section I

DIAGNOSTIC STRATEGIES AND GENERAL TOPICS / 1
VOLUME EDITOR: SANDRA S. RICHTER
SECTION EDITOR: ROBIN PATEL

1 Introduction to the 11th Edition of the Manual of Clinical Microbiology / 3
JAMES H. JORGENSEN AND MICHAEL A. PFALLER

2 Microscopy / 5
DANNY L. WIEDBRAUK

3 Laboratory Detection of Bacteremia and Fungemia / 15
MICHAEL L. WILSON, MELVIN P. WEINSTEIN, AND L. BARTH RELLER

4 Systems for Identification of Bacteria and Fungi / 29
KAREN C. CARROLL AND ROBIN PATEL

5 Automation and Design of the Clinical Microbiology Laboratory / 44
CHRISTOPHER D. DOERN AND MARTIN HOLFELDER

6 Molecular Microbiology / 54
FREDERICK S. NOLTE

7 Immunodiagnostic Tests for Diagnosis of Infectious Diseases / 91
ELITZA S. THEEL, A. BETTS CARPENTER, AND MATTHEW J. BINNICKER

section II

BACTERIOLOGY / 252
VOLUME EDITORS: KAREN C. CARROLL AND GUIDO FUNKE
SECTION EDITORS: KATHRYN A. BERNARD, J. STEPHEN DUMLER, MELISSA B. MILLER, CATHY A. PETTI, AND PETER A. R. VANDAMME

17 Taxonomy and Classification of Bacteria / 255
PETER A. R. VANDAMME

</tbody>
</table>
CONTENTS

47 Brucella / 863
GEORGE F. ARAJ

48 Bartonella / 873
DIANA G. SCORPIO AND J. STEPHEN DUMLER

49 Legionella / 887
PAUL H. EDELSTEIN AND CHRISTIAN LÜCK

ANAEROBIC BACTERIA

50 Approaches to Identification of Anaerobic Bacteria / 905
ELLEN JO BARON

51 Peptostreptococcus, Finegoldia, Anaerococcus, Peptoniphilus, Veillonella, and Other Anaerobic Cocci / 909
YULI SONG AND SYDNEY M. FINEGOLD

52 Propionibacterium, Lactobacillus, Actinomyces, and Other Non-Spore-Forming Anaerobic Gram-Positive Rods / 920
VAL HALL AND SARAH D. COPSEY

53 Clostridium / 940
DENNIS L. STEVENS, AMY E. BRYANT, AND KAREN C. CARROLL

54 Bacteroides, Porphyromonas, Prevotella, Fusobacterium, and Other Anaerobic Gram-Negative Rods / 967
EIJA KÖNÖNEN, GEORG CONRADS, AND ELISABETH NAGY

CURVED AND SPIRAL-SHAPED GRAM-NEGATIVE RODS

55 Algorithms for Identification of Curved and Spiral-Shaped Gram-Negative Rods / 994
IRVING NACHAMKIN

56 Campylobacter and Arcobacter / 998
COLETTE FITZGERALD AND IRVING NACHAMKIN

57 Helicobacter / 1013
ANDY J. LAWSON

58 Leptospira / 1028
PAUL N. LEVETT

59 Borrelia / 1037
MARTIN E. SCHRIEFER

60 Treponema and Brachyspira, Human Host-Associated Spirochetes / 1055
ARLENE C. SEÑA, ALLAN PILLAY, DAVID L. COX, AND JUSTIN D. RADOLF

MYCOPLASMAS AND OBLIGATE INTRACELLULAR BACTERIA

61 General Approaches to Identification of Mycoplasma, Ureaplasma, and Obligate Intracellular Bacteria / 1082
J. STEPHEN DUMLER

62 Mycoplasma and Ureaplasma / 1088
KEN B. WAITES AND DAVID TAYLOR-ROBINSON

63 Chlamydiaceae / 1106
CHARLOTTE A. GAYDOS AND ANDREAS ESSIG

64 Rickettsia and Orientia / 1122
DAVID H. WALKER AND DONALD H. BOUYER

65 Ehrlichia, Anaplasma, and Related Intracellular Bacteria / 1135
MEGAN E. RELLER AND J. STEPHEN DUMLER

66 Coxiella / 1150
STEPHEN R. GRAVES AND ROBERT F. MASSUNG

67 Tropheryma whipplei / 1159
WALTER GEIRDORFER, ANNETTE MOTHER, AND CHRISTIAN BOGDAN

section III

ANTIBACTERIAL AGENTS AND SUSCEPTIBILITY TEST METHODS / 1169
VOLUME EDITOR: SANDRA S. RICHTER
SECTION EDITOR: JEAN B. PATEL

68 Antibacterial Agents / 1171
JAMES S. LEWIS, II, AND KAREN BUSH

69 Mechanisms of Resistance to Antibacterial Agents / 1212
JEAN B. PATEL AND SANDRA S. RICHTER

70 Susceptibility Test Methods: General Considerations / 1246
JOHN D. TURNIDGE

71 Susceptibility Test Methods: Dilution and Disk Diffusion Methods / 1253
JAMES H. JORGENSEN AND JOHN D. TURNIDGE

72 Antimicrobial Susceptibility Testing Systems / 1274
JAMES A. KARLOW/SKY AND SANDRA S. RICHTER

73 Special Phenotypic Methods for Detecting Antibacterial Resistance / 1286
BRANDI M. LIMBAGO AND JANA M. SWENSON

74 Susceptibility Test Methods: Fastidious Bacteria / 1314
ROMNEY M. HUMPHRIES AND JANET A. HINDLER

75 Susceptibility Test Methods: Anaerobic Bacteria / 1342
AUDREY N. SCHUETZ AND DAVID W. HECHT

76 Susceptibility Test Methods: Mycobacteria, Nocardia, and Other Actinomycetes / 1356
GAIL L. WOODS, SHOU-YEAN GRACE LIN, AND EDWARD P. DESMOND

CONTENTS

105 Human Polyomaviruses / 1803  
RICHARD S. BULLER

106 Parvovirus B19 and Bocaviruses / 1818  
KEVIN E. BROWN

107 Poxviruses / 1828  
LAURA HUGHES, VICTORIA A. OLSON, AND INGER K. DAMON

108 Hepatitis B and D Viruses / 1841  
REBECCA T. HORVAT AND RYAN TAYLOR

SUBVIRAL AGENTS

109 Transmissible Spongiform Encephalopathies / 1859  
MARKUS GLATZEL AND ADRIANO AGUZZI

section V

ANTIVIRAL AGENTS AND SUSCEPTIBILITY TEST METHODS / 1867

VOLUME EDITOR: MARIE LOUISE LANDRY
SECTION EDITORS: ANGELA M. CALIENDO, CHRISTINE C. GINOCCHIO, AND ALEXANDRA VALSAMAKIS

110 Antiviral Agents / 1869  
AIMEE C. HODOWANEC, KENNETH D. THOMPSON, AND NELL S. LURAIN

111 Mechanisms of Resistance to Antiviral Agents / 1894  
ROBERT W. SHAFER AND SUNWEN CHOU

112 Susceptibility Test Methods: Viruses / 1913  
DIANA D. HUANG AND MATTHEW J. BANKOWSKI

section VI

MYCOLOGY / 1932

VOLUME EDITOR: DAVID W. WARNOCK
SECTION EDITORS: MARY E. BRANDT AND ELIZABETH M. JOHNSON

GENERAL

113 Taxonomy and Classification of Fungi / 1935  
MARY E. BRANDT AND DAVID W. WARNOCK

114 Specimen Collection, Transport, and Processing: Mycology / 1944  
KARIN L. McGOGAN

115 Reagents, Stains, and Media: Mycology / 1955  
MARK D. LINDSLEY, JAMES W. SNYDER, RONALD M. ATLAS, AND MARK T. LAROCCHI

116 General Approaches for Direct Detection and Identification of Fungi / 1965  
H. RUTH ASHBEE

FUNGI

117 Candida, Cryptococcus, and Other Yeasts of Medical Importance / 1984  
SUSAN A. HOWELL, KEVIN C. HAZEN, AND MARY E. BRANDT

118 Pneumocystis / 2015  
MELANIE T. CUSHION

119 Aspergillus and Penicillium / 2030  
SHARON C.-A. CHEN, TANIA C. SORRELL, AND WIELAND MEYER

120 Fusarium and Other Opportunistic Hyaline Fungi / 2057  
SEAN X. ZHANG, KERRY O’DONNELL, AND DEANNA A. SUTTON

121 Agents of Systemic and Subcutaneous Mucormycosis and Entomophthoromycosis / 2087  
DEA GARCIA-HERMOSO, ALEXANDRE ALANIO, OLIVIER LORTHOLARY, AND FRANÇOISE DROMER

122 Histoplasma, Blastomyces, Coccioidioides, and Other Dimorphic Fungi Causing Systemic Mycoses / 2109  
GEORGE R. THOMPSON III AND BEATRIZ L. GÓMEZ

123 Trichophyton, Microsporum, Epidermophyton, and Agents of Superficial Mycoses / 2128  
ANDREW M. BORMAN AND RICHARD C. SUMMERBELL

124 Curvularia, Exophiala, Scedosporium, Sporothrix, and Other Melanized Fungi / 2153  
JOSEP GUARRO AND G. SYBREN DE HOOG

125 Fungi Causing Eumycotic Mycosis / 2173  
ABDALLA O. A. AHMED, G. SYBREN DE HOOG, AND WENDY W. J. VAN DE SANDE

126 Mycotoxins / 2188  
KURT THROCKMORTON, NANCY C. ISHAM, MAHMOUD A. GHANNOUM, AND NANCY KELLER

127 Lacazia, Lagenidium, Pythium, and Rhinosporidium / 2196  
RAQUEL VILELA AND LEONEL MENDOZA

128 Microsporidia / 2209  
RAINER WEBER, PETER DEPLAZES, AND ALEXANDER MATHE
section VII

ANTIFUNGAL AGENTS AND SUSCEPTIBILITY TEST METHODS / 2221

VOLUME EDITOR: DAVID W. WARNOCK
SECTION EDITORS: MARY E. BRANDT AND ELIZABETH M. JOHNSON

129 Antifungal Agents / 2223
   SHAWN R. LOCKHART AND DAVID W. WARNOCK

130 Mechanisms of Resistance to Antifungal Agents / 2236
   DAVID S. PERLIN

131 Susceptibility Test Methods: Yeasts and Filamentous Fungi / 2255
   ELIZABETH M. JOHNSON AND MAIKEN CAVLING-ARENDRUP

section VIII

PARASITOLOGY / 2282

VOLUME EDITOR: DAVID W. WARNOCK
SECTION EDITORS: BOBBI S. PRITT AND GARY W. PROCP

GENERAL

132 Taxonomy and Classification of Human Parasitic Protozoa and Helminths / 2285
   FRANCIS E. G. COX

133 Specimen Collection, Transport, and Processing: Parasitology / 2293
   ROBYN Y. SHIMIZU AND LYNN S. GARCIA

134 Reagents, Stains, and Media: Parasitology / 2310
   ANDREA J. LINSCHOTT AND SUSAN E. SHARP

135 General Approaches for Detection and Identification of Parasites / 2317
   LYNN S. GARCIA, GRAELE P. PALTRIDGE, AND ROBIN Y. SHIMIZU

PARASITES

136 Plasmodium and Babesia / 2338
   BOBBI S. PRITT

137 Leishmania and Trypanosoma / 2357
   DAVID A. BRUCKNER AND JAIME LABARCA

138 Toxoplasma / 2373
   JAMES B. McAULEY, JEFFREY L. JONES, AND KAMALJIT SINGH

139 Pathogenic and Opportunistic Free-Living Amebae / 2387
   GOVINDA S. VISVESVARA

140 Intestinal and Urogenital Amebae, Flagellates, and Ciliates / 2399
   SUSAN NOVAK-WEEKLEY AND AMY L. LEVER

141 Cystoisospora, Cyclospora, and Sarcocystis / 2425
   DAVID S. LINDSAY AND LOUIS M. WEISS

142 Cryptosporidium / 2435
   LIHUA XIAO AND VITALIANO CAMA

143 Nematodes / 2448
   HARSHA SHEOREY, BEVERLEY-ANN BIGGS, AND NORBERT RYAN

144 Filarial Nematodes / 2461
   SOUMYA CHATTERJEE AND THOMAS B. NUTMAN

145 Cestodes / 2471
   HECTOR H. GARCIA, JUAN A. JIMENEZ, AND HERMES ESCALANTE

146 Trematodes / 2479
   MALCOLM K. JONES, JENNIFER KEISER, AND DONALD P. MCMANUS

147 Less Common Helminths / 2493
   GARY W. PROCP AND RONALD C. NEAFIE

148 Arthropods of Medical Importance / 2505
   SAM R. TELFORD III

section IX

ANTIPARASITIC AGENTS AND SUSCEPTIBILITY TEST METHODS / 2527

VOLUME EDITOR: DAVID W. WARNOCK
SECTION EDITOR: GARY W. PROCP

149 Antiparasitic Agents / 2529
   KARIN LEDER AND PETER F. WELLER

150 Mechanisms of Resistance to Antiparasitic Agents / 2550
   W. EVAN SECOR, JACQUES LE BRAS, AND JERÔME CLAIN

151 Susceptibility Test Methods: Parasites / 2563
   JACQUES LE BRAS, JERÔME CLAIN, AND W. EVAN SECOR

MICHAEL D. BOWEN
Gastroenteritis and Respiratory Viruses Laboratory Branch, Division of Viral Diseases, NCIRD, Centers for Disease Control and Prevention, Atlanta, GA 30333

CLAUDIA BRANDT
Institute of Medical Microbiology, Johann Wolfgang Goethe University, Paul Ehrlich Str. 40, 60596 Frankfurt, Germany

MARY E. BRANDT
Mycotic Diseases Branch, Centers for Disease Control and Prevention, 1600 Clifton Road NE, Atlanta, GA 30329-4018

BERNARD M. BRANSON
Division of HIV/AIDS Prevention, National Center for HIV/AIDS, Viral Hepatitis, STD, and TB Prevention, Centers for Disease Control and Prevention, Atlanta, GA 30333

KEVIN E. BROWN
Virus Reference Department, Public Health England, London, NW9 5EQ, United Kingdom

BARBARA A. BROWN-ELLIOTT
University of Texas Health Science Center at Tyler, Department of Microbiology, 11937 U.S. Highway 271, Tyler, TX 75708

DAVID A. BRUCKNER
Dept. of Pathology & Laboratory Medicine, David Geffen UCLA School of Medicine, 3741 Mountain View Ave., Los Angeles, CA 90066-3111

AMY E. BRYANT
Veterans Affairs Medical Center, Boise, ID 83702, and University of Washington School of Medicine, Seattle, WA 98195

RICHARD S. BULLER
Department of Pediatrics, Box 8116, Washington University School of Medicine, 660 S. Euclid Ave., St. Louis, MO 63110

KAREN BUSH
Departments of Molecular and Cellular Biochemistry and Biology, Indiana University, Bloomington, IN 47405

ANGELA M. CALIENDO
Department of Medicine, Warren Alpert Medical School of Brown University, Providence, RI 02903

VITALIANO CAMA
CGH/Div. of Parasitic Diseases and Malaria/Parasitic Diseases Branch, Centers for Disease Control and Prevention, 1600 Clifton Road NE, Atlanta, GA 30329-4018

A. BETTS CARPENTER
Molecular Microbiology & Cytology Laboratories, LabCorp, and Department of Pathology, Joan C. Edwards School of Medicine, Marshall University, Huntington, WV 25704

KAREN C. CARROLL
Department of Pathology, Division of Microbiology, The Johns Hopkins University School of Medicine, Baltimore, MD 21287

MARIA DA GLÓRIA SIQUEIRA CARVALHO
Streptococcus Laboratory, Respiratory Diseases Branch, Division of Bacterial Diseases, Centers for Disease Control and Prevention, Mail Stop C2-2, Atlanta, GA 30333

MAIKEN CAVLING-ARENDRUP
Dept. of Microbiology & Infection Control, Statens Serum Institut, Arrilervej 5, DK-2300 Copenhagen, Denmark

SOUMYA CHATTERJEE
Laboratory of Parasitic Diseases, National Institute of Allergy and Infectious Diseases, National Institutes of Health, Bethesda, MD 20892

SHARON C.-A. CHEN
Centre for Infectious Diseases and Microbiology Laboratory Services, ICPMR - Pathology West, Sydney Medical School, University of Sydney, and Westmead Hospital, Darcy Road, Westmead, NSW 2145, Australia

JENS JØRGEN CHRISTENSEN
Department of Clinical Microbiology, Slagelse Hospital, Slagelse, Denmark
OANA CIOFU  
Department of Immunology and Microbiology, Faculty of Health Sciences, University of Copenhagen, Copenhagen, Denmark

JÉRÔME CLAIN  
UMR 216 IRD, Faculté de Pharmacie, Université Paris Descartes, 4 av de l’Observatoire, 75006 Paris, France

TOM COENYE  
Laboratory of Pharmaceutical Microbiology, Ghent University, B-9000 Gent, Belgium

GEORG CONRADS  
Division of Oral Microbiology and Immunology, RWTH Aachen University Hospital, 52074 Aachen, Germany

PATRICIA S. CONVILLE  
Microbiology Service, Department of Laboratory Medicine, Warren Grant Magnuson Clinical Center, National Institutes of Health, U.S. Department of Health and Human Services, Bethesda, MD 20892

PIET COOLS  
Laboratory for Bacteriology Research, Department Clinical Chemistry, Microbiology & Immunology, Faculty of Medicine & Health Sciences, University of Ghent, 3BlokA, De Pintelaan 185, UZ Gent, 9000 Gent, Belgium

SARAH D. COPSEY  
Public Health Wales, Anaerobe Reference Laboratory, University Hospital of Wales, Heath Park, Cardiff, CF14 4XW, United Kingdom

NATALIE A. COUNIHAN  
School of Medicine, Deakin University, Waurn Ponds, 3218, Australia

DAVID L. COX  
Treponema Immunobiology and Syphilis Serology Activities, Division of STD Prevention, Laboratory Reference and Research Branch, Centers for Disease Control and Prevention, Atlanta, GA 30333

FRANCIS E. G. COX  
Department of Disease Control, London School of Hygiene and Tropical Medicine, London WC1E 7HT, United Kingdom

BART J. CURRIE  
Menzies School of Health Research and Northern Territory Medical Program, Royal Darwin Hospital, Darwin, Northern Territory 0811, Australia

MELANIE T. CUSHION  
University of Cincinnati College of Medicine, Cincinnati, OH 45267-0555, and Cincinnati Veterans Affairs Medical Center, Cincinnati, OH 45220

INGER K. DAMON  
Centers for Disease Control and Prevention, Mailstop G-06, 1600 Clifton Rd. NE, Atlanta, GA 30330

G. SYBREN de HOOG  
CBS Fungal Biodiversity Centre, Institute of the Royal Netherlands Academy of Arts and Sciences, Uppsalalaan 8, 3584 CT, Utrecht, The Netherlands

PETER DEPLAZES  
Institute of Parasitology, University of Zurich, Winterthurerstrasse 266a, CH-8057 Zurich, Switzerland

EDWARD P. DESMOND  
Mycobacteriology Section, Microbial Diseases Laboratory, California Department of Public Health, Richmond, CA 94804

DANIEL J. DIEKEMA  
Division of Infectious Diseases, Department of Internal Medicine, and Division of Medical Microbiology, Department of Pathology, University of Iowa College of Medicine, Iowa City, IA 52242

CHRISTOPHER D. DOERN  
Department of Pathology, Virginia Commonwealth University Medical Center, Richmond, VA 23298

GARY V. DOERN  
Emeritus, Department of Pathology, Carver College of Medicine, University of Iowa, Iowa City, IA 52242

FRANÇOISE DROMER  
Unité Mycologie Moléculaire, CNRS URA3012, Centre National de Référence des Mycoses Invasives et Antifongiques, Institut Pasteur, Paris, France

J. STEPHEN DUMLER  
Departments of Pathology and Microbiology & Immunology, University of Maryland School of Medicine, 322D Health Science Facility–I, 685 West Baltimore St., Baltimore, MD 21201

JAMES J. DUNN  
Department of Pathology, Texas Children’s Hospital, and Department of Pathology and Immunology, Baylor College of Medicine, Houston, TX 77030

MARCELA ECHAVARRIA  
Clinical Virology Unit, CEMIC University Hospital, Galvan 4102 (1431 FWO) Buenos Aires, Argentina

PAUL H. EDELSTEIN  
Department of Pathology and Laboratory Medicine, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA 19104-4283

JOHANNES ELIAS  
Institute for Hygiene and Microbiology, University of Würzburg, 97080 Würzburg, Germany

HERMES ESCALANTE  
Department of Microbiology and Parasitology, School of Biological Sciences, Universidad Nacional de Trujillo, Jr. Bolognesi 334, Trujillo, Peru
ANDREAS ESSIG  
Institute of Medical Microbiology and Hygiene, University Ulm, Albert-Einstein Allee 23, D-89081 Ulm, Germany

RICHARD R. FACKLAM  
Streptococcus Laboratory, Respiratory Diseases Branch, Division of Bacterial Diseases, Centers for Disease Control and Prevention, Mail Stop C0-2, Atlanta, GA 30333

FERRIC C. FANG  
Departments of Laboratory Medicine and Microbiology, University of Washington School of Medicine, Seattle, WA 98195

J. J. FARMER, III  
Silver Hill Associates, 1781 Silver Hill Road, Stone Mountain, GA 30087-2212

PATRICIA I. FIELDS  
Enteric Diseases Laboratory Branch, Centers for Disease Control and Prevention, Atlanta, GA 30333

SYDNEY M. FINEGOLD  
Infectious Diseases Section, VA Medical Center, and Department of Medicine and Department of Microbiology, Immunology, and Molecular Genetics, University of California at Los Angeles, Los Angeles, CA 90073

COLLETTE FITZGERALD  
National Campylobacter and Helicobacter Reference Laboratory, Enteric Diseases Laboratory Branch, Centers for Disease Control and Prevention, Atlanta, GA 30329

MICHAEL S. FORMAN  
Division of Medical Microbiology, Department of Pathology, The Johns Hopkins Hospital, 600 North Wolfe Street, Meyer B1-193, Baltimore, MD 21287-7093

STEPHEN J. FORSYTHE  
Nottingham Trent University, Nottingham, NG11 8NS, United Kingdom

RICHARD FRANKA  
Poxvirus and Rabies Branch, Division of High Consequence Pathogens and Pathology, Centers for Disease Control and Prevention, Atlanta, GA 30333

RENO FREI  
Universitätsspital Basel, Klinische Mikrobiologie, Petersgraben 4, CH-4031 Basel, Switzerland

MATTHIAS FROSCH  
Institute for Hygiene and Microbiology, University of Würzburg, 97080 Würzburg, Germany

CHARLES F. FULHORST  
Department of Pathology, The University of Texas Medical Branch at Galveston, Galveston, TX 77555-0609

GUIDO FUNKE  
Risch Laboratories Group, Landstrasse 157, FL-9494 Schaan, Principality of Liechtenstein

NAOMI J. GADSBY  
Specialist Virology Centre, Department of Laboratory Medicine, Royal Infirmary of Edinburgh, 51 Little France Crescent, Edinburgh, EH16 4SA, United Kingdom

HECTOR H. GARCIA  
Center for Global Health, Department of Microbiology, Universidad Peruana Cayetano Heredia, & Cysticercosis Unit, Instituto Nacional de Ciencias Neurologicas, H. Delgado 430, SMP, Lima 31, Peru

LYNNE S. GARCIA  
LSG & Associates, 512 12th Street, Santa Monica, CA 90402

DEA GARCIA-HERMOSO  
Unité Mycologie Moléculaire, CNRS URA3012, Centre National de Référence des Mycoses Invasives et Antifongiques, Institut Pasteur, Paris, France

BARRIE A. GÄRTNER  
Virology, Institute for Microbiology, University of the Saarland, D-66421 Homburg/Saar, Germany

CHARLOTTE A. GAYDOS  
Johns Hopkins University, Division of Infectious Diseases, Department of Medicine, 530 Rangos Building, 855 N. Wolfe St., Baltimore, MD 21205

WALTER GEIßDÖRFER  
Mikrobiologisches Institut - Klinische Mikrobiologie, Immunologie und Hygiene, Friedrich-Alexander-Universität Erlangen-Nürnberg and Universitätsklinikum Erlangen, 91054 Erlangen, Germany

PETER GERNER-SMIDT  
National Center for Emerging and Zoonotic Infectious Diseases, Centers for Disease Control and Prevention, Atlanta, GA 30333

MAHMOUD A. GHANNOUM  
Center for Medical Mycology, Department of Dermatology, Case Western Reserve University, Cleveland, OH 44106

CHRISTINE C. GINOCCHIO  
Hofstra North Shore-LIJ School of Medicine, 500 Hofstra University, Hempstead, NY 11549, and bioMérieux, 100 Rodolphe St., Durham, NC 27712

LORI M. GLADNEY  
IHRC Inc. contractor at the Enteric Diseases Laboratory Branch, Division of Foodborne, Waterborne and Environmental Diseases, Centers for Disease Control and Prevention, Atlanta, GA 30333

MARKUS GLATZEL  
Institute of Neuropathology, University Medical Center Hamburg-Eppendorf, Martinistraße 52, D-20246 Hamburg, Germany

BEATRIZ L. GÓMEZ  
School of Medicine and Health Sciences, Universidad Rosario, Bogota, and Medical and Experimental Mycology Unit, Corporación para Investigaciones Biológicas (CIB), Medellín, Colombia
CONTRIBUTORS

JUAN A. JIMENEZ
Department of Microbiology, Universidad Peruana Cayetano
Heredia, H. Delgado 430, SMP, Lima 31, Peru

ELIZABETH M. JOHNSON
Mycology Reference Laboratory, Public Health England,
South West Laboratory, Myrtle Road, Kingsdown, Bristol BS2 8EL, United Kingdom

JEFFREY L. JONES
Parasitic Diseases Branch, Division of Parasitic Diseases,
Center for Global Health, Centers for Disease Control and Prevention, 1600 Clifton Road NE, MS F-22, Atlanta, GA 30329

Acknowledgment of Previous Contributors

The Manual of Clinical Microbiology is by its nature a continuously revised work which refines and extends the contributions of previous editions. Since its first edition in 1970, many eminent scientists have contributed to this important reference work. The American Society for Microbiology and its Publications Board gratefully acknowledge the contributions of all of these generous authors over the life of this Manual.
The Manual of Clinical Microbiology (MCM) is the most authoritative reference text in the field of clinical microbiology. This edition of the Manual benefited from the talents of a team of 22 editors and almost 250 authors who were supported by a very capable production team at ASM Press. This, the 11th edition, is presented after the usual 4-year publication cycle following the 10th edition. All of the editorial team are proud members of the American Society for Microbiology and strong supporters of its book publishing arm, ASM Press. We have followed in the footsteps of previous authors and editors of the Manual and remain steadfastly committed to the utmost quality and timeliness that the MCM readership has come to expect. For the first time, we have had co-editors in chief of MCM. The length and scope of the Manual now require this division of labor to ensure thoroughness and timeliness of the editing process. We hope that readers of the Manual will recognize the commitment to excellence by everyone associated with its production.

