); (iii) protease inhibitors (PIs); (iv) entry/fusion inhibitors; and (v) integrase strand transfer inhibitors (INSTIs). Current information on each drug is available through the AIDSinfo website (http://AIDSinfo.nih.gov), which has separate guidelines for use of approved antiretroviral agents in (i) adolescents and adults, (ii) pediatric patients, and (iii) pregnant HIV-1-infected women (8–10). These guidelines describe the agents along with dosage, adverse effects, and drug interactions. Working groups for each of these patient populations regularly update the guidelines. Additional information can be obtained from the package inserts available from the pharmaceutical company websites. Changes in recommended drug doses as well as observed adverse effects and drug interactions occur frequently, making it necessary to consult the most up-to-date sources.

Antiretroviral agents are administered in combinations of different drug classes termed combined antiretroviral therapy (cART) to maximize efficacy and to minimize the induction of drug resistance. cART is now generally regarded as any combination regimen designed to achieve the goal of complete virus suppression. These regimens comprise a minimum of three drugs, which are usually NNRTI based (2 NRTIs and/or NtRTIs plus 1 NNRTI), PI-based (2 NRTIs and/or NtRTIs plus 1 or more PIs), or more recently INSTI based (2 NRTIs and/or NtRTIs plus an INSTI) (9).

There are currently 26 approved antiretroviral drugs (1) with numerous possible combinations for treatment regimens. Recommended regimens for adults and adolescents are given in the guidelines (9) for treatment-naive and treatment-experienced patients. The large number of drugs creates a tremendous potential for drug interactions among the different classes as well as interactions with other types of drugs prescribed for conditions associated with HIV infection. Close monitoring of these complex interactions is required to avoid detrimental changes in drug levels and/or toxicity.

Table 1 summarizes the structure, mechanism of action, and major adverse effects of the individual drugs and drug combinations approved by the FDA. The drug interactions described below for each drug are only highlights of potential interactions. Frequent updates and more-comprehensive information can be obtained from the AIDSinfo website listed above.

Nucleoside and/or Nucleotide Reverse Transcriptase Inhibitors

The NRTI-NtRTI class of drugs is not active as administered but must be phosphorylated by cellular kinases to the nucleoside triphosphate form, which lacks a 3′-phosphate group for DNA chain elongation. The NRTIs require triphosphorylation, while the NtRTIs require only diphosphorylation (1). These antiviral agents act as competitive inhibitors of the viral reverse transcriptase (RT), which results in chain termination. They are active against both the HIV-1 and HIV-2 RTs, and they are used as dual-combination backbones in regimens with NNRTIs, PIs, and INSTIs (9). Several of them also are active against the HBV DNA polymerase, which has reverse transcriptase activity (see “Agents against Hepatitis B Virus” below) (11). Lactic acidosis with hepatic steatosis is a rare but very serious adverse effect associated with all members of this class. These toxic effects of NRTIs and NtRTIs appear to be the result of inhibition of the mitochondrial DNA polymerase γ (12, 13).

Abacavir

Pharmacology

The oral bioavailability of abacavir (ABC) is 83%. The plasma half-life is 1.5 h, and the intracellular half-life is 12

**Pharmaceutical companies:** Abbott Laboratories, North Chicago, IL; BI, Boehringer Ingelheim Pharmaceuticals, Ridgefield, CT; BMS, Bristol-Meyers Squibb, Princeton, NJ; Gilead Sciences, Foster City, CA; GSK, GlaxoSmithKline, Research Triangle Park, NC; Merck & Co., Whitehouse Station, NJ; Pfizer, New York, NY; Roche Pharmaceuticals, Nutley, NJ; Tibotec Therapeutics, Division of Ortho Biotech Products, L.P., Raritan, NJ.

**Abbreviations:** GI, gastrointestinal (symptoms include nausea, vomiting, and diarrhea); AST, aspartate aminotransferase; ALT, alanine aminotransferase; CPK, creatine phosphokinase.

ABC can be administered with or without food. It is metabolized by alcohol dehydrogenase and glucuronyltransferase, and 82% of the metabolites are excreted by the kidneys. Placental passage has been demonstrated in animal studies (10). ABC penetration of the central nervous system (CNS) is adequate to inhibit HIV replication (14). ABC is recommended as an alternative drug in dual NRTI backbones. Although several studies suggested that ABC is associated with an increased risk of cardiovascular disease, more-recent data have failed to show an association (15–17). The guidelines recommend using caution when prescribing ABC in patients with high risk for cardiovascular disease. ABC is contraindicated as an alternative drug in dual NRTI/NtRTI backbones in combination with a NNRTI or PI in patients who are positive for the HLA-B*5701 major histocompatibility complex class I (MHC-I) allele, which is associated with a hypersensitivity reaction to the drug (9, 18). Combination formulations of 2 and 3 NRTIs and/or NtRTIs containing ABC are commercially available (Table 1).

**Drug Interactions**

ABC decreases the level of methadone. Ethanol increases the concentration of ABC in plasma through common metabolic pathways (9).

**Didanosine**

**Pharmacology**

The oral bioavailability of didanosine (ddl) is 30 to 40%. The serum half-life is 1.5 h, and the intracellular half-life is >20 h. It should be administered without food. One-half of the drug is excreted by the kidney. There is low penetration of the CNS, but ddl has been shown to cross the human placenta (10). DDI is no longer recommended for use in treatment-naive patients (9).

**Drug Interactions**

Administration of ddl with either stavudine (d4T) or tenofovir disoproxil fumarate (TDF) can increase the rate and severity of toxicities associated with each individual drug. Ganciclovir (GCV), valganciclovir (val-GCV), ribavirin (RBV), and allopurinol also increase ddl exposure, leading to increased ddl toxicity (9, 19, 20).

**Emtricitabine**

**Pharmacology**

The oral bioavailability of emtricitabine (FTC) is 93%. The plasma half-life is 10 h, and the intracellular half-life is >20 h. FTC can be administered with or without food. It is excreted mostly unchanged (86%) by the kidneys, and the remainder is eliminated in the feces. It has intermediate penetration of cells of the CNS (21), but it is not known whether FTC crosses the human placenta (10). FTC is recommended as a preferred drug in combination with tenofovir (TDF) in NNRTI-based, PI-based, or INSTI-based regimens for treatment-naive patients. Coadministration with lamivudine (3TC) is not recommended, because both drugs have similar resistance patterns and there is no therapeutic advantage for the combination (9).

**Drug Interactions**

No significant interactions with other antiretroviral agents have been reported (9, 22).

**Lamivudine**

**Pharmacology**

The oral bioavailability of lamivudine (3TC) is 86%. The serum half-life is 5 to 7 h, and the intracellular half-
life is 18 to 22 h. The drug can be administered with or without food, and 71% is excreted by the kidney. TDF crosses the human placenta (10) and has intermediate penetration of the CNS (21). TDF is recommended in alternative dual-NRTI regimens with ABC, combined with either an NNRTI, PI, or INSTI for treatment-naive patients (9). Co-administration of TDF with FTC is not recommended (see “Emtricitabine” above).

Drug Interactions

TDF combined with ddi can increase the rate and severity of toxicities associated with each individual drug. Zidovudine (ZDV) and RBV inhibit the phosphorylation of d4T (24, 25).

Tenofovir Disoproxil Fumarate

Pharmacology

The oral bioavailability of tenofovir disoproxil fumarate (TDF) is 25% without food and 39% with a high-fat meal, although the drug is administered without regard to meals. The serum half-life is 17 h, and the intracellular half-life is >60 h. The drug is excreted mostly unchanged (70 to 80%) by the kidneys. TDF has been shown to cross the placenta in animal studies, but it has low penetrance of the CNS (10, 21). TDF is no longer recommended for use in treatment-naive patients (9).

Drug Interactions

TDF increases the concentration of ddi in plasma, leading to increased toxicity (19, 20). There may be increased toxicity associated with coadministration of GCV, val-GCV, acyclovir (ACV), or cidofovir (CDV) (9).

Zidovudine

Pharmacology

Zidovudine (ZDV, AZT) was the first agent used for antiretroviral therapy (28). The oral bioavailability is 60%, the serum half-life is 1.1 h, and the intracellular half-life is 7 h. ZDV can be administered without regard to meals. It is metabolized to the glucuronide form, which is excreted by the kidneys.

ZDV crosses the blood-brain barrier to achieve effective concentrations in the CNS (21) and also crosses the placenta. ZDV with 3TC is a preferred dual-NRTI backbone for combination regimens in pregnant women (10). It can be given intravenously to pregnant women during labor to prevent maternal-fetal transmission if the mother has >400 copies/ml of HIV or if the HIV viral load is unknown near the time of delivery. Intrapartum ZDV is no longer recommended for HIV-infected mothers who achieve virologic control on cART. ZDV can be administered orally to the child at birth (10, 29). For adults and adolescents, ZDV can be given with 3TC as dual-NRTI backbone with NNRTI-based and PI-based regimens. However, this is no longer considered a preferred or alternative regimen, as it requires twice-daily dosing and has greater associated toxicity than TDF/FTC or ABC/3TC (9).

Drug Interactions

ZDV inhibits the phosphorylation of d4T by thymidine kinase (24). RBV inhibits phosphorylation of ZDV (25). GCV and α interferon (IFN-α) may enhance the hematologic toxicity associated with ZDV (30, 31).

NRTI/NRTI Combination Formulations

There are seven fixed-dose combinations involving NRTIs and NtRTIs, which are available as commercial formulations for convenience of administration: ABC-3TC-ZDV (Trizivir); ABC-3TC (Epzicom); FTC-TDF (Truvada); FTC-ZDV (Combivir); FTC-TDF-EFV (Atirpla); FTC-RPV-TDF (Complera); and FTC-elenitegravir (EVG)-cobicistat (COBI)-TDF (Striibild). Clinical trials have shown the triple combination ABC-3TC-ZDV to be equivalent to PI-based regimens but inferior to NNRTI-based regimens in reducing HIV RNA load in plasma below detectable levels (9, 32). Therefore, ABC-3TC-ZDV is no longer recommended for initial therapy. The dual combinations are used as NRTI/NRTI backbones in combination with an NNRTI, PI, or INSTI in triple- or quadruple-drug therapy. The triple combination FTC-TDF-EFV is a preferred initial regimen, while FTC-RPV-TDF and FTC-EVG-COBI-TDF are considered alternative regimens (9).

Nonnucleoside Reverse Transcriptase Inhibitors

Drugs in the NRTI class do not require intracellular anabolism for activation. There is no common structure; however, they bind noncompetitively to the HIV-1 RT close to the catalytic site. Disruption of DNA polymerization activity leads to premature DNA chain termination. The HIV-2 RT is resistant to this class of drugs (1).

There are currently four available NNRTIs: nevirapine, efavirenz, etravirine, and rilpivirine. All are metabolized by the cytochrome P450 (CYP450) system, which also metabolizes the PIs (see below) and other drugs used to treat conditions associated with HIV infection. The common pathway can lead to serious interactions, which either induce or inhibit individual drug metabolism. NNRTIs are often preferred for first-line therapeutic regimens with two NRTIs and/or NtRTIs for the following reasons: (i) there is a low incidence of gastrointestinal (GI) symptoms; (ii) NNRTIs have a long half-life that tolerates missed doses; and (iii) use of NNRTIs saves PIs for future regimens. The disadvantages of the NNRTIs are (i) the relatively low number of mutations required to confer cross-
resistance to many of the drugs in this class; (ii) side effects related to the central nervous system; and (iii) the teratogenic effects associated with the preferred NNRTI, efavirenz (EFV) (9, 33).

Efavirenz

Pharmacology

The oral bioavailability of efavirenz (EFV) is undetermined. The serum half-life is 40 to 55 h. The drug should be administered without food. EFV is 99.5% protein bound in plasma, mainly to albumin. CNS penetration is intermediate (21), but EFV has been shown to cross the placenta in animals (10). EFV is metabolized by CYP3A4 and CYP2B6 and is an inducer and inhibitor of CYP3A4. Glucuronidated metabolites are excreted in the urine (14 to 34%) and eliminated in the feces (16 to 61%). EFV is the preferred NNRTI in triple regimens with 2 NRTIs or NtRTIs, except in pregnant women, because teratogenic effects have been observed in cynomolgus monkeys during the first trimester of pregnancy (10).

Drug Interactions

Dose modifications may be necessary for potential drug interactions between EFV and the following: indinavir (IDV), lopinavir-ritonavir (LPV-r), fosamprenavir (FPV), nelfinavir (NFV), saquinavir (SQV), clarithromycin, rifabutin, rifampin, simvastatin, lovastatin, methadone, itraconazole, anticonvulsants, and oral contraceptives (9, 25). Contraindicated drugs are rifampin, cisapride, midazolam, triazolam, ergot derivatives, St. John’s wort, voriconazole, and, in treatment-experienced patients, atazanavir (ATV).

Etravirine

Pharmacology

The oral bioavailability of etravirine (ETR) is unknown. The serum half-life is 41 ± 21 h. Drug levels are reduced under fasting conditions; therefore, ETR should be taken with meals. ETR is 99.9% protein bound in plasma, mainly to albumin. It is not known whether ETR penetrates the CNS or crosses the placenta. ETR is metabolized by CYP3A4, 2C9, and 2C19. It induces CYP3A4 and inhibits 2C9 and 2C19. ETR is eliminated in the feces (93.7%) and excreted in the urine (14 to 34%) and eliminated in the feces (16 to 61%). EFV is the preferred NNRTI in triple regimens with 2 NRTIs or NtRTIs, except in pregnant women, because teratogenic effects have been observed in cynomolgus monkeys during the first trimester of pregnancy (10).

Drug Interactions

Dose modifications may be necessary for potential drug interactions between ETR and the following: indinavir (IDV), lopinavir-ritonavir (LPV-r), fosamprenavir (FPV), nelfinavir (NFV), saquinavir (SQV), clarithromycin, rifabutin, rifampin, simvastatin, lovastatin, methadone, itraconazole, anticonvulsants, and oral contraceptives (9, 25). Contraindicated drugs are rifampin, cisapride, midazolam, triazolam, ergot derivatives, St. John’s wort, voriconazole, and, in treatment-experienced patients, atazanavir (ATV).

Nevirapine

Pharmacology

The oral bioavailability of nevirapine (NVP) is > 90%, and the serum half-life is 25 to 30 h. NVP is 60% protein bound. Penetration into the CNS is high; the concentration in the CSF is 45% of the concentration in plasma (21). Nevirapine can be administered with or without food. It is metabolized in the liver by CYP450 isoenzymes and is a CYP3A4 inducer. Glucuronidated metabolites are excreted in the urine (80%) and feces (10%). NVP is known to cross the human placenta (10). It has been used in resource-limited regions as a single oral agent in an intrapartum/newborn prophylaxis regimen to prevent maternal-to-child transmission (10, 36). NVP has been associated with serious hepatic events, particularly among patients with high baseline CD4+ T cell counts. NVP is no longer considered a preferred or alternative agent for initial therapy. However, in certain circumstances NVP may be considered in women with CD4+ T cell counts of <250 cells/mm³ or in males with counts of ≤400 cells/mm³ in the absence of moderate to severe hepatic impairment (Child-Pugh class B or C) (9).

Drug Interactions

NVP reduces the concentrations in plasma of IDV, SQV, oral contraceptives, fluconazole, ketoconazole, clarithromycin, and methadone (25). Coadministration of ATV, ETR, rifampin, rifapentine, or St. John’s wort with NVP is contraindicated (9).

Rilpivirine

Pharmacology

The oral bioavailability of rilpivirine (RPV) is unknown, and the serum half-life is 50 h. It is not known whether RPV penetrates the CNS or crosses the placenta. RPV should be administered with food. It is a CYP3A4 substrate (9). RPV in combination with TDF-FTC or ABC-3TC is an alternative regimen for treatment-naive patients. However, RPV use is not recommended in patients with pretreatment HIV viral load of >100,000 copies/ml, as it has been associated with virologic failure in these patients. In addition, patients with CD4+ T cell counts of <200 cells/mm³ are more likely to experience virologic failure when treated with an RPV-based regimen (9).

Protease Inhibitors

Protease inhibitors, like the NNRTIs, require no intracellular anabolism for antiviral activity. The target is the HIV-encoded protease, which is required for posttranslational processing of the precursor gag polyprotein (37). Most PIs are peptidomimetic, because they mimic the peptide bond necessary for assembly for antiviral activity. The target is the HIV-encoded protease, which is required for posttranslational processing of the precursor gag polyprotein (37). Most PIs are peptidomimetic, because they mimic the peptide bond necessary for assembly
associated protein (MRP). These are efflux transporters, which enhance elimination of the drugs from cells in the intestine, liver, and kidneys and reduce intracellular drug concentrations (40). All of the PIs are metabolized in the intestine and liver by enzymes of the CYP450 system (41), mainly by CYP3A, CYP2C9, and CYP2C19. An individual PI can induce and/or inhibit specific CYP450 isoenzymes, which can enhance or reduce its own metabolism or that of other PIs. As noted above, the CYP450 system metabolizes the NNRTIs and numerous other drugs that may be used for conditions associated with HIV infection. Thus, the choice of treatment regimens is complicated by multiple potential drug-drug interactions, which may enhance toxicity and/or require dose modifications of coadministered drugs (9).

Although most PIs are inhibitors of CYP3A4, ritonavir (RTV) is the most inhibitory. For this reason, RTV is used in boosting regimens to improve the pharmacokinetic profile of a second PI (40, 42). Subtherapeutic concentrations of RTV increase the systemic exposure of a second PI by reducing the rate of metabolism and increasing the half-life (41), which lowers dosing requirements and food effects for the second drug. An example is LPV, which alone has very little bioavailability and a very short half-life but in combination with RTV is used therapeutically both in treatment-naive patients and in salvage therapy (40, 42, 43). The effect of RTV on the pharmacokinetics of other PIs varies as a result of differences in interaction with components of the CYP450 system that determine bioavailability (40). Specific recommendations are described below for each drug.

Atazanavir

Pharmacology

Atazanavir (ATV) is an azapeptide PI that differs structurally from other peptidomimetic PIs. The bioavailability is undetermined, and the serum half-life is 7 h. The bioavailability, however, is increased by administration with food. ATV is 86% protein bound and penetrates the CNS (44). It is metabolized in the liver by CYP3A4, and it is also an inhibitor of this enzyme. The metabolites are eliminated in the feces (79%) and urine (13%). ATV crosses the placenta at minimal levels (10).

ATV has the advantage of once-daily dosing and a low pill burden, and the drug exposure can be increased by boosting with RTV (45). ATV boosted with RTV is a preferred PI for use in regimens with 2 NRTIs or NtRtIs. TDF or ddl combined with 3TC is not recommended in regimens with unboosted ATV (9).