We represent only the fifth and sixth editors in chief in the 45-year history of the Manual. We are grateful for the example set by our predecessors and by the sage advice offered by recent editors in chief Patrick Murray and James Versalovic. We offer our deep appreciation to Ken April, the production editor at the outset of this edition, and to Ellie Tupper, who succeeded him and completed the editorial production process.

This is only the second edition of the Manual to have a full-scale, searchable, Web-based HTML electronic edition. We hope that users of the Manual will find this electronic alternative to the print version of MCM to be convenient and user friendly. It is likely that future editions of MCM will rely more heavily on the electronic format for delivery of the vast content of the Manual.

This is a very dynamic era in clinical microbiology, with new technical tools (MALDI-TOF, ribosomal and total gene sequencing, and other molecular methods) that are profoundly influencing our approaches to organism detection and identification. The Manual continues to include classic microbiological techniques such as microscopy and culture as a foundation in addition to the newer methods cited above. Some organisms have become prominent causes of disease recently, e.g., Ebola, enterovirus D-68, and Gram-negative bacteria that produce carbapenemases. Every effort was made to include up-to-date information in the Manual on these recently emergent organisms. In addition, the studies of the human microbiome have informed our understanding of normal microbial communities and have posed the possibility of polymicrobial rather than single-agent infections.

In conclusion, we are profoundly grateful for the privilege of guiding the Manual through the publication of this 11th edition. We hope that the efforts of the editors and authors will prove useful to the clinical microbiology community until the next edition is available in about 4 more years.

JAMES H. JORGENSEN
MICHAEL A. PFALLER
April N. Abbott (coauthor on chapter 77) has participated in research studies supported by Cepheid, ELITech, and Nanosphere.

Ellen Jo Baron (chapters 18, 50) is an employee of Cepheid.

Karen Bush (coauthor on chapter 68) has received retirement compensation from Bristol-Myers Squibb, Johnson & Johnson, and Pfizer (Wyeth). She has served as advisory board member or consultant for or has received research support from Allegra, Apple Tree Partners, AstraZeneca, Basilea, Cempra, Cubist, Fedora, Medivir, Merck, Novartis, Rempex, Roche, Shionogi, The Medicines Company, Theravance, and Wockhardt.

Karen C. Carroll (volume editor; coauthor on chapters 4 and 53) has received research funding or has been a consultant for Abbott Molecular, Inc., Accelerate, Inc., AdvanDx, Inc., BD Diagnostics, Inc., BioFire, Inc., Quidel, Inc., Nanosphere, Inc., and NanoMR. She also receives royalties from McGraw-Hill Publishers.

Maiken Cavling-Arendrup (coauthor on chapter 131) has received research funding and/or been a consultant for Astellas, Cephalon, Gilead Sciences, Merck Sharp & Dohme, Pfizer, Schering-Plough, and Swedish Orphan.

Sharon Chen (coauthor on chapter 119) has served on antifungal advisory boards of Merck, Gilead Sciences, and Pfizer and received untied grants from Merck, Pfizer, and Gilead Sciences.

Christopher Doern (coauthor on chapter 5) has served as a consultant to ThermoFisher and Copan and has received research funding from Becton Dickinson, BioFire, and bioMérieux.

J. Stephen Dumler (section editor; chapter 61; coauthor on chapters 48 and 65) holds a patent for the in vitro cultivation of *Anaplasma phagocytophilum* that is used as a primary method to prepare serodiagnostic tests. The technology is licensed to Focus Laboratories and he receives periodic royalties for this license.

Ferric C. Fang (coauthor on chapter 77) has participated in research studies supported by Cepheid, ELITech, and Nanosphere.

Charlotte Gaydos (coauthor on chapter 63) has received research funding from Hologic/GenProbe, Abbott, Bectin Dickinson, Roche, and Cepheid.

Christine C. Ginocchio (section editor; coauthor on chapters 80, 81, and 104) is an employee of bioMérieux. She has received clinical trial/research funding from Diagnostic Hybrids/Quidel, Inc. and research funding and Advisory Board fees from Hologic.

Patti E. Gravitt (coauthor on chapter 104) has received research funding from Roche and Merck and served on an Advisory Board for Qiagen.

Patricia Harris (coauthor on chapter 80) is a former employee of Diagnostic Hybrids/Quidel, Inc.

Randall Hayden (coauthor on chapter 103) is a consultant for Quidel Corporation and has research agreements and collaborations with Focus Diagnostics, Luminex Molecular Diagnostics, Inc., EliTech, and BioFire Diagnostics, Inc.

Janet A. Hindler (coauthor on chapter 74) has received funding for research from bioMérieux, Siemens Healthcare, and BD Biosciences.

Romney M. Humphries (coauthor on chapter 74) has received funding for research from bioMérieux, Siemens Healthcare, and BD Biosciences.

Elizabeth M. Johnson (section editor; coauthor on chapter 131) has received research funding and/or been a consultant and/or invited speaker for Astellas, Gilead Sciences, Merck Sharp & Dohme, Pfizer, and Schering-Plough.
James H. Jorgensen (co-editor in chief; coauthor on chapters 1 and 71) serves on an advisory board for Accelerate Diagnostics and has received research support from Merck Pharmaceuticals.

Daryl M. Lamson (coauthor on chapter 88) has a patent application pending for the discovery of HRV-C sequences and their uses (application number PCT/US 2009/0275636).

James S. Lewis, II (coauthor on chapter 68), has served as consultant to Acceler8 Technology, Astellas, Forest, Merck, Pfizer, Trius, Cubist, Rempex, and Theravance and is on the speakers bureaus of Astellas, Forest, and Merck.

Stephen E. Lindstrom (coauthor on chapter 84) has a patent on realtime RT-PCR assays for influenza.

Melissa Miller (section editor) has served as consultant to Becton Dickinson, Meridian Biosciences, and GenMark Dx and has received clinical trial and research funding from Becton Dickinson, Luminex Molecular Diagnostics, Cepheid, Hologic, and Nanosphere.

Susan Novak-Weekley (coauthor on chapter 140) was a member of the Roche Advisory Board in 2012.

Robin Patel (section editor; coauthor on chapter 4) has received research support from Pfizer, Pradama, Astellas, Tornier, bioMérieux, NanoMR, 3M, BioFire, and Bruker. She has patents on an antibiofilm substance, a method and apparatus for device sonication, and a PCR assay for *Bordetella pertussis* and *Bordetella parapertussis*.

David Perlin (chapter 130) is listed on a pending patent application concerning diagnostics for echinocandin resistance.

Michael A. Pfaller (co-editor in chief; coauthor on chapter 1) is an employee of T2 Biosystems.

Bobbi S. Pritt (section editor; coauthor on chapter 136) has received a grant to perform research in collaboration with the University of Minnesota to improve the performance of rapid diagnostic tests, funded through the Minnesota Partnership for Biotechnology and Medical Genomics program. She has also participated in research studies supported by Roche Diagnostics and Gen-Probe.

Sandra Richter (volume editor; coauthor on chapters 72 and 79) has participated in research studies supported by Achaogen, BD Diagnostics, bioMérieux, BioFire, Forest Laboratories, Nanosphere, Pocared, and OpGen.

Robert Shafer (coauthor on chapter 111) has consulted for Celera. He has received unrestricted research gifts from Celera, Siemens Health Care, and Hoffman LaRoche and research funding from Merck Pharmaceuticals, Bristol-Myers Squibb, Hoffmann-LaRoche, and Gilead Sciences.

Jennifer S. Smith (coauthor on chapter 104) has received research funding or advisory board consultation fees from BD, GlaxoSmithKlein, Hologic, Merck, Qiagen, and Trovogene.

Tania Sorrell (coauthor on chapter 119) has served on antifungal advisory boards of Merck, Gilead Sciences, and Pfizer and received untied grants from Merck, Pfizer, and Gilead Sciences.

Yi-Wei Tang (section editor; coauthor on chapters 81 and 86) has research agreements and collaborations with Alere, Cepheid, Luminex, and Roche.

Introduction to the 11th Edition of the Manual of Clinical Microbiology

JAMES H. JORGENSEN AND MICHAEL A. PFALLER

The 11th edition of the Manual of Clinical Microbiology (MCM11) marks a significant change from prior editions in that there are co-editors in chief for the first time. There has been only one editor in chief for all prior editions since the first edition in 1970. However, as the Manual has grown in size and scope, it has become a Herculean effort for a single editor in chief. Since the 8th edition of the Manual, it has been published as two volumes. We have divided our duties primarily by volume: volume 1 (Jorgensen) and volume 2 (Pfaller). This edition of the Manual contains 151 chapters comprising almost 2,600 pages. It includes a comprehensive array of content on all aspects of microbiology contributed by world experts on each subject, with their chapters edited by a highly committed team of volume and section editors working within the usual 4-year publication cycle. This edition includes one new volume editor (Sandra Rich-ter) and three new section editors in addition to the new editors in chief. Four volume editors, Karen Carroll, Guido Funke, Marie Louise Landry, and David Warnock, served for the past edition of the Manual. Underscoring the international importance of the Manual, 20% and 37% of section editors and chapter authors, respectively, contributed content from countries outside the United States (up from 19 and 30% in the previous edition). There were 88 authors who contributed content to the Manual for the first time.

The overall organization of the Manual and the chapter formats are quite similar to those of the 10th edition. However, readers will note some new or expanded content in this edition. Since publication of the 10th edition, the application of matrix-assisted laser desorption ionization–time of flight mass spectrometry (MALDI-TOF MS) has rapidly been developed and embraced by clinical microbiology laboratories for identification of a vast array of bacteria and fungi. Most of the “organism” chapters now include comments on the utility of MALDI-TOF MS for the particular genera and species under discussion. Microbiologists have quickly joined this bandwagon due to the speed, accuracy of identifications, and low cost per test of this technique (despite the high initial instrument acquisition cost). The technology is still evolving, as the required extensive databases needed for all of the relevant organism groups are being painstakingly constructed. Assuming the adequacy of the databases, this technology may supplant much of the conventional phenotypic testing of the past and even the use of sequence-based identification approaches. Having said that, the cost and complexity of gene sequencing has continued to decrease rapidly, making it likely to be accessible to more clinical microbiology laboratories in the next few years. We have learned that no one genomic, proteomic, or phenotypic approach is perfect for the identification of all organisms, and different approaches may need to be used in concert to accurately identify some organisms.

Readers will note many new genus and species names in this edition. These result from initial descriptions of some species and reclassification of some genera and species from a previous taxon to a new or different one based upon 16S or 23S gene sequencing studies, sequencing of certain housekeeping genes, or DNA hybridization efforts that have demonstrated new phylogenetic associations. Some of these may seem bewildering at first due to the many new names that are unfamiliar to both microbiologists and practicing clinicians. Some of the newly designated organisms may not be recognized by conventional phenotypic testing and may not be found in the databases of FDA-cleared identification devices. They may require gene sequencing, use of microarrays, or perhaps mass spectrometry for accurate identifications. This will put pressure on clinical microbiology laboratories to either adopt newer technologies or place greater reliance on reference laboratories when it is important to know the contemporary identities of significant organisms. This offers an opportunity for dialogue between clinical microbiologists and the clinicians that they serve regarding the situations in which intensive identification efforts are justified.

The structure of volume 2 is largely the same as that found in MCM10. In Section IV (Virology), the chapter on Hendra and Nipah viruses from the previous edition has been folded into chapter 85 (“Paramyxoviridae”) and also includes other members of the Paramyxoviridae, and chapter 106 now highlights bocaviruses along with paroviruses to recognize the emergence of the former as a human pathogen since its discovery in 2005. The Mycology and Parasitology sections remain largely unchanged, with the exception of the movement of the chapter on microsporidia from the Parasitology section to the Mycology section in recognition of the reclassification of these agents to the kingdom Fungi. As with the Bacteriology chapters,
the chapters in volume 2 reflect the tremendous advances in the area of molecular taxonomy which have resulted in the reclassification of many different organisms, the recognition of several so-called “cryptic” species, and the discovery of several “new” pathogens as molecular and proteomic tools find their way from the research setting to the clinical laboratory.

Now entering its 6th decade, the Manual strives to continue to be the leading, most authoritative reference for the “real-world” practice of clinical microbiology. In order to create and assemble each edition, this publication builds on the content of past editions, and the process requires about 3 years of careful planning, design, writing, and review of chapters before the final phases of copyediting, composition, printing, and binding. In the intervening 1 to 2 years from the time of chapter acceptances until printing, new diagnostic trends, technologies, pathogens, and patterns of infectious diseases may emerge or change in ways that affect the timeliness and relevance of this comprehensive reference. This sobering reality simply “goes with the territory” of compiling any authoritative body of work. Hopefully the Manual continues to provide a highly respected benchmark and authoritative reference for the entire field of clinical microbiology. In the era of mass collaboration and rapid communication, our team at the Manual trusts that our readership, each of you, will contribute to the future of this field by pointing out errors, issues, and trends that serve to strengthen the Manual and its next edition. The work never stops, and the knowledge base keeps growing. So let us all continue to enhance the practice and contribute to the evolution of our cherished profession of clinical microbiology.
The history of microscopy has been closely linked to the beginning of microbiology since 1665, when Hooke published his treatise *Micrographica*, which included illustrations of mold forms and the anatomy of the flea (1). Today, light microscopy is used not only in microbiology, pathology, and cell biology but also in metallurgy, materials science, computer chip design, and microsurgical applications. This chapter will attempt to describe the basic concepts of light microscopy as they are practiced in the microbiology laboratory.

**TECHNICAL BACKGROUND AND DEFINITION OF TERMS**

**Aberration**

Aberrations are unwanted artifacts in the microscopic image that are caused by elements in the optical path. Aberration can be caused by physical objects, such as dust or oils, on the optical surfaces, by alterations in the light path caused by improper alignment or aperture settings, and by lens system imperfections. Two main types of optical aberration, spherical aberration and chromatic aberration, can occur when white light passes through a convex lens. Spherical aberration is exhibited by images that appear to be in focus in the center of the field and out of focus at the periphery (2). Chromatic aberration occurs because shorter light wavelengths are refracted to a greater extent than longer wavelengths (2). This wavelength separation (also called dispersion) produces color fringes within the image field. Lenses that are not corrected for chromatic aberration can cause difficulties when interpreting Gram and other staining that appear to be in sharp focus. Depth of field decreases as the numerical aperture (NA) of the lens increases (4). Depth of focus is the area around the image plane where the image will appear to be sharply focused. The image plane is formed within the microscope tube at or near the level of the ocular lenses. Microscopes with greater depths of focus allow the user to employ ocular lenses with different working distances, magnification factors, and visual compensation systems without losing image sharpness. Like depth of field, depth of focus depends upon the numerical aperture of the objective. However, depth of focus increases as the numerical aperture increases (4).

**Immersion Fluid (Immersion Oil)**

Immersion fluid is a term used to describe any liquid that occupies the space between the object and microscope objective lens. Immersion fluids are usually required for objectives that have working distances of 3 mm or less (2). Many microscopy applications employ immersion fluids that possess the same refractive index as the glass slide (refractive index = 1.515) (2, 4). This procedure produces a homogeneous optical path which minimizes light refraction and maximizes the effective numerical aperture of the objective lens. Immersion fluids are also used between the condenser and the microscope slide in transmitted light fluorescence microscopy and in dark-field microscopy to minimize refraction, to increase the numerical aperture of the objective, and to improve optical resolution (2, 4).

**Köhler Illumination**

Köhler illumination was first introduced in 1893 by August Köhler of the Carl Zeiss Corporation as a method for providing the optimum specimen illumination (2). In this procedure, the collector lens projects an enlarged and focused image of the lamp filament onto the plane of the aperture diaphragm. Because the light source is not focused at the specimen, the specimen is bathed in a uniformly bright, glare-free light that is not seriously affected by dust and imperfections on the glass surfaces of the condenser. Köhler illumination is required to produce the maximum optical resolution and high-quality photomicrographs (2, 5).

**Mechanical Tube Length**

Mechanical tube length describes the light path distance within the microscope body tube. Tube length is measured...
increases the maximum theoretical numerical aperture of the same power (refractive index of immersion oil = 1.515) to an oil immersion objective that uses air as the imaging medium (refractive index of air = 1.003) to an oil immersion objective above. Moving from a high dry microscope to a similar objective with an oil immersion medium increases the numerical aperture (see Fig. 2). Refractive index is also an important factor in calculating numerical aperture (see Table 1). Light dispersion causes chromatic aberration in microscope objectives when light beams of different wavelengths (e.g., white light) are dispersed when they move into a different medium because the wavelengths are deflected (refracted) to a greater extent. The refractive index of a medium depends upon the wavelength of light passing through it. Light beams containing multiple wavelengths (e.g., white light) are dispersed when they move into a different medium because the wavelengths are deflected to slightly different degrees. Light dispersion causes chromatic aberration in microscope objectives. Refractive index is also an important variable in calculating numerical aperture (see "Numerical Aperture" above). Moving from a high dry microscope objective that uses air as the imaging medium (refractive index of air = 1.003) to an oil immersion objective of the same power (refractive index of immersion oil = 1.515) increases the maximum theoretical numerical aperture of a given lens from 1.0 to 1.5, producing a 50% increase in light-gathering capability.

Numerical Aperture

NA is a measure of the light-gathering capability of a lens or condenser. Higher NA objectives have better resolving power and brighter images than lower NA objectives. Higher NA objectives also have a shallower depth of field. The equation for determining NA is given by $\text{NA} = n \times \sin(\theta)$, where $n$ is the refractive index of the imaging medium between the objective and the specimen and $\theta$ is one-half the angular aperture of the objective (Fig. 2).

Resolution (Resolving Power)

The resolution of an optical microscope is defined as the shortest distance between two points that can be distinguished as separate entities by the observer or camera system. The resolving power of a microscope is the most important feature of the optical system because it defines our ability to distinguish fine details in a specimen. The theoretical limit of resolution ($r$) for a given lens is defined mathematically as $r = \kappa/(2\text{NA})$, where $\kappa$ is the imaging wavelength and NA is the numerical aperture of the lens. From this equation, it is obvious that only the light wavelength and NA directly affect the resolving power. Thus, a 40× oil objective with an NA of 1.30 can have the same resolving power as a 100× oil objective. In the same manner, the resolving power of a 100× oil objective will be higher when ultraviolet (UV) wavelengths are used than when visible light is used.

Working Distance

Working distance is the distance between the leading edge of the objective lens and the top of the cover glass when the specimen is in focus (Fig. 2). The working distance of an objective generally decreases as magnification increases. The working distance of an objective may not be inscribed on the barrels of older objectives, but newer objectives often contain the working distance in millimeters. Longer working distance objectives are important when examining the inside surfaces of glass tubes (tube cultures) and cell culture flasks.

SIMPLE MICROSCOPE

Common objects, such as jeweler’s loupes, photographic slide viewers, and simple magnifying or reading glasses, are all examples of simple microscopes. A simple microscope contains a single bi-convex magnifying lens which is...

thicker in the center than at the periphery. In contrast, with compound microscopes, simple microscopes produce a magnified image that is in the same orientation as the original object. Because of their low NA, simple microscopes have limited resolution and magnifying power. Most commercial magnifiers are able to produce a ×2 to 30 magnification, and the better lenses will have a resolution of about 10 µm. Simple magnifiers are useful for dissection, examination of bacterial colonies, and interpretation of agglutination reactions.

**COMPOUND MICROSCOPE**

The first compound microscopes were constructed around 1590 by Dutch spectacle makers Zaccharias Janssen and Hans Janssen. The Janssen microscope consisted of an object lens (objective) that was placed close to the specimen and the eye, or an ocular lens that was placed close to the eye. The lenses were separated by a body tube. In this microscope, the objective lens projected a magnified image into the body tube and the eyepiece magnified the projected image, thereby producing a two-stage magnification. Modern compound microscopes still use this general design and have two separate lens systems mounted at opposite ends of a body tube.

The stereoscopic microscope combines two compound microscopes, which produce separate images for each eye. The three-dimensional stereoscopic effect is produced in the brain when two images are viewed with slightly offset viewing perspectives. Placing a camera on one of the eyepieces or on a dedicated camera port will not produce a three-dimensional photo image. Stereoscopic microscopes are used with reflected or transmitted illumination, but the absence of a substage condenser limits their NA and resolution. Stereomicroscopes are useful in examining the colonial morphology of bacteria, fungi, and cell cultures.

**Optical Train**

The modern light microscope is composed of optical and mechanical components that, together with the mounted specimen, make up the optical train. The optical train of a typical bright-field microscope consists of an illuminator (light source and collector lens), a substage condenser, a specimen, an objective, the eyepiece, and a detector. The detector can be a camera or the observer’s eye.

Specimen illumination is one of the most critical elements in optical microscopy. Inadequate or improper sample illumination can reduce contrast in the specimen and significantly decrease the resolving power of any microscope (7). Fifty or 100-watt tungsten halogen lamp systems have been the most popular means of providing light for visible-light microscopy because they have a relatively low cost and provide a white light. Newer microscopy systems now use light-emitting diode (LED) light matrices. These systems have reduced energy requirements, do not heat the specimen or the lower optical train, and last for decades.

Light generated by the light source is passed through a collector and a field lens (Fig. 3) before being directed into the substage condenser and onto the specimen. Image-forming light rays are captured by the microscope objective and passed into the eyepieces or a camera port. Alignment of the optical components of a microscope is critical to producing a good image.

**Field Diaphragm**

The field diaphragm is located in the light path between the light source and the substage condenser (Fig. 3). This iris-like mechanism controls the width of the light beam that enters the substage condenser. The field diaphragm does not affect the optical resolution, numerical aperture, or intensity of illumination. However, the field diaphragm should be centered in the optical path and opened far enough that it just overfills the field of view. This adjustment is important for preventing glare and loss of contrast in the observed image. When the field diaphragm is opened...
too far, scattered light and reflections can degrade image quality (1).

**Substage Condenser**

The substage condenser is typically mounted beneath the microscope stage in a bracket that can be raised or lowered independently of the stage (Fig. 3). The substage condenser gathers light from the field diaphragm and concentrates it into a cone of light that illuminates the specimen with uniform intensity over the entire field of view. Adjustment of the substage condenser is probably the most critical element for achieving proper illumination, and it is the main source of image degradation and poor-quality photomicrography. The condenser light cone must be properly adjusted to optimize the intensity and angle of light entering the objective. Because each objective has different light-gathering capabilities (numerical aperture), the substage condenser should be adjusted to provide a light cone that matches the numerical aperture of the new objective. This is done by adjusting the aperture (or condenser) diaphragm control. Substage condensers on newer microscopes have a scale embossed on the condenser and an index mark on the aperture control that allows the user to quickly switch from one NA range to another. Many manufacturers are now synchronizing the NA gradations to correspond with the approximate numerical aperture of the objectives.

In clinical laboratory practice, the condenser aperture is often made smaller to improve the contrast of wet mounts and some stained preparations (1). This practice, while effective for some applications, will result in decreased resolution (3). It should be noted that the intensity of illumination should not be adjusted by opening and closing the condenser aperture diaphragm or by moving the condenser laterally in the light path. Illumination intensity should be controlled through the use of neutral density filters placed into the light path or by reducing voltage to the lamp. It should be noted that reducing the voltage will also alter the color of the light emanating from a tungsten halogen bulb (5). The lighting intensity provided by LED light systems can be reduced without altering the color of the light. The color of the incoming light will affect photomicroscopic color balance, and it can influence the interpretation of stained specimens.