Drug Interactions

Drugs that may require dose modifications or cautious use with ATV include antifungal agents, rifabutin, clarithromycin, oral contraceptives, atorvastatin, the anticonvulsants carbamazepine, phenobarbital, and phenytoin, methadone (RTV boosted), erectile dysfunction agents, H2 receptor antagonists, proton pump inhibitors, antacids, and buffered medications. Drugs that are contraindicated for coadministration with ATV include IDV, NVP, ETR, EFV (in treatment-experienced patients), the antihistamines astemizole and terfenadine, the calcium channel blocker bepridil, simvastatin, lovastatin, rifampin, rifapentine, cisapride, proton pump inhibitors, pimozone, midazolam, triazolam, ergot derivatives, St. John’s wort, and inhaled corticosteroids (9).

Darunavir

Pharmacology

The bioavailability of darunavir (DRV) is 37% alone and 82% when boosted with RTV, and the serum half-life is 15 h when boosted. It should be administered with food. The plasma protein binding is 95%, mainly to AAG. DRV is metabolized in the liver by CYP3A4, for which it is an inhibitor. It is eliminated in the feces (79.5%) and the urine (13.9%). It is not known whether it crosses the placenta (10). DRV boosted with RTV is recommended in preferred PI-based regimens with 2 NRTIs or NtRtIs for treatment-naive patients (9).

Drug Interactions

Drugs that may require dose modifications are the antidepressants paroxetine and sertraline, erectile dysfunction drugs, methadone (RTV boosted), atorvastatin, and rosuvastatin. Drugs that are contraindicated are LPV-r, SQV, TDF, lovastatin, simvastatin, midazolam, triazolam, ergot derivatives, St. John’s wort, rifampin, rifapentine, astemizole, terfenadine, cisapride, pimozone, carbamazepine, phenobarbital, phenytoin, and flucacain.

Fosamprenavir

Pharmacology

Fosamprenavir (FPV) is a prodrug with no antiviral activity, which must be converted to amprenavir (APV) by cellular phosphatases (46). The bioavailability of APV is determined, and the serum half-life is 7.7 h. It can be administered with or without food. The plasma protein binding is 90%. APV is metabolized in the liver by CYP3A4, for which it is an inhibitor and inducer (47). It is eliminated in the feces (75%) and urine (14%). It is not known whether APV crosses the placenta (10). FPV boosted with RTV has high penetration in the CNS (21). However, it is not recommended for treatment-naive patients (9).

Indinavir

Pharmacology

The bioavailability of indinavir (IDV) is 65%, and the serum half-life is 1.5 to 2.0 h. IDV should be administered with low-caloric, low-fat food. It is 60% plasma protein bound, mainly to AAG (39). IDV is an inhibitor of CYP3A4. The majority of the drug (83%) is eliminated as metabolites in the feces. There is minimal passage of IDV across the placenta (10), but RTV-boosted IDV penetrates the CNS (21, 48).

RTV-boosted or unboosted IDV is not recommended as a component of PI-based regimens for treatment-naive patients, because of inconvenient dosing (unboosted) and the adverse complication of nephrolithiasis (RTV boosted) (9).

Drug Interactions

Coadministered drugs that may require dose modifications or cautious use include antifungal agents, anticonvulsants, calcium channel blockers, atorvastatin, erectile dysfunction drugs, methadone (RTV boosted), and vitamin C, especially in grapefruit juice. Drugs that are contraindicated for coadministration with IDV include ATV, TPV,
amiodarone, simvastatin, lovastatin, rifampin, rifapentine, ergot derivatives, midazolam, triazolam, cisapride, pimozide, and St. John’s wort (9, 25).

Lopinavir-Ritonavir

Pharmacology
LPV is administered only in combination with low-dose RTV (LPV-r), and the combined formulation (trade name, Kaletra) is commercially available. The bioavailability of LPV-r is undetermined, and the half-life is 5 to 6 h. The oral tablet formulation can be taken with or without food; the oral solution should be taken with food of moderate fat content. The plasma protein binding is 99%, mainly to AAG. LPV-r inhibits CYP3A4 and to a lesser extent CYP2D6. It is eliminated mainly in the feces (82.6%) and urine (10.4%) as metabolites. LPV crosses the placenta (10). LPV-r has high penetration of the CNS (21) and is an alternative drug in PI-based regimens with 2 NRTIs and/or NRTIs for treatment-naive patients (9).

Drug Interactions
Drugs that may require dose modifications when coadministered with LPV-r include erectile dysfunction drugs, rosuvastatin, atorvastatin, calcium channel blockers, and methadone. Drugs that are contraindicated for coadministration include DRV, FPV, TPV, simvastatin, lovastatin, oral contraceptives, midazolam, triazolam, flecainide, propafenone, rifampin, rifapentine, astemizole, terfenadine, cisapride, pimozide, ergot derivatives, fluticasone, and St. John’s wort (9, 25).

Nelfinavir

Pharmacology
The bioavailability of nelfinavir (NFV) is 20 to 80%, and the serum half-life is 3.5 to 5 h. NFV shows the greatest accumulation in cells of all the other PIs; however, the protein binding is >98% (39). It should be administered with food. NFV is both an inhibitor and inducer of CYP3A4 (47). The majority of the drug (87%) is eliminated with food. NFV is >99.9% protein bound in plasma to both albumin and AAG. Metabolism is mainly through the protein binding is >98% (39). It should be administered with food. NFV is both an inhibitor and inducer of CYP3A4 (47). The majority of the drug (87%) is eliminated with food. NFV is >99.9% protein bound in plasma to both albumin and AAG. Metabolism is mainly through

Drug Interactions
Drugs that require dose modifications or cautious use include rifabutin, atorvastatin, calcium channel blockers, and methadone. Drugs that are contraindicated for coadministration with NFV include TPV, the antihistamines amiodarone and quinidine, simvastatin, lovastatin, rifampin, rifapentine, astemizole, pimozide, midazolam, triazolam, terfenadine, ergot derivatives, St. John’s wort, and oral contraceptives, St. John’s wort (9, 25).

Ritonavir

Pharmacology
The oral bioavailability of ritonavir (RTV) is undetermined, and the serum half-life is 3 to 5 h. RTV should be administered with food. It is 98% plasma protein bound and is metabolized by CYP3A. The major metabolite is isopropylthiazole, which has the same antiviral activity as the parent drug. RTV is eliminated in the feces (86.4%) and urine (11.3%) (9). Passage across the placenta is minimal (10).

The main role of RTV in current HIV therapeutics is to enhance the pharmacokinetics of a second PI (42), because RTV is such a strong inhibitor of CYP3A4. Low-dose RTV is a pharmacoenhancer of IDV, FPV, SQV, LPV, ATV, TPV, and DRV. RTV alone in PI-based regimens is not recommended because of gastrointestinal intolerance (9). RTV-boosted PIs are recommended in combination with 2 NRTIs and/or NRTIs in PI-based regimens for treatment-naive and treatment-experienced patients (9, 42).

Drug Interactions
In general, RTV is a very strong inhibitor of CYP3A4 and has numerous potential drug interactions requiring close monitoring (9, 25). Coadministered drugs that may require dose modifications or cautious use include ketoconazole, itraconazole, rifampin, rifabutin, clarithromycin, atorvastatin, pravastatin, carbamazepine, clonazepam, ethosuximide, methadone, erectile dysfunction drugs, atovaquone, quinine, rosuvastatin, desipramine, trazodone, and theophylline. Drugs that are contraindicated for coadministration with RTV include ETR, bepridil, amiodarone, flecainide, propafenone, quinidine, simvastatin, lovastatin, rifapentine, cisapride, pimozide, midazolam, triazolam, ergot derivatives, oral contraceptives, and St. John’s wort.

Saquinavir

Pharmacology
The oral bioavailability of saquinavir (SQV) is approximately 4%. The serum half-life is 1 to 2 h. SQV is a CYP3A4 inhibitor. It should be administered with food. SQV is 97% bound to plasma proteins and is eliminated mainly in the feces (81%) (9). There is minimal passage of SQV across the placenta (10) and very low penetration of the CNS (21). SQV RTV-boosted and unboosted regimens with 2 NRTIs and/or NRTIs are not recommended for treatment-naive patients (9).

Drug Interactions
Coadministered drugs or foods that require dose modifications or cautious use include antifungal agents, dihydropyridine, diltiazem, atorvastatin, rosuvastatin, anticonvulsants, methadone, erectile dysfunction agents, proton pump inhibitors, and grapefruit juice. Drugs that are contraindicated for coadministration with SQV include TPV, DRV, amiodarone, bepridil, flecainide, propafenone, quinidine, astemizole, terfenadine, fluticasone, simvastatin, lovastatin, rifampin, rifapentine, cisapride, pimozide, oral contraceptives, midazolam, triazolam, ergot derivatives, St. John’s wort, garlic supplements, and dexamethasone (9, 25).

Tipranavir

Pharmacology
Tipranavir (TPV) is a nonpeptidic protease inhibitor (49). The oral bioavailability is undetermined, and the half-life is 6 h. It can be administered with or without food. TPV is >99.9% protein bound in plasma to both albumin and AAG. Metabolism is mainly through CYP3A4. TPV is eliminated in the feces (82.3%) and urine (4.4%). It is not known whether TPV crosses the placenta (10), and penetration of the CNS is low (21). TPV requires coadministration with RTV to reach effective levels in plasma (5, 41). TPV is not recommended for
use in PI-based regimens for treatment-naive patients. The current indicated use is in patients who are highly treatment experienced or who are infected with virus strains resistant to multiple protease inhibitors.

**Drug Interactions**

Coadministration of TPV with the following drugs may require dose modification: rosuvastatin, atorvastatin, methadone, and erectile dysfunction agents. Coadministration of the following drugs is contraindicated: ATV, ETR, FPV, LPN, NVP, SQV, bepridil, amiodarone, flecainide, propafenone, quinidine, rifampin, rifapentine, lovastatin, simvastatin, midazolam, triazolam, ergot derivatives, cisapride, pimozide, astemizole, terfenadine, oral contraceptives, St. John’s wort, and flucytosine (5, 9, 41).

**Entry Inhibitors**

Newer classes of antiretroviral agents that target the entry of HIV into the host cell have been developed. Enfuvirtide (T20), a fusion inhibitor, was the first of these drugs to be approved. It is a linear synthetic peptide of 36 l-amino acids that binds to the first heptad repeat in the gp41 subunit of the HIV-1 envelope glycoprotein. The sequence of the peptide was derived from that of HIV-1LA1, a subtype B strain (50). The binding prevents conformational changes that are required for fusion between the virus envelope and the cell membrane (2). Entry is inhibited, thereby preventing infection of the target cell.

Maraviroc (MVC), a CCR5 antagonist, is a second drug targeting viral entry. The use of this drug is dependent on the prior determination of the viral tropism, because only virus strains utilizing the CCR5 coreceptor (R5) are susceptible. The rationale for this antiviral target is that coreceptor tropism of primary HIV-1 infection is most commonly CCR5, and the switch to CXCR4 or dual tropism occurs much later in the course of infection. Allosteric binding of MVC to the CCR5 coreceptor results in a conformational change, which inhibits HIV-1 gp120 binding and viral entry into the target cell (51).

**Enfuvirtide**

**Pharmacology**

The bioavailability of enfuvirtide (T20) by subcutaneous injection is 84% (2), and the serum half-life is 3.8 h. T20 is 92% protein bound in plasma. It is assumed that the metabolism of the drug produces the constituent amino acids, which enter the amino acid pool in the body and are recycled. It is not active against HIV-2, but there are recent data suggesting that it is active against HIV-1 non-B subtypes and possibly group O as well (52). Limited data indicate that T20 does not cross the placenta (10) and that it does not penetrate the CNS (70). T20 is not recommended for use in NNRTI- or PI-based regimens in treatment-naive patients, because there are no data from clinical trials, and it requires injection for delivery. It is presently used in salvage therapy regimens for treatment-experienced patients who have not responded to their current antiretroviral therapy (10, 53).

**Drug Interactions**

There is no evidence that T20 induces or inhibits any of the CYP450 isoenzymes; therefore, it is unlikely to interact with any of the drugs that are metabolized by the CYP450 system. No significant interactions with other antiretroviral drugs have been identified (2).

**Maraviroc**

**Pharmacology**

Maraviroc (MVC) prevents HIV-1 binding of R5 strains to the CCR5 coreceptor but has no activity against X4 strains. The bioavailability is 33%, and the serum half-life is 14 to 18 h. It is 76% protein bound in the plasma to both albumin and AAG. It can be administered with or without food. MVC is metabolized by CYP3A4 and eliminated in the feces (76%) and urine (20%). It is not known whether it crosses the placenta (10). Although MVC may be used in combination with NRTI and/or NNRTIs in treatment-naive patients known to have CCR5-tropic virus, it is not considered a preferred or alternative agent because of its twice-daily dosing schedule and need for tropism testing (9, 54).

**Drug Interactions**

Coadministration of MVC with the following drugs may require dose modification: itraconazole, ketoconazole, voriconazole, carbamazepine, phenobarbital, phenytoin, clarithromycin, rifabutin, rifapentin, EFV, and all PIs except TPV. Coadministration with rifapentin and St. John’s wort is contraindicated.

**Integrate Strand Transfer Inhibitors**

Integrate strand transfer inhibitors, a class of antiretroviral drugs, target the HIV-1 integrase enzyme that mediates transfer of the reverse-transcribed HIV-1 DNA into the host chromosome. The activity of this enzyme includes 3-prime processing of the reverse-transcribed DNA to generate hydroxyls at the 3-prime ends of both strands followed by strand transfer that joins viral and host DNA. The integrase inhibitors that are approved are recommended for use in INSTI-based regimens for treatment-naive patients (1, 4).

**Raltegravir**

**Pharmacology**

Raltegravir (RAL) is the first approved INSTI. It is reportedly active against HIV-1 group O isolates (35) as well as HIV-1 group M and HIV-2 (4). The bioavailability has not been established, and the serum half-life is 9 h. It is 83% protein bound in plasma. RAL crosses the placenta (10). It can be administered with or without food. It is eliminated in the feces (51%) and urine (32%). Clearance is by UDP-glucuronosyltransferase (UGTA1) glucuronidation. RAL with TDF-FTC is now recommended as an INSTI-based preferred regimen for treatment-naive patients (4, 9, 55, 56).

**Drug Interactions**

Coadministration of the following drugs may require dose modification: rifampin, phenytoin, phenobarbital, ATZ, TPV, EFV, ETR, and TDF. RAL is not an inducer or inhibitor of cytochrome P450 enzymes; therefore, it does not affect the pharmacokinetics of most of the drugs that interact with the other classes of antiretroviral agents (4).

**Elvitegravir**

**Pharmacology**

Currently, elvitegravir (E VG) is approved only in combination with other antivirals plus coformulation (EVG-COB TDF-F TC; trade name, Stribild). It achieves therapeutic concentrations only when combined with a pharmacologic booster (COBI). EVG has a serum half-life of 13 h. It is 99% protein bound in plasma (57). EVG should be taken with food. CSF and placental penetration levels are unknown. The combination pill EVG-COB TDF-F TC is
recommended as an alternative regimen in treatment-naive patients (9).

COBI was developed for use with EVG, because it has no anti-HIV activity, but like RTV, it is a strong inhibitor of CYP3A4. The result is higher concentrations of EVG at lower doses (58). COBI also interacts with intestinal transport proteins to increase absorption of other anti-HIV drugs, including atazanavir and darunavir (59).

Drug Interactions

EVG is primarily metabolized by the cytochrome P450 pathway and therefore interacts with other drugs that utilize this pathway. Because EVG is available only as a coformulated tablet, data regarding interactions of EVG are lacking. EVG-COBI-TDF-FTC may increase levels of selective serotonin reuptake inhibitors, tricyclic antidepressants, itraconazole, posaconazole, and voriconazole. EVG-COBI-TDF-FTC administration should be separated from antacid administration by more than 2 hours. Coadministration of rifabutin, rifampin, rifapentine, lovastatin, or simvastatin is contraindicated (9).

Dolutegravir

Pharmacology

Dolutegravir (DTG), the newest INSTI, was FDA approved in August 2013. It is approved for use in both HIV treatment-naive and treatment-experienced patients. It has been shown to have little cross-resistance with the other available INSTIs, RAL and EVG (60). DTG has a 14-hour half-life and can therefore be administered once a day in select patients. Twice-daily dosing is recommended in patients with known/suspected INSTI resistance and when coadministered with EFV, FPV-RTV, TPV-RTV, or rifampin (61). DTG can be administered with or without food (62). It is eliminated in the feces (53%) and urine (31%).

Drug Interactions

Coadministration with the following drugs may require dose modification: EFV, FPV-RTV, TPV-RTV, or rifampin (61). The following drugs should not be coadministered with DTG: carbamazepine, phenytoin, NVP, phenobarbital, and St. John’s wort.

AGENTS AGAINST HEPATITIS C VIRUS

Until recently, the only available antiviral regimens with the potential to achieve a sustained virologic response (SVR) against chronic HCV infection were those combining an α-interferon with ribavirin (RBV) (63) (Table 2). Unfortunately, these regimens achieve an SVR in only 40 to 50% of more-difficult-to-treat subsets of HCV-infected patients (64). There are many factors that impact the virologic response to HCV therapy. One of the most important factors is the HCV genotype. Of the six HCV genotypes, genotypes 2 and 3 are the most IFN-responsive, while the rates of SVR are lower for genotypes 1, 4, 5, and 6 (65–67). Other factors associated with poor virologic response include HIV coinfection, African American race, and cirrhosis (64). Single nucleotide polymorphisms (SNPs) near the IL28B gene are also predictive of response to IFN-α-containing regimens. The C/T polymorphism of reference SNP 12979860 is most commonly reported (68). The highest rates of response are associated with the C/C allele; the lowest response rates are associated with the T/T allele. Response rates for the C/T allele are marginally better than those for T/T.

In 2011, two PIs, telaprevir and boceprevir, were approved by the FDA for use in combination with pegylated IFN-α and ribavirin for the treatment of HCV infection. These agents were the first direct-acting antiviral agents (DAAs) approved for the treatment of HCV, and they resulted in a dramatic improvement in SVR rates. However, in the short time since their approval, telaprevir and boceprevir have already been replaced by new DAAs with less frequent dosing requirements, fewer side effects, and fewer drug interactions (and will therefore not be reviewed in detail here). New DAAs are being combined in highly effective, well-tolerated, IFN-free regimens. Given the rapidly changing landscape of HCV treatment, please visit www.hcvguidelines.org for the most current information (69).