**Objectives**

The objective lens is the most important single determinant of the quality of the image produced by a particular microscope (1). When choosing a microscope, the purchaser must select the magnification factor, the NA, and the level of correction for each objective. Lenses with higher NA values will have higher resolution and produce a brighter field of view. Choosing an appropriate level of optical correction will depend upon the ultimate use of the microscope. Achromatic (achromat) objectives are the least expensive objectives found on laboratory microscopes. Achromat objectives are corrected for axial chromatic aberration in two wavelengths (red and blue), and they are corrected for spherical aberration in one color (green) (2). The limited correction of achromatic objectives can cause a number of optical artifacts when specimens are examined and photographed in color (e.g., green images often have a reddish-magenta halo) (2). Achromat objectives produce the best results when the light passes through a green filter and when black-and-white photomicroscopy is performed. Flatness of field is also a problem when using straight achromat objectives because the center of the field is in focus while the edges are out of focus (2). In the past few years, most manufacturers have begun providing flat-field corrections for achromat objectives. These objectives are called plan-achromats.

The next-higher level of correction and cost is found in objectives called fluorites or semiapochromats. Fluorite objectives are produced from advanced glass formulations that allow for greatly improved correction of optical aberration. Like achromat objectives, fluorite objectives are corrected chromatically for red and blue light (2). Fluorites, like achromats, are corrected spherically for two or three colors instead of a single color (2). The superior correction of fluorite objectives compared to that of achromat objectives enables these lenses to be made with a higher numerical aperture. Fluorite lenses produce brighter images than achromats. Fluorite objectives also have better resolving power than achromats and provide a higher degree of contrast, making them better suited for color photomicrography in white light (2, 4).

APOCHROMATS ARE THE MOST HIGHLY CORRECTED MICROSCOPE LENSES AND THE MOST COSTLY. APOCHROMATS ARE CORRECTED CHROMATICALLY FOR THREE COLORS (RED, GREEN, AND BLUE), WHICH ALMOST ELIMINATES CHROMATIC ABERRATION, AND ARE CORRECTED SPHERICALLY FOR EITHER TWO OR THREE WAVELENGTHS (2). APOCHROMAT OBJECTIVES ARE THE BEST CHOICE FOR COLOR PHOTOMICROGRAPHY IN WHITE LIGHT. BECAUSE OF THEIR HIGH LEVEL OF CORRECTION, APОСHРОМАТ OBJECTIVES USUALLY HAVE, FOR A GIVEN MAGNIFICATION, HIGHER NUMERICAL APERTURES THAN DO ACHROMAT OR FLUORITE OBJECTIVES (2, 4).

Fluorescence objectives are designed with quartz and other special glasses that have high rates of transmission of UV, visible, and infrared light. These objectives are extremely low in autofluorescence and use specialized optical elements and antireflection coatings that protect the lens and allow it to operate with a wide variety of excitation wavelengths. Correction for optical aberration and numerical aperture values in UV fluor objectives usually approaches that of apochromats, which contributes to image brightness and enhanced image resolution (2, 8). The primary drawback of high-performance fluorescence objectives is that many are not corrected for field curvature and produce images that do not have uniform focus throughout the entire field of view. This is not a large problem when performing direct or indirect fluorescent antibody testing but it can be troublesome if you have to use the same objectives for bright-field or phase-contrast microscopy.

Microscope objectives that use air as the medium between the coverslip and the objective lens are considered dry objectives. The maximum working numerical aperture of a dry objective system is limited to 0.95, and greater values can be achieved only with optics designed for immersion media. Immersion media have the same refractive index and dispersion values as glass (refractive index = 1.51). The use of immersion media produces a homogeneous light path from the coverslip to the lens so that light is not refracted away from the objective. The use of immersion fluids and lenses significantly increases the numerical aperture and the optical resolution of the system. In addition to oil lenses, specially corrected objective lenses designed for glycerine and water immersion are available commercially. The proper immersion fluid type is always stamped on the side of the objective. The advantages of oil immersion objectives are severely compromised if the wrong immersion fluid is utilized. Microscope manufacturers produce immersion objectives with tight refractive index and dispersion tolerances (2). It is therefore advisable to use only the immersion
Dark-field microscopy is a specialized illumination technique used to detect thin organisms, such as spirochetes and *Leptospira* spp. High-resolution dark-field microscopy utilizes a specialized high-NA cardioid dark-field condenser that blocks the central light path light and produces a hollow cone of illumination that is directed away from the objective lens at an oblique angle (Fig. 4). Bacteria on the slide have a slightly different refractive index than the surrounding medium, and light rays passing through the organism are refracted into the objective lens, producing bright organism profiles against a dark background. Dark-field microscopy requires careful alignment of the condenser and placement of immersion oil between the slide and the substage condenser. Dark-field microscopy, when done correctly, increases the resolution of the microscope to 0.1 μm or less (3). The resolution of bright-field microscopy is 0.2 μm (1).

**PHASE-CONTRAST MICROSCOPY**

Many unstained biological specimens are virtually transparent when observed under bright-field illumination. To improve visibility in wet mounts and cell cultures, microscopists often reduce the opening size of the substage condenser iris diaphragm, but this maneuver is accompanied by a serious loss of resolution and the introduction of diffraction artifacts (2, 3). Phase-contrast microscopy significantly improves the contrast in these specimens without significant loss in resolution (3).

In phase-contrast microscopy, a ring annulus is placed directly under the lower lens of the condenser to produce a hollow cylinder of light. This light is essentially unchanged as it passes into the objective, and it arrives at the rear focal plane of the objective in the shape of a ring. Light that goes through the specimen is refracted and slowed slightly so that it is out of phase with the unchanged light by about 1/4 wavelength. This light is spread over the entire focal plane. Light passing through the rear focal plane of the objective interacts with a ring-shaped phase plate that alters the direct light path by 1/4 wavelength (3). When the direct light and the refracted light arrive at the image plane, they are out of phase by 1/2 wavelength. This out-of-phase light interacts destructively, so that specimen details appear as dark areas against a lighter background (3). Because the phase-shifting calculations are based upon a 1/4 wavelength of green light, the phase image has the best resolution when a green filter is placed in the light path (3). Green filters also allow the microscopist to use less expensive achromat lenses that are spherically corrected for green light. Phase microscopy is an important tool for examining living and/or unstained material in wet mounts and cell cultures. However, phase-contrast microscopy has lower resolution than bright-field microscopy of stained specimens (3). In addition, viewed objects are often surrounded by halos that can obscure boundary details. Phase-contrast microscopy does not work well with thick specimens because the phase shift may be greater than the expected 1/4 wavelength.
**FLUORESCENCE MICROSCOPY**

The fluorescence microscope was developed in the early 1900s, and many of the initial microscopic studies involved identification and localization of compounds that autofluoresced when irradiated with UV light. In the 1930s, a number of investigators began using fluorescent compounds to identify specific tissue components and infectious agents that did not autofluoresce (8). Examples of this type of stain include acridine orange (intercalates into DNA and RNA), auramine-rhodamine (for mycolic acids), Calcofluor White (for fungal cell wall polysaccharides), Evans blue (for the cytoplasm of fixed cells), and Hoechst 33258 (for the minor groove of AT-rich double-stranded DNA).

The use of fluorochrome-antibody conjugates (immuno-fluorescence) was first described in the 1940s, when Coons et al. (9, 10) used fluorescein-labeled antibodies to detect pneumococcal polysaccharide antigens in tissue sections of infected mice. Fluorescent-antibody staining expanded significantly with the development of fluorescein isocyanate in 1950 (11) and the more stable fluorescein isothiocyanate (FITC) derivative in 1958 (12–16).

Quantum dots have recently emerged as a new class of fluorescent labels for biology and medicine (17). When conjugated to antibodies and other biological ligands, these tiny light-emitting particles can overcome many of the disadvantages of traditional fluorophores used in clinical pathology. Quantum dots have superior signal brightness, they are resistant to photobleaching, and multiple fluorescent colors can be excited by the same wavelengths of light. The last property makes multicolor fluorescence microscopy easy to perform and, when the wavelengths are tuned properly, provides quantitative information about ligand abundance (18). Quantum dots have been used for staining live cells (18), fixed cells (17), and tissues (17). Today, fluorescence microscopy is also used in conjunction with nucleic acid hybridization to visualize the locations of fluorescent in situ hybridization (FISH) and multicolor FISH probes (19, 20).

Fluorescence microscopy is dependent upon the ability of fluorescent substances to absorb near-UV energy and reemit that energy (light) at a lower wavelength (8). To work properly, the fluorescence microscope must irradiate the specimen with UV excitation light and separate the much weaker emitted light from the brighter excitation light so that only the emitted light reaches the eye. The resulting image consists of brightly shining areas against a dark background (8). Older fluorescence microscopes are configured for dark-field illumination or transmitted light fluorescence (8). These systems were cumbersome to use and lacked resolution. Most modern fluorescence microscopes use reflected light (epifluorescence). In these instruments, the excitation light is directed downward through the objective and onto the specimen. The emitted light and the reflected excitation light are collected by the objective, and they pass through a dichromatic mirror, which removes the excitation light and allows the longer-wavelength emitted light to form an image. With epifluorescence, the objective acts as a condenser and the alignment and oiling issues associated with a dark-field condenser are eliminated (8). The visual field is brighter with epifluorescence, the resolution is higher, and fluorescence quenching occurs only in the field of view (8).

Fluorescence microscopy requires high levels of illumination because the quantum yield of most traditional fluorochromes is low. The most common lamps used in fluorescence microscopy are mercury vapor (HBO) lamps ranging in wattage from 50 to 200 watts or Xenon vapor (XBO) lamps that range from 75 to 200 watts. It should be noted that lamp wattage is not necessarily a measure of usable brightness in a fluorescence microscope. The 100-watt HBO lamp is 4 times brighter than the 200-watt HBO lamp and 11 times brighter than the 150-watt XBO lamp (8). HBO and XBO lamps are under high pressure, and care must be taken to prevent the lamps from exploding. One should never touch these lamps with bare hands because oils on the fingers can etch or discolor the glass.

Fluorochromes must be excited by specific light wavelengths in order to generate the maximum amount of emitted light. Therefore, specific exciter and barrier filter combinations are used to maximize the quantum yield of the fluorophore. Exciter filters are used to select the required light wavelengths from the spectrum of light generated by the lamp (8). Excitation filters are provided in narrow, medium, and wide bandwidth configurations that pass narrow, midsize, and wide ranges of light frequencies, respectively. Barrier filters block shorter light wavelengths and allow longer wavelengths to pass through the filter. Barrier filters are important because they remove the high-intensity excitation light, which can overwhelm the low-intensity emitted light. Barrier filters also prevent UV light from entering the eye, where it can cause cataracts and retinal damage. Wide-bandpass barrier filters generally produce brighter images, but care must be taken to prevent the introduction of background light, which can overwhelm the emitted light. Epifluorescence microscopes also have a dichromatic mirror (beam splitter) that reflects the incoming excitation light to the objective and allows the emitted light to pass to the barrier filter and on to the objectives (7). In most modern epifluorescence microscopes, the barrier filter, excitation mirror, and beam splitter are housed in removable optical blocks, and several of these blocks can be installed in the microscope at one time. This configuration allows the user to quickly change the excitation and barrier filters to accommodate different fluorochromes. Care must be exercised when selecting optical blocks. The excitation filter should match the excitation wavelength of the fluorophore (Table 2), and the emission barrier should allow the emitted light to

*Excitation and emission wavelengths can vary depending upon the solvent and the pH of the solution.*
Microorganisms can be measured directly by placing them on a calibrated microscope slide or a counting chamber. The accuracy of this method depends upon the separation distance between ruled lines, but it averages between 10 and 50 \( \mu m \).

The most common procedure used in the clinical laboratory utilizes a graduated scale (reticle) located within one of the eyepieces (23). Reticles must be calibrated against a stage micrometer for each objective (23). To avoid unnecessary recalibrations, the calibration information for each objective should be recorded and stored near the microscope workstation. The accuracy of reticle measurement is approximately 2 to 10 \( \mu m \) (3 to 5\%), depending on magnification and the resolution of the stage micrometer (23).

### PHOTOMICROSCOPY

Microscopists began capturing microscopic images on film shortly after the photographic process was invented (5). Micrographic images have long been used for investigations of morphology, in scientific publications and lectures, and in teaching. Modern film technologies have high resolution and clarity, but the use of photomicrographs in day-to-day microscopy has been hampered by long turnaround times associated with film development and printing. Reacquiring fluorescence images is a particular concern because the fluorescence can fade (8). The availability of high-quality digital cameras has significantly changed how photomicrographs are used in the microbiology laboratory. Today it is not unusual for digital photomicrographs to be shared with experts via the Internet. This process significantly extends the capabilities of the on-site microbiologist and can enhance patient care. Microscope-based digital cameras and video systems are also used to perform “plate rounds” in remote hospitals and clinics within a multihospital system. Newer Internet technologies involving robotic microscopes and high-resolution video systems now allow microbiologists to change the focus and change the slide positioning of a microscope located anywhere in the world and to view the resulting images on a monitor in their office. The availability of digital photomicroscopy has significantly enhanced the microbial identification process, and it has helped to standardize microbe identification.

A wide variety of microscopes can be purchased with integrated camera systems and sophisticated light metering and exposure controls. Accessory cameras are also available from a large number of aftermarket manufacturers. However, an expensive camera system does not automatically confer the ability to produce high-quality images. Publication-quality photomicrographs require proper specimen illumination and optical train alignment to achieve the microscope’s ultimate potential (5). Color photography can be especially demanding because specimens may appear yellow or blue under tungsten halogen (3,200 K) light, depending upon whether the lamp voltage is above or below the recommended 9-volt setting. Newer camera systems have sophisticated exposure, lighting, and white balance controls that make image capture easier, but they cannot correct for poor technique.

Not all microbiologists can afford a microscope with an integrated camera system. Simple eyepiece cameras can be used to capture bright-field images for Internet consults, training manuals, and plate rounds. The simplest configuration for eyepiece photography involves the use of a point-and-shoot digital camera. A number of adapters that allow

### LINEAR MEASUREMENTS (MICROMETRY)

The first reported micrometric procedures were credited to Antonie van Leeuwenhoek, who used fine grains of sand as a gauge to determine the sizes of human erythrocytes. Since then, a variety of methods have been used to determine the dimensions of microscopic organisms. The crudest method involves comparing the object size to the measured or calculated view field size. Another rough micrometric method is to compare the sizes of larger organisms to the size of a red blood cell (6 to 8 \( \mu m \)) in the image. Other micrometric techniques include the addition of polystyrene beads of known size into the specimen. Comparative measurements are then performed by utilizing a photomicrograph or digital image. The accuracy of these methods is variable and depends on the homogeneity of the comparison objects.
coupling a fixed-lens camera to a microscope eyepiece tube are now available. Photographs taken in this manner are often acceptable, but they may be dark and have some chromatic aberration (due to different lens correction factors) and vignetting (pipe view effect).

Another method for photomicroscopy is to use the camera port on microscopes fitted with a trinocular head. Olympus and Nikon have introduced adapters that allow their digital cameras to attach to the camera tube of their microscopes. In addition, camera tube and eyepiece adapters for a number of digital cameras are available from Microscope Depot (Tracy, CA). Photography under these conditions is best done using a camera with through-the-lens exposure metering. These devices work well if the exposure is not longer than several seconds or shorter than 1/3 second (5). Many of these cameras have built-in flashes that should be turned off during photomicroscopy. Consumer-grade digital cameras may have problems with fluorescence microscopy due to the extreme contrast of fluorescent images and the tendency of metering systems to average exposure values over the entire field (5).

CARE AND USE OF THE MICROSCOPE

Proper care and maintenance of the microscope will prolong the usable life of the instrument and allow for more accurate interpretation of microbiological images. The microscope should be kept in a low-vibration, low-dust environment to facilitate viewing and to decrease damage to the optical systems. The optical elements should be kept completely free of dust, dirt, oil, solvents, and other contaminants (23). Ideally, the microscope should be covered and the lamp should be turned off when the microscope is not in use. Do not touch the optical surfaces with your fingers (23). Keep the lenses clean, and be sure to remove oil or mounting fluid from the objectives, condenser, and mechanical stage after each session. Immersion oils act as a slow-acting solvent that can weaken the optical mounting cement (7). Avoid dragging the high dry objective through oil or fluorescence mounting fluid. One way to avoid accidental contact with these fluids is to place the high dry objective and the oil immersion objective in the nosepiece on opposite sides of the low-power objective (5). Lenses should be dusted with a fine lens brush and a bulb syringe and cleaned with lens paper and a commercial lens cleaner that is approved by the microscope manufacturer (7). Compressed air is not recommended because it can leave a residue on glass surfaces (7). Commercial cleaners, such as Windex and Sparkle, should not be used on optical surfaces because they often contain acids or bases that can erode the antireflection coatings on the lens (7). Organic solvents, such as alcohols and acetone, should not be used on the lenses because these solvents may dissolve the optical mounting cement (7). Unused spaces in the nosepiece (Fig. 3) should be plugged, and the eyepieces should remain installed at all times to prevent introduction of dust into the body tube. The stage should be cleaned regularly, and any spilled immersion oil or mounting fluid must be removed, or slides will stick when they are moved across the stage. Oils and mounting fluids also collect dust and grit, which can damage the optical and mechanical parts. Microscopists should not attempt to remove or disassemble the objectives, as this increases the potential for damage (23). This is a job that is best left to professionals (23). Do not use lubricating oils on the gears or bearing surfaces of the microscope because this may cause the condenser and stage to sink from their own weight (23). Annual or semiannual cleaning and adjustment by a professional microscope repair person will also help to extend the usable life of the microscope.

ERGONOMICS

Peering into a microscope eyepiece for long periods is not an activity for which the body is well adapted. Microscope work requires the head and arms to be locked in a forward position and inclined toward the microscope with rounded shoulders. This unusual positioning is further exaggerated when the feet are placed on the ring-style footrests that are common on many laboratory stools. Poor posture and awkward positioning during microscopy can cause pain or injury to the neck, wrists, back, shoulders, and arms (24). In one regional survey of cytotechnologists, Kalavar and Hunting (25) found that 70.5% of respondents reported neck, shoulder, or upper back pain during microscopy and that 56% had an increased prevalence of hand/wrist symptoms. Eye strain, leg discomfort, and foot discomfort have also been documented with long-term microscope use (26). With older microscopes, users often have their heads inclined up to 45 degrees from vertical and their upper backs may be inclined by as much as 30 degrees. Even 30-degree inclinations of the head can produce significant muscle contractions, fatigue, and pain (26). For this reason, microscopists should be taught to sit upright and hold their head in a neutral position (27).

During microscopy, the laboratorian should sit erect while maintaining the natural curve of the spine (27). The lower back and shoulder blades should be supported by the chair, and a lumbar support cushion should be used if necessary. The legs and feet should rest firmly on the floor or a footrest. The chair should have a pneumatic height adjustment (23), and the seat should have a sloping front edge to prevent undue pressure on the thighs. The backrest should be adjustable for both height and angle. The chair should have a five-pointed star base with caster wheels. Knee spaces, which are often used for laboratory storage, should be free from obstructions, and there should be a minimum of 2 inches of clearance between the thigh and the bottom of the desk or counter (25). Obstructions that prevent the microscopist from holding his or her shoulders perpendicular to the ocular axis of the microscope should be removed (24). The upper arms should be perpendicular to the floor with the elbows close to the body. The forearms should be parallel with the floor, and the wrists should be straight. The head should be upright, and the neck should bend as little as possible, preferably no more than 10 to 15 degrees. The eyepieces should be just below the eyes, and the eyes should look downward at a 30- to 45-degree angle. The use of tilting microscope heads can significantly improve the comfort of the microscopist (25, 28, 29). Repetitive motions of the hands and the contact stress of arms resting on (the edge of) a hard surface can cause pain and nerve injury, leading to repetitive stress injuries and/or carpal tunnel syndrome (24). The use of padded armrests can moderate some of these problems. In addition, microscopes should not be placed under an air vent in order to prevent stiffening of the muscles during microscopy.

Most laboratory microscopes are used by multiple individuals, and it is often a challenge to find conditions or microscope configurations that satisfy everyone. Some laboratories place microscopes on books or heavy blocks of wood.
to accommodate taller microscopists (23). This configuration creates a number of problems. If the microscope is raised to a sufficient height to prevent neck flexion, users may be forced to bend their wrists into an unnatural position. If the microscope is lowered to allow the forearms to remain parallel to the floor, the neck is forced to bend. Lowering the chair to its lowest position causes leg discomfort. Shorter individuals may have to raise the chair to a level where their feet no longer touch the floor. Footrests can ameliorate this problem, but some individuals may have insufficient space under the benchtop to accommodate their legs. In practice, most laboratories will elect to use a suboptimum, but workable, microscope configuration that all users can employ. Under these conditions, microscopists can reduce stress and fatigue by taking 1-min “microbreaks” every 10 to 15 min during which they can stand, stretch, and allow the eyes to focus at a distance.

Eye fatigue can be a major problem for microscope users, especially if they have poor vision. The dioptr adjustment provided on most microscope eyepieces can be adjusted to compensate for minor near- and far-sightedness and allow the user to remove his/her glasses during microscope use. The dioptr adjustments do not adjust for astigmatism, and users with moderate to severe astigmatism should wear glasses when using the microscope. Most microscope manufacturers now produce high-eyepoint eyepieces that move the visual observation point further from the eyepiece, thereby facilitating the use of glasses during microscopy. Ensuring that the microscope images are as bright, sharp, and crisp as possible will also help to reduce eye fatigue and associated headaches. The importance of proper alignment of the microscope and optical components cannot be overstressed. Proper optical alignment and the use of newer objectives with higher NA values will produce brighter images and better resolution, which eases the strain of searching for tiny specimen details. The use of a neutral blue (daylight) filter during bright-field microscopy can also help to lessen eye strain when examining microbiological specimens. In the future, many new microscopes will display the specimen image on a computer monitor. This innovation may alleviate many of the eyestrain problems that develop during extended microscope use (29).

Microscopes are as different as the people who use them, and the previous comments should not be construed as a prescription for alleviating strain or repetitive-motion injuries in every situation. When purchasing a microscope, every effort should be made to allow microscopists to evaluate the new microscope under their normal working conditions. Some microscopes will be comfortable for some users and uncomfortable for others. In the long run, the fit and feel of the microscope is just as important as the optical characteristics.

CONCLUSIONS

Advances in the design, resolution, and ergonomics of modern microscopes have greatly enhanced our ability to study and identify microorganisms. Microscopy still has a central role in the detection of infectious agents despite highly publicized advances in DNA and RNA detection systems. Microscopic examination of clinical specimens provides a rapid and inexpensive “first pass” in the detection and identification of infectious agents. Thus, clinical microscopy will continue to be a core competency in clinical microbiology laboratories for the foreseeable future.

REFERENCES

The laboratory detection of bacteremia and fungemia remains one of the most important—and complex—roles of clinical microbiology laboratories. This is, in part, because the attributable mortality for bacteremia and fungemia remains as high as 12% (1) but also because rapid, accurate, and reliable identification of patients with bacteremia or fungemia is of critical importance in influencing treatment. Blood culture results guide antimicrobial therapy and also subsequent surgical procedures, removal of vascular access lines, and other clinical interventions. Moreover, diagnosis of bacteremia and fungemia requires more than just a single test. It requires more than one blood culture, drawn from different sites, identification of isolates recovered from blood specimens, antimicrobial susceptibility testing of isolates, and interpretation of results in conjunction with other tests and cultures.

The goal of this chapter is to provide a summary of the clinical importance of bacteremia and fungemia, the scientific and medical principles underlying current diagnostic methods, a summary of alternative diagnostic approaches, and a brief review of those tests that are emerging as potential additions to or replacements for traditional procedures.

ASSESSMENT OF METHODS FOR DETECTING MICROORGANISMS IN BLOOD

No method has been shown to be an ultimate standard for the detection of either bacteria or fungi from blood. It has been recognized for decades that even with the best blood culture systems, use of optimal methods for collecting blood specimens, and limiting collection of blood specimens from patients with a high pretest probability of bacteremia or fungemia, usually only 8 to 12% of blood cultures will yield microbial isolates, of which one-third to one-half will be contaminating skin flora. The reasons for this are not fully understood. The single biggest cause is that many blood cultures are obtained from patients who are at low or no risk for bacteremia or fungemia. A recent study, using a Bayesian prediction model of objective clinical and laboratory risk factors, showed the likelihood of true bacteremia to range from 0.4 to 18.4%, with a mean prevalence of 6.9% in a large cohort of patients (2). Other causes also play a role: (i) many patients are receiving empiric antimicrobial therapy at the time blood specimens are collected, thereby reducing the yield from blood cultures; (ii) patients may have temporarily cleared microorganisms from blood; (iii) specimens may be mishandled, leading to falsely negative results; (iv) some microorganisms cannot be recovered adequately using broth-based blood cultures; (v) the number of microorganisms in a given specimen may be too low to be recovered by current methods; and (vi) current use of 4- or 5-day incubation and testing cycles on automated systems will result in a small number of isolates being undetected.

It was long expected that molecular methods would provide a gold standard test for the detection of bacteremia or fungemia, but this has not been the case. As will be reviewed below, some molecular methods are not even as sensitive as cultures, some have been shown to detect nucleic acids in persons without bacteremia or fungemia, and some proteins in blood have been shown to act as inhibitors to some nucleic acid amplification assays.

One approach has been to use composite standards, such as the use of combined results from different assays. From a statistical standpoint, this is a flawed analysis because any given assay cannot be compared against itself (as part of the gold standard). Moreover, the entire point of developing a standard is to be able to use the standard in many different studies; these “combined” gold standard assays preclude that for the obvious reason that it quickly becomes impractical to use multiple assays as a standard in every evaluation. Assays also change over time, or are no longer marketed at all, which would eliminate their use as part of a combined gold standard.

For all these reasons, and despite their shortcomings, blood cultures remain the imperfect gold standard laboratory test for the diagnosis of bacteremia and fungemia.

DIAGNOSTIC IMPORTANCE

Determining which patients have bacteremia or fungemia and subsequent identification of pathogens and their antimicrobial susceptibility profiles are the most important objectives for using blood cultures as a diagnostic test. However, the identity of pathogens and the pattern of recovery from blood cultures provide important diagnostic clues as to the location and type of infection. There are strong associations between sites of infection and which pathogens are recovered from the bloodstream (3), observations that give critically important information to providers as to the nature of the infection. It should be remembered that up to 29% of blood culture isolates do not have an identifiable source of infection (1).
PROGNOSTIC IMPORTANCE

The attributable mortality rate of about 12% is an overall rate for hospitalized adult patients with bacteremia or fungemia. When the site of infection, type of service, and other variables are used to further categorize patients, mortality rates have been shown to vary widely (1, 3). There is less known about the prognostic importance of blood culture isolates recovered from outpatients as a group, primarily due to a lack of controlled studies but also because most patients with bacteremia or fungemia are sick enough to be admitted to the hospital and therefore become inpatients. Moreover, the frequency of community-acquired occult bacteremia in children has been greatly reduced or eliminated where conjugate pneumococcal and Haemophilus influenzae type b vaccines are used. What data have been published indicate that, for bacteremic patients with uncomplicated pyelonephritis or other uncomplicated infections that do not require subsequent hospitalization, blood cultures generally are not needed because the results have minimal prognostic (and little or no diagnostic) value (4–7).

CRITICAL FACTORS

During the past 40 years, a number of studies established and clarified which factors were most important in the recovery of pathogens from patients with bacteremia or fungemia. Many of the findings are pertinent today, while others now largely have historic interest only. The factors that remain the most important are described in the following paragraphs, but it should be emphasized that optimal recovery of pathogens from blood requires that all of these factors be addressed together, not in isolation.

Volume of Blood Cultured

For adult patients and older children, the volume of blood cultured is the most important factor in recovery of pathogenic microorganisms from blood. It is still important in younger children, but there are practical limits to the volumes of blood that can be withdrawn for laboratory tests such as blood cultures (8). This importance stems from the observation that there is a direct relationship between the total volume of blood cultured and the likelihood of recovery of pathogens (8–12). The research that established this often was done in conjunction with controlled clinical evaluations of different blood culture bottles and systems, which guided development of many of the commercial products that are available today. The outcome of many studies was that, for adult patients, 8 to 10 ml of blood should be inoculated into each of two bottles per blood culture, for a total of 16 to 20 ml of blood. This observation, combined with the finding that 2 to 4 blood cultures are needed to detect bacteremia or fungemia during a septic episode, means that up to 80 ml (four blood cultures of 20 ml each) should be drawn to optimize microbial recovery. Although this is a large amount of blood, and the full 80 ml is not necessary for all patients, it may be necessary to establish whether or not a patient is bacteremic or fungemic depending on the clinical situation and causative organism. This volume of blood may be reduced by half to 40 ml with use of blood culture bottles containing certain additives. For patients with anemia or other reasons for concern about the overall volume of blood drawn for laboratory testing, it is of no benefit to decrease the volume of blood drawn per culture; to do so will only result in decreased recovery of pathogens. A better diagnostic alternative is to modify the number of blood cultures drawn (as discussed below) and to limit the overall number of blood draws to those that are essential for patient care.

For older children, the volume of blood that should be drawn for culture differs little or not at all from that specified for adults. There are no controlled clinical trials that provide guidance, but broadly speaking, children age 12 and older (except for very small children) should have blood cultures drawn according to the criteria used for adult patients. For younger children, the total volume of blood that should be drawn for culture is lower than that for adult patients. For neonates, infants, and very young children, the volume of blood drawn for culture needs to be reduced by two mechanisms: the volume drawn per culture as well as the number of cultures. The number of blood cultures drawn should not exceed 1% of the patient’s blood volume, but this may need to be modified if the patient is anemic at the time of the blood draw (8). As discussed in the following section, the number of blood cultures drawn at one time is critical for proper interpretation of blood culture results. Therefore, no fewer than two blood cultures should be drawn from pediatric patients.

Number of Blood Cultures

Collecting the correct number of blood cultures has two benefits. First, it helps ensure that an adequate volume of blood is drawn for culture. Second, it allows providers to correctly interpret results of blood cultures. Single blood cultures yield information that is difficult to interpret, unless the isolate is one that rarely, if ever, is recovered as a contaminant (e.g., pathogenic fungi such as Histoplasma capsulatum). Aside from examples such as that, however, most isolates recovered from blood cultures require the isolation from more than one blood culture to be considered a cause of sepsis. Contaminants generally occur in only one blood culture of a series, whereas pathogens typically occur in more than one of the blood cultures in a series. For patients with intravascular foci of infection, such as infective endocarditis, all blood cultures in a series should yield the pathogen.

A common question concerns the diagnostic sensitivity and specificity of a blood culture. Because the clinical presentation of patients with bacteremia or fungemia is so varied, clinical signs and symptoms cannot be used as a gold standard against which blood cultures can be prepared. There also is no other laboratory test (or combination of tests) that can serve as a surrogate gold standard. In the absence of another gold standard test, then, only estimates can be made regarding diagnostic sensitivity and specificity. Four studies have addressed this question directly (9, 13–15). Because these studies were conducted during the period from 1975 to 2007, only rough comparisons should be made of the results. This is because (i) the studies used different blood culture systems; (ii) different volumes of blood were cultured; (iii) the relative distribution of pathogenic species changed during this time; (iv) markedly different classes of antimicrobial agents were in use; (v) this time period was the one in which a large number of intravenous devices, implants, and prostheses were introduced and later used widely; (vi) new pathogens were discovered; and (vii) the study design were different. A summary of the results from these four studies is shown in Table 1.

The question, then, is whether the traditional recommendation of drawing two to three blood cultures for the detection of common pathogenic bacteria and yeasts remains valid. Clearly, a single blood culture is insufficient. Because two blood cultures will only recover 80 to 90% of pathogens, at least three blood cultures are necessary, as
that will recover 96 to 98% of pathogens. Although four blood cultures will recover close to 100% of pathogens, routinely drawing this number of blood cultures has several drawbacks: (i) it is not necessary for all patients, (ii) it adds substantially to costs if done on all patients, and (iii) it isn't practicable for some patients. One recommended approach is to draw two blood cultures in the first 24 h, followed by an additional two blood cultures during the subsequent 24 h (9). The main criticism of this approach is that it can delay detection of bacteremia for an additional 24 h. Because this approach also suffers from the aforementioned drawbacks, the available evidence supports drawing three blood cultures in the first 24 h.

Although adult patients vary substantially in both height and weight, in general, the number of blood cultures drawn does not need to be adjusted by either parameter for previously healthy adult patients. For patients with anemia, for whom withdrawing blood for laboratory testing may worsen their anemia, the most important decision is whether blood cultures (or other laboratory tests) are necessary at all. If blood cultures are clinically indicated, it makes neither clinical nor laboratory sense to decrease the number of blood cultures or volume drawn; to do either is not in the patient's best interest.

Dilution of Blood

Dilution of blood was more important with older blood culture media, where the antimicrobial effects of blood per se, and antimicrobial agents in the blood, needed to be diluted by higher volumes of broth medium. Over time it became clear that, with modern blood culture systems using standardized blood culture media, anticoagulants, and other factors, a blood-to-broth ratio of between 1:5 and 1:10 was sufficient. With the addition of additives to the broth medium that bind or sequester antimicrobial agents, a blood-to-broth ratio of as little as 1:4 may be sufficient.

Anticoagulants

In the past, a number of different anticoagulants have been considered for blood culture bottles, since clotted blood diminishes yield (16). Almost all have now been abandoned based on bacterial inhibition studies with seeded blood cultures. Most commercial blood culture bottles today contain sodium polyanethol sulfonate (SPS) in a narrow range of concentrations; some also have sodium citrate alone or in combination with SPS. SPS, in addition to its anticoagulant property, inhibits complement activity, inactivates clinically achievable concentrations of some aminoglycoside antibiotics, inactivates lysozyme, and blocks phagocytosis. The relative effects these four properties have on recovery of pathogenic microorganisms from blood cultures is unknown; however, controlled clinical trials have shown improved recovery of Gram-negative rods and streptococci with adequate concentrations of SPS.

Agitation

Agitation of aerobic blood culture bottles, by any mechanism, has been shown to increase recovery of pathogens, and all automated systems include agitation of aerobic bottles and most anaerobic bottles as well.

Medium and Additives

Although at one time there were many types of broth media used for blood cultures, today most commercial blood culture bottles contain soybean casein digest broth, also known as Trypticase soy broth (BD). Other types of media have shown comparatively little advantage over soybean casein digest broth, even those that were designed to recover specific groups of pathogens.

In the past, a wide variety of additives were added to broth media, many of which are no longer available. Current additives, which were designed to improve recovery of pathogens primarily from patients receiving antimicrobial therapy at the time of culture, clearly are beneficial in terms of recovery of pathogens and have the added advantage of allowing for use of smaller volumes of blood without a concomitant decrease in microbial recovery. Use of some additives may also result in increased recovery of bacterial contaminants.

SPECIMEN COLLECTION

Skin Disinfection

Trials of different skin disinfectants have been published for half a century, with development of reasonable conclusions as to which disinfectants perform better. It cannot be overemphasized, however, that the margin of difference between disinfectants is small and that what is by far more important is the technique used to disinfect skin (17). As a general guide, the best skin disinfectant is chlorhexidine, followed by tincture of iodine, povidone-iodine, and then various alcohols. Specific procedures for disinfection of skin provide with each product, and so will not be presented here, but should be followed closely by users. For infants less than 2 months of age, chlorhexidine should not be used but rather alcohol swabs should be used. Perhaps the single most important point to be made is that skin disinfection takes time: time to perform the procedure and adequate time for the disinfecting solution to work. As noted below, adequacy of disinfection can easily be audited by monitoring contamination rates.

For most adults and older children, blood should be drawn from veins in the antecubital fossae. Not only are these veins readily accessible by venipuncture, but also they are sufficiently large to allow for drawing blood by a needle and syringe (i.e., a “butterfly” apparatus is not needed) and the veins are less likely to collapse. Although the practice is common, as a best practice, blood cultures should not be drawn through indwelling vascular access lines, owing to higher contamination rates. For patients with suspected line-related infection, blood should be drawn through the line and from venipuncture sites and the results compared (8, 18), as described below.

Number and Timing of Cultures

As stated previously, three to four blood cultures should be drawn simultaneously to detect bacteremia or fungemia. A single blood culture lacks sufficient sensitivity to detect bacteremia, and for many isolates, the result cannot be interpreted (e.g., coagulase-negative staphylococci). There is no benefit to waiting an arbitrary amount of time between drawing blood cultures (19), even though that practice was widely used for decades.

For patients with suspected infective endocarditis, or other intravascular foci of infection, three microbiological factors are of importance: determining bacteremia, determining the identity of the infecting pathogen, and characterizing the antimicrobial susceptibility profile. Documenting continuous bacteremia, while necessary in some cases, is probably of less relative importance for most patients. In cases where it is necessary because of a confusing clinical or microbiological presentation, drawing three to four blood cultures spaced 30 to 60 min apart is a reasonable approach. For patients with prosthetic valves or an implanted device, for whom infections are likely to be caused by coagulase-negative staphylococci, skin disinfection is of critical importance to minimize the risk of contamination. It is also important to not draw blood cultures through indwelling vascular catheters in these patients. Most cases of infective endocarditis are caused by common bacterial pathogens, and therefore, blood cultures do not require use of special media or prolonged incubation and monitoring. For patients who are more likely to have infection caused by Abiotrophia spp. or Granulicatella adiacens, although special media are not necessary, it is important to notify the laboratory so that the pattern of growth on agar plates can be monitored (e.g., lack of growth on sheep blood agar plates) (8). The duration of incubation does not need to be more than 5 days; two studies have documented that all isolates from patients with infective endocarditis are recovered within that time (9, 20).

INTERPRETATION OF BLOOD CULTURE RESULTS

Unlike straightforward laboratory tests that yield a binary test result of positive or negative, blood cultures yield a complex set of data that can only be interpreted in the context of the clinical scenario that prompted their collection. The information generated by blood cultures includes the identity of any bacteria or fungi isolated from the specimen (or combination of microorganisms), the number of positive and negative cultures, and the time for detection of microbial growth, all of which must be interpreted in light of the pretest probability for bacteremia or fungemia; the results of other clinical, laboratory, or radiographic findings; type(s) of isolates recovered from other body sites; response (or lack of response) to therapy; clinical signs and symptoms; and the clinical judgment of the ordering clinician.

In routine clinical practice, interpretation should not rely solely on the identity of the microorganism(s) isolated. While some isolates almost never are contaminants (e.g., Brucella spp., Francisella tularensis, and Histoplasma capsulatum) and are easy to interpret, isolation of most bacteria and fungi requires further interpretation. Isolates such as Staphylococcus aureus, Streptococcus pneumoniae, and Enterococcus faecalis, and Staphylococcus lugdunensis, which can cause infections of foreign devices or of host tissue in a manner similar to that of S. aureus, but it also can be a contaminant (21). Isolation of this bacterium from blood cultures, as with other coagulase-negative staphylococci, requires additional information for proper clinical interpretation. Isolation from even a single culture can be clinically important.

Interpretation of blood culture results collected by venipuncture is more straightforward than that for blood cultures collected from indwelling venous lines. For blood cultures collected via lines, interpretation involves analysis of the additional factors of the type of line, where it is inserted in the body, how long it has been in place, and whether isolates are recovered from the line only, from an accompanying blood culture collected via venipuncture, or from both. A number of interpretive criteria have been proposed, but the multiplicity of studies with various methodologies makes interpretation and comparison difficult. Although complex by necessity, the current CLSI criteria (8) remain useful and are shown in Table 2.

Other criteria have been suggested for making the interpretation of blood culture results more accurate and reliable. The time required for an automated blood culture system to flag a bottle as positive (i.e., to detect a growth signal), or so-called “time to positivity,” has been studied in a number of settings. Although there is a correlation between the earlier detection of pathogens compared with that of contaminates, as documented many years ago, there is so much overlap between the time needed to detect growth of both groups that the information is of minimal clinical use. Moreover, time to positivity obviously is not useful for slowly growing microorganisms and probably is not useful in patients who are receiving antimicrobial therapy, which can delay detection of microbial growth. One exception to this principle is that most isolates recovered after more than 72 h of incubation represent contaminants, with the obvious exceptions of some slowly growing pathogenic bacteria and yeasts.

Another commonly used criterion is that of considering the number of positive bottles, rather than the number of positive cultures. Although there are conflicting data regarding this issue, the most thorough study, by Mirrett and colleagues (22), showed that, for coagulase-negative staphylococci, there is no correlation between the number of bottles positive in blood culture sets and the clinical importance of the isolates. This observation held true for sets that consisted of two, three, or four blood culture bottles (22). Fewer data are available regarding other types of blood culture isolates, but because microorganisms in blood cultures show a Poisson distribution, there is no reason that the principle for coagulase-negative staphylococci should not hold true for other types of isolates.

Last, the issue of quantitative blood cultures still arises on occasion. Although methods for quantitation (or semiquantitation) have been devised and there are some data to

**Support this approach, in reality, the approach is not practicable for routine use. Moreover, as newer technologies are developed with increasing analytical sensitivity, it is possible that methods will be devised to quantitate the number of pathogens in blood via surrogate markers.**

**LABORATORY DETECTION—CULTURE-BASED METHODS**

Conventional detection of bacteremia or fungemia has been either direct, via recovery of pathogenic microorganisms by culture of blood specimens, or indirect, by identification of surrogate markers. The latter method was investigated widely during the 1970s and 1980s by attempts to identify methods such as detection of limulus endotoxin assays, or detection of bacterial antigens in blood, but these efforts are largely only of historic interest. As a result, culture remains the only widely used laboratory method for detection of bacteremia or fungemia.

Blood cultures were first described more than a century ago and, by the 1930s, had prompted a number of investigations that defined some of the methods still used today. By the 1960s, blood cultures were widely used, but methods varied considerably, a multiplicity of methods were in use (with varying degrees of success), and it became increasingly clear through time that the overall approach left much to be desired. During the 1970s, John Washington and other investigators began a series of experiments and controlled clinical trials to define the critical factors in the detection of bacteremia and fungemia, identify best practices for blood cultures, and establish scientific evidence upon which future blood culture systems could be developed and used on a widespread basis. Out of these studies emerged a growing body of knowledge regarding the critical factors for recovering pathogenic microorganisms from blood, knowledge that
has resulted in more refined clinical approaches to blood cultures and to development of commercially available blood cultures systems that incorporate these critical factors into their design and use.

**Manual Blood Culture Systems**

Relatively few nonautomated blood culture systems are still manufactured and sold commercially in the United States. Those that are available commercially are well characterized as to their diagnostic strengths and limitations. These systems are adequate for the detection of common bacterial and fungal pathogens, are easy to use, require only a non-CO\textsubscript{2} incubator, and are inexpensive (12). The main drawback to manual systems is that they are labor-intensive, which precludes their use in laboratories processing even moderate numbers of blood cultures. Moreover, with the availability of smaller instrumented blood culture systems, even laboratories processing low numbers of blood cultures can opt for using an automated system.

The first manual blood culture systems consisted of little more than blood culture bottles containing various medium formulations, an anticoagulant, and occasionally additives or supplements. Detection of microbial growth was via two methods: subcultures after 24 or 48 h and at the end of the incubation period (so-called terminal subcultures) and visual observation of bottles for hemolysis (color change), gas production, or turbidity. This approach was not practicable for laboratories performing more than a small number of blood cultures. Because early instrumented/automated blood culture systems had their own issues with practicability, a number of alternative manual blood culture systems were developed and marketed. Of these, only two remain available in most markets: Septi-Chek (BD Biosciences, Sparks, MD) and Oxoid (Remel, Lenexa, KS).

Septi-Chek is a variation of the biphasic system originally developed by Castaneda to recover *Brucella* spp. from blood. These systems are called biphasic because there is the traditional liquid broth medium phase combined with a solid phase consisting of various agar media. In biphasic systems, blood is inoculated into the culture bottle and mixed with the broth medium. By one of several devices, the broth-broth mixture is then flooded over the solid media that acts as a direct subculture. The Septi-Chek variant of a biphasic system consists of a plastic paddle that is attached to the bottle after receipt in the laboratory. This obviously is an aerobic system, and for recovery of anaerobic bacteria, there is a separate bottle that does not have a corresponding paddle. Bottles are then incubated (with or without agitation) and inspected visually once or twice each day for evidence of microbial growth. The agar-coated paddle not only provides for earlier isolation of microbial colonies but also provides for early isolation of microbial colonies. Aerobic bottles are inverted following each inspection, providing further subcultures of the blood-broth mixture.

Current versions of Septi-Chek bottles contain one of several broth media with 0.05% SPS as an anticoagulant. Two bottle sizes are available: bottles containing 70 ml of broth, accommodating blood specimens of up to 10 ml (to maintain an adequate blood-to-broth ratio), and bottles containing 20 ml of broth accommodating blood specimens of up to 3 ml. Bottles are available that contain soybean-casein digest broth, soybean-casein digest/Columbia broth, soybean-casein digest/thioglycolate broth, or brain heart infusion broth. Agar paddles use chocolate, MacConkey, and malt agars.

In controlled clinical evaluations, Septi-Chek has been shown to perform well and to be an acceptable manual system for routine practice (23–27). It is not practicable for use in laboratories processing large numbers of blood cultures, but cost-effectiveness studies defining the practical upper limit of Septi-Chek bottles that can be handled before labor costs become prohibitive have not been performed.

In contrast to Septi-Chek, the manual blood culture system Oxoid Signal is a one-bottle system without an anaerobic version. Oxoid is another variant of the Castaneda bottle. With Oxoid Signal, bottles are inoculated with blood through a rubber septum in a lid. The Signal device consists of an empty plastic cylinder attached to a needle, which when inserted into the bottle extends to below the surface of the blood-broth mixture. During microbial growth, release of gases into the blood-broth mixture increases the concentrations of those gases, which reach equilibrium with those in the bottle headspace. Through time, this increases the atmospheric pressure within the bottle, eventually forcing some of the blood-broth mixture upward through the needle into the attached Signal device. Although this provides a second mechanism for detecting microbial growth, unlike Septi-Chek it does not provide for earlier isolation of microbial colonies. In controlled clinical evaluations, the Oxoid Signal system has not performed as well as other blood culture systems (28–31).

**Lysis-Centrifugation**

Only one commercial lysis-centrifugation blood culture system has been marketed, the Isolator blood culture system (Wampole Laboratories, Cranbury, NJ). With lysis-centrifugation, the blood specimen is inoculated into tubes containing a mixture of the lysing agent saponin, an anticoagulant, and a fluorocarbon-cushioning agent. The blood is then lysed by the saponin, and the mixture is centrifuged to separate the components. The supernatant is then removed and discarded, and the suspended pellet is used to inoculate whatever culture media are deemed necessary to recover specific pathogens. The system has been used for detection of routine bacterial pathogens, but because delayed processing has been reported to reduce recovery of anaerobic bacteria, some *Haemophilus* species, and *Streptococcus pneumoniae*, other commercial broth-based systems are likely better for routine use (32–36). Although at one time Isolator was a good method for recovery of pathogenic yeasts, dimorphic fungi, mycobacteria, and *Bartonella* spp., other systems (see below) are at least equal for recovering these pathogens. Detection of *Bartonella* spp. is best achieved by use of nucleic acid amplification; if not available, serologic testing can be used. These issues, combined with the manual nature of lysis-centrifugation, have made it less practicable for routine use.

**Automated Blood Culture Systems**

As the number of blood cultures performed began to increase during the 1960s and 1970s, with the resulting need for methods that were less labor-intensive, there developed a growing interest in development of automated blood culture systems. A number of these were developed and tested, but only a few have been commercially successful.

The first of these was the Bactec 460 radiometric system (Becton Dickinson, Sparks, MD), a derivative of the original Bactec 220 system that was developed in the late 1960s and first marketed in the early 1970s. During the next two decades, the Bactec 660, 730, and 860 systems in turn succeeded the 460 system. All of these systems had in common the detection of microbial growth by monitoring CO\textsubscript{2} production by growing microorganisms. The 220 and 460 systems used radiometric detection of $^{14}$C-labeled CO\textsubscript{2},
whereas the 660, 730, and 860 systems detected CO₂ production by infrared spectrophotometry. Because both radiometric and nonradiometric detection methods required removal of an aliquot of the atmosphere in the bottle headspace, monitoring more than once or twice per day was not possible. This is because an equal volume of sterile gas had to be added to bottles after sampling to maintain the appropriate pressure in each bottle. This, in turn, reduced slightly the CO₂ present in the atmosphere, thereby limiting the frequency of sampling. Because once or twice daily sampling did not allow for detection of microbial growth at the earliest possible time, a newer generation of blood culture technology was needed.

The next generation, conceived in the late 1980s and introduced in the 1990s, was that of the continuous-monitoring blood culture systems (CMBCS). These systems take their name from the fact that, unlike previous automated blood culture systems, which monitored bottles for CO₂ production only a few times each day, the newer systems monitor CO₂ production much more frequently, typically once every 10 to 15 min (12). Unlike older automated systems which flagged potential microbial growth when the CO₂ level in a bottle exceeded an arbitrary threshold level, CMBCS use one of several computer algorithms to detect microbial growth. The first is use of a threshold level, second is a sustained linear increase in CO₂ production, and third is an increase in the rate of CO₂ production (although specific computer algorithms used by each manufacturer are proprietary). Because the latter two criteria depend upon actively growing microorganisms, delayed placement of bottles in instruments, which allows microorganisms to grow and thereby produce CO₂ prior to testing, can result in delayed (or lack of) detection of microorganisms in bottles. Because of the large amount of data to be analyzed for each bottle, and for the many bottles in each incubator, the success of CMBCS is as much due to the development of more powerful computer processors and memory as it is to anything else.

For CMBCS to monitor CO₂ levels on a frequent basis, two other barriers to testing had to be removed. The first was to eliminate the need for sampling and replenishing the atmosphere in the bottle headspace. This was achieved by the development of sensors that could be read through the wall of the bottles without need for invasive testing. The second was to eliminate the need for repeated manual loading and loading of bottles onto instruments for testing. Although this was achieved to some degree by the Bactec 860 system, each bottle still had to be moved to the testing apparatus. In contrast, CMBCS have a mechanism for monitoring the sensor of each bottle individually, thereby eliminating the need to ever move bottles during incubation and testing. Overall, the change to more frequent testing with CMBCS reduced the time to detect microbial growth by 1 to 1.5 days compared with Bactec radiometric and nonradiometric systems (12).

**Bactec/Alert**

The first of the CMBCS was Bact/Alert, with prototypes under development in 1988 and the first limited clinical trials conducted by 1990 (37). Bact/Alert is a colorimetric system, detecting changes in CO₂ concentration in bottles via changes in color of a pH-sensitive device in the base of the bottles. Since it was introduced, the system has undergone several changes in style and configuration, with the Bact/Alert 3D being the most current version of the instrument. Sequential medium formulations include standard aerobic and anaerobic media; aerobic, anaerobic, and pediatric (aerobic only) fastidious antimicrobial neutralization (FAN) media (which include activated charcoal and Fuller’s earth [designed to inactivate or bind antimicrobial agents]); FAN aerobic (FA), FAN anaerobic (FN), and pediatric FAN (PF) bottles; FA Plus, FN Plus, and PF Plus media (which contain proprietary adsorbent polymeric beads); and the Mycobacteria Process (MP) bottle designed to recover mycobacteria. Since it was introduced more than 20 years ago, a number of clinical evaluations of Bact/T/Alert have been published that have established the performance characteristics of the system and different bottle types that have been produced. These findings are summarized in Table 3.