Interferon-Ribavirin

Pegylated interferon-α 2a and 2b

The IFN-α agents are produced through recombinant DNA technology from cloned human leukocyte interferon genes expressed in Escherichia coli. The pegylated interferons (PEG-IFN) are covalent conjugates of standard IFN-α with a single-branched (IFN-α 2a) or straight (IFN-α 2b) polyethylene glycol (PEG) chain. The molecular masses are 60,000 (2a) and 31,000 (2b) Da. Pegylation reduces clearance of the drug, which in turn prolongs the half-life compared to standard IFN (71).

Pharmacology

Both PEG-IFN 2a and 2b are administered by subcutaneous injection. For HCV antiviral therapy, PEG-IFN 2a and 2b are always administered with RBV. PEG-IFN has decreased renal clearance and an extended half-life of 160 h (2a) or 40 h (2b), which allows for once-weekly dosing (72). PEG-IFN is eliminated in part (30%) by the kidneys.

Ribavirin

Pharmacology

The bioavailability of ribavirin (RBV) is reported to be 52% (73) and is increased by a high-fat meal; therefore, RBV should be administered with food. The half-life in plasma is 120 to 170 h, and the drug may persist in other body compartments for up to 6 months. The pathway for elimination has not been determined. RBV appears not to be a substrate for the CYP450 isoenzymes. RBV is used as standard therapy, always in combination with other antiviral agents, for the treatment of HCV. RBV monotherapy is not effective against HCV infection.

RBV has been used as monotherapy to treat other RNA viruses, including respiratory syncytial virus (RSV), Lassa fever virus, influenza virus, parainfluenza virus, and hantavirus; however, there are no conclusive data demonstrating RBV treatment efficacy (74–81). An aerosolized formulation of RBV (Virazole; Valeant Pharmaceuticals, Costa Mesa, CA) has been approved for treatment of

*Pharmaceutical companies: AbbVie, North Chicago, IL; Gilead, Foster City, CA; Janssen Pharmaceutica, Beersse, Belgium; Merck & Co., Inc, Whitehouse Station, NJ; Roche Pharmaceuticals, Nutley, NJ.*

*Ribavirin can cause anemia via hemolysis or decreased red cell production.

*GI (gastrointestinal) symptoms include nausea, vomiting, and diarrhea.*

hospitalized infants and young children with severe RSV lower respiratory tract infections.

**Drug Interactions**
Coadministration of ddI or d4T with RBV is contraindicated. ZDV plus RBV is linked to higher rates of anemia (9, 82).

**Protease Inhibitors**
The HCV PIs are inhibitors of the nonstructural 3/4A HCV protease enzyme. Although these agents exhibit potent anti-HCV activity when administered as monotherapy, they exhibit a low barrier to resistance and therefore must be given in combination with other anti-HCV agents. In addition, there are several mutations associated with decreased PI susceptibility.

**Simeprevir**
Pharmacology
Simeprevir (SMV) is administered orally. It has a longer half-life (41 hours in HCV-infected subjects) than the other approved PIs, allowing for once-daily dosing. It is eliminated in the feces by biliary excretion (U.S. National Library of Medicine [http://dailymed.nlm.nih.gov]).

**Drug Interactions**
SMV is metabolized by CYP3A. Levels of the following drugs and drug classes may be increased when coadministered with SMV: antiarrhythmics, calcium channel blockers, statins, and benzodiazepines. Coadministration of SMV with azoles, HIV-Pis, EFV, NVP, and rifampin is not recommended (see U.S. NLM website above).

**Polymerase Inhibitors**
The NS5B RNA-dependent RNA polymerase represents another target for anti-HCV therapy. Drugs in this class include nucleoside or nucleotide analogue inhibitors (NIs) and nonnucleoside inhibitors (NNIs). In 2013, sofosbuvir, a nucleotide inhibitor, was the first agent in this class to be FDA approved. The availability of this agent is a remarkable advancement in HCV therapy, as sofosbuvir has pangenotypic activity, has limited drug-drug interactions, and is associated with high response rates even when used in short treatment courses (85). Sofosbuvir is not recommended as monotherapy.

**Sofosbuvir**
Pharmacology
Sofosbuvir (SOF) is a prodrug that is converted to an active metabolite following oral administration. It can be
taken with or without food. SOF is primarily eliminated by the kidneys (85, http://dailymed.nlm.nih.gov).

**Drug Interactions**

SOF is a substrate of P-gp and should therefore not be coadministered with potent P-gp inducers. However, as metabolism of SOF does not involve P450 CYP3A/4, it has few clinically significant drug-drug interactions (85).

**NS5A Inhibitors**

NS5A is a nonstructural protein that is integral to HCV viral replication and assembly (83). There are currently two agents approved for the treatment of HCV that target this protein: ledipasvir and ombitasvir. Both of these drugs are available only in combination with other anti-HCV agents. Please see “HCV Combination Therapies” below for additional information on these agents.

**New HCV Combination Therapies**

**Ledipasvir-Sofosbuvir**

This fixed-dose combination (FDC) was approved in 2014 for the treatment of genotype 1 chronic HCV infection. It was the first combination pill to be approved for HCV treatment and was the first IFN-free regimen to be approved for HCV treatment. Ledipasvir is an inhibitor of the HCV NS5A protein (necessary for HCV replication), and sofosbuvir is a polymerase inhibitor.

**Pharmacology**

This FDC is administered by mouth once daily. Sofosbuvir is primarily excreted in the urine, ledipasvir in the feces. It is not recommended for use in patients with end-stage renal disease or a creatinine clearance of <30 ml/min (84).

**Drug Interactions**

Both ledipasvir and sofosbuvir are substrates of P-gp. This FDC should therefore not be coadministered with strong inducers of P-gp and monitoring is recommended when co-administering with P-gp inhibitors and substrates. Increases in gastric pH may decrease the concentration of ledipasvir. Administration of this FDC should therefore be separated from antacid administration (84).

Ombitasvir, Paritaprevir, Ritonavir, and Dasabuvir

This is a copackaged product consisting of ombitasvir, paritaprevir, and ritonavir as a FDC and dasabuvir as an individual tablet. Ombitasvir is an NS5A inhibitor, paritaprevir is an NS3/4A protease inhibitor, and dasabuvir is an HCV RNA polymerase inhibitor. This product is approved for the treatment of genotype 1 HCV infection. In some patients (those with cirrhosis or genotype 1a infection), it is recommended that RBV be added to the regimen (86).

**Pharmacology**

Please see the prescribing information for the pharmacologic properties of the components of this regimen (86).

**Drug Interactions**

Due to the inclusion of ritonavir in this regimen, there are significant interactions with CYP3A4 inducers and inhibitors. Please see the prescribing information for the drug interactions of the components of this regimen (86).

**Agents Against Hepatitis B Virus**

There are two major classes of drugs available to treat HBV: nucleoside or nucleotide analogues and interferons. Because a large percentage of patients are coinfected with HIV, these agents are categorized by whether they have activity against both viruses or only HBV. Of the drugs that are specifically approved for HBV, PEG-IFN 2a or 2b and telbivudine (LdT) are active only against HBV, while 3TC, TDF, adefovir (ADV), and entecavir (ETV) are active against both HBV and HIV (Table 3). Though neither ADV nor ETV is currently recommended for the treatment of HIV, use of these agents should be avoided in HIV/HBV-coinfected patients who are not on a suppressive antiretroviral regimen in order to prevent the development of HIV resistance. FTC is approved only for HIV, but it has been shown to have activity against HBV (9, 88).

The common target for antiviral drugs active against both viruses is the reverse transcriptase function of the HBV and HBV replication enzymes (11, 89, 90).

Chronic HBV infection plays an important role in the morbidity and mortality of HIV-infected patients (91). The strategy for selecting antiviral therapy regimens for coinfected patients is based on the need to treat one or both viruses. If only HIV requires treatment, drugs with activity against both HIV and HBV, such as 3TC or FTC, should be withheld. If only HBV needs to be treated, drugs without HIV activity, such as PEG-IFN 2a/2b or LdT, can be used. However, it is recommended that all patients with HIV and HBV coinfection be started on cART regardless of CD4 count, as this may slow the progression of liver disease (9).

cART regimens with dual NRTIs and/or NtRTIs, such as TDF with 3TC or FTC, that suppress replication of both viruses are preferred (9, 91). 3TC monotherapy rapidly selects for HBV resistance (92); therefore, combination therapy with one NRTI (3TC or FTC) and one NtRTI (TDF or ADV) is required. PEG-IFN can be used to treat HBV infection, but the side effects limit the length of therapy, and the response appears to be lower in HIV-HBV-coinfected patients (91). It should be noted, however, that PEG-IFN is the only drug that can eliminate covalently closed circular (ccc) HBV DNA to cure chronic HBV infection (93).

Of note, there are 8 different HBV genotypes (A to H), each with certain geographic predilections (94). There is evidence that genotype impacts IFN responsiveness. In particular, in the treatment of hepatitis B e antigen-positive chronic hepatitis B, greater rates of hepatitis B e antigen seroconversion have been observed for genotype A than for genotype D and for genotype B than for genotype C (95). A correlation between genotype and treatment response to other anti-HBV therapies has not been established.

**Nucleoside/Nucleotide Analogues**

**Adefovir Dipivoxil**

**Pharmacology**

Adefovir-dipivoxil is a diester prodrug that is converted to the active drug ADV. ADV-dipivoxil is administered without regard to food, and the bioavailability is 59%. The half-life of ADV is 7.5 h, and it is excreted by the kidneys. There are no data for placental passage of the drug. ADV was originally developed as an antiretroviral drug; however, the high dose required for HIV therapy is associated with nephrotoxicity (91). A much lower dosage is effective against HBV (90, 91). ADV is effective for treatment of chronic HBV infection. The rate of viral load decline is slower, but development of drug resistance is delayed compared to that seen with other NRTIs and NtRTIs (96) that are active against HBV. The primary role of ADV is in the treatment of 3TC-resistant HBV.

infection (97). However, TDF and entecavir have largely replaced ADV for this indication.

### Drug Interactions
ADV is not a substrate, inhibitor, or inducer of any of the CYP450 isoenzymes. There is no interaction with 3TC, ETV, or TDF. It is possible that drugs that reduce renal function or compete for active tubular secretion could increase the concentration of ADV and/or the coadministered drug in serum.

### Emtricitabine

#### Pharmacology
See the discussion on HIV antiviral agents above and Table 1. Emtricitabine (FTC) is approved for antiviral therapy in HIV-infected patients. It has activity against HBV but is not licensed for HBV antiviral therapy. FTC and 3TC are biochemically similar and appear to be interchangeable for potential use in treatment of HIV-HBV-coinfected patients. However, they also share the same HBV resistance mutations; therefore, combined therapy with these two drugs is not recommended (11, 91). In addition, as with 3TC, severe acute exacerbations of HBV can occur once therapy is discontinued (9).

### Drug Interactions
See the discussion on HIV antiviral agents above.

### Entecavir

#### Pharmacology
The bioavailability of entecavir (ETV) is approximately 100%, and the half-life is 24 h. ETV should be administered without food. It is excreted by the kidney (62 to 73%) mainly as unmetabolized drug. ETV maintains activity against lamivudine-resistant HBV, but a higher dose is recommended for patients with lamivudine-resistant HBV infection (91). ETV has shown low activity against HIV; however, there is evidence that resistance mutations are selected. For this reason, it is recommended that ETV only be used in HIV-coinfected patients if they are receiving effective antiretroviral therapy (90, 91, 98).

#### Drug Interactions
ETV is not a substrate, inhibitor, or inducer of any of the CYP450 isoenzymes. There is no interaction with 3TC, ADV, or TDF. It is possible that drugs that reduce renal function or compete for active tubular secretion could increase the concentration of ETV and/or the coadministered drug in serum.

### Lamivudine (3TC)

#### Pharmacology
See the discussion on HIV antiviral agents above as well as Table 1. Lamivudine (3TC) was the first nucleoside
analogue that was approved for chronic HBV infection. Because it has activity against both HIV and HBV, it has been effective in reducing loads of both viruses in plasma as part of cART regimens. However, HBV-specific drug resistance mutations are selected over long-term therapy at a higher rate (20% per year) in coinfected patients than in those that are HIV negative (90). Selection of HBV drug resistance mutations eventually decreases efficacy for treatment of chronic hepatitis. Discontinuation of 3TC in HBV-infected patients can produce severe flare-ups of hepatitis, which are usually self-limited but have been fatal in a few cases. Another common problem is the rebound viremia that occurs when therapy is terminated (9). This is thought to be derived from the viral cccDNA, which is not affected by nucleoside or nucleotide therapy and remains in the infected hepatocytes (11). For coinfected patients, recent recommendations suggest using combination dual NTRI-NtRTI therapy that includes TDF to reduce the rate of selection of HBV 3TC-resistant strains (99).

**Drug Interactions**
See the discussion on HIV antiviral agents above.

Tenofovir Disoproxil Fumarate

**Pharmacology**
The bioavailability of tenofovir (TDF) is 68%, and it can be administered with or without food. The half-life is 40 to 50 h, and the drug is excreted mainly by the kidneys. TDF has a relatively low genetic barrier to resistance; therefore, it is not recommended as a first-line drug for treatment of chronic HBV (100). Hepatitis exacerbations have also been reported upon discontinuation of TDF.

**Drug Interactions**
Tenofovir and FTC or TDF are HIV coinfected, (ii) are hypersensitive to PEG-IFN, (iii) have autoimmune hepatitis, or (iv) have hepatic decompensation (91, 104). Agents of action, route of administration, and adverse effects of each drug are summarized in Table 4.

**Acyclovir and Valacyclovir**

Acyclovir (ACV) was one of the first effective antiviral compounds available clinically and has been in general use for the past 30 years. Valacyclovir (val-ACV), the L-valyl ester produg, is rapidly converted to ACV after oral administration (106). ACV is phosphorylated by the viral thymidine kinases (TK) of herpes simplex virus 1 (HSV-1), HSV-2, and varicella-zoster virus (VZV) and by the UL97 kinase of human cytomegalovirus (HCMV) (107).

**Spectrum of Activity**
ACV and val-ACV are active against HSV-1, HSV-2, VZV, and EBV (108). Of note, ACV and val-ACV are active only against replicating virus. Therefore, their role in the treatment of EBV-associated disease processes, which are primarily driven by latent virus, is limited (109). In addition, both drugs have some activity against HCMV. Although ACV and val-ACV are not recommended for HCMV treatment, they have been used prophylactically to prevent HCMV disease in some patients following transplantation (110, 111).

**Pharmacology**
The pharmacokinetics of ACV after oral administration has been evaluated in healthy volunteers and in immunocompromised patients with HSV and VZV infection. The plasma protein binding for val-ACV is 13.5 to 17.9% and for ACV is 22 to 33%. The bioavailability of ACV administered as val-ACV is 54%, while the bioavailability resulting from oral ACV is 12 to 20%. The ACV half-life is 2.5 to 3.3 h in patients with normal renal function but increases to 14 h in patients with end stage renal disease (106). ACV may be administered with or without food.

ACV is excreted by the kidney with inactive metabolites 9-[(carboxymethoxy) methyl] guanine and 8-hydroxy-9-[2- (hydroxyethoxy)methyl]guanine. A dosage adjustment is recommended for patients with reduced renal function (106).

**Drug Interactions**
There are no clinically significant drug-drug interactions in patients with normal renal function.

<sup>b</sup>GI (gastrointestinal) symptoms include nausea, vomiting, and diarrhea.

<sup>c</sup>Valacyclovir used in some transplant settings for HCMV prophylaxis.

<sup>d</sup>Cidofovir also has reported activity against human papillomavirus, polyomavirus, adenovirus, and poxvirus.

<sup>e</sup>Ganciclovir and valganciclovir also have in vitro activity against EBV, HHV-6, HHV-7, and HHV-8.

<sup>f</sup>Penciclovir is used to treat herpes labialis but also has activity against HSV2 and VZV.

<sup>g</sup>Trifluridine is used to treat herpes keratitis but also has activity against HSV2 and VZV.
Cidofovir
Cidofovir (CDV) is a nucleotide analogue of deoxycytidine monophosphate, which does not require a virus-encoded enzyme for activation. After phosphorylation by cellular kinases, CDV diphosphate becomes the active nucleotide triphosphate, which inhibits the HCMV DNA polymerase. In HCMV, two successive CDV molecules must be incorporated for complete chain termination (112).

Spectrum of Activity
CDV is active against several herpesviruses, including HCMV, HSV, and VZV (108). CDV also has antiviral activity against poxviruses (113), adenovirus (114), polyomaviruses (115), and human papillomavirus (116, 117).

Pharmacology
CDV must be administered with probenecid (118, 119). Approximately 90% of the CDV dose administered is recovered unchanged in the urine within 24 hours. The half-life is 2.4 to 3.2 h. When CDV is administered with probenecid, the renal clearance of CDV is reduced to a level consistent with creatinine clearance, suggesting that probenecid blocks active renal tubular secretion of CDV (119). In vitro, CDV is less than 6% bound to plasma or serum proteins.

Drug Interactions
No clinically significant interactions have been identified for CDV. However, the required administration of probenecid with CDV may produce drug-drug interactions resulting from the potential block of acidic drug transport in the kidney (119).

Foscarnet

Spectrum of Activity
Although foscarnet (FOS) is active against several herpesviruses including HSV, HCMV, VZV, and EBV, it is most commonly used to treat drug-resistant HSV and HCMV.

Pharmacology
Pharmacokinetic data indicate that FOS undergoes negligible metabolism, appears to be distributed widely from the circulation, and is eliminated via the renal route. The available data, however, indicate that the pharmacokinetics of the drug varies among patients and within the individual patient, particularly with regard to plasma FOS levels (120). The FOS terminal half-life determined by urinary excretion is 87.5 ± 41.8 hours, possibly due to release of FOS from bone (121). Approximately 90% of FOS is excreted as unchanged drug in urine. Systemic clearance of FOS decreases and half-life increases with diminishing renal function, which may require FOS dosage modification (122).

Drug Interactions
Because FOS is reported to decrease calcium concentrations in serum, caution is advised for patients receiving agents known to affect calcium levels in serum such as intravenous pentamidine. Renal impairment is a major adverse effect of FOS; therefore, the use of FOS in combination with other potentially nephrotoxic drugs such as aminoglycosides, amphotericin B, and intravenous pentamidine (123) should be avoided.

Ganciclovir and Valganciclovir
Ganciclovir (GCV) was the first effective anti-HCMV drug developed for clinical use. GCV is an acyclic nucleoside analogue of 2′-deoxyguanosine, which requires phosphorylation by a viral kinase to become active. GCV monophosphate is subsequently phosphorylated to the di- and triphosphate forms by cellular kinases (7).