Broadly speaking, these characteristics hold true for all of the bottles available with CMBCS: bottles with additives outperform bottles without additives, only a 4- to 5-day incubation and testing cycle is necessary, blind and/or terminal subcultures are not necessary, and bottles containing additives increase recovery of contaminating microbial flora.

**Bactec 9000 Series**

In 1992, Becton Dickinson introduced the second of the CMBCS, the Bactec 9000 series. Initially there were two versions, the Bactec 9120 (holding 120 bottles per cabinet) and the Bactec 9240 (holding 240 bottles per cabinet). Several years later, the Bactec 9050 (holding 50 bottles) was introduced for laboratories needing an automated system with a smaller capacity (38). The Bactec technology is similar to that of Bact/T/Alert, the main difference being that Bactec CMBCS use a fluorescence-sensing mechanism to detect CO₂ production.

Bactec systems make use of several medium formulations, including standard aerobic/F and anaerobic/F bottles, Plus aerobic/F and Plus anaerobic/F bottles, which contain antibiotic-binding resins attached to tiny glass beads, lytic/10 anaerobic/F medium bottles, Peds Plus/F bottles, and Myco/F lytic bottles that are designed to increase recovery of fungi and mycobacteria (39). Each of these bottle types accepts up to 10 ml of blood, except for the Peds Plus/F bottles, which accept 1 to 3 ml of blood. A large number of clinical evaluations of Bactec Standard and Plus/F bottles used on the 9050, 9120, and 9240 systems have been published. The performance characteristics of these systems are summarized in Table 4.

In contrast to Standard/F and Plus/F bottles, Bactec Myco/F lytic bottles were developed to allow for recovery of mycobacteria and fungi as well as common bacterial pathogens. Myco/F lytic bottles differ from all other Bactec 9000 bottles in that the fluorescent sensor in the bottle detects decreasing oxygen concentration (i.e., detects oxygen consumption) as opposed to detecting increased concentrations of carbon dioxide. In a number of clinical trials, Myco/F lytic bottles have been shown to compare favorably with other systems for detection of mycobacteria and fungi. In an early study, the Myco/F lytic bottle detected fewer *H. capsulatum* isolates but more *Cryptococcus neoformans* isolates than the Isolator system (40). Myco/F bottles have been shown to be equivalent to ESP II bottles for recovery of mycobacteria overall, with significantly better recovery of *Mycobacterium avium* complex in Myco/F lytic bottles (40). More recent studies have shown Myco/F lytic bottles and Bact/T/Alert MB bottles to be equivalent to but appreciably faster than the Isolator 10 system for recovery of *Mycobacterium tuberculosis* and *Mycobacterium avium* complex clinical isolates (41, 42).

**VersaTREK Blood Culture System**

The third CMBCS introduced during the 1990s was the ESP system (Difco Laboratories), now marketed by Thermo

Scientific (Cleveland, OH) as VersaTREK. VersaTREK differs from the BacT/Alert and Bactec systems in several fundamental ways. First, VersaTREK uses a different system for detecting microbial growth. Once received in the laboratory, bottles are fitted with an adapter mechanism before being loaded into the instrument. The detector mechanism allows for the system to monitor pressure changes within the headspace of each bottle as oxygen, hydrogen, nitrogen, and carbon dioxide are consumed or produced by growing microorganisms. Second, the blood broth mixture within aerobic bottles is agitated by use of a stir bar contained within each bottle. Anaerobic bottles are not agitated. Third, the broth medium in VersaTREK Redox 1 aerobic bottles is soy casein peptone broth, whereas the broth medium in Redox 2 anaerobic bottles is proteose-peptone broth. Fourth, bottles are monitored for growth less frequently: at 12 min for aerobic bottles and 24 min for anaerobic bottles. Last, unlike BacT/Alert FAN and Bactec Plus bottles, both of which contain additives to minimize or negate antimicrobial activity in blood specimens, VersaTREK Redox 1 and Redox 2 bottles contain 80 ml of broth medium, the larger volumes providing greater dilution of blood and any antimicrobial agents contained therein. The smaller Redox 1 EZ Draw and Redox 2 EZ Draw bottles, which are marketed to allow for direct collection of blood specimens into the bottles, still contain 40 ml of broth medium for greater dilution of blood specimens compared with BacT/Alert and Bactec bottles. A number of clinical evaluations of VersaTREK have been published. Based on the results of these evaluations, the performance characteristics of this system are summarized in Table 4.

Pediatric Blood Culture Bottles

A number of blood culture bottles intended for use with pediatric patients have been developed and marketed. Because of the practical difficulties in conducting clinical trials involving large numbers of hospitalized children, these products have not been evaluated to the same extent as those for adult patients. While there is no drawback to using these bottles (other than cost differences), there appears to be little advantage to using them in regions where immunization with pneumococcal conjugate and Haemophilus influenzae type b vaccines are given widely.

LABORATORY DETECTION—NON-CULTURE-BASED METHODS

Surrogate Markers for Sepsis

A number of nonmicrobiological tests have been evaluated for their ability to detect bacteremia or fungemia. Although most of these evaluations state that assays were evaluated for the ability to detect sepsis, it should be remembered that sepsis is foremost a clinical diagnosis. What most of these

studies were evaluating, in fact, was the ability to detect patients with bacteremia or fungemia who subsequently developed the clinical signs and symptoms of sepsis.

Early assays, such as the limulus amoebocyte assay, showed promise but were never fully developed or marketed. Perhaps the most widely studied assays have been those that measure procalcitonin and serum lactate levels. For procalcitonin, the available evidence shows that the assay is not useful for the detection of bacteremia or fungemia, due to a lack of both sufficient sensitivity and specificity. The assay has been shown to be useful, however, when used to monitor patients with a diagnosis of bacteremia or fungemia as a guide to stopping antimicrobial therapy. The findings with serum lactate levels are similar. The assay lacks both sensitivity and specificity for the diagnosis of bacteremia or fungemia, but serial measurements may be of use both for prognosis and for modifying antimicrobial therapy.

Nucleic Acid Amplification Methods

A number of laboratory-developed assays designed for the direct detection of bacteremia or fungemia from blood specimens have been evaluated and reported (43). As presented elsewhere in this chapter, although laboratory-developed assays may serve a role as a proof of concept, they are of little use to the community at large because the assays cannot be marketed or distributed to other laboratories. Moreover, development and use of such assays is likely prohibitively expensive and beyond the expertise available in most clinical laboratories.

SeptiFast (Rotkreuz, Switzerland) is currently available in parts of the European Union but not in the United States. The system is a real-time PCR assay designed to detect, directly from blood, 10 species of Gram-negative bacilli, 6 species of Gram-positive cocci, 5 species of yeasts, and 1 filamentous fungus. The method uses the LightCycler system; although this technology is available for use in the United States, SeptiFast reagents are not.

Overall, the system has shown mixed results in clinical evaluations (44). Taken together, the data from these evaluations indicate that SeptiFast shows comparatively low sensitivity for detecting pathogens in blood. The number of studies, conflicting study designs and definition, and other factors make interpretation of the data difficult, but overall, the assay lacks sufficient sensitivity to be used as a stand-alone test. SeptiFast has been evaluated as an adjunct to blood cultures, in which a positive result from SeptiFast between days 3 and 7 following a positive blood culture result predicted an increased risk of patients developing complicated bloodstream infections (45). Whether the same risk stratification could be achieved using other laboratory tests has not been evaluated.

Another molecular assay, Xpert MTB/RIF (Cepheid, Sunnyvale, CA), has been evaluated for detection of Mycobacterium tuberculosis directly from blood specimens. In one small clinical evaluation, the calculated sensitivity of Xpert was only 21% (a figure notably similar to some of the data for SeptiFast, as described above), but in this group of patients, a positive Xpert test result was useful for stratifying patients into those who were or were not at increased risk for early death (46).

At this time, therefore, the data are clear that no molecular assay is available that can act as a substitute for blood cultures, but these tests may be useful as adjuncts to blood cultures.

Rapid Identification of Microbial Isolates

A number of rapid identification methods have been introduced over the years, with increasingly effective results. Early attempts were largely modifications of biochemical tests or early molecular methods (e.g., DNA probes) that did not have the desired effect. More-recent methods have yielded substantially better results for rapid identification of select groups of microbial pathogens. Moreover, there is evidence that earlier detection and identification of bloodstream pathogens, or antimicrobial resistance, improves outcomes (47) and facilitates antimicrobial stewardship (48, 49).

Peptide Nucleic Acid-Fluorescent In Situ Hybridization

The peptide nucleic acid-fluorescent in situ hybridization (PNA-FISH) method (AdvanDx, Woburn, MA), although limited to a few select pathogens, has been shown to reduce the time needed to identify microbial pathogens present in blood cultures. The principle of the method is simple, being based on the widely used principle of in situ hybridization. Unlike DNA and RNA probes, which have negatively charged sugar-phosphate backbone structures, the PNA backbone structure is composed of an electrically neutral polyamide (peptide) structure. The neutral electrical charge allows for more-rapid, tighter, and more-specific hybridization with nucleic acid targets. The probes are labeled with fluorescent dyes, which can be observed by using a fluorescent microscope. Once a blood culture bottle is flagged as positive, a smear is made of the blood-broth mixture and a Gram stain is performed. Based on those results, the appropriate PNA-FISH probe(s) can be selected for testing.

The method is easy to use, only marginally expensive, and requires little in the way of infrastructure beyond that already present in most clinical microbiology laboratories (other than a fluorescent microscope) (50). However, to take full advantage of the method, it is necessary to perform the test on an ad hoc basis for individual isolates, which is not practicable in many microbiology laboratories. The method does not provide any data regarding antimicrobial susceptibility or resistance.
Nucleic Acid Amplification Tests

Although nucleic acid amplification test technology would appear to lend itself to this application, surprisingly few commercial assays have been developed. In contrast, a large number of laboratory-developed assays have been reported, but their usefulness is limited by that of all user-developed assays: assays may not be adaptable for use in other laboratories, development and validation costs may be prohibitive, and regulatory issues limit use of these assays in some countries (43). Their usefulness at this time is also limited by the relatively small number of pathogens that can be detected, preliminary evidence indicating that the assays are not as useful when more than one type of microorganism is in the blood-broth mixture (polymicrobial isolates), and the ability to test for only a small number of antimicrobial resistance determinants. Thus, the number of commercial assays available for this purpose is limited, as are clinical evaluations as to their effectiveness.

Multiplex Assays

Two commercial systems have been developed, the Verigene assay (Nanosphere, Northbrook, IL) and the FilmArray (Biofire, Salt Lake City, UT). The Food and Drug Administration has cleared both for marketing in the United States. For Verigene, separate assays for detection of either Gram-positive or Gram-negative bacteria directly in blood cultures are FDA cleared; an assay for detection of common pathogenic yeasts is under development. The FilmArray product, called the blood culture identification panel, detects a combination of 24 Gram-positive bacteria, Gram-negative bacteria, and yeasts and three antimicrobial resistance genes in a single combined assay.

Verigene is a multiplex assay based on PCR amplification of nucleic acid targets with subsequent detection by hybridization with oligonucleotides bound to nanosphere particles, followed by signal amplification using what the manufacturer calls a silver staining process. FilmArray also is a multiplex assay, with an initial nucleic acid extraction and purification step followed by PCR-based amplification in two stages. The first is a multiplexed reaction; this is followed by individual PCR amplification reactions designed to detect specific products from the first-stage amplification step. Final detection is based on use of endpoint melting curves.

The Verigene Gram-positive blood culture assay, which is cleared for detection of 12 genera or species and three antimicrobial resistance genes, has been evaluated in several clinical trials. In the first, blood cultures processed on the VersaTREK blood culture system were used for the analysis. The evaluation of 203 total positive blood cultures showed 94% concordance for microbial identification and 97% concordance for detection of drug resistance for 178 monomicrobial isolates, with 92% and 96% concordance for 25 polymicrobial isolates (51). Results were available 24 to 48 hours sooner than with conventional identification and susceptibility test methods. In the second study, blood cultures were processed using the BacT/Alert system (32). Results from this study of 186 blood cultures were similar to those of the first, in that for 176 monomicrobial cultures the concordance for identification was 96% for microbial identification and 99% for detecting drug resistance. Results were available 31 to 50 hours sooner than with conventional methods. A third study showed overall concordance of 95% with conventional identification methods: 99% for monomicrobial isolates but only 33% for a small number of polymicrobial isolates (53). A fourth study was more specific and limited in scope, evaluating use of the assay as part of an antimicrobial stewardship program targeting patients with enterococcal bacteremia (49). In this study of 74 patients, compared with the preintervention use of conventional identification and antimicrobial susceptibility testing, the postintervention phase when Verigene was used showed shortening of the time required for appropriate antimicrobial therapy to be given, shortened length of hospitalization, and lower hospital costs. Finally, in an evaluation of the assay in a pediatric hospital, the findings reported were similar to those of the first three studies: the assay showed 95.8% concordance with conventional methods for identification of Gram-positive bacteria (54). The assay also showed 100% correlation for detection of methicillin-resistant S. aureus isolates, 100% correlation for detection of vancomycin-resistant E. faecium isolates, and 98% detection of methicillin-resistant Staphylococcus epidermidis isolates (54). As in earlier studies, time to detection was substantially shorter with the Gram-positive blood culture assay than with conventional methods (54).

The Verigene Gram-negative blood culture test, which is cleared to detect eight genera or species and six antimicrobial resistance genes, has been evaluated in only one published clinical trial (55). In this evaluation of 102 isolates, the Gram-negative blood culture test showed 97.9% concordance with conventional identification methods. The reported performance characteristics for detecting antimicrobial resistance or susceptibility were a positive predictive value of 95.8% and a negative predictive value of 100% (55).

Only one clinical evaluation of FilmArray blood culture identification has been published (56). In this study, FilmArray showed 91.6% concordance with conventional identification methods for samples with monomicrobial growth and 71% concordance for polymicrobial samples. The assay did detect additional microorganisms in 3.6% of samples for which isolates were not recovered by conventional culture methods.

Other Nucleic Acid Amplification Tests

The Gene Xpert (Cepheid, Sunnyvale, CA) has several assays that can be used in conjunction with blood cultures for identification of blood culture isolates or for detecting antimicrobial resistance. The two assays that would fit into this category are an assay for detecting the meca gene in methicillin-resistant strains of Staphylococcus epidermidis and Staphylococcus aureus and one for detecting the vanA gene in vancomycin-resistant strains of enterococci. As with other methods for detecting pathogens or antimicrobial drug resistance in blood culture isolates, these assays do not replace blood cultures but are only an adjunct.

Antigen Detection

The BinaxNOW Staphylococcus aureus test (Alere Scarborough, Inc., Scarborough, ME) is an immunochromatographic assay that uses polyclonal antibodies to detect an S. aureus-specific protein, thereby allowing for differentiation between S. aureus and other Gram-positive cocci in blood culture bottles. Current FDA clearance is for use with BacT/Alert blood culture bottles. In one off-label evaluation using VersaTREK blood culture bottles, the test showed 95.8% sensitivity and 99.6% specificity compared with culture and a direct tube coagulation test, both performed on aliquots of the blood-broth mixture (57). In a second off-label evaluation, the assay was compared with conventional methods using Bectec blood culture bottles (58). In this study, the BinaxNOW assay showed 97.6% sensitivity and 100% specificity.
MALDI-TOF (MS)
Matrix-assisted laser desorption ionization—time of flight (mass spectrometry) (MALDI-TOF [MS]) has been the most widely evaluated approach to rapid microbial identification of blood culture isolates. Currently, two manufacturers of MALDI-TOF (MS) systems have instruments cleared by the FDA for marketing in the United States to identify microbial isolates from solid media (i.e., not directly from blood culture bottles): the Microflex LT Biotyper (Bruker Daltonics, Bremen, Germany) and the Vitex MS IVD (bioMérieux, Marcy l’Etoile, France). In an early study, 90% of bacterial isolates were identified directly from positive blood culture bottles (59). Other early studies of this technology also showed good results for identifying bacteria and fungi directly from blood culture broth specimens. One evaluation of the Biotyper evaluated the ability of MALDI-TOF (MS) to identify bacterial pathogens in 212 blood cultures (60). Of these, 42 (19.8%) showed insufficient numbers of bacteria in the blood-broth mixtures for MALDI-TOF (MS) to identify the bacteria (61). Of the other 170 blood cultures, MALDI-TOF (MS) showed 95.3% concordance in correctly identifying the bacteria compared with conventional identification methods (61). In another evaluation using the Biotyper (62), 330 positive blood culture bottles were analyzed, of which 318 showed growth on subcultures and 12 were considered to be false-positive signals by the blood culture instrument. Of the latter group, the MALDI-TOF (MS) results were fully concordant with culture results (62). For the 318 blood cultures that yielded growth on cultures, all were monomicrobial. When compared with results of conventional identification methods, MALDI-TOF (MS) results were concordant to the species level for 83.3% and to the genus level for 96.6% of blood cultures (62).

In the most comprehensive comparison of the two MALDI-TOF (MS) systems, a total of 202 positive blood culture bottles processed on the Bactec system were tested with both versions of MALDI-TOF (MS) (62). In this evaluation, there were 181 monomicrobial and 21 polymicrobial isolates. Biotyper correctly identified 171 of 181 (97.8%) monomicrobial isolates compared to 167 of 181 (92.3%) identified by the Vitex system (62). Neither system performed well for identification of polymicrobial isolates (62). Although time to identification was not evaluated in this study, two previous studies showed a reduction in the time to identification of between 26.5 and 34.3 h compared to conventional methods (63, 64). Despite this, the inability to perform antimicrobial susceptibility testing limits the usefulness of this method.

DIRECT RAPID ANTIMICROBIAL SUSCEPTIBILITY TESTING FROM BLOOD CULTURE BOTTLES
A large number of studies have attempted to answer whether direct testing of the blood-broth mixture (without the intervening step of subcultures) using conventional (not molecular) methods can be used to decrease the time needed for susceptibility test results. Theoretical obstacles to this approach are straightforward. The main obstacle is the inability to standardize the number of microorganisms in the blood-broth mixture to be used for testing. None of the CMBCS flag bottles as positive based on the number of microorganisms present. Depending on which system is used, the initial number of microorganisms present in the blood specimen, the metabolic characteristics of the microorganism (e.g., growth rate and gas production), and the number of microorganisms per milliliter when bottles are flagged as positive may vary. Second, testing aliquots of the blood mixture, with or without additives, introduces a complex liquid matrix (i.e., broth, anticoagulant, and any additives) that was not intended for use in commercial antimicrobial susceptibility assays. Even with centrifugation, or other procedures, this “matrix effect” cannot be eliminated or mitigated fully. A third issue, although perhaps not as important, concerns the presence of antimicrobial agents present in blood. Because these agents are given in dosages to achieve blood concentrations at or above levels designed to inhibit bacterial growth, even with dilution by the broth medium, there may still be residual antimicrobial activity in the blood-broth mixture (65). Fourth, this is a moving target. Interpretive criteria for breakpoints may change over time, thereby requiring repeated validation of the method, which would not be practicable in most settings. A fifth obstacle is regulatory: most commercial antimicrobial susceptibility assays do not include direct testing of a blood-broth mixture in the package insert, making such use off-label and, in some cases, not reimbursable. Last, the published evidence on these approaches is not persuasive: some published studies have shown these approaches to work, but others have arrived at the opposite conclusion. In an era that emphasizes evidence-based laboratory medicine, objective analysis of the literature yields the conclusion that current evidence does not support this practice.

QUALITY AUDITS AND BENCHMARKS
The most commonly studied, documented, and reported quality metric regarding blood cultures is the contamination rate. There has been a long-standing recommendation that blood-culture contamination rates be kept at or below 3% for hospitalized patients. This figure is not derived from anything more than the belief that it generally is not possible to maintain rates below 1% and that rates above 5% result in a confounding of the clinician’s ability to distinguish between contaminants and pathogens. Because blood culture contaminants result in increased health care costs, contamination rates above 5% also are associated with increased costs. Whether the 3% figure is realistic for outpatient settings, particularly in emergency departments, is another unanswered question. For patient safety, quality, and costs, it makes sense to target the lowest possible contamination rates, but targeting specific rates should be done with the understanding that different contamination rates occur in different settings.

Another common assessment of quality is the number of blood cultures drawn per septic episode. As noted previously, interpretation of blood culture results depends heavily upon drawing both an adequate volume of blood and more than one culture. Determining the clinical importance of isolates recovered from single blood cultures can be impossible depending on the type of isolate recovered. At the same time, collecting more blood cultures than is necessary is wasteful, contributes to phlebotomy-caused anemia, and results only in recovery of more contaminants. For both reasons, laboratories should monitor the number of blood cultures collected per septic episode.

A third important measurement is the adequacy of fill of blood culture bottles. Weighing filled bottles and comparing weights against those of a known standard most readily achieve this goal. Bottles filled with inadequate volumes of blood diminish yield and should be reported to the provider, with a recommendation to recollect the blood culture. Adequacy of filling should be monitored through time and by site so that any patterns of underfilling (or overfilling) can be identified and the appropriate corrective action taken.
SUMMARY
Detection of bacteremia and fungemia remains one of the most important roles of clinical microbiology laboratories. Despite the development and introduction of a number of novel technologies, the blood culture using liquid-based media still remains the only practicable approach for routine patient care. Molecular detection methods show promise, but the available methods do not have the sensitivity of blood cultures (except for a select few pathogens), provide only limited information regarding antimicrobial susceptibility testing, if used alone would not allow for retention of isolates for epidemiologic investigations, at this time are not effective for detecting polymicrobial isolates, and are more expensive to use on a routine basis. Other methods such as MALDI-TOF (MS) also can achieve similar results for rapid identification of microorganisms isolated on solid media but currently are not cleared by the FDA for identification of pathogens directly from blood cultures. Experience has shown that novel technologies rarely replace older technologies but rather serve as adjunct methods to enhance older technologies. Because the isolation of pathogens from blood serves multiple clinical roles—prognosis, guiding therapy, monitoring response to therapy, and epidemiology—any approach to the laboratory detection of bacteremia and fungemia must be able to fulfill each of these roles. It is unlikely that any new technology will replace blood cultures entirely in the foreseeable future. What already is happening is that newer technologies are being integrated with blood cultures into an algorithmic approach that takes advantage of the benefits of each method.

Traditionally, the identification of bacteria and fungi has been based on conventional tube-based biochemical reactions, with results compared to historical charts of expected biochemical reactions. Due to the need for faster, simpler methods, manual biochemical-based testing kits and instrument-based semiautomated or automated methods were introduced. Automation in microbiology first occurred in the early 1970s with the introduction of semiautomated blood culture instruments (see chapter 3), followed by instrumented systems for identification and antimicrobial susceptibility testing of bacteria. More rapid semiautomated and automated systems for antimicrobial identification and susceptibility testing followed, relying on microorganisms’ biochemical characteristics, fatty acid patterns, and/or other metabolic properties for their identification. Commercially available biochemical platforms may include decision support software integrating identification and susceptibility test results with surveillance strategies for antimicrobial resistance and guidelines for therapy. A recently introduced automated technique for microorganism identification relies on proteomic analysis of bacterial or fungal cells using matrix-assisted laser desorption ionization–time of flight mass spectrometry (MALDI-TOF MS). Nucleic acid-based approaches, typically used for bacterial and fungal identification when biochemical and/or proteomic strategies fail, include broad-range DNA target sequencing or array-based approaches and organism-specific amplification techniques. Whether a laboratory uses manual or automated, biochemical-, protein- or DNA-based methods, the scientific approach to identify microorganisms relies on the same fundamental principles. This chapter provides an overview of technologies used for the identification of bacteria and fungi recovered from clinical specimens. Discussions relevant to systems for automated blood cultures (chapter 3), antimicrobial susceptibility testing (chapter 72), immunoassays (chapter 7), molecular diagnostics (chapter 6), and detection of Mycobacterium species (chapter 30) are found elsewhere in this Manual.

**Systems for Identification of Bacteria and Fungi**

KAREN C. CARROLL AND ROBIN PATEL

**4 ORGANISM IDENTIFICATION SYSTEMS**

**Overview of Methods and Mechanisms of Identification**

Historically, microorganisms have been identified by what we now refer to as “conventional procedures,” which include reactions in tube media and observation of physical characteristics, such as colonial morphology and odor, coupled with results of Gram staining, agglutination tests, and antimicrobial susceptibility profiles. Over the years, identification methods miniaturized commonly used biochemical reactions into a more convenient format (http://www.asmusa.org/index.php/guidelines/sentinel-guidelines) and developed into a system-dependent approach that became the industry standard. The system-dependent method relies on a set of substrates that are carefully selected for their positive and negative reactions. These patterns create metabolic profiles that are compared with established databases.

Biochemical profiles are determined by reactions of individual organisms with each of the substrates in the system. The accuracy of the reactions is dependent upon users following the directions of the manufacturer regarding inoculum preparation, inoculum density, incubation conditions, and test interpretation. Most systems rely upon one or a combination of several indicators. These include (i) pH changes resulting from utilization of a substrate, (ii) enzymatic reactions that release a chromogenic or fluorogenic compound, (iii) tetrazolium-based indicators of metabolic activity in the presence of a variety of carbon sources, (iv) detection of volatile or nonvolatile compounds, and (v) recognition of visible growth (Table 1). Additional biochemical tests for microbial identification that use other means of detecting a positive response for a given substrate may also be included.

Although no formal definition of “rapid” exists for describing the time required for results to be generated, most microbiologists expect rapid systems to provide usable results within 4 h. Clearly, the generation times of microbes (typically 30 min or longer) will not allow growth-dependent methods to generate detectable biochemical responses within this time. To overcome the problem of generation times, manufacturers of rapid systems use novel substrates with which preformed enzymes, produced by the organisms to be tested, may react to elicit responses detectable within 1 to 4 h.

Proteomic analysis using MALDI-TOF MS, which enables identification of bacteria and fungi in a matter of
minutes, is rapidly being adopted into clinical microbiology laboratories (2). Molecular methods that amplify particular gene targets novel enough to distinguish among genera and species and automated sequencing technology are used for identification of difficult-to-identify microorganisms. Proteinomic and molecular methods have expanded our knowledge of pathogenesis and have, in some cases, resolved erroneous taxonomic classifications.

System Construction

Microbial identification systems are either manual or automated. Manual methods use the analytical skills of the technologist for reading and interpreting the tests, whereas automated systems offer a hands-off approach, providing technologists more time for other duties and providing the laboratory with increased standardization. For all systems, the backbone of accuracy is the strength and utility of the database. Databases are constructed using known, clinically relevant strains as well as type strains of most taxa. In some cases, before an organism is added to the database, it is evaluated to confirm its relationship to other strains in the same taxon by using the likelihood fraction. This compares the characteristics of the new strain to those of a typical culture of the same species. Unusual microorganisms or common microorganisms with atypical properties often cannot be reliably identified by commercial systems unless they are well-represented in the system’s database.

The number of species included in a database may vary from just a few for some manual assays to thousands for automated instruments. For most commercial systems, database maintenance is a continuous process and software upgrades incorporating major taxonomic changes are provided by the manufacturer at regular intervals. Some systems may allow users to make minor changes at the local workstation.

System identifications are supported by algorithm-based decision making that is generally available through a computer. Occasionally, these identifications are compiled into a preprinted index, which is used to manually convert the organism’s profile number into identification. Bayes’s theorem, or modifications of it, is often the basis of algorithm construction from data matrices.

Bayes’s theorem is one of the statistical methods that manufacturers of biochemical identification systems use to arrive at an identification of a certain taxon based on the biochemical reaction profile produced by the unknown clinical isolate (3). Bayes’s theorem considers two important issues in order to arrive at an identification of a certain taxon: (i) \( P(t_i|R) \) is the probability that an organism exhibiting test pattern \( R \) belongs to taxon \( t_i \), and (ii) \( P(R|t_i) \) is the probability that members of taxon \( t_i \) will exhibit test pattern \( R \). Before testing, we make the assumption that an unknown isolate has an equal chance of being any taxon and that each test used to identify the isolate is independent of all other tests. In this case, Bayes’s theorem can be written as

\[
P(t_i|R) = \frac{P(R|t_i)}{\sum_i P(R|t_i)}
\]

By observing reference identification charts derived by conventional biochemical tests, we know the expected pattern of the population of taxon \( t_i \) (e.g., Escherichia coli) is indole positive and citrate negative. \( R \) in the formula is the test pattern composed of \( R_1, R_2, \ldots, R_n \), where \( R_i \) is the result for test 1 and \( R_j \) is the result for test 2, etc., for a given taxon. We can then incorporate the percentages (likelihoods that \( t_i \) will exhibit \( R_1 \), etc.) into Bayes’s theorem to arrive at an accurate taxon.

Clinical microbiologists must not, however, become dependent upon these likelihoods and percentages when interpretive judgment would suggest an alternative taxonomic conclusion. Bacteria often tend to stretch the rules of nomenclature when isolated from clinical specimens, and they may not react as expected in a commercial system, even though a legitimate result is produced (e.g., lactose-positive *Salmonella* species or H₂S-positive *Escherichia coli*). The result from the most reliable systems can be misleading. In these cases, an alternative method of identification must be used. D’Amato et al. have described how the systems use the database profiles and probability matrices to arrive at an identification of an unknown taxon (4).

The manufacturers of commercial identification systems rely heavily on input from their customers. Laboratories are encouraged to communicate with product manufacturers about problems, such as unusual organism identifications that develop when a method or system is being used. Manufacturers depend on customer satisfaction, and most are willing to assist in problem solving or in projects that could add strength to their systems. These companies, like their users, are clearly interested in the highest quality of cost-effective patient care.

**CRITERIA FOR SELECTING INSTRUMENTED SYSTEMS**

When selecting a method for identification and antimicrobial susceptibility testing, the laboratory must consider several important issues. Laboratory supervisors and managers should make such major decisions carefully and with expert consultation. The process begins by answering key questions about the needs for a new system in the context of laboratory versus patient benefits.

Once these questions are answered, the next step is to begin the search for the right instrument or system to meet the needs of the laboratory and the medical staff. As a general rule, it is best not to be the first to purchase a new system without having seen in the peer-reviewed literature the results of evaluations performed by reputable clinical laboratories. The manufacturer’s representative can be asked to supply peer-reviewed articles about the ability of the system to correctly identify the range of isolates usually seen in the user’s laboratory. This phase requires demonstrations and conversations regarding space requirements, technical applications, manufacturer issues such as interface capabilities and service contracts, and personnel-related concerns such as sample preparation and throughput.

It is often helpful to visit other laboratories similar to one’s own that are using the system under consideration to ask if they like the system, whether they would buy it again, how much downtime they have experienced, whether the service from the manufacturer has been acceptable, and whether the system has been mechanically reliable.

The laboratory should select a system that has been fully evaluated and whose accuracy exceeds 90% in its overall ability to identify common and uncommon bacteria normally seen in that particular hospital or laboratory. The system should be able to identify commonly isolated organisms with at least 95% accuracy compared with conventional methods.

The accuracy of antimicrobial susceptibility testing for combination panels is as important as the accuracy of identification, perhaps more so. Chapter 72 of this Manual discusses the issues involved in instrument susceptibility test methods. Finally, with increasing use of automation in clinical microbiology laboratories, it is important to understand how automated identification systems fit in with other automated systems in the laboratory and with the laboratory information system (see chapter 5 of this Manual).

### EVALUATING AN INSTRUMENT OR SYSTEM

#### Validating a New Instrument or Method

Several references provide useful information on the approach to evaluation, verification, and validation of kits, assays, and instruments in the clinical laboratory (5–9). When an identification system is added to the laboratory, laboratories must demonstrate that the system performs as described by the manufacturer (10, 11). Published reports by other laboratories that have evaluated the system in a sound, scientific manner provide the first level of evidence of acceptable performance (9). Next, the purchasing laboratory must provide evidence of acceptable performance of the new identification instrument by in-laboratory verification. Verification involves documentation of test accuracy in the laboratory where the instrument will be used (6). The Clinical Laboratory Improvement Amendments of 1988 (12) specify the conditions for systems placed into service.

Although smaller laboratories may have fewer resources than larger laboratories for verification of the accuracy of an identification system, laboratory size has no bearing on the need to ensure the accuracy of laboratory identification methods and of the work performed by a laboratory in support of patient care. The role of verification by the purchasing laboratory ensures that personnel can use the system at performance levels of accuracy already documented by the manufacturer and published in the literature. The laboratorian should expect a level of 95% agreement with the existing system or reference method and accept, in the final analysis, no less than 90% agreement. This takes into account the fact that the new system may be more accurate than the old one.

As of 1998, the Food and Drug Administration (FDA) no longer performs premarket [510(K)] evaluations to “clear” automated or manual phenotypic identification systems, nor does it receive or approve quality control protocols from these devices to meet the 1988 Clinical Laboratory Improvement Amendment requirements. Laboratorians must be aware that the identification component of the new or modified system that they are using is not cleared by the FDA because this approval is no longer required. This makes it even more important for laboratorians to search the literature for valid evaluations of their chosen instrument and to conduct their own in-house validation to make sure that the instrument meets the claims of the manufacturer regarding identification. Devices and methods incorporating probes, nucleic acid amplification and other genetic methods, MALDI-TOF MS, and the antimicrobial susceptibility test component of commercial instruments will continue to be reviewed by the FDA for clearance.

### LIMITATIONS OF MICROORGANISM IDENTIFICATION SYSTEMS

The databases of microbial identification systems must be revised frequently to accommodate newly named species. For example, had *Cronobacter sakazakii* (the yellow-pigmented variant of *Enterobacter cloacae*) not been added to the databases of these instruments, the clinical correlation of *C. sakazakii* with neonatal meningitis would likely be obscured if only *E. cloacae* had been reported. Laboratorians must be aware that the accuracy of a system is limited to the
claims of the manufacturer for the version of the database currently in the instrument and that the database may be outdated.

The laboratory procedure manual must stipulate the action to be taken when a result is questionable either because of the unusual biochemical profile of the organism or because of the appearance of an unexpected susceptibility profile. A backup method must be used to achieve an accurate identification profile. Otherwise the isolate should be sent to a reference laboratory for analysis.

Closely related species may be difficult or impossible to distinguish using certain systems; however, the inability to accurately identify all species within a genus does not always have a negative effect on patient outcome. For example, correct identification of all of the newly recognized Citrobacter species may not be possible for some of the systems. In this case, the effect on patient outcome because of the inability of a system to recognize Citrobacter werkmanii may be negligible, and a simple report of "inability of a system to recognize species may not be possible for some of the systems.

Users of automated systems should be aware of the limitations of commercial products with respect to their bioprocessing capabilities. Users should be aware of the published literature describing the potential problems encountered by others using these identification systems. Likewise, the user has a responsibility to report continued problems with a system or product where poor performance may lead to adverse patient outcomes.

PHENOTYPIC IDENTIFICATION SYSTEMS

Automated Instruments (Vitek, Phoenix, MicroScan, TREK)

The last five decades have witnessed an evolution of sophistication in automated organism identification and antimicrobial susceptibility testing systems. There are several systems available, and this section will highlight their features with respect to organism identification. Chapter 72 will discuss their antimicrobial susceptibility testing performance. The interested reader is encouraged to seek out the latest information provided by the manufacturers as companies are constantly updating their products and, with the advent of MALDI-TOF MS, will be enhancing expert systems to link identification by proteomics with updated and expanded susceptibility testing panels.

The first automated identification system to become available for clinical laboratories more than 40 years ago was the Vitek system (bioMérieux, Inc., Durham, NC). This system was developed by NASA to test astronauts for unusual organisms acquired during the burgeoning space expeditions. The current versions, called the Vitek 2 systems, consist of a personal computer (PC), reader/incubator, and smart carrier station. The smart carrier station is a sample preparation module that standardizes the inoculum and identifies the specimen through a barcode label prior to loading the cassettes. There are several available systems depending upon the desired instrument footprint and volume of testing needed (Table 2). Depending upon the size, the instruments can accommodate 15, 30, 60, or 120 cards (Vitek 2XL). Two reader/incubator instruments can be connected to one computer. The PC has a bidirectional interface capability with the laboratory information system (www.biomerieux-usa.com).

The Vitek system has cards for the identification of anaerobes and coryneforms; yeast; Neisseria species, Haemophilus species, and other fastidious organisms; Gram-positive organisms; and Gram-negative pathogens (Enterobacteriaceae, non-Enterobacteriaceae, and highly pathogenic organisms such as Brucella and Francisella species) (Table 2). The system also contains an advanced expert system that matches 2,000 organism phenotypes with 100 resistance mechanisms. Organisms for which the phenotype and MIC values match are flagged green and do not require user verification. Isolates that flag yellow (inconsistent results), red (unknown phenotype), or purple (phenotype is not in the database) require user review and problem resolution (www.biomerieux-usa.com).

The Vitek 2 system, as well as the other automated systems, continues to be reviewed in the literature as new features are added and software versions are updated. New publications revisit these systems in the context of comparisons to novel molecular array platforms and MALDI-TOF MS. A few recent papers have compared the performance of several platforms; this information is useful for laboratories seeking to purchase one of these systems (13-17).

Siemens Healthcare Diagnostics, Inc. (Deerfield, IL) manufactures the MicroScan WalkAway system. The available instruments include the WalkAway-40 plus and the WalkAway-96 plus, which accommodate 40 and 96 panels, respectively. The autoSCAN-4 system is a small instrument designed for low-volume laboratories; it accommodates and reads one panel at a time within several seconds. The instruments have front panel controls, and the systems include a PC keyboard, monitor, and LabPro software. The MicroScan uses system-wide bar code authentication of panels to minimize potential errors from manual labeling and/or keystroke entry when placing panels into the instrument (www.siemens.com/diagnostics).

There are a variety of MicroScan panels—conventional, rapid, specialty, and Synergies plus—which are available in over 60 configurations. The conventional panels contain traditional biochemicals for identification and broth microdilution MICs and can be read visually. The rapid panels provide organism identifications as early as 2 to 2.5 h and broth microdilution susceptibility results can be read visually. The rapid panels provide organism identifications as early as 2 to 2.5 h and broth microdilution susceptibility results are flagged when ready. Specialty panels are available for identification of yeast, anaerobes, fastidious Gram-negative rods, and streptococci (www.siemens.com/diagnostics). Conventional panels contain modified biochemical and chromogenic tests for the identification of a broad range of species (Table 2) (18). Rapid panels utilize fluorogenic substrates or fluorogenic indicators to detect pH changes following substrate

cOvernight growth on particular media is required; assay takes about 2 h to perform.

utilization and the production of specific metabolic products (19). Similar to other systems, identification is based on
detection of substrate utilization, pH changes, and growth
in the presence of certain antimicrobial agents. Depending
upon the panel used, results may be available from 2 to 42
h after incubation at 35°C (18, 19). Results can be read
manually, which is useful for resolving aberrant reactions
and for smaller facilities that do not have automation.
Some of the panels can be stored for up to 1 year at room
temperature.

The company offers a device called the PROMPT system
for inoculating panels in place of having to create a 0.5
McFarland standard. The user touches three well-isolated
colonies that are as large as the unique wand tip. The wand
is then placed into a small bottle containing 30 ml of
aqueous Pluronic-D solution. After mixing well by shaking,
the suspension is poured into a seed tray for inoculation into
a MicroScan panel. There is also the RENOK rehydrating
inoculator that can be used to simultaneously inoculate all
96 wells of any available MicroScan panel from the seed
tray created by the PROMPT device (www.siemens.com/ diagnostics).

The LabPro with AlertEX contains a database of predefined rules based upon Clinical and Laboratory Standards
Institute (CLSI) recommendations (20). The user can customize the rules as needed to match formularies and infection
control alerts and for other uses. The software automatically notifies the user when an isolate requires attention.
This may include the need for supplemental testing, a quality control issue, or another actionable item. The epidemiology
management feature can provide information to infection control and pharmacy. Antibiogram tools are based on the

The BD Phoenix Automated Microbiology System (BD Diagnostics, Sparks, MD) became available in Europe in
2001 and in the United States in 2004. Currently, the complete system consists of the Phoenix instrument, numerous
test panels, the AP instrument for panel inoculation (introduced in 2008), and the BD EpiCenter system for
data management (http://www.bd.com/ds/productCenter/ IS.asp). The Phoenix instrument can test up to 99 test
panels and one control panel simultaneously. There are numerous panels available for Gram-positive and Gram-
negative pathogen identification (ID) and/or antimicrobial susceptibility testing (AST); a yeast identification panel
was introduced in 2011. The combined ID and AST panels consist of 136 wells divided into 51 wells on the ID side.
and 85 wells on the AST side. Organisms are identified on the basis of 48 individual biochemical tests using a combination of fluorometric and colorimetric detection of the various substrate reactions. Identification of Gram-negative and Gram-positive organisms requires 2 to 12 h, whereas yeast identification requires 4 to 15 h. Once results are available by the Phoenix instrument, the BD Xpert system software manages the interpretation of the results. Users can finalize results directly at the Phoenix instrument, using the EpiCenter, or through the laboratory’s information system.

The BD EpiCenter System is a data management software system. It has a bidirectional laboratory information system interface and tools that allow the user to create specific institutional rules for AST and other types of reporting. These tools or programs also allow the user to analyze epidemiological trends and generate reports from multiple BD instruments, not just the Phoenix instrument, including the new BD Bruker MALDI Biotyper.

One of the initial problems with the workflow using the Phoenix compared to other systems was the manual set up of the panels which resulted in a longer mean time of setup than for other instruments (e.g., 3 min for Phoenix compared to 1.5 min for Vitrek 2) (21). In 2008, BD introduced the AP instrument to reduce the hands-on time required to set up Phoenix panels and to better standardize the inoculum preparation. The user places ID and AST broth for up to 5 isolates into a rack that gets loaded onto the AP system for automated standardization of the ID broth inoculation and subsequent inoculation of the AST broth and addition of the AST reagent indicator. The user must manually transfer the rack to an inoculation station, scan the bar code labels, pour the ID and/or AST broth into the panel, seal them, and then place them into the Phoenix instrument (http://www.bd.com/disproducerCenter/182.asp). A study by Junkins et al. reports a reduction in hands-on-time by 50% using the AP instrument (22).

Trek Diagnostic Systems (now part of Thermo Fisher Scientific) are best known for the extensive and customizable microbroth dilution panels for susceptibility testing (discussed in chapter 72). The company manufactures identification panels (Sensititre ID plates) that contain fewer substrates than the larger systems discussed above and are designed to identify the most commonly encountered aerobic Gram-negative and Gram-positive pathogens. The separate Gram-negative and Gram-positive plates contain 32 reaction wells containing fluorogenic substrates that allow for identification in as short a time as 5 h, and which can be extended to overnight incubation if needed. Each ID microtiter plate can test three separate organisms. ID panels can be read on the same instrumentation used to read the susceptibility MIC plates. In addition, laboratories can purchase an auto inoculator called the Sensititre AIM and a nephelometer to enhance inoculum standardization. The Sensititre ARIS 2X is a fully automated benchtop instrument that incubates and reads the bar-coded plates. The system has a 64-plate capacity and accommodates all TREK plates: MIC, breakpoint, and identification. Up to 192 tests per day can be run on a single instrument. The ARIS instrument is connected to a computer that contains the SWIN software, an expert system used for interpretation of the plates. In addition, the company has an epidemiology module on SWIN that allows the user to design five customizable reports for tracking workload, MIC values, and organisms of epidemiological significance. There are no recent publications evaluating the Sensititre Gram-negative identification panels. A publication by Staneck et al. comparing the Sensititre Gram-negative identification panel to API 20E and Rapid NFT using a large number of isolates demonstrated comparable performance for the more common genera of Enterobacteriaceae and non-Enterics (23). A study from Mexico evaluated the Sensititre Gram-positive ID plate to assess its utility for identifying common staphylococci compared to API STAPH v4.1 (10). Discordant isolates were resolved by PCR and sequencing of partial sequences of the 16S rRNA, sodA, and tuf genes. The Sensititre plates correctly identified only 69% of the isolates compared to 90% by API STAPH, indicating limited utility for identification of this group of Gram-positive organisms (24).

The Biolog OmniLog ID System (Biolog, Hayward, CA), introduced in 1989, is a fully automated instrument based upon the ability of an organism to utilize or oxidize a panel of 95 carbon sources. The 96-well microtiter plate uses reduction of tetrazolium violet that is incorporated into each substrate as an indication of utilization of the carbon source (25). The “carbon fingerprint” is analyzed by the software of the instrument and compared to an extensive database (GEN III) of over 2,500 species of aerobic and anaerobic bacteria, yeasts, and fungi (26). Similarity indices are used to identify the test organism from the index of <0.5, no identification; similarity index of 0.50 to 0.75, good identification; similarity index of >0.75, excellent identification (25). A variety of configurations, levels of automation, and identification databases are available (26). The fully automated GEN III OmniLog ID system has the capacity to inoculate and monitor up to 50 Biolog MicroPlates (26). A requirement for testing is subculture of isolates to be tested to Biolog universal growth agar (25). The Biolog system has been evaluated in the literature over the last two decades (25, 27, 28). The most recent publication evaluated the accuracy of the system for identification of “atypical” clinical isolates, that is, isolates not routinely included in routine identification databases such as certain aerobic actinomycetes, Bacillus species, and fastidious Gram-negative rods (25). In this study of 159 bacterial isolates, the OmniLog system was compared to 16S rRNA gene sequencing and an extensive panel of biochemical assays; compared to conventional methods, the overall accuracy of the Biolog system was 68.3% (25). The best performance was seen with the aerobic actinomycetes (100 versus 74% accuracy with 16S rRNA gene sequencing), while the performance for fastidious Gram-negative rods was poor (20 versus 100%) (25). At least one study has also demonstrated variable performance of the Biolog system for identification of Gram-positive cocci (27).

The Sherlock microbial identification system (MIDI, Inc., Newark, DE) has been available since 1991 and spun out of a partnership between Hewlett-Packard Co. (now Agilent Technologies) and the University of Delaware's Plant Pathology Department (www.midi-inc.com). The system can identify a broad range of bacterial pathogens (approximately 1,500 species) using gas chromatographic analysis of cellular fatty acids. The traditional method of identification requires about 1.5 to 2 h perform. Organisms to be tested are subcultured to specific media and incubated for 24 h, and then a defined biomass is transferred to tubes for fatty acid extraction before gas chromatography is performed (29). The Sherlock software identifies organisms using a set of fatty acid methyl esters (29). A more recently developed rapid system for aerobes and anaerobes called Q-FAME requires less biomass and less time (approximately 24 min), but it is not FDA cleared. The Sherlock system is used as a reference method in food microbiology, by environmental laboratories, and in some clinical laboratories. Some users have
expanded the manufacturer’s library by incorporating their own strains over time, and this has been shown to enhance identification and differentiation of genera such as Corynebacterium (30). In 2005, MIDI received FDA clearance for its aerobic bioterrorism library (http://www.midi-inc.com/).

The BIOMIC V3 is a digital imaging system that automates the reading and interpretation of disk diffusion tests and the results of other commercial manual identification and AST kits or tests. This system requires off-line incubation after which the user manually places the plate or test onto the instrument. The BIOMIC is programmed to read API panels, RapID tests (Remel), and Crystal panels (Becton Dickinson). It also automates the reading of Etest MICs and broth microdilution panels (www.biomic.com).

**Manual Kits, Assays, and Nonautomated Platforms**

An array of kits, assays, and nonautomated platforms are available for identification of a variety of common and unusual pathogens. In many circumstances, these are used to supplement automated systems for identification of fastidious organisms that may fail to adequately grow in the panels of those systems or as a backup for unusual or failed results. The basis of these systems is the principles of turbidity or growth of organism in the presence of a substrate. Table 3 contains the list of many of the more commonly used assays stratified by the organism groups that they identify. It is recommended that the interested reader contact manufacturers for the most up to date information regarding availability and performance.

**PHENOTYPE-INDEPENDENT METHODS FOR IDENTIFICATION**

Phenotypic microbial identification can be limiting and is often not rapid. MALDI-TOF MS is being adopted into clinical microbiology laboratories as a rapid, cost-effective method for identification of a wide range of bacteria and fungi. For challenging organisms, nucleic acid-based methods may still be required, including broad-range DNA target sequencing or arrays and organism-specific detection techniques. Amplified DNA sequence-based methods do not necessarily require optimal growth or even a viable microorganism, enable data exchange between laboratories, and may help define taxonomic relationships between microorganisms.

**PROTEOMIC IDENTIFICATION SYSTEMS: MALDI-TOF MS (BASED IN PART ON REFERENCE 31)**

MALDI-TOF MS provides rapid, inexpensive identification of bacterial and fungal colonies (32). MALDI stands for matrix which assists in desorption and ionization of highly abundant bacterial and fungal proteins through energy from a laser (2). Although protein extraction may be performed, the most user friendly approach is to test colonies directly by moving whole cells from a bacterial or fungal colony (using a plastic or wooden stick, loop, or pipette tip) to a “spot” on a MALDI-TOF MS target plate (a disposable or reusable plate with test spots) (Fig. 1). Spots are overlaid with matrix (or first with a formic acid solution, which is more viscous) and dried, and the target plate is placed into a mass spectrometer (Fig. 2). The matrix (e.g., α-cyano-4-hydroxycinnamic acid dissolved in 50% acetonitrile and 2.5% trifluoroacetic acid) isolates bacterial or fungal molecules from one another, protecting them from fragmentation and enabling their desorption by laser energy; the majority of the laser energy is absorbed by the matrix, converting it to an ionized state. As a result of random collision in the gas phase, charge is transferred from matrix to microbial molecules; ionized microbial molecules are then accelerated through a positively charged electrostatic field into a time of flight, or TOF, tube. Inside the tube, which is under vacuum, the ions travel toward an ion detector, with small analytes traveling the fastest, followed by increasingly larger analytes; a mass spectrum is produced, representing the number of ions of a given mass impacting the detector over time. It is highly abundant (predominantly ribosomal) proteins which generate the mass spectrum. Although they are not individually characterized, together they provide a profile unique to individual types of microorganisms, with peaks specific to genera and species. Computer software compares the generated mass spectrum to a database of reference spectra, generating a list of the most closely related organisms with numeric rankings. Depending on how high the value (percent or score) of the top match is (and considering the next best matches), the organism is identified at the family, genus, or species level.