Spectrum of Activity
GCV is active against HCMV as well as HSV-1, HSV-2, VZV, EBV, HHV-6, HHV-7, and HHV-8 (124–127).

Pharmacology
Valganciclovir (val-GCV), the l-valyl ester prodrug of GCV, is rapidly converted to GCV after oral administration (128). The bioavailability of val-GCV is 60.9% compared to 5.6% for the oral formulation of GCV. The half-life of GCV is 4 h in healthy volunteers and 6.5 h in transplant recipients (129, 130). GCV is only 1 to 2% protein bound. Renal excretion of unchanged drug by glomerular filtration and active tubular secretion is the major route of elimination of GCV (91%). Val-GCV should be administered with food.

Penciclovir and Famciclovir
Famciclovir (PCV), an oral prodrug, is the diacetyl 6-deoxy analogue of penciclovir (PCV) (131), which undergoes rapid conversion to the active compound, PCV. PCV is available only as a 1% cream for the topical treatment of herpes labialis (132). FCV was developed to improve the bioavailability of the parent compound (133).

Spectrum of Activity
PCV and FCV are active against HSV-1, HSV-2, and VZV (134). Neither of these compounds is active against other human herpesviruses.

Pharmacology
The bioavailability of PCV is 77%, and the half-life is 2 h. It can be given with or without food. PCV is <20% protein bound and is eliminated in the urine (73%) and feces (27%) (135). Although PCV is structurally related to ACV, it has a higher affinity for the HSV TK than ACV. However, ACV triphosphate has a higher affinity for the HSV DNA polymerase than does PCV triphosphate. As a result, the two compounds have similar anti-HSV potencies (136).

Drug Interactions
No clinically significant drug interactions have been identified for PCV.

Trifluridine

Spectrum of Activity
Trifluridine is a fluorinated pyrimidine nucleoside approved for the topical treatment of epithelial keratitis
caused by HSV (137). It has activity against HSV-1, HSV-2, and vaccinia virus (138).

**Pharmacology**

Intraocular penetration of trifluridine occurs after topical instillation into the eye. Decreased corneal integrity or stromal or uveal inflammation may enhance the penetration of trifluridine into the aqueous humor. Systemic absorption following therapeutic dosing with trifluridine appears to be negligible (139).

**Drug Interactions**

There are no reported drug interactions by the topical route of administration.

**n-Docosanol**

**Spectrum of Activity**

*n*-Docosanol exhibits *in vitro* antiviral activity against several lipid-enveloped viruses including HSV-1, HSV-2, and RSV (140).

**Pharmacology**

A topical preparation of *n*-docosanol is available without prescription as a 10% cream for the treatment of herpes labialis.

**Drug Interactions**

There are no reported drug interactions with topical administration.

**Other Drugs against Herpesviruses**

There are several antiviral agents that are undergoing clinical trials or that are approved for conditions other than antiviral therapy. Maribavir is a novel antiviral agent in the benzimidazole drug class (141). Unlike ganciclovir, which is phosphorylated by the UL97 kinase, maribavir inhibits UL97 kinase activity directly. Importantly, maribavir has also been found to be effective *in vitro* against ganciclovir-resistant strains of HCMV. Maribavir is not associated with nephrotoxicity or hematologic toxicities but has been associated with taste disturbances (142). Unfortunately, phase 3 clinical trials of maribavir for the prevention of CMV disease in stem cell and liver transplant recipients have found maribavir to be inadequate for prevention of CMV disease (143, 144). However, there is speculation that this lack of demonstrable efficacy may be due to inadequate dosing.

Two agents that have antiviruses against activity and are currently in phase 3 studies are brincidofovir and letermovir. Brincidofovir is an orally administered lipid conjugate of cidofovir (145). It has activity against all of the herpesviruses, including GCV-resistant CMV and ACV-resistant HSV, as well as polyomaviruses, poxviruses, and adenovirus. Letermovir prevents CMV replication through inhibition of the terminase complex (145).

Two additional drugs that are approved for other medical conditions also have been reported to have antiviral activity against HCMV, although no clinical trials have been conducted. These are leflunomide, which is approved for treatment of rheumatoid arthritis (146, 147), and arteasunate, which is an antimalarial agent (148, 149).

**Agents Against Influenza Viruses**

The two classes of antiviral agents for the treatment of influenza are M2 protein inhibitors and neuraminidase inhibitors. The M2 inhibitors are active against only type A influenza viruses, while the neuraminidase inhibitors have activity against both type A and type B viruses (150–152). The structure, mode of action, route of administration, and adverse effects of each drug are summarized in Table 5. Recommendations for use of these antivirals for influenza prevention and therapy are available from the Centers for Disease Control and Prevention website (http://www.cdc.gov/flu).

**M2 Protein Inhibitors**

The virus-encoded M2 protein facilitates the hydrogen ion-mediated dissociation of the matrix protein-ribonucleoprotein (RNP) complex within the endosome and the release of the viral RNP into the cytoplasm of the host cell. The M2 inhibitors block the passage of H+ ions

through the M2 ion channel, which prevents uncoating of the virus (105, 150, 153, 154).

Amantadine and Rimantadine
The adamantanes differ in their metabolism and adverse effects, but they have similar antiviral activity against influenza A viruses. Neither drug has activity against influenza B viruses. Recent reports indicate that both the seasonal influenza virus, H3N2, and the current pandemic virus, H1N1, have a high incidence of resistance to both drugs (156, 157); therefore, the adamantanes are no longer recommended for influenza prophylaxis and empiric therapy.

Neuraminidase Inhibitors
The influenza virus neuraminidase (NA) is an envelope glycoprotein that cleaves the terminal sialic residues, releasing the virion from the infected cell. The virus-encoded NA allows the influenza virus to spread from cell to cell. Three neuraminidase inhibitors (NAIs) are approved for the treatment of influenza A and B viruses: oseltamivir, zanamivir, and peramivir (158). Of these, oseltamivir is the most widely used. In 2007–2008, a high percentage of seasonal H1N1 influenza virus isolates were resistant to oseltamivir as the result of a single amino acid substitution, but they remained sensitive to zanamivir (157, 159). In 2011, the CDC estimated that greater than 99% of circulating influenza virus strains were susceptible to the NAIs (160, 161).

Oseltamivir
Pharmacology
Oseltamivir phosphate is an ethyl ester prodrug requiring ester hydrolysis for conversion to the active form, oseltamivir carboxylate. After oral administration, oseltamivir phosphate is readily absorbed from the gastrointestinal tract and is extensively converted to oseltamivir carboxylate, predominantly by hepatic esterases (162). At least 75% of an oral dose reaches the systemic circulation as oseltamivir carboxylate. The binding of oseltamivir carboxylate to plasma protein is low. The plasma half-life is 6 to 10 hours. There are fewer side effects if administered with food. Oseltamivir carboxylate is not further metabolized and is eliminated in the urine (161). The efficacy of oseltamivir in preventing naturally occurring influenza illness has been demonstrated in treatment and prophylaxis studies (163–165).

Drug Interactions
Studies of oseltamivir suggest that clinically significant drug interactions are unlikely, because neither the drug nor the metabolite oseltamivir carboxylate is a substrate for the CYP450 isoenzymes or for glucuronyltransferases. The potential exists for interaction with other agents such as probenecid that are excreted in the urine by the same pathways (161). Oseltamivir should not be administered in a time period 2 weeks before and 48 h after administration of live influenza vaccine.

Peramivir
Peramivir was approved in late 2014 for the treatment of uncomplicated influenza.

Pharmacology
Peramivir has poor oral bioavailability and is therefore only available as an intravenous formulation. It is given as a single dose for the treatment of uncomplicated influenza. It is primarily eliminated by the kidneys (86).

Drug Interactions
There are no significant drug interactions (87).

Zanamivir
Zanamivir treatment has been shown to reduce the severity and duration of naturally occurring, uncomplicated influenza illness in adults (166). Zanamivir is administered only to the respiratory tract by oral inhalation using a blister pack (167). The contents of each blister are inhaled using a specially designed breath-activated plastic device for the inhaling powder. This route rapidly provides high local concentrations at the site of delivery. Because of the respiratory route of administration, zanamivir is contraindicated in patients with underlying airway disease such as asthma. As noted above, the H1N1 strains that have become resistant to oseltamivir remain sensitive to zanamivir.

Pharmacology
The absolute oral bioavailability of zanamivir is low, averaging 2%. After intranasal or oral inhaled administration, a median of 10 to 20% of the dose is systemically absorbed, with maximum concentrations in serum generally reached within 1 to 2 hours. The remaining 70 to 80% is left in the oropharynx and is eliminated in the feces. The median serum half-life ranges between 2.5 and 5.5 hours, and the systemically absorbed drug is excreted unchanged in the urine. The low level of absorption of the drug after inhalation produces low concentrations in serum with only modest systemic zanamivir exposure (161).

Drug Interactions
Zanamivir is not metabolized; therefore, there is a very low potential for drug-drug interaction (168).

Mechanisms of Resistance to Antiviral Agents
ROBERT W. SHAFAER AND SUNWEN CHOU

Antiviral drug resistance is mediated most often by mutations in the molecular targets of drug therapy, and the development of drug resistance is the most compelling evidence that an antiviral drug acts specifically by inhibiting the virus rather than its cellular host. Drug-resistant virus subpopulations may exist at low levels in clinical isolates or may arise only during drug exposure. The error-prone polymerase enzymes in RNA viruses render the development of resistance more frequent than in DNA viruses.

Drug-resistant viruses are identified by in vitro passage experiments in which wild-type viruses are cultured in increasing concentrations of an inhibitory drug and by ex vivo analysis of virus isolates obtained from individuals receiving antiviral therapy. Measuring drug susceptibility involves culturing a fixed inoculum of virus in serial dilutions of an antiviral therapy. Measuring drug susceptibility involves culturing a fixed inoculum of virus in serial dilutions of an inhibitory drug and by experiments in which wild-type viruses are cultured in vitro. Drug susceptibility assays are not designed to determine the drug concentration required to inhibit virus replication in vivo. They are instead designed to identify viruses with reduced drug susceptibility relative to wild-type viruses. The clinical significance of reductions in drug susceptibility is determined by studying the treatment response of individuals harboring viruses with reduced susceptibility.

One of the fundamental paradigms of viral drug resistance to emerge in the past 2 decades is that antiviral drug resistance mutations often consist of major mutations that reduce drug susceptibility by themselves and accessory mutations that generally compensate for the decreased fitness associated with many of the major mutations. With a few notable exceptions, major drug resistance mutations do not occur in previously untreated patients, whereas accessory mutations are often polymorphic.

HERPESVIRUSES
All currently licensed systemic drugs for the herpesviruses target the viral DNA polymerase (Table 1). Nucleoside analogs that are selectively phosphorylated by viral enzymes are preferred as initial therapy. Oral bioavailability is improved by the use of prodrugs that are metabolized to the parent drug. Acyclovir (ACV), its prodrug valacyclovir, and famciclovir, the prodrug of penciclovir (PCV), have been used successfully for genital herpes simplex virus (HSV) infections, varicella-zoster virus (VZV) infections, and mucocutaneous HSV infections in immunocompromised hosts. Ganciclovir (GCV) and its prodrug valganciclovir are used to treat cytomegalovirus (CMV) infection. These guanosine analog antivirals are supplemented by foscarner (phosphonoformate [FOS]), a pyrophosphate analog, and cidofovir (CDV), a cytosine nucleotide analog, which do not depend on prior activation by viral enzymes. FOS and CDV are generally used as second- and third-line drugs when there is a lack of response to initial therapy. An orally bioavailable hexadecylxypoxyl conjugate of CDV (brincidofovir, CMV001) is in clinical trial.

Herpes Simplex Virus
ACV and PCV are initially monophosphorylated by the HSV thymidine kinase (TK) and then converted to triphosphates by cellular enzymes. ACV triphosphate causes chain termination of replicating DNA and formation of a dead-end complex that strongly inhibits the viral DNA polymerase (1). As compared with ACV, PCV triphosphate is formed at higher concentration and persists longer in infected cells but is a less potent inhibitor of the viral DNA polymerase (2). Because the viral TK enzyme is not essential for HSV replication, a wide variety of TK mutations may decrease the phosphorylation of nucleoside analogs, and this is by far the most common mechanism of ACV and PCV resistance (3). TK mutations confer no cross-resistance to drugs that act independently of virally mediated phosphorylation, including FOS and CDV.

Drug-resistant TK mutants are classified as TK negative, usually arising from frameshift or stop mutations that delete important functional domains, or TK low, where the mutation reduces the phosphorylation of both natural nucleosides and antiviral drugs (3–5). TK-altered mutants that selectively reduce the phosphorylation of antiviral nucleosides occur less commonly. Although TK mutations selected by PCV may differ from those selected by ACV, cross-resistance is expected (6, 7). Among clinical isolates, frameshifting nucleotide insertion or deletion mutations at homopolymeric TK loci (e.g., runs of G bases) are among the most common mutations (5). TK amino acid substitutions show some clustering at conserved regions such as ATP and nucleoside binding sites. The effect of specific mutations on TK activity and drug susceptibility can be defined by site-directed mutagenesis of control strains, but many remain uncharacterized because of the tremendous diversity of TK mutations and sequence polymorphisms (3–5, 7). Mixed heterogeneous populations of resistant genotypes evolve in individual subjects (8, 9). Because these factors complicate the genotypic

**Varicella-Zoster Virus**

VZV infections are generally treated with the oral produgs valacyclovir or famciclovir, or with intravenous ACV, with outcomes dependent more on the early initiation of adequately potent therapy than on antiviral susceptibility. However, immunocompromised subjects may develop prolonged and recurrent infection, increasing the risk of emergence of resistant strains after extensive antiviral treatment (19, 20).

Mechanisms of VZV drug resistance are analogous to those of HSV. Most ACV-resistant VZV contains TK gene mutations that result in TK deficiency or altered substrate specificity (21). These include stop, frameshift, and substitution mutations (21, 22). Detection of such mutations may be used for genotypic resistance assays (23), since the phenotypic resistance testing of VZV clinical isolates is more limited than for HSV. Although VZV TK appears to have less sequence polymorphism than the HSV TK, uncharacterized amino acid substitutions prevent clear interpretation (23). Alternative drugs for ACV-resistant VZV are FOS (24, 25) and CDV. ACV and FOS resistance maps to codons in conserved functional domains II and III of the VZV DNA polymerase, with some mutations conferring cross-resistance (21).

**Cytomegalovirus**

CMV lacks a TK, but does have another kinase encoded by the UL97 gene, which is essential for the normal production of normal amounts of infectious virus in cell culture and is a potential antiviral drug target (26). GCV, the standard initial therapy for CMV disease, is monophosphorylated by the UL97 kinase and subsequently converted to the active triphosphate form in infected cells (27). Risk
factors for CMV drug resistance are prolonged viral replication (as seen in immunocompromised hosts) coupled with extended antiviral drug exposure, usually a few months or more (28). Genotypic resistance testing for CMV is standard clinical practice because of the unavailability of timely phenotypic testing on clinical isolates. An extensive database of resistance mutations validated by recombinant phenotyping provides a basis for practice guidelines (29).

More than 90% of GCV-resistant CMV isolates contain UL97 mutations that are proven or presumed to impair GCV phosphorylation with relative preservation of biological kinase function (28). UL97 mutations in GCV-resistant CMV isolates are preferentially localized to codons 460, 520, and 590-607, with the seven most common mutational alleles being M460V/I, H520Q, C592G, A594V, L595S, and C603W (28). These specific mutations confer a 7- to 10-fold increased resistance to GCV (drug EC50), except for C592G, which confers 3-fold increase. Various other point mutations and in-frame deletion mutations conferring varying degrees of GCV resistance have been observed, mainly at codons 590-607 (30). UL97 mutation is not known or expected to be involved in resistance to FOS or CDV.

After prolonged exposure to GCV, mutations in the UL54 DNA polymerase (pol) gene may be selected, usually adding to preexisting UL97 mutations and contributing to an increased overall level of resistance to the drug (31–33), although the pol mutations by themselves typically confer low-grade resistance. Uncommonly, mutation in the pol gene may precede the initial marker of GCV resistance (28). Cross-resistance to other drugs is expected for GCV-resistant pol mutants. Mutations conferring GCV and significant CDV resistance have been reported at pol codons 301, 408-413, 501-545 (which corresponds to exonuclease regions), and 978-985 (region V), namely A987G (28).

FOS-resistance mutations in CMV pol range widely but often map to amino-terminal, palm, and finger structural features of the enzyme, including conserved sequence regions II (e.g., codons 700 and 715), III (e.g., codons 802 and 809), and VI (e.g., codon 781) and also some nonconserved loci (e.g., codon 756) (28). Most FOS-resistance mutations confer 2- to 5-fold increased EC50 values. FOS-resistance mutations may confer low-grade GCV ± CDV cross-resistance (28), but are not preferentially selected after initial treatment with GCV. Such cross-resistance likely involves polymerase residues with roles in recognition of the incoming nucleotide triphosphate and in pyrophosphate exchange. Uncommonly, single pol mutations (e.g., A834P or 981-2del) are sufficient to confer significant resistance to all three drugs, GCV, CDV, and FOS (32, 34). Some CMV pol mutations, especially in the codon range 578-845, have been associated with a slow growth phenotype (20, 35–37). Despite the extensive database of baseline sequence polymorphisms, there remain many pol sequence variants of unclear relevance for drug resistance and that require characterization by recombinant phenotyping (28).

**HUMAN IMMUNODEFICIENCY VIRUS**

Twenty-seven antiretroviral drugs belonging to six classes have been approved for human immunodeficiency virus type 1 (HIV-1) treatment, including eight nucleoside and one nucleotide reverse transcriptase (RT) inhibitor (NRTI), nine protease inhibitors (PIs), five nonnucleoside RT inhibitors (NNRTIs), three integrase inhibitors (INIs), one fusion inhibitor, and one CCR5 inhibitor (Table 2).

HIV-1 genetic variability results from the high rate of RT enzyme errors, the high rate of virus replication in vivo, and recombination when viruses with different sequences infect the same cell, and the accumulation of proviral variants during the course of infection (38). The virus population within an individual consists of an ensemble of innumerable related genotypes often called a quasispecies. The selection of drug-resistant variants depends on the extent to which a virus replication continues during incompletely suppressive therapy, the ease of acquisition of a particular mutation, and the effect of drug-resistance mutations on drug susceptibility and virus replication.

In previously untreated individuals with drug-susceptible HIV-1, combinations of three drugs from two drug classes lead to prolonged virus suppression and, in most patients, immune reconstitution. Once complete HIV-1 suppression is achieved, it usually persists indefinitely if therapy is not interrupted. However, because antiretroviral therapy does not inhibit proviral HIV-1 DNA, viral eradication is not possible. Recurrent viremia and immunological decline ensue whenever therapy is discontinued, regardless of the previous duration of virologic suppression.