Commercial MALDI-TOF MS systems are available from bioMérieux, Inc. (Durham, NC) and Bruker Daltonics, Inc. (Billerica, MA). Another system, called Andromas (Paris, France), is primarily used in France and will not be further discussed. AnagnosTec (Zossen, Germany) marketed a microbial database called Spectral Archiving and Microbial Identification System (SARAMIS) used with Shimadzu’s AXIMA Assurance mass spectrometer (Shimadzu, Columbia, MD), which bioMérieux acquired in 2010 and changed the name to VITEK MS RUO; bioMérieux then developed a new database, software, and algorithms called VITEK MS IVD (including a prerelease version of the VITEK MS v1.1 database, the v1 system/v1.1 database, the v2.0 system/v2.0 database and algorithms, and the v3.0 system/v3.0 database and algorithms). The FDA-cleared platform is called Vitek MS. VITEK MS Plus incorporates the VITEK MS and SARAMIS v4.0 databases. The Bruker Biotype system includes a mass spectrometer, software, and library. The FDA-cleared platform is called the MALDI Biotyper CA System. At the time of this writing, there are more published studies using the Bruker than the bioMérieux system. The systems differ in databases, identification algorithms, and instrumentation. Numeric rankings, reported on different scales, are not directly comparable. Bruker’s Microflex LT mass spectrometer is a desktop instrument, whereas bioMérieux’s is a larger floor model.

Rapidly implemented progressive improvements in both systems render it difficult to compare studies because of diverse specimen preparations, organism test sets (i.e., enriched for unusual organisms or not), reference identification methods, mass spectrometers, software, interpretive guidelines, and databases. In general, the technology performs at least as well as, if not better than, automated biochemical systems for identification of common bacteria and yeast (Table 4) and better for many unusual organisms (37). Usually, organisms are either correctly identified or yield a low score/percent, indicating that identification has not been achieved; the latter typically implies no “match” in the database but can occur due to technically poor preparation. Misidentifications are unusual but occur with closely related organisms; Escherichia coli and Shigella species are notably not well-differentiated by MALDI-TOF MS.

Richter et al. performed a multicenter study comparing VITEK MS v2.0 to 16S rRNA gene sequencing (with supplemental phenotypic testing as needed) for identification
of 965 Enterobacteriaceae isolates representing 17 genera and 40 species (38). MALDI-TOF MS results agreed with the reference methods for 96.7% of isolates, with 83.8% correctly identified to the species level, 12.8% limited to genus-level identification, and 1.7% yielding no identification. Seven isolates had wrong genus identification, including three Pantoea agglomerans isolates misidentified as Enterobacter species and single isolates of Enterobacter cancerogenus, Escherichia hermannii, Hafnia alvei, and Raoultella ornithinolytica misidentified as Klebsiella oxytoca, Citrobacter koseri, Ob-
from Campylobacter jejuni (44). Salmonella enterica subsp. enterica serovar Typhi may be distinguished from other S. enterica serovars, although typing within the genus Salmonella is generally not possible (45). It may be possible to identify Burkholderia cepacia complex members, including Burkholderia cenocepacia, Burkholderia cepacia, Burkholderia stabilis, and Burkholderia vietnamiensis (46). With database enhancement, HACEK organisms (Haemophilus, Actinobacillus/Aggregatibacter, Cardiobacterium, Eikenella, Kingella; 47) and Legionella species (48) can be identified. Francisella tularensis and Brucella species may be accurately identified; however, the Bruker Biotyper library does not contain and will not identify these organisms. Use of Bruker’s “Security Relevant” database enables their identification (49).

Rychert et al. reported findings from a multicenter study evaluating the Vitek MS v2.0 system for the identification of 1,146 isolates of aerobic Gram-positive bacteria (50). For 92.8%, a single accurate, species-level identification was provided. With MALDI-TOF MS, overall identification of staphylococci (51), β-hemolytic streptococci (52), aerococci (53), and enterococci is excellent. Some α-hemolytic streptococci are problematic. S. mitis and S. oralis may be poorly differentiated from S. pneumoniae, at least with the Bruker system (54, 55); the VITEK MS system may overcome this limitation (56, 57). While MALDI-TOF MS reliably identifies viridans group streptococci to the species group level, it may not be able to discriminate some closely related species (58). Other streptococci, such as S. canis, S. dysgalactiae, and S. pyogenes and S. infantarius, S. equinus, and S. lutetiensis may not be well differentiated from one another (33). Arcanobacterium haemolyticum and Rhodococcus equi can be reliably identified, as can all but select closely related Corynebacterium species (using lower score cutoffs than recommended by the manufacturer) (59).

MALDI-TOF MS can be used to identify many clinically relevant anaerobic bacteria (60, 61). Jamal et al. reported species-level identification of 89 and 100% of 274 routinely isolated anaerobic bacteria (enriched in Bacteroides fragilis) using the Biotyper DB Update–V3.3 and the VITEK MS v1 system/v1.1 database, respectively (62). Identification of more esoteric anaerobes, including Prevotella species, has been successful in 83% of cases with user supplementation of Bruker’s Reference Library 3.2.1.0 (63). Schmitt et al. evaluated a diverse collection of 253 clinical anaerobic isolates using the Bruker system and a user-supplemented database; 92 and 71% of isolates were correctly identified to the genus and species levels, respectively (64). Barreau et al. tested 1,325 anaerobic isolates using the Bruker system and correctly identified 92.5% to the species level (using lower score cutoffs than recommended by the manufacturer) (65). Garner et al. evaluated 651 anaerobic bacterial isolates using the VITEK MS v2.0 system and reported correct species-level identification in 91.2% (65).

A small number of studies have reported using MALDI-TOF MS for mycobacteria, an endeavor which requires special processing to kill tested bacteria (for safety), disrupt clumped cells, and break down cell envelopes. Current commercial libraries inadequately address Mycobacterium
species, but with appropriate library construction, MALDI-TOF MS should be able to identify most clinically-relevant species, with a few caveats. Members of the Mycobacterium tuberculosis complex will likely be identifiable at the complex level only (66), and some species (e.g., Mycobacterium abscessus and Mycobacterium massiliense; Mycobacterium mucogenicum and Mycobacterium phocaicum; and Mycobacterium chimaera and Mycobacterium intracellulare) may not be well differentiated from one another (66). With enhanced databases, Nocardia species (67) may be identified, but as with Mycobacterium species, specific extraction procedures may be required.

MALDI-TOF MS can identify yeast (68), outperforming some conventional phenotypic systems, and distinguishing Candida dubliniensis and Candida albicans; Candida rugosa and Candida pararugosa; Candida norvegensis, Candida krusei, and Candida inconspicua; Candida parapsilosis, Candida orthopsilosis, and Candida metapsilosis (69); and (with database supplementation) Cryptococcus neoformans and Cryptococcus gattii (70–72). Dhiman et al. evaluated the Bruker system for identification of 138 common and 103 unusual yeast isolates and reported 96 and 85% accurate species-level identification, respectively (73). Although older studies used preparatory extraction for yeasts, we and others have used a direct colony testing strategy with formic acid overlay (Fig. 1) (34, 74). Westblade et al. performed a multicenter study assessing the Vitek MS system v2.0 for identification of 852 yeast isolates, including Candida species, Cryptococcus neoformans, and other clinically relevant yeasts, using direct application to a target plate followed by a formic acid overlay; 96.6% were identified to the genus level and 96.1% to the species level (74). MALDI-TOF MS may outperform current systems for esoteric species, such as Candida famata (69).

Filamentous fungi exhibit variable phenotypes and protein spectra may vary with growth conditions and with the zone of fungal mycelium analyzed; few are represented in current commercial databases. De Carolis et al. developed a library of Aspergillus species, Fusarium species, and Mucorales using the Biotyper system and identified 97% of 94 isolates to the species level (75). Using the VITEK MS v1 system/ v1.1 database and direct on-plate testing, Iriart et al. identified 82% of 44 Aspergillus isolates (including all isolates with species in the database) (76). With appropriate database building, dermatophytes can be identified (77, 78). Preliminary studies indicate that Pseudallescheria/Scedosporium complex species are identifiable (79). Lau et al. used a special fungal extraction procedure and their own mass spectral database comprising 294 isolates representing 49 genera and 152 species to test 421 mold isolates; they achieved accurate species- and genus-level identifications with 88.9% and 4.3% of isolates, respectively (80).

Turnaround time for MALDI-TOF MS is 3 or fewer minutes per isolate. Compared to standard methods, turnaround time for bacterial and fungal identification is shorter by an average of 1.45 days (81), and since only a small amount of organism is required, testing can be performed on single colonies on primary culture plates without subculture. MALDI-TOF MS has a low reagent cost (81), and compared to conventional phenotypic identification and sequencing, reduces costs by 5- and 96-fold, respectively (37). An estimated 87% of isolates may be identified on the first day (compared with 9% with standard techniques), with final identifications several days earlier for biochemically inert, fastidious, or slow-growing organisms (81). DNA sequencing expenses can be avoided for some esoteric organisms, waste disposal decreased, and tests for screening for certain enteric pathogens (e.g., triple sugar iron agar for Salmonella species) and quality control and laboratory technologist training/labor for replaced/retired tests eliminated (82, 83).

MALDI-TOF MS has several limitations. Unlike publicly available sequence databases such as GenBank, MALDI-TOF MS databases are proprietary. Although low identification percentages for some organisms may be improved by user addition of mass spectral entries of underrepresented species or strains (to cover intraspecies variability), or even readaptation of reference strain spectra to the database, doing so may be beyond the capability of some laboratories. Because of low scores/percentages, repeat testing may be required for ~10% of isolates (81). Growth on some media may be associated with low scores/percentages (84), and small or mucoid colonies may fail identification (40, 85). Refined criteria may be needed to distinguish closely related species and differentiate them from the next best taxon match (86). For certain species of organisms, genus- or
species-specific (including lowered) cutoffs may be appropriate (51, 59, 87). Errors may occur, including colony inoculation in erroneous target plate locations, testing impure colonies, smearing between spots, failure to clean target plates, and wrong result entry into laboratory information systems. There is a learning curve to applying ideal colony amounts to target plates (40). Although results are generally reproducible, sources of variability include the mass spectrometer, matrix and solvent composition, technologists, culture conditions, and biological variability; quality control strategies are incompletely developed. Instrument (e.g., laser) and software failure may occur.

**GENOTYPIC IDENTIFICATION SYSTEMS**

**DNA Target Sequencing**

DNA target sequencing may be performed on organisms growing in pure culture. For a comprehensive review, refer to articles and guidelines that specifically address this topic (88, 89). The selection of DNA targets to identify bacteria and fungi relies on the concept that some genes have conserved segments flanking variable regions. Conserved regions of gene targets are locations where PCR and DNA sequencing primers anneal. Variable regions have unique nucleotide sequences, enabling sequence-based identification of a particular genus and species. The gene target most commonly used for bacterial identification is the 16S rRNA gene (16S ribosomal DNA), an ~1,500 bp gene that encodes a portion of the 30S ribosomal subunit. Partial (500 bp) 16S rRNA gene sequencing is commonly used for sequence-based identification of Gram-negative and Gram-positive bacteria, anaerobic bacteria, and mycobacteria (88). For genera with high conservation of the partially sequenced 16S rRNA gene, full-length 16S rRNA gene sequencing or sequencing of an alternative DNA target may be useful. Potential targets for identification of yeasts and medically relevant molds include the internal transcribed spacer regions ITS1 and ITS2, which are variable regions located between conserved genes encoding 18S, 5.8S, and 28S rRNAs, and the D1-D2 region of 28S rRNA.

To identify the microorganism, its DNA sequence is compared to reference sequences found in public (e.g., GenBank) and/or private (e.g., MicroSeq [Applied Biosystems, Carlsbad, CA], SmartGene [Lausanne, Switzerland]) databases. After comparing the query and reference sequences, the number of nucleotide mismatches between the query and reference sequences is used to determine relatedness, and the final result is reported as percent identity. The acceptable percent identity to identify a microorganism to the genus or species level is variable and depends on the DNA target and microorganism. 16S rRNA genes are multicopy targets in most bacteria, and variations in sequence amongst 16S rRNA genes in single organisms can result in difficulty interpreting sequence data. A computer program called RipSeq Mixed (iSentio, Bergen, Norway) can be used to computationally decatenate underlying sequences in such cases. Nucleotide databases must be carefully evaluated for accuracy, quality of sequence data, frequencies of database updates, software, cost, and breadth of nucleotide entries. The Clinical and Laboratory Standards Institute published a comprehensive consensus document for identifying microorganisms to the genus and species levels by DNA target sequencing; this document can serve as a useful guide for laboratorians who wish to pursue or have already implemented DNA target sequencing (88). In the future, whole-genome sequencing will become more routine for clinical laboratories, providing information about the diversity of species, their virulence properties, epidemiology, and antimicrobial resistance mechanisms, and disease causation.

**PCR Electrospray Ionization Mass Spectrometry**

Another technique to characterize bacteria is the application of electrospray ionization-MS to analyze PCR products (PCR/ESI-MS) (90–92). Rather than measuring the mass of bacterial proteins, masses of amplified DNA from broad-range (e.g., rRNA) and specific genes are measured. The masses of amplified DNA are measured with sufficient accuracy to enable unambiguous calculation of the nucleotide compositions of the amplified DNA. Typically, a number of PCR assays are performed and analyzed as a panel. By considering which PCR assays yield amplification products, along with their nucleotide compositions, the identity of

the microorganism may be defined. This is conceptually similar to broad-range PCR followed by sequencing, except that here MS provides the base composition without knowing the order of the nucleotides. Analyzing multiple target sites on the microbial genome can compensate the lower information content of nucleotide composition over sequence. Simmer et al. recently evaluated the PLEX-ID Broad Fungal assay (Abbott Laboratories, Abbott Park, IL) for identification of 91 characterized fungal isolates; 95.6% and 81.3% were identified to the genus and species levels, respectively (93). The advantage of PCR/ESI-MS over sequencing is that it is fast and has a high throughput; however, it is currently quite costly. PCR/ESI-MS is being developed as IRIDICA by Abbott (Abbott Park, IL).

REFERENCES

Clinical microbiology laboratories (CML) are central to the operations of any health care system and take many different forms depending on the type of system they serve. There is no one right way to design a laboratory because appropriate design will be dictated by the space available, staffing requirements, services provided, test volume, and many other factors. Despite institution-to-institution differences in laboratory design, a few elements should be common to all laboratories.

First, the laboratory should be a safe environment for employees and visitors. The microbiology laboratory can be a dangerous environment, as the diagnosis of infectious diseases often requires that pathogens be propagated to high concentrations and processed for identification. Laboratory design should be optimized to ensure that the diagnostic process can take place as efficiently and safely as possible. Guidance for safely operating and designing a laboratory can come from many resources. The Centers for Disease Control first published the Biosafety in Microbiological and Biomedical Laboratories in 1984. Although the information provided in this document is advisory in nature, legislation and regulations have in some cases made compliance with this document mandatory (1). At baseline, all CMLs must meet biosafety level 2 criteria and, depending on the services rendered and pathogens encountered, may need to meet biosafety level 3 criteria (1).

Second, laboratories should be designed to efficiently handle specimens from initial processing to final result without contaminating the specimen or culture. The efficiency with which a specimen can be processed is an increasing challenge as the centralized laboratory model becomes more common. In these models, a central laboratory provides testing for external institutions that ship specimens to a single location. This model helps to reduce redundancy of resources but at the possible expense of testing efficiency. The time and manner of transport within a hospital and within a system should be considered when designing a laboratory so as to optimize turnaround time (TAT) and reduce contamination.

Third, laboratories should be designed so that their configuration can be flexible and accommodate emerging technologies and changing demands.

The goal of this chapter is to provide information regarding the proper design of a laboratory, bearing in mind that each institution requires something different from its laboratory. Microbiology is rapidly changing and so too are the spatial and geographical demands placed on facilities. The chapter is presented in two sections. The first will focus on laboratory design and workflow. This section will focus on some key elements of laboratory design, including the geography of a laboratory (i.e., where testing is performed), preanalytical considerations, staffing strategies, workflow, process improvement, and clinical impact. The second will address a new and important subject for clinical microbiologists, laboratory automation. Some historical perspective will be provided along with a discussion of currently available options for laboratory automation and considerations for implementation.

GEOGRAPHY OF THE LABORATORY
Almost every clinical service is a customer of the laboratory. It is therefore critical that the laboratory be well connected, both electronically and physically, to the facilities for which it provides testing. A wide variety of laboratory information systems (LISs) and electronic medical records can be found among institutions. These systems are now a vital component of laboratory testing and will likely become even more important as digital microbiology and total laboratory automation (TLA) become more common. A review of these numerous systems is beyond the scope of this chapter. The Association for Pathology Informatics provides a toolkit which can be used to assess currently available LISs (http://www.pathologyinformatics.org/toolkit).

In any health care setting, but especially teaching hospitals, convenient access to the laboratory is an important factor that encourages physicians and trainees to interact with the hospital directly. It is difficult to quantify the clinical benefit of this interaction, but most microbiologists and infectious disease practitioners agree that being able to readily access the laboratory for personal consultation is of great benefit.

Clearly, there can be real advantages to locating a laboratory within the hospital it serves. However, there can be significant benefits to the centralized model as well. The primary advantage is one of scale. Centralizing a laboratory service, while cumbersome from the perspective of specimen transport, simplifies spatial, technological, and staffing needs. By centralizing services, laboratories can focus all of their resources in a single area, thus minimizing the...
One advance that has greatly improved the ability to perform high-quality POCT outside the laboratory is instruments that autoverify results. In some cases, these instruments can be programmed for QC lockout, automated result interpretation, and autoverification of results. These instruments aid busy individuals in reading results at the appropriate time and automatically sending the information to the information management system. Lastly, the QC lockout is a function that forces proper QC testing by locking the instrument until QC is performed and passed.

**PREANALYTICAL MICROBIOLOGY**

A critical aspect of laboratory operations is the interaction with the client. Interactions include ordering, specimen tracking, and result reporting, all of which should be delivered electronically. The most obvious interaction with a laboratory involves specimen transport. There are three main forms of specimen transport utilized: manual, pneumatic tube, and robotic. Hospitals with internal laboratories commonly rely on a combination of all three transport modalities, although formal specimen pneumatic tubes are often preferred. Transporting is a much bigger challenge for the centralized laboratory model. This applies both to commercial reference laboratories and to hospital systems which serve a network of external clients. Efficient transport of specimens is imperative to providing reliable and accurate results. With labile pathogens present in specimens that constitute less-than-ideal environments for maintaining organism viability, minimizing specimen transport time is critical. Although there is surprisingly little literature addressing the importance of specimen transport time, Table 2 in chapter 18 of this Manual provides guidance on the matter. Table 2 recommends that specimens such as cerebrospinal fluid, blood culture bottles, abscess material, and body fluids all be transported (collection to processing) in less than 2 h (4). In scenarios where specimens must be transported to distant laboratories, whether across town or across the country, it would seem unlikely that these recommendations could be met. In light of this fact, some laboratory systems have elected to inoculate and preincubate select, high-priority cultures (such as cerebrospinal fluid) so they can be transported at regular intervals rather than on a STAT basis. Organism viability is one reason that minimizing transport time is critical. A secondary reason is simply that results can be provided faster when specimens are transported efficiently.

**STAFFING MODELS**

The most important resources in a CML are the personnel that perform testing. It is well documented that there is a shortage of skilled medical technologists entering the field. It is estimated that 39% of United States laboratories have budgeted openings, with 57% of those openings being for medical technologists (MT) or clinical laboratory scientists and 14% for medical laboratory technicians (MLT) (2). It is also estimated that laboratories must hire approximately 12,000 new employees annually to keep up with test volume growth. However, training programs are disappearing and only about 5,000 medical technologists enter the field each year. As a result, institutions utilize a number of different staffing models to optimize the effectiveness of their workforce.

Most laboratories break down their workday into three 8-h shifts which generally include a daytime, early evening, and night shift. Another approach is the “7 on, 7 off” or
An MLT is defined as someone who has a working comprehension of technical and procedural aspects of laboratory tests. The technician correlates tests with disease processes, understands basic physiology, and recognizes abnormal test results (6). The tasks that can be performed by MLTs will vary by institution but generally include quality assurance monitoring, computer applications, and instrumentation troubleshooting and require an understanding of specimen collection and processing. The American Society of Clinical Pathologists states that a technician may make technical decisions related to testing but should be supervised by a technologist, supervisor, or laboratory director. MLTs usually have an associate degree from a community or junior college or a vocational school. MLTs may become MTs through additional education and experience.

Medical laboratory assistants are individuals who receive on-the-job training and may have specialized education, but that is not required. The primary task of the medical laboratory assistant is specimen processing and using preanalytical systems. These professionals must have in-depth knowledge of specimen acceptability.

WORKFLOW

Batch Versus Immediate Testing

The organization of workflow and the selection and extent of batching procedures depend on several factors. Specimens that have direct diagnostic or therapeutic consequences can be batched only to a limited extent. When analytical process automation is involved to a high degree, specimens can be combined in larger series. The effects on TAT must be determined and accordingly taken into consideration. It should also be determined when the findings should be made available to the clinician. When the above conditions are met, the ideal size of a batch can be determined on the basis of the number of specimens, specimen type, time allotted for transport, distribution of specimens after arrival at the laboratory, desired tests, and selected laboratory equipment. The effects of an order entry system or the various options of digital transmission of the findings must also be taken into account.

The use of matrix-assisted laser desorption–ionization time of flight (mass spectrometry) (MALDI-TOF[MS]) and molecular methods for organism identification can shorten the TAT (7). Identification using MALDI-TOF (MS) is possible with only a single colony from the primary culture, and fewer subcultures are needed to obtain a pure culture. It thus becomes possible to identify bacteria 1 to 2 workdays earlier than with current phenotypic methods (8, 9). The TAT can be further shortened by changing the reading intervals for the culture plates. Instead of reading the plates only at a fixed time, traditionally in the morning, they could also be read at regular intervals in the afternoon and/or evening. This is particularly true for specimens arriving at the laboratory in the afternoon or evening. Batching the specimens according to the above reading modalities and deploying staff as described above make it possible to maximize laboratory efficiency.

Introduction of digital image processing into diagnostic microbiology offers new opportunities for organizing workflows and shortening TAT. Reading plates digitally results in earlier recognition of colony growth. Consequently, subsequent identification and susceptibility testing can be accelerated. The pictures of the plates are taken at individually defined intervals and times for further processing. The computer can be supportive in preselection of culture-negative
plates. The plates showing growth are sent through further diagnostic procedures. Imaging technology can detect even the smallest of colonies, which are difficult for the human eye to differentiate. Chromogenic media for diagnosing multidrug-resistant organisms such as methicillin-resistant Staphylococcus aureus, vancomycin-resistant enterococci, and multidrug-resistant Escherichia coli, Acinetobacter spp., or Salmonella spp. are particularly suitable for imaging technology, since results of the cultures can be documented earlier. Adapting work hours to conform to the above procedures should be considered. Incubation and digital image processing can also be applied to manually inoculated plates. The benefits of automation can be put to full use by baking the specimens for the process described.

The rapid development of easy-to-use molecular diagnostic test systems for detecting pathogens like methicillin-resistant S. aureus, Clostridium difficile, enterovirus, and respiratory viruses has led to progressively smaller batch sizes. Batching specimens for such tests would thwart the advantages of these systems (e.g., time savings and easy handling).

Role of Process Improvement
Economic pressure and new approaches in the domain of laboratory automation, as described below, open up opportunities for reconsideration and possible revision of the entire laboratory process.

Potential areas for improvement range from analyzing and developing solutions for the current laboratory situation, concerning workflow, staff utilization, and certain selected methods, up to introducing entirely new laboratory concepts and equipment. Changes in these areas can lead to increased capacity and flexibility within the laboratory and enable it to deal with unforeseen or planned increased numbers of specimens for processing. Another reason for evaluating the entire laboratory organization is to compensate for a dwindling laboratory work force. For instance, in Germany, the number of graduates from schools for medical technologists decreased from 2,273 between 1994 and 1995 to 1,471 between 2009 and 2010 (10).

The following steps should be taken to achieve sustained optimization. First, a list of laboratory processes should be compiled. Then an implementation plan should be drawn up. The plan should describe the individual steps: the necessary resources, organization, productivity, target TAT, and ways to deal with additional workload. Sustainability of the new process is achieved by regularly and closely tracking the implemented changes and by monitoring them to determine whether or not objectives have been achieved.

The entire process should be preceded by a comprehensive informative phase: visits to other laboratories and exchanges with colleagues. One can also seek the advice of external consulting firms. Manufacturers of medical equipment for diagnostic purposes also offer concepts. These firms provide a baseline evaluation and analysis of the laboratory's equipment in its entirety, including the work organization and the work processes, the stock of devices, and the computer systems and their usage. The proposed solutions generally lead to a greater degree of automation, which, along with potentially recommended middle software, provide better coordination of the devices and processes. Various methods for process analysis and optimization are being used in this context. The methods have been adopted from the automobile and shipping industries and are based on presentations from lean management and Six Sigma.

The lean management method originates from the automobile industry and was first used by Toyota. The aim was to identify all of the characteristics that enhance the value of the company and increase customer satisfaction. At the same time, superfluous activities and processes were to be discontinued. Lean management as it pertains to health care can be described in four components: (i) methods for analyzing processes, and thereby identifying and analyzing problems; (ii) methods for designing processes more effectively and efficiently; (iii) methods for better detecting errors, implementing solutions, and preventing damaging effects; and (iv) methods for managing these changes and problems and for finding solutions using a scientific approach (11).