HIV-1 drug resistance may be acquired or transmitted. Drug resistance is acquired in patients whom ongoing virus replication occurs in the presence of incompletely suppressive therapy. Whereas incompletely suppressive therapy was once a consequence of an insufficient number of active drugs, it is now usually a consequence of treatment interruptions or incomplete adherence. The proportion of HIV-1-infected persons with transmitted drug resistance is about 15% in the United States, 10% in Europe, 7% in South and Central America, and <5% in most parts of sub-Saharan Africa and South and Southeast Asia (39). The presence of either acquired or transmitted drug resistance before starting a new antiretroviral treatment regimen is associated with reduced virological response to that regimen.

**NRTI Resistance**

Of the eight U.S. Food and Drug Administration (FDA)-approved NRTIs, five are recommended for routine clinical use: abacavir, emtricitabine, lamivudine, tenofovir, and zidovudine. Dideoxycytidine has rarely ever been used. Stavudine and didanosine are being used less often because of their toxicities. NRTIs are usually administered in two-drug combinations together with an NNRTI, PI, INI, or CCR5 inhibitor. All recommended first-line and salvage therapy regimens include one of the cytosine analogs lamivudine or emtricitabine (40).

NRTIs must be triphosphorylated (or diphosphorylated in the case of the nucleotide analog tenofovir) to their active form. The dependence of NRTIs on intracellular phosphorylation complicates the in vitro assessment of their activity because phosphorylation occurs at different rates in the highly activated lymphocytes used for susceptibility testing and the wider variety of cells infected in vivo, explaining why NRTI resistance levels differ in their dynamic ranges (41, 42). Specifically, clinical isolates from persons failing NRTI therapy may have several hundred-fold reductions in susceptibility to zidovudine, lamivudine, and emtricitabine, but will rarely have more than 5-fold reductions in susceptibility to didanosine, stavudine, and tenofovir. However, slight reductions in susceptibility to this second category of drugs—as low as 1.5-fold—are clinically significant.

There are two biochemical mechanisms of NRTI resistance. One mechanism is mediated by discriminatory mutations that reduce RT affinity for an NRTI, preventing its addition to the growing DNA chain (43). Another mechanism is mediated by mutations that facilitate primer unblocking.

</table>
through the phosphorolytic removal of NRTIs incorporated into the HIV-1 primer chain (reviewed in reference 44). Primer unblocking mutations, because they are selected by the thymidine analog inhibitors zidovudine and stavudine, are also referred to as thymidine analog mutations or "TAMs." The most common TAMs include M41L, D67N, K70R, L210W, T215Y/F, and K219E. A subset of these mutations—M41L, L210W, and T215Y—is associated with greater cross-resistance to didanosine, abacavir, and tenofovir (45–47).

Lamivudine and emtricitabine have a low genetic barrier to resistance in that a single mutation—the discriminatory mutation M184V (or less commonly M184I)—confers >200-fold reduced susceptibility to these drugs. Indeed, M184V is the most common mutation to emerge in patients developing virological failure on a first-line regimen. Although M184V limits the antiviral activity of lamivudine and emtricitabine, they retain efficacy because M184V reduces HIV-1 fitness and increases susceptibility to zidovudine, stavudine, and tenofovir (42).

In patients receiving regimens without thymidine analogs, K65R, L74V/I, and Y115F are the mutations that occur most commonly in combination with M184V (48). K65R reduces susceptibility to tenofovir, abacavir, didanosine, stavudine, lamivudine and emtricitabine and increases susceptibility to zidovudine (49, 50). L74V/I reduces abacavir and didanosine susceptibility. Y115F reduces abacavir and tenofovir susceptibility. K65N and K70E/G/Q are uncommon discriminatory mutations that reduce susceptibility to tenofovir, stavudine, abacavir, and didanosine. T69SSS and Q151M are multi-NRTI resistance mutations. T69SSS is a double amino insertion at HIV-1 RT position 69, which usually occurs with multiple TAMs, and in this setting it causes intermediate resistance to lamivudine and emtricitabine and high-level resistance to the remaining NRTIs (51). Q151M usually occurs in combination with several other uncommon mutations (A62V, V75I, F77L, and F116Y). It causes intermediate resistance to tenofovir, lamivudine, and emtricitabine and high-level resistance to the remaining NRTIs (52, 53). Amino acid deletions between codons 67 and 69 are also associated with multi-NRTI resistance. Deletions at codon 67 generally occur with T69G and multiple TAMs or Q151M (54). Deletions at codon 69 generally occur with K65R or Q151M (54).

**NNRTI Resistance**

The NNRTIs inhibit HIV-1 RT allosterically by binding to a hydrophobic pocket about 10 Å from its active site (43). This hydrophobic NNRTI-binding pocket is less well conserved than the enzyme’s dNTP-binding active site. In-

**PI Resistance**

There are nine FDA-approved PIs: atazanavir, darunavir, fosamprenavir, indinavir, lopinavir, nelfinavir, ritonavir, saquinavir, and tipranavir. Ritonavir is now administered solely at subtherapeutic doses to increase or “boost” the tissue concentrations of other PIs via its inhibition of the cytochrome P4503A pathway. Nelfinavir and indinavir, once commonly used PIs, are rarely used because of their poor pharmacokinetic properties when administered alone and their toxicity when administered with ritonavir. Of the remaining six PIs, lopinavir (which is coformulated with ritonavir) and ritonavir-boosted atazanavir and darunavir are used most frequently.

More than 80 nonhomoplastic PI-selected mutations have been reported (63). Most of these reduce susceptibility to one or more PIs (64). Mutations in the substrate cleft, including D30N, V32I, I47V/A, G48V/M, I50V/L, V82A/I/L/F/S, and I84V, reduce PI-binding affinity. Several mutations in the enzyme flaps, including M46I/L and I54V/M/L/T/S/A, and the enzyme core, including L33F, L76V, and N88S, also markedly reduce susceptibility. These and other accessory mutations indirectly reshape the substrate cleft or compensate for the decreased kinetics of enzymes with substrate cleft mutations (65, 66). Compensatory mutations at several Gag cleavage sites are also selected during PI treatment (67).

Ritonavir-boosted lopinavir and darunavir have high genetic barriers to resistance, with multiple mutations required before antiviral activity is compromised (68, 69). Lopinavir/ritonavir alone and darunavir/ritonavir alone are each effective at fully suppressing HIV-1 RNA levels below detectable levels for 48 weeks in most patients, and monotherapy with these PIs is a highly effective simplification regimen (70). Viruses from patients with virological failure on an initial boosted-PI-containing regimen rarely contain PI-resistance mutations, suggesting that such virologic failure may often result from nonadherence rather than PI resistance. Indeed, a high proportion of such patients often experience reexpression of virus levels without a change in therapy.

**INI Resistance**

Following reverse transcription and the generation of double-stranded viral DNA, HIV-1 integrase catalyzes the cleavage of the conserved 3’ dinucleotide CA (3’ processing) and the ligation of the viral 3’-OH ends to the 5’ DNA
of host chromosomal DNA (strand transfer). HIV-1 IN is composed of three functional domains: the N-terminal domain (NTD), encompassing amino acids 1 to 50; the catalytic core domain (CCD), which encompasses amino acids 51 to 212 and contains the catalytic triad D64, D116, and E152; and the C-terminal domain (CTD), which encompasses amino acids 213 to 288 and binds host DNA nonspecifically. IN strand transfer inhibitors bind the CCD active site and chelate the divalent metal ions critical for enzymatic function. Raltegravir was licensed in 2008. Eltegravir was licensed in 2012 as a fixed-dose combination with the CYP3A4 inhibitor cobicistat and the NRTIs tenofovir and emtricitabine. Dolutegravir was licensed in 2013.

There are crystal structures of the CCD plus CTD domains, the CCD plus NTD domains, and the CCD bound to the prototype diketo acid inhibitor 5CITEP (71–73). But the relative conformation of the CCD, NTD, and CTD domains and the tetrameric functional form of HIV-1 IN have been inferred primarily from crystallographic studies of the homologous IN of the prototype foamy virus (74).

The mutations with the greatest effect on reducing INI susceptibility are highly conserved residues in the INI binding site and residues 145 to 149, which form a flexible loop important for catalysis following IN-DNA binding. Q148 interacts with a 5′-terminal cytosine of viral DNA and likely forms a hydrogen bond with most INIs (73, 75). N155 points into the active site and forms a hydrogen bond with D116, one of the three catalytic aspartate residues (76). Y143 is part of the highly flexible active-site loop that participates in DNA and INI binding.

There are three main overlapping genetic pathways to raltegravir resistance: (i) Q148H/R/K ± G140S/A/C ± E138A/K; (ii) N155H ± E92Q; and (iii) Y143C/R ± T97A (77–79). Eltegravir resistance is caused primarily by the first two mutational pathways and by T66A/I/K and S147G (80). Dolutegravir has a high genetic barrier to resistance. Clinically significant phenotypic resistance to dolutegravir appears to require Q148H/R/K + G140S/A/C plus one or more additional accessory resistance mutations (81, 82). There are also several rare mutations associated with marked reductions in eltegravir or raltegravir susceptibility, several common accessory INI-resistance mutations, and several mutations of uncertain significance selected by dolutegravir in vitro (reviewed in references 79 and 83).

### Fusion Inhibitor Resistance

The HIV-1 envelope consists of surface (gp120) and transmembrane (gp41) glycoproteins. gp120 binds to the CD4 receptor and to one of the chemokine coreceptors (CCR5 or CXCR4) on target cells. After gp120-CD4-coreceptor binding, gp41 undergoes a conformational change that promotes fusion of viral and cellular membranes. Two heptad repeat regions (HR1 and HR2) of gp41 form a helical bundle that contains trimeric belonging to HR1 and HR2. Enfuvirtide is a highly active synthetic peptide that inhibits fusion by binding to HR1 and preventing its bundling with HR2.

Enfuvirtide-resistant isolates contain either single or double mutations between positions 36 and 45 of gp41 HR1 (84, 85). Single mutants typically have on the order of 10-fold decreased enfuvirtide susceptibility, whereas double mutants typically have on the order of 100-fold decreased susceptibility. Despite the fact that enfuvirtide is one of the most potent inhibitors, the genetic barrier to enfuvirtide resistance is low, with virological rebound emerging rapidly when this drug is not administered with a sufficient number of other active inhibitors (86).

### CCR5 Inhibitor Resistance

Maraviroc allosterically inhibits gp120 ew of CCR5-tropic HIV-1 strains from binding to the seven-transmembrane G protein-coupled CCR5 receptor (87). Whereas HIV-1 gp120 binds to the N terminus and second extracellular loop region of CCR5, maraviroc binds to a pocket formed by the transmembrane helices (87). In patients receiving CCR5 inhibitors, the most common mechanism of virological failure is the expansion of preexisting CXCR4-tropic viruses that are intrinsically resistant to CCR5 inhibitors (88). Positively charged residues at positions 11 and 25 of the V3 loop of gp120 and several less common combinations of mutations primarily but not exclusively within the V3 loop are associated with CXCR4 tropism (89).

During in vitro passage experiments CCR5 inhibitor resistance develops by a different mechanism—gp120 mutations that enable HIV-1 to bind to the CCR5/CCR5-inhibitor complex, resulting in a plateau in the maximal percent inhibition at maximal CCR5 inhibitor concentrations (90). However, this mechanism of resistance occurs rarely in patients and it is not associated with a consistent pattern of responsible mutations.

### Inter-Subtype Variation

During its spread among humans, group M HIV-1 has evolved into multiple subtypes that differ from one another by 10 to 30% along their genomes (91). HIV-1 proteases and RTs of different subtypes differ by from 10 to 12% of their nucleotides and 5 to 6% of their amino acids. Naturally occurring polymorphisms differ among subtypes, but these polymorphisms are not responsible for clinically significant effects on drug susceptibility (56, 92).

Most data on the genetic mechanisms of HIV-1 drug resistance were based on observations of subtype B viruses. Although the drug-resistance mutations observed in subtype B isolates are the most common ones observed in non-B subtypes (93), many studies have reported differences in the frequency with which specific mutations occur in viruses belonging to different subtypes subjected to the same antiretroviral selection pressures (reviewed in reference 48).

### HEPATITIS B VIRUS

Hepatitis B virus (HBV) is a partially double-stranded DNA virus of about 3.2 kb. Following infection, its genome localizes to the nucleus, where it is converted to the covalently closed circular DNA (cccDNA) form that serves as template for transcription of mRNA and genomic RNA. Genomic RNA is then reverse transcribed to viral DNA, and the resulting viral cores either bud into the endoplasmic reticulum and are exported from the cell or return to the nucleus for conversion back to cccDNA. HBV cccDNA can be eliminated by cell turnover but not by drug therapy; therefore, eradication of infection occurs infrequently (94, 95).

HBV replicates at a high rate, producing about $10^{11}$ virions per day (96). In the absence of therapy, HBV DNA levels are often as high as $10^8$ to $10^9$ copies/ml. HBV polymerase, because it has RT activity, is functionally and structurally similar to HIV-1 RT and has an error rate similar to that of other retroviruses (97). However, the overlapping arrangement of open reading frames in the HBV genome limits the viability of any spontaneous mutants (98). For example, the nucleotides encoding the HBV polymerase also encode the HBV envelope in a different reading frame. Therefore, the rate at which mutations become fixed is considerably lower than for HIV-1 (99).
HBV is classified into at least eight genotypes differing from one another by about 10% of their nucleotides. Several small studies suggest that viruses belonging to different genotypes may respond differently to interferon, but there is no evidence that genotype influences the response to nucleoside analogs (102, 101). In 2001, a standardized numbering system for polymerase mutations was established for the RT part of the HBV pol gene (102).

### Anti-HBV Drug Therapy

There are two forms of interferon and five nucleoside analogs approved for the treatment of chronic HBV infection (Table 3). Alpha interferon was approved in 1992 and pegylated alpha interferon 2a was approved in 2005. Pegylated interferon remains an important treatment option because 1 year of therapy offers the possibility of sustained virological remission (103). Lamivudine (1998), adefovir (2002), entecavir (2005), telbivudine (2006), and tenofovir (2008) have also been approved. The antiretroviral drug emtricitabine, which is similar to lamivudine in its chemical structure and antiviral activity, is also used for HBV treatment because it is coformulated with tenofovir for treating HIV-1.

Both tenofovir and entecavir monotherapies are recommended regimens for initial HBV treatment because they are potent inhibitors and the emergence of drug resistance is exceedingly uncommon in patients receiving either one for initial therapy (103–105). Once the mainstay of NRTI therapy, lamivudine monotherapy is no longer recommended because of the high incidence of drug resistance associated with its use: 15 to 30% of patients treated for 1 year, 40 to 50% treated for 3 years, and 70% treated for 5 years (106). Telbivudine is associated with a 25% incidence of drug resistance at 2 years (107). Adefovir resistance occurs in about 10 and 30% of patients after 2 and 5 years, respectively (108).

### HBV RT and NRTI Resistance

Homology modeling suggests that HBV polymerase shares regions similar to the fingers, palm, and thumb configuration of HIV-1 (109, 110). High-level (>1,000-fold) lamivudine resistance is caused by a mutation, M204V/I, which is in the YMDD motif, characteristic of all RTs, and which is analogous to M184V/I, the HIV-1 lamivudine-resistance mutation (111, 112). M204V/I mutations are also frequently accompanied by compensatory mutations, particularly L180M and less commonly V173L and L80I. M204V/I causes high-level cross-resistance to emtricitabine and telbivudine but does not reduce susceptibility to the acyclic nucleotides adefovir and tenofovir (111, 112). Although viruses with M204V/I replicate less well than wild-type viruses, the development of M204V/I is associated with virological and clinical progression (113, 114).

Adefovir and tenofovir retain complete in vitro susceptibility to viruses with M204V/I and its associated mutations (115, 116). However, because tenofovir is more potent than adefovir, it is recommended for treating patients with lamivudine resistance (111). Adefovir resistance is caused by the mutations N236T and A181V/T (117–119). Although the levels of reduced susceptibility associated with these mutations—3- to 10-fold—are much lower than the levels of M204V/I-associated lamivudine resistance, these reductions are associated with virologic breakthrough (117). N236T confers intermediate cross-resistance to tenofovir but not to lamivudine, emtricitabine, or telbivudine (120, 121).

A181V and A181T emerge with lamivudine and, more commonly, adefovir (118, 122, 123). Isolates with these mutations remain susceptible to entecavir and have minimally reduced tenofovir susceptibility. A181T causes a stop codon in the S protein reading frame, potentially allowing for ongoing hepatocellular replication without accompanying viral load rebound (124). Although entecavir retains considerable antiviral activity against lamivudine-resistant variants, the risk of virological failure and emergence of high-level entecavir resistance is higher when entecavir is used to treat patients with lamivudine-resistance mutations than patients who have not been treated with NRTIs (125–127). High-level entecavir resistance results from the combination of M204V/I plus L180I and one or more of the following mutations: I169T, T184G, S202I, and M250V (111, 121, 128).

The adefovir-selected mutations N236T and A181VT confer partial cross-resistance to tenofovir (111, 121). Although tenofovir often maintains considerable antiviral activity in patients developing virological failure with adefovir, the risk of virological failure is increased in patients harboring adefovir-resistance mutations (129). In such patients, entecavir or tenofovir plus a lamivudine or emtricitabine are recommended (121).

There are anecdotal reports linking I233V to adefovir therapy and reduced adefovir susceptibility (130) and A194T to tenofovir therapy and reduced tenofovir susceptibility (131). However, neither of these mutations appears to be consistently selected by adefovir or tenofovir or to reduce their susceptibility in laboratory clones (132, 133).

### HEPATITIS C VIRUS

Hepatitis C virus (HCV) is a positive-sense, single-stranded enveloped virus with a genome of about 9.5 kb. The genome

*Emtricitabine (FTC) is not FDA approved for the treatment of HBV. Its activity and cross-resistance profile are similar to 3TC. It is frequently used in combination with tenofovir to treat HIV-coinfected patients.*
encodes a single 9.0-kb open reading frame flanked by conserved 5′- and 3′-untranslated regions. The 5′-untranslated region contains the internal ribosomal entry site (IRES), which is necessary for initiating translation. Viral replication occurs in a membrane-associated cytoplasmic replicase complex consisting of the nonstructural proteins NS3 protease, NS4A protease cofactor, NS5B RNA-dependent RNA polymerase (RdRp), and two proteins involved in maintaining the replicase complex: NS4B and NS5A. The resulting duplex RNA serves as a template for the synthesis of multiple copies of the positive-strand genome for protein production and packaging.

HCV plasma levels typically range from 10^{4.5} to 10^{6.5} IU/ml, where 1 IU is about one to five RNA copies depending on the assay used for quantification. HCV has an estimated half-life of about 3 hours and, in the absence of antiviral therapy, up to 10^{12} virions are produced daily. Like other RdRp, HCV polymerase has a high error rate, estimated at 10^{-4} substitutions per nucleotide per round of replication.

There are seven human HCV genotypes differing from one another by more than 30% of their genomes. Many of the genotypes have been subdivided into different subtypes that differ from one another by more than 15% of their genomes. HCV exists in vivo as an ensemble of viral genomes differing from one another by up to 5 to 10%.

HCV persists in up to 70% of untreated infected persons. The lifelong persistence of HCV in the majority of infected persons in the absence of treatment demonstrates its ability to evade the innate and adaptive immune system of its host. The absence of a stable intracellular reservoir, however, makes viral eradication possible. Indeed, the absence of detectable plasma virus at 6 months following treatment constitutes a sustained virological response and usually a virological cure.

Anti-HCV Therapy
Prior to 2011, pegylated interferon plus ribavirin for 6 to 12 months was the only recommended treatment for hepatitis C. This regimen cured about 45% of patients with genotype 1 infections and about 75% of patients with genotype 2 and 3 infections. In 2011, the PIs telaprevir and boceprevir became the first FDA-approved directly acting agents (DAAs) approved for use in combination with interferon plus ribavirin for treating genotype 1 HCV. Combinations of these PIs with interferon and ribavirin increased the cure rate for genotype 1 to about 70% but were associated with toxicity and a high frequency of PI resistance. In 2013, the PI simeprevir was approved for use in combination with pegylated interferon plus ribavirin for most genotype 1 viruses.

In 2013, the nucleotide analog sofosbuvir was approved for use in combination with either ribavirin alone or ribavirin plus pegylated interferon for genotype 1, 2, 3, and 4 viruses. Many other DAAs are in phase II and III clinical trials, including PIs, nucleoside/nucleotide (NIs) and nonnucleoside RdRp inhibitors (NNIs), and NS5A inhibitors (Table 4). Proof-of-concept phase II trials have demonstrated that agents targeting host factors required for HCV replication, such as microRNA-122 and cyclophilin A, markedly reduce plasma HCV levels.

Several interferon-free combinations have demonstrated higher cure rates than those obtained with the currently recommended telaprevir- and boceprevir-based regimens.

The NIs are usually active against all HCV genotypes and have high genetic barriers to resistance. The PIs, NS5A inhibitors, and particularly NNIs vary in their activity against viruses of different genotype and subtype and have lower genetic barriers to resistance (148). Most initial drug development efforts and clinical trials have targeted genotype 1 viruses. However, telaprevir is also active against genotype 2 viruses (149), and simeprevir is also active against genotype 2 and 4 viruses (150). As more data become available on the frequency of pretherapy drug-resistance mutations in different genotypes and subtypes, genotypic resistance testing will likely also be used to help select DAAs for interferon-free combination regimens.

The development of HCV replication and cell culture assays for different HCV genotypes has been essential for discovering DAAs, quantifying their inhibitory activity, and selecting for drug-resistance mutations and assessing their susceptibility.

**Interferon and Ribavirin**
Interferon plus ribavirin remains the backbone of therapy for use in combination with PIs. However, with the approval of the NI sofosbuvir and the presence of many more DAAs in development, most patients will be treated with interferon-free regimens. Ribavirin will likely remain an important component of many regimens because it is active against viruses of multiple genotypes, it does not select for resistance, and it is less expensive than DAAs. Ribavirin interferes with dNTP metabolism by inhibiting cellular inosine monophosphate dehydrogenase and may also directly inhibit HCV RNA polymerase or increase HCV mutagenesis. However, no genetic mechanism for clinically relevant ribavirin resistance has been identified.

**Protease Inhibitors**
The NS3 serine protease comprises the 189 N-terminal amino acids of NS3. NS3 protease forms a heterodimer with the 54-amino-acid NS4A, which together function to cleave four sites in the HCV polypeptide precursor to generate the N termini of NS4A, NS4B, NS5A, and NS5B. HCV protease also appears to take part in host immune evasion by cleaving several critical intracellular immune mediators (reviewed in reference 139). Multiple structures of protease with and without inhibitors have been solved by X-ray crystallography (134, 155). HCV protease contains an H57, D81, and S139 catalytic triad typical of other members of the trypsin family of serine proteases. The substrate-binding pocket contains a large number of residues including F56, V78, D79, Q80, V132, I1L135, K136, F154, K155, A157, C159, and A164 (156). HCV protease is a challenging drug target because it has a shallow substrate-binding pocket, which binds a long peptide substrate with which it forms multiple weak interactions.

Telaprevir and boceprevir are linear peptidomimetics, which bind covalently but reversibly to the protease substrate cleft (134). The newer PIs, including simeprevir (157), are noncovalent binding linear or macrocyclic peptidomimetics. Although the newer PIs have improved pharmacokinetic and toxicity profiles compared with telaprevir and boceprevir, they have overlapping resistance profiles and low genetic barriers to resistance (158, 159).

Most patients with virological failure on a PI-containing regimen develop antiviral resistance (158). The most commonly selected telaprevir- and boceprevir-resistance mutations include V36A/M and T54A/S, which cause low-level resistance, and R155K/T and A156S/T/V, which cause...
high-level resistance (160, 161). The macrocyclic PIs—including simeprevir and the investigational drugs ABT-450, asunaprevir, danoprevir, and vaniprevir—and the linear PI faldaprevir select for the mutations R155K/T, A156S/V/T, and D168A/V/T; D170A, which is associated with 2-fold reduced simeprevir susceptibility in genotype 1a and 1b replicons. Mericitabine: S282T + compensatory NS5B mutations are selected in vitro and associated with ~10-fold reduced susceptibility. L159F + L320F, which are associated with reduced mericitabine and simeprevir susceptibility and several inconsistent patterns of NS5B mutations, have been observed in patients receiving mericitabine.

The active site mutation S282T is the main NI resistance mutation selected in vitro by simeprevir, mericitabine, and simeprevir and other 2'-modified NIs (167–170). S282T, which usually requires additional NS5B mutations to compensate for its activity, increases viral mutagenesis and association with 2-fold reduced simeprevir susceptibility in genotype 1a and 1b replicons. Most HCV NIs differ from HIV-1 and HBV NRTIs in that chain termination is caused largely by steric hindrance rather than the absence of the 3'-hydroxyl group (167).

patients receiving an NI. However, these mutations have not been observed consistently or found to alone reduce NI susceptibility (168, 169).

NNIs are chemically diverse compounds belonging to four classes—thumb 1, thumb 2, palm 1, palm 2—based on their allosteric binding sites and drug-resistance mutations (134, 166, 172, 173). NNIs have a low genetic barrier to resistance, and their activity is largely restricted to genotype 1a or 1b viruses (172). Mutations associated with resistance to each of the four allosteric sites have been selected in vitro and in patients (158, 173–175). The two palm NNI-binding sites partially overlap and share several drug-resistance mutations. Several NNI-resistance mutations have been reported to occur in previously untreated individuals as dominant variants detected by standard sequencing and as minor variants detected by more sensitive methods (176, 177).

**NS5A Inhibitors**

NS5A is an ~450-amino-acid membrane-associated phosphoprotein that is an essential part of the HCV replicase complex and an antagonist of endogenous interferon. The structure of the N-terminal domain of NS5A has been crystallized, but how this protein functions is not known (134). Daclatasvir and the subsequently identified NS5A inhibitors emerged from high-throughput cell-based screens targeting nonenzymatic HCV targets (178). Daclatasvir has an EC_{50} ranging from the low picomolar range in genotype 1a and 1b replicons to the low nanomolar range for genotypes 2 through 6 (179). Rapid declines in plasma HCV levels have been reported for patients infected with genotype 1a, 1b, 3a, and 4a viruses. Daclatasvir, and at least two other NS5A inhibitors—ledipasvir and ABT-267—are in phase III trials as key components of highly effective interferon-free DAA combinations (146, 180).

The most commonly occurring daclatasvir-resistance mutations are Q30E/H/R, L31M/V, and Y93H/C/N. Each of these mutations reduces the susceptibility of both daclatasvir and ledipasvir to genotype 1a viruses by more than 100-fold. Genotype 3 viruses may be less susceptible to current NS5A inhibitors because of the natural occurrence of Y93H in 8% of patients and of several Q30 variants in 10% of patients (181).

**INFLUENZA VIRUSES**

Influenza A and B viruses have segmented minus-strand RNA genomes, each associated with a polymerase complex. The RNA particles are located inside an M1 protein shell that lines the viral lipid membrane. Embedded in the membrane of influenza A and B viruses are two spiked glycoproteins, hemagglutinin (HA) and neuraminidase (NA), and a channel protein.

Sixteen HA and nine NA influenza A antigenic subtypes have been reported in avian species. A subset of these has infected humans. There are two pandemic strains: A(H3N2), which became prevalent in 1968, and A(H1N1)pdm09, which emerged in 2009 (182) and soon replaced the previously circulating seasonal H1N1 strain. There are also two highly pathogenic avian influenza species responsible for human infections: A(H5N1), which has been widely disseminated in water fowl since at least 1997 and has infected persons in China, Southeast Asia, the Middle East, Africa, and Europe (183, 184), and A(H7N9), which has infected more than 142 persons in China since March 2013 (184).

There are two classes of licensed anti-influenza drugs in the U.S.: M2 channel blockers (the adamantane derivatives amantadine and rimantadine) and NA inhibitors (zanamivir and oseltamivir) (Table 5). M2 channel blockers are currently inactive against circulating influenza A viruses and are intrinsically inactive against influenza B viruses (185). These NA inhibitors are intrinsically active against most influenza A and B viruses. Zanamivir, which is approved for inhaled use, is also available as an investigational intravenous preparation for emergency use (186). Peramivir is an intravenous NA inhibitor that was available through an Emergency Use Authorization in 2009 during the emergence of A(H1N1)pdm09 (187).

**M2 Channel Blockers**

M2 is a tetrameric, pH-activated, proton-selective channel that plays a role in virus uncoating (188). Passage of hydrogen ions through the M2 channel into the virion following endocytosis promotes M1 dissociation from the ribonucleoprotein complexes. Amantadine and rimantadine interfere with the penetration of hydrogen ions through the M2 channel, thereby preventing transport of the ribonucleoprotein complex to the nucleus (189).

Cross-resistance to both amantadine and rimantadine results from single amino acid substitutions at position 26, 27, 30, 31 or 34 within the M2 transmembrane domain (190). Most mutations, such as those at positions 26 and 31, inhibit M2 channel binding, whereas others, such as those at position 27, may allow binding without affecting channel function (191). Adamantane resistance develops in about 30% of persons receiving amantadine or rimantadine (192, 193). Amantadine- and rimantadine-resistant variants maintain normal infectivity and virulence in animal models and cause typical disease in humans (190, 192).

Sharp increases in the prevalence of adamantane resistance began in 2002, caused almost entirely by the S31N

Neuraminidase Inhibitors (NAIs)

HA binds to sialic (N-acetylmuramidic) acid-containing cellular receptors to initiate viral infection. NA cleaves alpha-ketosidic bonds that link terminal sialic acid residues to adjacent oligosaccharide moieties, thus preventing the formation of aggregates between HA and cell surface sialic acids and allowing newly formed viruses to be released from the surface of infected cells (195). NA may also promote viral spread within mucosal secretions in the respiratory tract. Because HA binds to cellular receptors to initiate infection, whereas NA destroys cellular receptors to allow virus release from cells, a balance between these two activities is required for efficient infection (196). Indeed, HA mutations appear to modulate the replication fitness of viruses containing NAi-resistance mutations (197).

The three-dimensional structure of NA from influenza B and from several influenza A subtypes has been solved by X-ray crystallography (195, 198, 199). NA is a homotramer, containing monomers of about 470 amino acids depending on the type and subtype. NA has a hydrophobic stalk peptide at its N terminus, responsible for membrane anchoring. A globular head contains its active site—a pocket into which sialic acid and substrate analogs bind. The most commonly used numbering system is based on alignment to the influenza A N2 subtype.

Influenza NAs of different A subtypes differ from one another at about 50% of their amino acids, and influenza A differs from influenza B at about 70% of its amino acids. Nonetheless, the folded structure of the polyepitope brings into proximity a number of amino acids that are nearly invariant in all influenza strains. Eight of these strain-invariant amino acids directly contact sialic acid, including R118, D151, R152, R224, E276, R292, R371, and Y406. Ten provide the framework that supports these catalytic residues: E119, R156, W178, S179, DI/N198, I222, E227, H274, N294, and E425 (200, 201).

Oseltamivir and zanamivir are sialic acid analogs that competitively inhibit NA. They are active against a wide range of human and avian strains including influenza B and each of the nine identified avian influenza A NA subtypes (185, 201, 202). Although they are intrinsically less active against influenza B than A, oseltamivir and zanamivir have nonetheless demonstrated clinical efficacy at treating influenza B at the doses used in clinical trials (185). Oseltamivir, which is administered orally, is a carbocyclic analog of sialic acid with a bulky side chain necessitating a conformation change in NA to allow binding (199). Because zanamivir is administered as an aerosol, and because its structure is more similar to the natural sialic acid than oseltamivir, zanamivir resistance occurs much less frequently than oseltamivir resistance (200).

The NA mutations responsible for NAi resistance depend on the influenza type (A versus B) and subtype (e.g., N1 versus N2) for influenza A. In addition, specific genetic lineages within an influenza A subtype may differ in their levels of NAi susceptibility and in their predisposition to specific NAi-resistance mutations. Therefore, ongoing genotypic and phenotypic surveillance is required to identify changes in the intrinsic susceptibility of circulating NA variants and the spectrum of mutations selected in patients receiving NAIs.

NAi susceptibility is monitored primarily by genotypic and enzymatic NA inhibition assays (197, 203). Genotypic assays are useful for clinical management and surveillance (197). Enzymatic assays are useful for surveillance and for characterizing novel NA variants. Cell culture assays are possible but must be interpreted cautiously because the cells used for culture have variable concentrations of glycoconjugate receptors and different influenza viruses vary in their dependence on NA activity (204, 205).

During the first few years of its use, oseltamivir resistance was reported to occur in about 1 to 4% of treated adults and in a higher proportion of treated children (206, 207). There was no evidence of naturally occurring oseltamivir resistance, and there were no reports of transmitted resistance (208). In the 2007–2008 season, a significant proportion of worldwide H1N1 infections were caused by a strain containing the oseltamivir-resistant framework mutation H274Y (209, 210). By the 2008–2009 season, >95% of seasonal H1N1 strains in the U.S. were oseltamivir resistant (209).

H274Y reduces oseltamivir susceptibility by several hundred- to several thousand-fold and causes high-level cross-resistance to peramivir but not zanamivir (208). Epidemiologic and molecular phylogenetic data suggest that the fixation of H274Y in H1N1 strains was not a result of selective drug pressure (211). Rather, H274Y evolved in the dominant circulating strain in seasonal 2007–2008 H1N1 viruses or specifically complemented other "permissive" mutations in that clade, possibly R222Q, V234M, and D343N (199, 212). Although in vitro cell culture and ferret model experiments showed that viruses with H274Y have greatly diminished replication (213), the H274Y-containing H1N1 viruses that emerged in 2007 retained their transmissibility and pathogenicity (214).

H274Y is the most frequently occurring NAi-resistance mutation in patients receiving oseltamivir (215) and has been reported in a widespread community cluster of A(H1N1)pdm09 in Australia in 2011 (216). Although H5N1 viruses are intrinsically susceptible to oseltamivir and zanamivir (217, 218), virological failure resulting from H274Y appears to occur at a higher frequency among patients receiving oseltamivir than in pre-2007 seasonal H1N1 and in A(H1N1)pdm09 strains (219).

Additional NAi-resistance mutations in A(H1N1) or A(H1N1)pdm09 included Q136K, Y155H, I222M/K/R/V, S246N/G, and N294S (202, 202, 202, 211). I222 and S246 mutations appear to increase the replication fitness of viruses with H274Y and to cause low-level resistance (5- to 30-fold reduced susceptibility) to oseltamivir and zanamivir when they occur alone (220, 221). Q136K and Y155H are uncommon naturally occurring N1 mutations which reduce oseltamivir (Q136K) and oseltamivir and zanamivir (Y155H) susceptibility >30-fold (205, 222). Q136K was present at low proportions in primary clinical specimens but arose during cell culture, raising questions as to its clinical significance (222, 223).

Among H3N2 viruses, the catalytic mutations R292K, E119I/V, and N294S have been reported in patients receiving oseltamivir (202, 207, 215, 224). E119I/V reduces oseltamivir susceptibility by more than 30-fold and causes low-level cross-resistance to zanamivir. R292K and N294S cause high-level oseltamivir resistance and lower levels of zanamivir cross-resistance. R292K has also been reported in two H7N9 viruses from patients receiving oseltamivir (225).
Among influenza B viruses, the most commonly reported NAi-resistance mutations include D198E/N and I222T, and R371K, which was identified in a 2004–2008 surveillance study, was associated with >100-fold reduced susceptibility to oseltamivir and about 30-fold reduced susceptibility to zanamivir (210). R152K, which causes high-level resistance to both oseltamivir and zanamivir, has been reported in an immunocompromised patient receiving prolonged therapy with inhaled zanamivir (226).

Susceptibility Test Methods: Viruses*
DIANA D. HUANG AND MATTHEW J. BANKOWSKI

FDA-approved antiviral drugs are available and used for the treatment and management of herpes simplex virus types 1 and 2 (HSV-1, HSV-2), human cytomegalovirus (HCMV), varicella-zoster virus (VZV), human immunodeficiency virus type 1 (HIV-1) (1), hepatitis B virus (HBV), hepatitis C virus (HCV) (2, 3), and influenza virus. When the drugs are used over long periods of time and/or inconsistently, variants may be selected that may become “drug resistant” and are no longer susceptible to therapy (4–11). Since these variants are transmissible, learning if the virus may be drug resistant is a critical step in the treatment strategy (12).

Testing for viral susceptibility is now standard practice for the management of viral infections for optimum patient care. The only FDA-cleared assays available for viral susceptibility testing over the past decade target the HIV-1 protease (Pro) and reverse transcriptase (RT) genes. However, interest in testing for viral susceptibility has increased for other viruses, such as HBV, HCV, and HIV-1, for which there are newly approved antiviral drugs using research use only (RUO) test kits or analyte-specific reagents (ASRs) in laboratory-developed tests (LDTs) (13).

**ANTIVIRAL RESISTANCE AND CAUSES OF DRUG FAILURE**

Failure to respond to drug therapy can occur for different reasons. More commonly, the virus population being treated is inherently resistant to the drug(s) being given. Alternatively, host biological and sociobehavioral factors (e.g., therapeutic nonadherence) may influence therapeutic success. Viral susceptibility testing can identify resistant populations and guide patient management strategies.

**True Antiviral Resistance**

Antiviral resistance is expressed as a drop in the efficacy of a drug to inhibit viral replication. Resistance is demonstrated clinically by an increase or no change in amounts of circulating virus in the infected individual despite active treatment. The loss of susceptibility can be measured by in vitro testing, which evaluates the phenotypic activity of drug/virus combinations. If the decrease in drug effect is related to specific mutations in the virus genome, affecting function of the protein to which the drug is targeted, then the resistance to that drug may be an inherently transmissible feature of the virus. This genotypic and phenotypic expression provides combined evidence for the loss of drug activity against the virus and is documented during drug development. Independent confirmation of these correlations is made by antiviral testing of viral isolates obtained from participants in clinical drug trials. Diagnostic assays may then be developed that measure the change in response of the virus to a drug and/or identify the presence of the specific viral mutations associated with the observed loss of susceptibility. Interpretations of the data from these assays are used to clinically manage viral infections.

**Host Factors**

The failure to respond to therapy may occur even if the infecting virus does not harbor any mutations associated with antiviral susceptibility. Host physiologic factors can interfere with a successful clinical response. The genetic background of the host may lessen the effect of the drug where host polymorphisms, such as those identified for the IL28b gene, may affect the activity or bioavailability of pegylated-interferon (peg-IFN)/ribavirin in HCV treatment (14–16). Another nonviral factor is the potential for drug-drug interactions. For example, in early clinical trials of the newer protease inhibitors to treat chronic HCV, pharmacokinetic influences and drug-drug interactions occurred with some HIV-1 protease treatments in HIV/HCV-coinfected individuals (17). Coadministration of the HCV and HIV protease inhibitors could then cause the viral loads of either virus to increase (18). In this scenario, there were no identified mutations associated with antiviral resistance present in the viral genomes.

**Patient Sociobehavioral Influence**

Individuals undergoing drug treatment may not adhere to their prescribed antiviral regimen for a variety of reasons. For instance, physiologic and psychological side effects associated with antiretroviral drugs and IFN treatment may occur, fueling patient intolerance for the drug. The acute- and long-term symptoms, as well as complexities of the treatment such as pill burden and timing, may initiate problems with adherence (19). Consequently, the patient may choose to suspend treatment of his or her own accord. In addition, consistent access and follow-through of therapy may be difficult for some individuals due to socioeconomic concerns (20). In turn, this would result in treatment gaps which foster the selection or generation of an underlying
genetically resistant viral population. In this type of patient, the class of drug to which the virus has become resistant is no longer effective for future use (21). Clinical trials and studies are now being conducted that study adherence outcomes (22). Such studies are likely to also include genotypic resistance testing.

**CLINICAL INDICATIONS FOR ANTIVIRAL SUSCEPTIBILITY TESTING**

It is important to distinguish when the lack of effective response to treatment with an antiviral drug results from true antiviral resistance, i.e., genetic changes in the patient’s virus. Clinical resistance to a particular antiviral drug can be misinterpreted as viral resistance. The failure to recognize this difference could result in the inappropriate use of more toxic drugs, leading to higher morbidity and mortality with much higher test costs.

The clinical category and status of the patient are important in determining whether antiviral resistance testing is indicated. Table 1 presents instances for both immunocompetent and immunocompromised patients in whom resistance testing should be considered. In general, sustained or increasing viral load with a worsening clinical condition is a reliable indicator for the presence of emerging drug resistance. If these markers of resistance are present, it may be prudent to directly test the virus for drug resistance. Antiviral susceptibility test methods can be phenotypic or genotypic. The choice will often rely on the specific virus being tested. Interpretation of the testing data may be more complex for those individuals on combination therapy.

**TESTING METHODS: PHENOTYPIC ASSAYS**

**Plaque Reduction Assay and Dye Uptake**

The standard method of antiviral susceptibility testing is the plaque reduction assay or PRA as shown in Fig. 1. The PRA test principle relies on the ability of the antiviral agent to inhibit the production of viral plaques at a predetermined drug concentration. A 50% inhibition point (IC$_{50}$) is then calculated and subsequently reported in micrograms per milliliter or micromolar concentration. A higher IC$_{50}$ of the sample virus compared to that of a wild-type control strain denotes resistance. Depending on the virus, this value may vary for the drug. This method is especially useful for the herpesviruses (e.g., HSV, CMV, and VZV) but is time-consuming, exhibiting an extended turnaround time of about 2 to 3 days for HSV, approximately 7 days for VZV, and about a month for CMV (23–26). There is also the question of method standardization; an approved standard document from the Clinical Laboratory and Standards Institute (CLSI) for HSV has been published (M33A). The use of a phenotypic method such as PRA is still recommended because of the presence of uncharacterized mutations among the herpes viruses that can contribute to antiviral resistance. Table 2 lists the proposed guidelines for antiviral susceptibility results for PRA of herpes group and influenza A viruses.

The dye uptake (DU) assay is based upon the ability of viable cells to incorporate the neutral red vital dye (26). It results for PRA of herpes group and influenza A viruses.

**Enzyme Immunoassays**

Enzyme immunoassays (EIAs) have also been developed for antiviral susceptibility testing (5–7, 27–29). These methods have been used successfully for both the herpesviruses and influenza type A virus. They compare favorably with the PRA method, but are less labor-intensive and allow for a quantitative measurement. This method measures absorbance as related to viral antigen detection in virus-infected cells and results in the determination of an IC$_{50}$.

**Neuraminidase Inhibition Assay**

Two neuraminidase inhibitors, oseltamivir and zanamivir, have been FDA approved for the treatment of both influenza type A and type B virus infection (30). A fluorogenic assay resulting in the generation of an IC$_{50}$ was developed and

has been used successfully to detect antiviral resistance to the two neuraminidase inhibitor drugs (31). The assay was subsequently commercialized and is available under the name NA-Star (Applied Biosystems, Foster City, CA).

**Recombinant Virus Assays**

Recombinant virus assays (RVAs) for drug susceptibility have been developed for clinical use. These assays monitor phenotypic behavior in the presence of an antiviral drug that can be attributed to specific genes on the virus genome that may contain mutations known to correlate with antiviral resistance. The first clinically useful RVA was used to measure the phenotypic resistance of HIV-1 to protease and RT inhibitors. In the RVA protocol strategy, the gene of interest (e.g., HIV-1 protease or RT) is PCR-amplified directly from virus in the patient specimen. Afterwards, the PCR product is ligated into a retroviral vector where the protease or RT gene was removed. The concept is that the ligation adds back the protease or RT activity associated with the gene from the patient’s virus. The vector also has the env gene, which codes for the receptor-binding protein, replaced with a reporter gene coding for a light-emitting protein such as luciferase. This vector, which now contains the HIV-1 gene of interest, is then cotransfected into a susceptible cell line along with a different plasmid. However, this plasmid contains a gene to provide a non-HIV receptor-binding protein able to attach to and infect the chosen test cells. After transfection, the newly assembled chimeric virus, called a pseudotype, incorporates the non-HIV receptor-binding protein, the genome from the retroviral vector containing the added HIV-1 protease or RT from the patient virus, and the reporter gene. The pseudotype virus can now infect the cells of choice to start replication for a single round. This RVA strategy allows the activity of the protease or RT derived from patient HIV to be tested in cells in the presence of antiretroviral drugs. Measurements of the replication efficiency of the engineered virus can be monitored by light emission of the luciferase expressed in the cells only during successful replication of the virus. Chimeric virus containing a protease or RT sensitive to the antiviral drug would then not emit light from infected cells, while virus containing a protease or RT resistant to the antiviral drug would emit measurable light.

The RVA is labor-intensive and time-consuming and requires a long turnaround time. RVA utilizes cell culture; however, the use of a standard cell line also provides assay consistency that is not possible with the use of primary cells such as peripheral blood mononuclear cells. An advantage of a recombinant assay compared to conventional culture is that it provides direct evidence of the antiviral activity associated with a specific gene derived from the virus population in a patient specimen. Also, if RVA were linked with genotyping the patient’s virus to show the presence of known resistance mutations, a direct correlation between the level of phenotypic resistance could be made to the mutations observed, especially in patients on a complex treatment regimen. This information would allow a more accurate snapshot of HIV-1 resistance and could offer the clinician a more accurate choice of antiretroviral drugs available if a change in treatment is contemplated.

Modifications of the RVA have been made to allow fusion, integrase, and coreceptor usage to be monitored in instances where inhibitors of these HIV-1 activities are candidates for a patient’s antiviral therapy. Currently, HIV-1 RVA testing is provided from commercial reference labs. Available RVAs measure HIV-1 protease-reverse transcriptase, fusion, integrase, and coreceptor activities. There is also an LDT variation of this strategy that has been

Genotypic Platforms

Genotypic platforms used for antiviral susceptibility testing may include Sanger sequencing, pyrosequencing, in vitro reverse-hybridization line-probe assay (LiPA), and single-nucleotide polymorphism (SNP) analysis. Real-time RT-PCR allelic discrimination is also being evaluated as an LDT targeting single mutations (33, 34). In general, these assays analyze data and yield results more quickly than phenotypic testing, often at a lower cost. Currently, sequencing assays are more frequently used to detect mutations associated with antiviral resistance. However, most sequencing platforms will require the use of bioinformatics software for accurate and reproducible data interpretation. Viral genomes with multiple, clustered resistance mutations are mostly analyzed by the use of assays based on Sanger dideoxynucleotide sequencing (35). For example, in the case of HIV-1 or HCV chronic infection, the viral population consists of multiple variants referred to as “quasi-species” (36). Raw data from Sanger sequencing are displayed in chromatograms, which can show the presence of minor populations in the total virus population. The operator should evaluate the chromatograms and proofread the data manually to determine that the quality of the sequence chromatogram produced is of acceptable resolution (Fig. 2) (37). Every consensus sequence developed should include sequencing the PCR-derived template in both the forward and reverse directions in order to ensure sequence accuracy.

by verifying the presence of the identical mutation(s) in both strands of the sequencing template. This process will validate true nucleotide change as opposed to an artifact generated during the sequencing protocol (i.e., breach in the enzyme proofreading or inconsistencies during the preparation of the sequencing sample). Sanger sequencing is useful in monitoring longer contiguous regions of the genome. Good-quality sequencing reactions can yield up to 600 to 700 readable nucleotides per sequencing primer, assuming the template is generated from a clean PCR product. However, Sanger sequencing does not detect a variant in a mixed virus population reproducibly if the minor population is less than 20 to 25%.

The introduction of next-generation sequencing (NGS) (also called massively parallel sequencing or MPS) technologies has the potential to further elucidate gene sequences and detect minor populations between 1 and 5%. This “ultra-deep sequencing” can detect much lower levels of variants in mixed samples because of the enormous number of genomic sequence reads. These valuable sequence data provide a “snapshot” of the population of the infectious agent in the patient. NGS also allows for accurate verification of single-nucleotide variations that might otherwise be misinterpreted using Sanger sequencing. NGS technology is rapidly evolving and will serve as an important diagnostic tool in the management of human infectious disease.

Pyrosequencing is a more recently developed method used for identifying mutations associated with antiviral drug resistance. This method has been widely used to sequence 16S rRNA for bacterial identification. Pyrosequencing is fundamentally different from Sanger sequencing in several ways and is described thoroughly by Metzker (38). Pyrosequencing...

has a lower limit of detection for the discrimination of minor variants in a mixed population because the protocol is more clonal, a result of preparing sequencing template that is derived from one single DNA molecule for the assay. Each copy of sequencing template is bound to a solid support, such as beads, to perform the assay. The sequence output is not produced and captured electrochemically, but are the result of an enzyme-cascade reaction that generates a bioluminescent signal after single addition of each complementary dNTP. The data produced are not visually represented by chromatograms, but are expressed through numerical compilation of the order and strength of the peaks of light which are then converted to represent the sequence of the template by a statistical algorithm. The sequence output is shorter (currently 300 to 400 usable nucleotides), run times are faster, and the assay allows for high-throughput analysis. The testing is more automated, which allows less oversight and manual intervention by the operator than Sanger sequencing. Generally, pyrosequencing is useful for mixed infections and where the mutations are widely spaced throughout the genome and less clustered. Pyrosequencing is not FDA approved/cleared for use in antiviral susceptibility testing at this time. Verification of test performance will be required to adapt this method as an LDT assay in the clinical diagnostic laboratory (39). In addition, operators will be needed who are highly trained on assorted bioinformatics software handling large quantities of data in order to ensure accurate data analysis and results interpretation. LiPA testing for antiviral susceptibility testing involves PCR-generated biotin-tagged oligonucleotides from the genetic region of interest of the patient’s virus. The amplified product is then hybridized to nitrocellulose strip-bound oligonucleotide probes, spatially embedded on this solid matrix. The probes are derived from a reference virus genome and contain single mutations, which correlate to antiviral drug resistance. Both the probes for the reference and the mutation sequences are on the membrane. Each single mutation to be identified is represented by a different probe. The pattern of probe reactivity on the strip (i.e., color reaction produced by an EIA-type process) indicates the mutations present in the patient’s viral population. The LiPA assay will only detect known, previously identified mutations specific for the probes included in the test kit (40). LiPA is also not FDA approved/cleared for use in antiviral susceptibility testing at this time. Real-time PCR and SNP assays have also been developed for antiviral susceptibility testing. They are especially useful for detecting antiviral resistance in influenza type A virus infection with the introduction of anti-neuraminidase inhibitor drugs (41, 42). SNP assays are multiplexed, so that more than one primer/probe pair is added to each reaction. The probes will distinguish, for example, a wild-type virus from one that carries a resistance mutation. The probes for each are labeled with a different fluorescent dye, and detection of the bound dye indicates the presence or absence of the mutation. These assays are mostly LDTs (ASR) and are more likely to be performed by large commercial reference laboratories.

Applications (Genotyping)

Herpesviruses

HCMV

There are currently no FDA-approved/cleared kits/systems or RUO kits to screen for HCMV antiviral drug resistance mutations. Sanger sequencing is currently used to
that will increase the cost of this assay. It is for this reason that the assay is usually performed by large medical centers or commercial reference laboratories.

HCMV genotyping sequence data from antiviral resistance testing must be carefully interpreted, because some common mutations observed in genotypic assays may not be responsible for phenotypic resistance. For example, a moderate number of the codon changes identified in UL97 are not associated with antiviral drug resistance (50). The laboratory should confirm such mutations with those identified by “recombinant phenotyping” (52) if the literature is not supportive or clinical drug efficacy has not been achieved. (47, 49, 58). In these instances, the aforementioned recombinant assays, which have been developed for HCMV, may be considered (32).

HSV-1 and -2

Currently available antiviral drugs for HSV infection are acyclovir (ACV), penciclovir (PCV), and their prodrugs; valacyclovir and famciclovir (Table 3). These drugs target the HSV thymidine kinase (TK) and DNA polymerase (pol). Drug-resistant isolates frequently develop in HSV-infected immunocompromised patients. The use of antiviral susceptibility testing is especially useful for this patient population (Table 1).

Common target genes for genotypic sequencing assays are the HSV TK (UL23) and the DNA pol genes (UL30), which are associated with ACV and PCV drug resistance (59). Many cases of ACV resistance correlate with observed mutations in UL23, especially in areas of photopolymer repeats consisting of guanines or cytosines where hypermutation occurs (60, 61). In contrast, the mutations found in clinical isolates observed in UL30 are scattered over the structural regions II, III, VI, and VII (59).

Antiviral susceptibility testing should be considered when ACV and PCV treatment fails and other reasons for drug failure are ruled out. HSV genotyping is not commonly requested and there are no specific guidelines available to aid in the interpretation of the mutations for drug resistance. Therefore, the resulting mutations are usually compared to the published literature in order to distinguish true antiviral resistance from viral polymorphisms (59).

VZV

In the VZV-infected patient, treatment is usually initiated if the patient is immunocompromised (e.g., HIV-infected, transplant, and cancer patients). Some of the same antiviral drugs used for HSV infection are used for VZV infection and target similar genes (i.e., TK and DNA pol) (Table 3). There are fewer studies in the literature on VZV antiviral drug resistance compared to HSV. However, there are supportive data for genotypic testing from a recent phenotypic study (62), which examined cross-reactivity patterns associated with mutations in the VZV TK and DNA pol genes. Mutations correlating with drug resistance were mapped for both genes and this information could be used as a source reference for evaluation of mutations found in genotypic assays. However, the phenotypic method has been mostly offered as a commercial reference laboratory test.

HIV

Genotypic screening for mutations associated with HIV resistance is considered the preferred method for monitoring treated, nonresponding patients (http://www.aidsinfo.nih.gov/Guidelines/ accessed 21 September 2009). Regularly updated algorithms released by expert panels are used to interpret mutations detected in genotypic assays. There are
currently two FDA-cleared test kits, the TrueGene HIV-1 Genotyping Assay (Siemens Medical Solutions Diagnostics, Tarrytown, NY) and the ViroSeq HIV-1 Genotyping System (Celera/Abbott Diagnostics). The former utilizes dideoxynucleotide PCR amplification of a sequencing template to generate sequence for the entire protease gene. The RT sequence obtained spans codons 40–247 and codons 1–335 for the Trugene and ViroSeq assays, respectively. The assays were validated for HIV-1 subtype B strains, but have been used successfully for genotyping non-subtype B strains, including recombinant HIV-1 strains (64, 66, 68–70), which show mutations similar to those observed for subtype B (71). In recent years, a growing number of clinical laboratories, both commercial and government-supported, have also developed LDT genotyping assays. Genotypic screening for antiretroviral mutations is used for monitoring treatment failures (11, 72, 73) and is recommended for baseline screening of newly diagnosed patients with viral loads of >1,000 copies/ml as well as pregnant women (http://www.aidsinfo.nih.gov/Guidelines). Identification of preexisting HIV mutations will then serve to guide their initial treatment strategy (74, 75) (http://www.aidsinfo.nih.gov/Guidelines).

The drugs currently available to treat HIV-1 infection target the protease, RT, integrase, viral fusion, and entry (http://aidsinfo.nih.gov/drugs; http://www.fda.gov). In the past decade, new HIV-1 drugs for non-Pro-RT targets have been FDA approved. For example, enfuvirtide targets the fusion peptide in gp41 coded for in the env gene and is used as an option in heavy treatment-experienced individuals. Resistance mutations for enfuvirtide have been mapped to the ENV first heptad repeat sequence in gp41 (codons 36–43) (76). Raltegravir, approved in 2007, is an inhibitor of the integrase protein coded for in the pol gene. Maraviroc, also approved in 2007, is an entry inhibitor based on CCR5 usage and is associated with the V3 loop in the env gene (74). Next-generation drugs for all three of these antiretrovirals are available or are being developed. Currently, genotypic assays to identify known antiviral mutations for these drugs are being developed as LDTs. One commercial RUO genotyping kit is available for the detection of integrase-resistance mutations, the ViroSeq HIV-1 Integrase Genotyping system (Celera/Abbott). The system used in this assay is similar to the ViroSeq system for Pro-RT in the extraction method, but uses a combined RT-PCR step to make the sequencing template. The double-stranded sequencing product is detected using an ABI sequencer (ABI/Life Sciences). The resulting chromatograms are then assembled and edited to generate a consensus sequence which spans the entire integrase gene. Software is now available with this system for editing the sequence information similar to the ViroSeqpro-RT system. Previously, sequences were analyzed using SeqScape v.2.5 or later (ABI/Life Sciences). There is no official report generated from the data because of the RUO kit designation. The consensus sequence obtained can be examined by the operator to identify the presence of mutations associated with resistance. Afterwards, the consensus sequence can be submitted to other outside websites (e.g., Stanford University HIV-1 drug resistance database or the Geno2Pheno site) to obtain an interpretation for the observed mutations.

There are no RUO or FDA-approved commercially available kits to screen for resistance to maraviroc or other CCR5 inhibitors. The expanded use of maraviroc as a first-line treatment option in drug-naïve individuals carrying virus with a CCR5 tropism (http://www.aidsinfo.nih.gov/Guidelines/, accessed 21 September 2009) requires determination of the baseline coreceptor usage of the virus. Currently, a tropism assay, Trofile, is available commercially to phenotypically determine if the virus employs the CCR5 or CXCR4 coreceptor.

Molecular phenotypic assays are costly and the turnaround time is lengthy. An alternative strategy to determine coreceptor usage is to sequence the V3 loop using Sanger or a pyrosequencing method. Here, the genotypic determination of resistance to maraviroc entails the observation of a coreceptor switch from a CCR5 sequence profile to a mixed coreceptor or solely a CXCR4 profile in the V3 loop. The consensus sequences generated are subsequently submitted to interactive websites employing databases correlating genotype with phenotypic outcome. The analysis infers coreceptor usage using different algorithms to determine the amino acid patterns and net charges of the entire V3 loop or only positions 11 and 25, which predict CCR5 or CXCR4 usage (77–79). Two algorithms frequently used to predict coreceptor tropism are the position-specific scoring matrix (PSSM) (80) and the Geno2Pheno coreceptor algorithm (81). The successful use of this strategy as a clinical tool has been evaluated and reported by several groups (78, 82, 83). Although protocols for sequencing the V3 loop have been circulating for years, development of the various algorithms for analysis, some of which are free Web-based services, has made this an approach feasible and attractive for most LDT users.

Commercially, a tropism assay is also available based on V3 loop sequencing and analysis by either the PSSM and/or Geno2pheno algorithms coupled with a separate heteroduplex assay (84). This is performed using a capillary array on the ABI 37xx sequencer platform.

**Hepatitis Virus**

HBV. The 5′ nucleoside/nucleotide analogs approved for the management of chronic HBV infection targeting the HBV DNA polymerase/RT are listed in Table 3 (85, 86). Alpha-2b interferon (IFN-α2b) and peg-IFN have been the recommended treatment; however, treatment efficacy is dependent upon the HBV subtype (87, 88) and interferon does not directly target HBV. Since HBV grows poorly in culture, genotyping methods are the tests of choice to monitor resistance. HBV genotypic assays detect known mutations (Table 3) in the polymerase/RT gene. The most common genotypic method for HBV is to directly sequence the polymerase/RT gene in HBV from plasma and determine the resistance-associated mutations. Alternatively, the generation of a PCR product from the specimen can be interrogated using specific probes in a reverse-hybridization assay (86). There are no FDA-approved/cleared sequencing assay systems for HBV antiviral susceptibility testing. However, there are two RUO kits available for HBV genotyping, which partially sequence the HBV pol/RT gene. The Trugene HBV Genotyping kit (Siemens Medical Solutions Diagnostics) generates a consensus sequence of ~1.2 kb in the center of the gene (89). This is the same sequencing platform as the Trugene HIV system and it has internal software to generate a consensus sequence. The other assay is the ViroSeq HBV Genotyping Kit (Celera/Abbott), which targets the HBV pol/RT and generates a consensus sequence of ~1.0 kb. This consensus sequence covers an area between bases 130 and 1,161, where known antiviral resistance mutations reside. The sequences are generated using the ABI sequencers 3130/3130XL. There is no associated software with this assay to generate a consensus sequence from the...
chromatograms, but the use of SeqScape v2.5 or later is recommended for the analysis. The parameters used in the analysis of the HBV sequence in SeqScape are provided with the test kit protocol.

HBV strains possess a small genome of only ~3,200 nucleotides, which varies depending upon the subtype. This feature is used in LDT sequencing assays to detect the HBV genotype and/or for the detection of antiviral drug resistance (90). The ability to consistently detect variants in the HBV population using genotyping assays is usually not achievable unless the minority population is greater than 25% (85, 90). However, the method is capable of detecting all mutations that are known or compensatory, as well as novel mutations that might be associated with antiviral resistance (86). Interpretation of the associated mutations would require a virtual phenotype and the consensus data must be analyzed further by other relational databases such as Seq-HepB (Eivirar) (91, 92).

A commercial (CE-marked) reverse-hybridization assay, Innogenetics INNO-LiPa HBV DR version 2 (Innogenetics N.V., Ghent, Belgium), also available outside the United States, is capable of detecting known HBV mutations in the pol/RT gene. These mutations are associated with resistance to lamivudine, adefovir, emtricitabine, and telbivudine (40, 93) (Table 3). This assay is more sensitive for the detection of minority HBV populations. It is also less labor-intensive than the population sequencing method (85). However, the sensitivity can be affected by neighboring polymorphisms within the sequence (93, 94). The RUO INNO-LiPa HBV genotyping kit (Innogenetics), based on the HBV Sag (hepatitis B virus surface antigen) sequence, can also be used for HBV genotyping (95).

HCV. Treatment of chronic HCV infection was historically limited to pegIFN/ribavirin therapy. Success of this treatment varied and was affected by the virus genotype. Genotype 1 is the least responsive to IFN therapy and the most likely to evolve into a chronic infection (96). Therefore, management of HCV infection should always include virus genotyping (subtyping) to predict the efficacy of pegIFN/ribavirin. Two newly introduced antivirals, boceprevir and telaprevir (Table 3), have been recently FDA approved. They are direct-acting antiviral agents (DAA) which target the nonstructural protein 3/4A (NS3/4A) serine protease of HCV (2, 97).

HCV chronic infection is similar to HIV. However, HCV has the ability to generate a higher number of quasispecies which circulate in the infected individual due to the higher replication error and greater number of new virions produced during each replication cycle. Since the virus is not known to establish itself in reservoirs outside of the liver, the potential exists for curing the chronic infection with the new DAAs (98). There are also many drugs being developed for use as IFN-free treatment (99). Another drug target is NS5B, the viral polymerase gene, where resistance mutations noted during the development phase have been mapped (3, 98). It is possible that genotyping HCV to identify additional mutations related to antiviral resistance will be undertaken in treatment failure cases or to determine if resistance mutations have been transmitted in new infections.

There are currently no FDA-approved/cleared or RUO/ASR kits available to sequence the HCV protease gene. However, there are several LDT assays being developed for clinical use based on sequencing. One study evaluated the performance of 23 laboratories affiliated with the French National Agency for Research on AIDS and Viral Hepatitis (ANRS) Coordinated Action on Hepatitis Virus Resistance to Antiviral Drugs (AC33). Each laboratory used its own LDT to detect resistance mutations associated with protease inhibitors (100). Sequence data from a blinded panel of 12 samples were evaluated for reproducibility, sensitivity, specificity, and accuracy. A common tool to identify mutations was also provided for optional use. The data revealed that only 0.7% of the data produced was incorrect, suggesting that most protocols will provide equivalent data, although the preference would be to develop a more uniform protocol. Pyrosequencing has also been used to detect antiviral resistance mutations (101, 102). In the United States, testing is also commercially available since 2011 through one of the large reference laboratories under HCV GeneSure.

**Influenza Virus**

Mutations responsible for influenza type A antiviral resistance to amantadine and rimantadine have been mapped to the M2 protein (6) (Table 3). However, these drugs are no longer recommended, because current circulating influenza type A strains show heightened resistance. Current guidelines for the treatment of influenza recommend use of the neuraminidase inhibitors oseltamivir and zanamivir as the drugs of choice against influenza type A (103). Mutations conferring resistance to the neuraminidase inhibitor drugs are located on the neuraminidase gene (NA). Genotypic assays for the determination of anti-neuraminidase resistance have been developed as LTDs. Sequencing assays are also performed to detect other mutations in the NA gene. Although both Sanger and pyrosequencing protocols have been reported in the literature, pyrosequencing is the more widely used method to identify the H275Y mutation in the NA gene (104–107). A pyrosequencing protocol to detect this mutation is available on the Internet (108). Other approaches for the detection of H275Y include a real-time assay (41), a SNP analysis method performed on a sequencer (42), and a real-time allelic discrimination (34), which was adopted by World Health Organization for screening H1N1 isolates. Detection of mutations is more likely to be performed for infected high-risk immunocompromised individuals and for surveillance purposes.

**INTERPRETATION OF ANTIVIRAL SUSCEPTIBILITY TESTING**

**Genotyping**

The two FDA-cleared genotypic assays for HIV susceptibility, Trugene (Siemens) in 2001 and ViroSeq (Celera) in 2002, include kit-associated software to analyze the raw data sequences generated from each sample to produce a consensus sequence. In turn, both assays provide guideline-based interpretations of the mutations found in the consensus sequence and generate a formal report. The report helps the physician in choosing the regimen for the patient by indicating the likelihood of antiretroviral drug efficacy. FDA clearance included the software validation and periodic updates of the guidelines for use and interpretation. These systems are considered model protocols for diagnostic genotype testing used for antiviral susceptibility drug testing formats.

**Bioinformatics: Virtual Phenotypes**

Results generated using RUO or LDT assays are dependent upon bioinformatics sources for providing an interpretation. The laboratory has the option of analyzing the data following sequencing at various steps in the protocol.
Fig. 2). The clinician has the task of determining the significance of the mutations observed based upon the interpretation provided by the laboratory. These assays are mostly represented by the antiviral susceptibility testing for HBV, HCV, and HIV-1 infections.

The clinical laboratory wishing to perform its own sequence-based antiviral susceptibility assays with either an RUO or LDT will need access to analysis software in order to examine raw sequence data. Software for general sequence analysis and for the formation of consensus sequences can be purchased. Access to specialized “expert systems,” as explained by Schafer (11), will also be needed to complete the interpretation. These systems are interactive, complex databases that use rules-based algorithms for individual drugs and associated mutations to infer the significance of the data (Table 5). The algorithms are guided by “knowledge-based” systems, which associate primary and secondary mutation(s), phenotypic data, and clinical outcomes.

Another consideration that should be addressed is access to adequate secured computer space or servers for storage of the raw data, software, and analysis results. These cumulative files of sample data analysis can be very extensive. If the laboratories or their institutions are in a position to allocate this computer storage space, it can be very useful for comparison purposes when monitoring a patient over time. There are also commercial entities available at a cost that can provide this service.

Models for the knowledge-based expert systems originated from commercial entities. A system developed early in the highly active antiretroviral therapy (HAART) era was the virtual-phenotype system based on the "Antivirogram" (Virco, now Jannsen Diagnostics). Genotypic sequence data, obtained from a clinical sample sent to this company, were analyzed and interpreted by an algorithm compared against a private database in order to infer a phenotype (11, 109). Their extensive database contained known genotypes which were correlated with phenotypes and/or clinical outcomes. The Monogram Biosciences GeneSure MG test compares an HIV genotype, derived from a submitted specimen, to its own expansive database of linked genotypes and phenotypes. The objective is to identify resistance mutations and predict phenotypic resistance using a proprietary algorithm. Both companies supply an official interpretative report of the analysis.

Consensus sequences can also be submitted through non-commercial interactive websites where interpretative data providing a virtual phenotype are returned to the submitting laboratory (Table 5). These sites are useful but are not regulated or standardized at this time. They employ different algorithms for different virus/drug combinations and allow different levels of operator input (79–81, 91, 92, 110–113). The databases linked with their algorithms connecting genotype and phenotype are also public. The reliability and consistency of the sites have been compared by several investigators (78, 79, 82). Most of these sites can examine consensus sequences to detect relevant mutations linked to resistance, and some can provide interpretations of the significance of the observed mutations with regard to drug efficacy. Some of the sites also provide additional tools for further analyses. All of these sites analyze data derived by Sanger sequencing. Currently, Geno2Pheno is also in the process of optimizing modules that would accept data from pyrosequencing (83, 114–117).

Test Interpretation

There is often minimal or no standardization among the various antiviral testing methods at a technical level, but required proficiency testing will provide some assurance of quality testing. Sequencing assays can be affected by several factors. Assuming the laboratory follows good laboratory practice (GLP), adhering to the stringency of defined use and separation of space to control the possibility of contamination of patient sample is critical. This is especially important when the VL of the patient sample is low. The commercial kits for HIV-1 were optimized for a minimum VL of 1,000 to 2,000 copies/ml of virus in the patient sample, and additional safeguards to reduce the effects of contamination were added within the protocol by using non-nested PCR to produce a sequencing template. Initial required volumes for extraction were between ~200 and 500 μl of, usually, plasma. In situations where the initial starting volumes are much less, as for genotyping of bloodspot samples, or where VL in the patient is much reduced to near undetectable, many LDT assays are incorporating nested PCR into the amplification which is vulnerable to contamination. Generation of quality data in these circumstances can still occur if performance of the assay is conducted under rigorous conditions.

The analysis software provided with FDA-cleared diagnostic sequencing assays incorporates algorithms to accurately provide interpretations generated from test results. Updates to the algorithms are also FDA cleared before they are released. Alternatively, non-FDA-cleared assays developed as LDTs rely upon the individual laboratory both to establish test performance and to provide useful interpretations. The sources for such interpretations may come from the literature, actual testing by the laboratory, established Internet sites, or other sources. There is also no standardization or oversight of the interpretation algorithms used, although the inferred clinical significance of the data may be very similar regardless of the algorithm used. Ultimately, the use of these results and the interpretations provided by the laboratory in care of the patient are the responsibility of the primary health care provider.

FUTURE DIRECTIONS AND EMERGING TECHNOLOGIES

Antiviral test methods have dramatically evolved over recent years in parallel with the emerging molecular technologies. These genotypic assays have provided invaluable tools for detecting resistance in viruses that are difficult to culture or cannot even be propagated in culture (e.g., HBV and HCV). This is possible because the gene and the location of the mutations responsible for antiviral resistance are known. In cases where a phenotypic assay can be performed (e.g., HSV), a genotypic assay may provide the same or even more accurate results in far less time. However, in these cases, newly emerging mutations associated with resistance may not be detected by the genotypic assay and phenotypic assay may be more predictive of viral resistance. Consequently, phenotypic assays will remain as very useful laboratory tests until genotypic assays are more predictive of emerging viral resistance.

There is a definite need for more standardization of both phenotypic and genotypic assays. Unfortunately, antiviral assay standardization is very limited. Examples include a CLSI standardized approach reported for HSV plaque assays (118) and approaches at standardizing CMV using the UL97 gene target (119, 120).

The pharmacology industry is actively investigating and developing new antiviral drugs, especially for chronic viral disease agent (e.g., HCV, HBV, and HIV-1). Concurrently, antiviral assays (mostly genotypic) need to be developed

</table>
for detecting and monitoring antiviral drug resistance. This is especially important due to the high cost of such antivirals and their long-term use, which is conducive to the development of resistance. One of the ultimate goals is to develop assays that would predict the likelihood of emerging resistance. Such assays may be possible with the newer NGS technologies, which for HIV-1 and CMV can now detect variants at a level of <5%. However, the clinical significance of the presence of such small populations will have to be determined. Also, as previously mentioned, there are logistical concerns with data management and storage, as well as with proficiency and consistency in expertise, which should be addressed in parallel with assay development. In a more immediate timeframe, screening tests for known mutations that can serve as guides for treatment strategies will be needed, which are less costly and allow for wider usage. There may be a trend towards development of more focused LDTs to detect individual mutations associated with resistance, including use of NGS for detection of very low levels of minority resistant variants. Most assays are sequence based, but there are assays using other genotypic platforms. Examples include the real-time allelic discrimination assay used for influenza (107), proposed for use in the detection of M184V in HIV RT (33). It is very likely that antiviral susceptibility testing applications will evolve quickly as new technology is introduced and the characteristics of viral infection and treatment change. Evaluation of the clinical significance of the data acquired from these new technologies will need to keep pace.

Addendum in proof. Trugene (Siemens) was withdrawn from the market as of January 2015.

Taxonomy and Classification of Fungi
MARY E. BRANDT AND DAVID W. WARNOCK

There are at least 100,000 named species of fungi. However, it has been estimated that the number of undiscovered species ranges from 1 million to more than 10 million, and it has been calculated that about 1,000 to 1,500 new species are described each year (1, 2). Of the named species of fungi, fewer than 500 have commonly been associated with human or animal disease, and no more than 50 are capable of causing infection in otherwise normal individuals. On the other hand, an increasing number of ubiquitous environmental molds are now being implicated as opportunistic pathogens, capable of producing serious or lethal disease in hosts that are immuno-compromised or debilitated. These molds are organisms whose natural habitats are in the soil or on plants, wood, compost heaps, or decomposing food. Many are familiar to mycologists, plant pathologists, and food microbiologists, but they present problems for the clinical microbiologist, who often has had no formal training in the identification of fungi. Fungal identification can be challenging and sometimes frustrating because of the importance placed on the morphological characteristics of the organisms, and the need to become familiar with a range of different structures and terms. Indeed, it is fair to state that obscure mycological terms are one of the major factors that discourage many microbiologists from mastering fungal identification. However, investing time to learn the basic structures and principles of taxonomy, classification, and nomenclature can result in the ability to recognize and identify correctly many medically important fungi.

MORPHOLOGICAL CHARACTERISTICS OF THE FUNGI