A practical example is the implementation of lean management using the concept of the five Ss: exclusively, very necessary materials are allowed in the work area (sorting), the entire laboratory area is straightened up and each piece of working equipment is assigned its own designated place (straightening), the area is cleaned systematically on a regular basis (sweeping), the processes in the laboratory are standardized (standardizing), and sustainability is achieved through regular evaluation and analysis of these processes (sustaining).

The aim of the Six Sigma method is to reduce process variance and simultaneously reduce errors and deviations in the analysis to a minimum. This is achieved through implementation of control mechanisms that link workers, work processes, quality requirements, responsibilities, and costs. The method was developed in the 1970s in Japan for the shipbuilding industry and is used today in many branches of industry worldwide. Six Sigma is based on statistical methods for quality improvement aimed to increase organization success and customer satisfaction. The most frequently used Six Sigma method is the so-called DMAIC cycle (define, measure, analyze, improve, and control). Using DMAIC, processes become measured variables, which can be improved in a sustainable manner. The sigma value describes how often an error is expected to occur. The best sigma value in use is 6; this signifies that fewer than 3.4 defects or errors per million opportunities (DPMO: defects per million opportunities) are expected to occur. A sigma value of 1 for laboratory processes would signify that 691,462 defects are expected to occur per million analyses. A laboratory implementing Six Sigma was able to increase its sigma value from 3.9 (7,210 DPMO) to 4.5 (1,387 DPMO) (12).

The methods described above are used in various combinations to improve the laboratory organization as part of the optimization process and the implementation of high-grade automation. There are a number of publications on this subject that describe how this process can be applied successfully in many sectors of health care (11, 13–19). Rutledge et al. demonstrated in a clinical laboratory a decreased walk pattern for technologists by 70% and a mean TAT reduction of more than 50% for creatinine, complete blood count, urine analysis, and ionized calcium after implementing lean management and Six Sigma (13). Persoon et al. used the lean production system from Toyota to improve the preanalytic processes in a clinical chemistry laboratory (20). The median preanalytic processing time was reduced from 29 to 19 min. Overall, these process improvement systems promise to increase staff efficiency and reduce costs and errors with the ultimate goal of improving patient outcomes.

LABORATORY AUTOMATION: HISTORICAL PERSPECTIVES
The microbiology laboratory has changed very little over the past 30 years with respect to laboratory automation.
The field, though, is now poised to undergo a shift to automate what has traditionally been a very manual discipline. Despite the fact that clinical chemistry laboratories adopted TLA over 20 years ago, the concept has been slow to be accepted in microbiology (21). A number of factors have contributed to the delay in automating clinical microbiology laboratories.

First, the complexity of the microbiological specimen has hindered the development of TLA solutions. The clinical chemistry specimen is of relatively uniform volume and consistency and, perhaps most importantly, is collected in standardized containers. These factors are conducive to automation and are in sharp contrast to the specimen received in CMLs. The CML must be able to process and analyze an enormous variety of specimen types which are collected in highly variable containers.

Second, the nature of diagnosing an infectious disease is complicated by nonspecificity of clinical manifestations. The diagnostic process must therefore include testing for a large number of pathogens, and automated platforms must be able to accommodate this reality. Artificial intelligence programs may one day be able to replicate the complex interpretations required by microbiology technologists. Currently, though, culture interpretation requires human judgment and cannot be automated.

Third, the cost of automation is a significant barrier to entry into the CML. Relative to chemistry testing, microbiology specimen volumes are much smaller, thus reducing the need for automation and making for less appealing returns on investment. However, the high-volume, centralized laboratory model is becoming common and may be an attractive setting for automation. How these systems will fit into the smaller laboratory is yet to be determined.

CURRENT SYSTEMS FOR MICROBIOLOGY LAB AUTOMATION

Organism Identification and Susceptibility Testing
Microbiologists have a number of different options for performing organism identification and susceptibility testing. Susceptibility testing systems are reviewed in chapter 72 of this Manual. MALDI-TOF (MS) is a technology capable of providing identifications based on assessment of protein profiles and database comparison. In actuality, these systems are semiautomated, although they currently require significant manual manipulation prior to analysis. The two major platforms for MALDI-TOF (MS) organism identification are the Vitek MS (bioMérieux) and the Biotype (Bruker Daltonic, Billerica, MA). These are discussed in more detail in chapter 4.

Molecular Automation
Traditional molecular biology is a tedious and labor-intensive process requiring experience and great care to prevent contamination. The future of molecular biology is going to look very different as manual molecular processes are being automated and consolidated into single systems. These systems are commonly referred to as being “sample-to-answer” or “walk-away.” In addition to fully automated systems, a number of manufacturers offer automated nucleic acid extraction platforms. Discussing each product individually is outside the scope of this chapter.

Automated molecular testing platforms are reviewed in chapter 6 of this Manual.

Automated Specimen Processing
Automated inoculation of clinical specimen has been the center of research and development for several years (22). Just recently, these devices became available on the market. Automation of microbiological specimen processing promises to improve the quality of the streaking process, avoid cross-contamination, alleviate ergonomic issues, and reduce processing time and costs. It is expected that the automated streaking process will be reproducible and reliably yield isolated colonies. This will reduce the number of subcultures necessary for identification and susceptibility testing. Available devices have been scientifically evaluated in only a few cases (23–26). The systems usually process swabs in liquid transport media such as E-Swab (Copan Diagnostics, Murrieta, CA) or Sigma swab (Medical Wire, Corsham, United Kingdom). These swab systems consist either of an open-pore polyurethane foam tip and a modified Amies medium (Sigma swab) or a nylon flocked swab with Amies medium (E-Swab). These systems lead to a significantly improved transition of microorganisms from the swab to the transport medium and allow better evaluation of the microorganisms from the Gram stain (20, 25). Swabs in solid or half-solid transport media can only be processed in semiautomatic devices. The devices available are divided according to different inoculation techniques using the loop, comb applicator, or bead technique. In Table 1, the automated inoculation systems are compared according to specimen type processed, inoculation technique, capacity (inoculated plates/hour), and additionally required disposables.

Innova Innovia (Becton Dickinson, Sparks, MD) has five specimen drawers that can accept a total of 200 specimens. A specimen drawer can only accept one type of specimen at a time. The specimens are decapped and recapped automatically and agitated. Up to 270 whole plates as well as biplates of up to six different types can be loaded simultaneously into the device. The streaking pattern can be defined according to the material and selected from a variety of streaking options. The inoculating loop is thermally sterilized. Each loop can be used for up to 15,000 inoculations. For inoculation volumes of 200 μl, a pipette is available. The inoculated plates are sorted according to the type of media into five different groups. The device is a closed system, containing air that is cleaned by a HEPA filter system.

InoquLA FA/MI
InoquLA (BD-Kiestra) FA/MI (full automation/manual interaction) can process liquid media in FA mode, and swabs or other types of specimen in MI mode. A barcode is attached to the side of the plates. In MI mode, the swab or the material to be inoculated is placed manually on the agar plate and streaking is performed with magnetic beads as in FA mode. Slides are prepared in MI mode. Processing can be carried out in MI mode or in FA mode but not in both simultaneously. In FA mode, the specimens are automatically agitated as well as decapped and recapped. A magnetic rolling bead (Fig. 1) is used for streaking, and a maximum of five whole plates or biplates can be inoculated at one time. The streaking pattern can be either selected from a variety of patterns or defined by the customer for each material. The inoculated plates can be presorted into four different cassettes for incubation. The system is equipped with a HEPA filter system.
5. Laboratory Design and Workflow

<sup>a</sup>Capacity depends on the number of inoculated plates or biplates per specimen and chosen streaking pattern.

<sup>b</sup>—, capacity depends on the number of inoculated plates or biplates per specimen.

PREVI Isola
PREVI Isola (bioMérieux, Marcy l’Etoile, France) has five racks designed for various types of specimen. A rack can accept only one type of specimen container at a time. However, the device only processes liquid media. Whole plates and biplates can be loaded into five input cassettes, each of which can accept 30 plates. The specimens must be decapped and recapped manually. The type of streaking pattern is predefined by the comb applicator (Fig. 2). The inoculated plates are stored in three output cassettes (30 plates/cassette). A HEPA filter system is provided.

WASP
The WASP (walk-away specimen processor; Copan) processes various specimen types; the specimens are automatically decapped and recapped as well as agitated or centrifuged. Between 342 and 370 whole plates and biplates can be stored in up to nine-plate silos; only one plate type should be used per silo. The streaking pattern can be selected from a variety of options. The inoculating loop is thermally sterilized. The inoculum in the loop is documented per photo. An agar plate can be inoculated one-half each with two different specimens. The inoculated media are sorted according to the plate type. The plates are labeled on the side or on the base. Gram slide preparation, inoculation of enrichment broths, and an antibiotic disk dispenser for susceptibility testing are available. Cultured plates can be reloaded in the WASP for disc diffusion susceptibility testing. The WASP is equipped with a HEPA filter system.

**Total Laboratory Automation**
TLA in microbiology aims to improve quality, reduce time to result, better manage an increasing number of specimens, compensate for reduction in skilled staff, and be more economically effective (27–30).

Three companies provide different solutions for TLA in microbiology: BD-Kiestra, bioMérieux, and Copan. The field is evolving quickly. More methods and devices are expected to be automated in the near future. These include automated colony picking for MALDI-TOF MS identification and preparation of dilutions for susceptibility testing.

**BD-Kiestra TLA Concept**
The BD-Kiestra TLA Concept is a conveyer-connected system (Fig. 3). This system comprises the following work steps: inoculation of liquid specimen as well as swabs and other nonliquid specimens using InoqulA, incubation in aerobic and CO₂ atmospheres, and digital imaging. Each incubator

![FIGURE 1 InoqulA magnetic bead. doi:10.1128/97815555817381.ch5.f1](image1)

![FIGURE 2 PREVI Isola-inoculated agar plate. doi:10.1128/97815555817381.ch5.f2](image2)
has a capacity of 1,152 plates. The plates are stored individually in the incubator. Automated colony picking for identification with MALDI-TOF (MS), automated susceptibility tests, and expansion with molecular diagnostics equipment (BD-Max) are in the planning stage. Actual concepts are individualized with respect to the size and capacity of the installation. In this way, the laboratory can gradually approach full automation and remain open for future developments.

**bioMérieux Concept FMLA**

The bioMérieux Concept FMLA (full microbiology lab automation) (Fig. 4) is a modular design. The instruments are connected and regulated by the middle software Myla. This system automates the following processes: inoculation of fluid specimen on agar plates using PREVI Isola, incubation in aerobic and CO$_2$ atmospheres, and digital imaging in a smart incubator system. An incubator has a capacity of 1,000 plates with single-plate location. These instruments can be connected by a conveyor system. At present, measures are being taken to automate the colony picking from agar plates for identification using MALDI-TOF (MS) and susceptibility testing. Additional instruments can be connected to the system using the middle software Myla. These include blood culture systems, Gram-staining devices, Vitek 2, and others.

**WASP Lab**

The WASP Lab (Copan) (Fig. 5) is a modular construction and connects the individual machines through a conveyor-connected system. The system processes smears, sputum, stool, and liquid samples. It includes specimen processing with the WASP, incubation in aerobic and CO$_2$ atmospheres, and digital imaging. An incubator has a capacity of 800 to 1,760 plates with single-plate location. Preparation is being made to incorporate identification (using MALDI-
Digital Imaging
Digital imaging is one of the central components in TLA. The methods will be described collectively, since all of the manufacturers adhere to similar principles of image assessment. Digital imaging software is designed to simulate and improve the visual assessment of organism growth. Each system (BD-Kiestra, bioMérieux, and Copan) can take pictures of plates with several exposures and at various angles. With the incorporation of digital imaging and the automation of MALDI-TOF (MS) identifications, the percentage of plates needing manual processing can be greatly reduced. In each system, colonies of bacteria can be labeled for further processing on a screen. Digital processing facilitates early detection of organism growth and shortens the time of identification. Decision making can be automated for certain criteria, e.g., growth or no growth. In addition, all samples from one patient, e.g., urine, sputum, and multidrug-resistant organism screening, can be evaluated simultaneously with computer-assisted processing. Lastly, images can be archived and later used for training or for QC programs.

Limitations of the Systems
The strength of the automatic systems described lies in the processing of standardized and uncomplicated specimens. Those specimens needing special processing methods, such as organ or tissue biopsies, are not easily accommodated by such systems. However, the possibilities for automatic processing can be expanded considerably through the use of liquid-based specimen transport systems. This effectively converts a very high volume specimen, the swab, into a liquid specimen that can be easily managed with an automated specimen processor (25, 27, 31, 32).

A high level of flexibility and system compatibility is especially necessary for small laboratories. The modular nature of the automation systems described enables the laboratories to achieve various levels of automation. The combination of modular automation and process improvement, as explained, promises scalability of the current automation systems for laboratories independent of their size. For this reason, the costs of automation for small laboratories may not outweigh the benefits.

Criteria for Evaluation and Selection of an Automation System
Prior to choosing an automation system, the daily routine in the laboratory should be evaluated. Data regarding specimen volume, arrival time of specimen, and workflow must be determined to negotiate the future lab design with the manufacturers being considered. If possible, it is recommended that institutions conduct a thorough assessment of the systems installed in other institutions to determine whether or not each system is capable of fulfilling a laboratory's needs. All types of laboratory personnel should be involved in the project to incorporate their suggestions and ideas as well as to increase general support for the necessary changes. There are only a few publications addressing this issue (27, 29, 30, 33).

Factors to consider when selecting an automated system are outlined below.

Productivity
The productivity of the automation systems depends upon the number of specimens processed and the TAT for the
entire analysis process. Productivity is affected by a number of factors. Specimen type and the number of plates per sample must be considered. Respiratory material, urine, wound swabs, genitourinary tract specimens, and screening swabs for multidrug-resistant organisms are processed with different types of media (34). The productivity is influenced by the choice of a streaking pattern, the number of pictures taken by digital imaging, and whether a whole plate or a biplate is inoculated.

Reliability, Stability, and Durability
Indicators showing possible malfunction of a system should be used. Contingency plans for possible failures of the system should be planned in advance. Allowance for a certain number of inspections and service procedures should be considered, allotting time for their duration. Staff to service the system should be available on weekends and during holidays.

Technical Aspects
In the beginning, do a survey of the buildings and determine the infrastructure of the rooms: calculate the required space and the weight of the machines; determine the power supply and, if necessary, the compressed-air outlets. At present, the dimensions of the devices and systems are continually decreasing in size. Future developments must also be taken into account. The possible integration of more devices, e.g., PCR equipment, should also be considered.

Software Applications
The instruments should be connected with a bidirectional interface to the LIS. It might be necessary to use middleware. Coordinating the middleware software and LIS is essential. If required, instruments from other manufacturers should be integrated.

Safety and Hygiene
The automated specimen processors should be closed and an appropriate air filter system, e.g., HEPA filter, applied. The risk of contamination must also be taken into account, and protocols for cleaning and disinfecting the incubators and conveyors should be established. Occupational health and safety regulations should be taken into account. There are no current regulations or guidelines addressing the issue of safety in laboratory automation. Of significant concern is the matter of containing exposures generated through errors in automatic incubation.

Quality Control and Scientific Aspects
The entire system should be integrated into the quality management program. The individual work steps must be monitored in compliance with the laboratory regulations: from reading the barcode on the samples and plates to inoculating and transporting the plates, digital image processing, and waste disposal. Inoculators should ensure that particles and air bubbles in the specimen are detected to avoid false-negative inoculations. Measures against transposition and cross-contamination of the samples should be ensured. Only one study evaluating cross-contamination by automated systems has been published (24). In this study, sterile and E. coli-inoculated Vacutainer tubes as well as E-Swab tubes were alternately loaded on the WASP. No colonies were observed from the sterile specimen.

Costs
Laboratories must take into consideration not only the amount invested in the purchase of the devices, but also the consumable supplies, e.g., pipettes, combs, or beads. It might be necessary to purchase agar plates and broths from different manufacturers. Changes in workflow can lead to alterations in the staffing requirements on different shifts and may necessitate installing a night shift if one does not currently exist. This must be taken into account when budgeting expenses. Service and repair charges, as well as the costs of the interfaces, must also be included. Possible structural changes in the laboratory should also be represented in the financial plan.

The Final Decision
The choice of the type and extent of lab automation is, of course, dependent upon the individual circumstances and the financial resources available. It has been a long time since diagnostic medical microbiology has experienced such an enormous innovative surge. It is therefore necessary to take into account future innovations in organism identification and susceptibility testing. New methods can influence procedures in the work process and drastically change the demands on capacity.

FUTURE PERSPECTIVES
The degree of automation as well as the variability of the procedures that can be automated will continue to increase. Continued development will make the systems more flexible and result in products that can better accommodate the conditions of each individual lab. Automated technology is evolving quickly. It will soon include additional testing, e.g., direct testing of blood culture systems and molecular diagnostics.

The primary objective of automating microbiology laboratories is to improve the quality and consistency of processes that suffer from high variability and are labor-intensive. The hope is that these technologies will allow the laboratory staff to concentrate on the processing of more technically demanding specimens. Software solutions for integrating POCT devices will further improve the analytic process.

Lastly, digital image processing as an integral part of bacteriological clinical diagnostics will promote further development in telemedicine. In many centralized laboratory models, sample processing and plate reading may not take place in the same location. In such situations, quality standards can still be maintained in small labs or in remote areas by offering access to experienced personnel. Telemedicine can help counter the lack of skilled personnel in these areas.

Further scientific evaluation of TLA could also facilitate an appraisal of its clinical relevance and its impact on patient care. It could reduce errors and improve the quality of diagnostic microbiology.

SUMMARY
New advances in technology as well as staffing shortages are causing microbiologists to rethink laboratory design. It may be that the traditional laboratory model as we know it today will cease to exist in the near future. TLA will certainly become commonplace in high-volume laboratories and may eventually be found in smaller laboratories. Automation is unlikely to replace medical technologists, but it will change requirements in two important ways. First of all, manual processing of the plates will be replaced by digital imaging. Second, the efficiency of automation may cause more laboratories to adopt the 24-h culture-reading strategy. Clinical microbiology is changing at a rapid pace,
primarily due to a surge in technological advances. Laboratory designs will need to be more flexible to accommodate future developments.

Since the publication of the 10th edition of this Manual, significant changes have occurred in the practice of diagnostic molecular microbiology. Nucleic acid amplification techniques are now commonly used to diagnose and manage patients with infectious diseases. The growth in the number of Food and Drug Administration (FDA)-cleared/approved test kits and analyte-specific reagents (ASRs) has facilitated the use of this technology in the clinical laboratory. Technological advances in nucleic acid amplification techniques, automation, nucleic acid sequencing, and multiplex analysis have reinvigorated the field and created new opportunities for growth. Simple, sample-in, answer-out molecular test kits and analyte-specific reagents (ASRs) has facilitated the laboratory on more traditional antigen detection and culture procedures. With the growth in the number of peroxides, emits light. The hybridization protection assay can be completed in several hours and does not require removal of unbound single-stranded probe or isolation of probe-bound double-stranded sequences (1).

In solid-phase hybridization, target nucleic acids are bound to nylon or nitrocellulose and are hybridized with a probe in solution (2). The unbound probe is washed away, and the bound probe is detected by means of fluorescence, luminescence, radioactivity, or color development. Although solid-phase hybridization is a powerful research tool, the length of time required and the complexity of the procedure limit its application in clinical practice.

In situ hybridization is another type of solid-phase hybridization in which the nucleic acid is contained in tissues or cells that are affixed to microscope slides and is governed by the same basic principles described previously (3). In most clinical applications, formalin-fixed, paraffin-embedded tissue sections are used. The sensitivity of in situ hybridization is often limited by the accessibility of the target nucleic acid in the cells.

In general, due to the poor analytical sensitivities of nonamplified-probe techniques, the application of these techniques to direct detection of pathogens in clinical specimens is limited to those situations in which the number of organisms is large. Such situations include cases of group A streptococcal pharyngitis and agents associated with vaginosis and vaginitis. These techniques are used most effectively in culture confirmation assays for mycobacteria and systemic dimorphic fungi. These culture confirmation tests have a positive effect on patient management by providing rapid and accurate detection of these slowly growing, often difficult-to-identify pathogens.

Nucleic acid probes for direct detection of group A streptococci, *Chlamydia trachomatis*, and *Neisseria gonorrhoeae* are available from Hologic Gen-Probe. Probes for identification of Blastomyces dermatitidis, *Coccidioides immitis*, *Histoplasma*
capsulatum, campylobacters, enterococci, group A streptococci, group B streptococci, Haemophilus influenzae, Listeria monocytogenes, mycobacteria, N. gonorrhoeae, Staphylococcus aureus, and Streptococcus pneumoniae isolated in culture are also available from Hologic Gen-Probe.

A solid-phase nucleic acid probe test for detection and identification of Gardnerella vaginas, Trichomonas vaginals, and Candida albicans in vaginal fluid from patients with vaginosis or vaginitis is available from BD Diagnostic Systems (Sparks, MD). It uses two distinct probes for each organism, a capture probe and a color development probe, in an easy-to-use format.

Peptide nucleic acid (PNA) probes are DNA mimics in which the negatively charged sugar phosphate backbone of DNA is replaced with a noncharged polyamide or “peptide” backbone. PNA probes contain the same nucleotide bases as DNA and follow standard Watson-Crick base-pairing rules when hybridizing to complementary nucleic acid sequences (4). Because PNA probes are noncharged, they do not have to overcome the destabilizing electrostatic repulsion that occurs when two negatively charged DNA molecules hybridize. As a result, PNA probes bind more rapidly and tightly to nucleic acid targets. In addition, the relatively hydrophobic character of the PNA probes enables them to penetrate the hydrophobic cell membrane following preparation of a standard smear.

PNA fluorescent in situ hybridization probes targeting rRNA sequences for rapid, direct identification of S. aureus, coagulase-negative staphylococci, Enterococcus faecalis, selected other species of enterococci, Escherichia coli, Pseudomonas aeruginosa, Klebsiella pneumoniae, and several Candida spp. from positive blood culture bottles are available from AdvanDx (Woburn, MA) (5-7). Figure 1 shows an image of a mixture of E. coli, K. pneumoniae, and P. aeruginosa stained with PNA fluorescent in situ hybridization probes for each organism labeled with three different-colored fluorophores and examined by fluorescence microscopy.

AMPLIFIED NUCLEIC ACID TECHNIQUES

The development of the PCR by Saiki et al. (8) was a milestone in biotechnology and heralded the beginning of the modern era of molecular diagnostics. Although PCR is the most widely used nucleic acid amplification strategy, other strategies have been developed, and several have clinical utility. These strategies are based on signal, target, or probe amplification. Examples of each category are discussed in the sections that follow. These techniques have sensitivity unparalleled in laboratory medicine, have created new opportunities for the clinical laboratory to have an effect on patient care, and have become the new gold standards for laboratory diagnosis of many infectious diseases.

SIGNAL AMPLIFICATION TECHNIQUES

In signal amplification methods, the concentration of the probe or target does not increase. The increased analytical sensitivity comes from increasing the concentration of labeled molecules attached to the target nucleic acid. Multiple enzymes, multiple probes, multiple layers of probes, and reduction of background noise have all been used to enhance target detection (9). Target amplification systems generally have greater analytical sensitivity than signal amplification methods, but technological developments, particularly in branched-DNA (bDNA) assays, have lowered the limits of detection to levels that rival those of some earlier target amplification assays (10).

Signal amplification assays have several advantages over target amplification assays. In signal amplification systems, the number of target molecules is not altered, and as a result, the signal is directly proportional to the amount of the target sequence present in the clinical specimen. This reduces concerns about false-positive results due to cross contamination and simplifies the development of quantitative assays. Since signal amplification systems are not dependent on enzymatic processes to amplify the target sequence, they are not affected by the presence of enzyme inhibitors in clinical specimens. Consequently, less cumbersome nucleic acid extraction methods may be used. Typically, signal amplification systems use either larger probes or more probes than target amplification systems and, consequently, are less susceptible to errors resulting from target sequence heterogeneity. Finally, RNA levels can be measured directly without the synthesis of a cDNA intermediate.

bDNA Assays

The bDNA signal amplification system is a solid-phase, sandwich hybridization assay incorporating multiple sets of synthetic oligonucleotide probes (11). The key to this technology is the amplifier molecule, a bDNA molecule with 15 identical branches, each of which can bind to three labeled probes.

The bDNA signal amplification system is illustrated in Fig. 2. Multiple target-specific probes are used to capture the target nucleic acid onto the surface of a microtiter well. A second set of target-specific probes also binds to the target. Preamplifier molecules bind to the second set of target probes and up to eight bDNA amplifiers. Three alkaline phosphatase-labeled probes hybridize to each branch of the amplifier. Detection of bound labeled probes is achieved by incubating the complex with dioxetane, an enzyme-triggerable substrate, and measuring the light emission in a luminometer. The resulting signal is directly proportional to the quantity of the target in the sample. The quantity of the target in the sample is determined from an external standard curve.

Nonspecific hybridization of any of the amplification probes and nontarget nucleic acids leads to amplification of the background signal. In order to reduce potential hybridization to nontarget nucleic acids, isocytidine (isoC) and isoguanosine (isoG) were incorporated into the preamplifier and labeled probes were used in the third-generation bDNA assays (12). IsoC and isoG form base pairs with each other but not with any of the four naturally occurring bases (13).

The use of isoC- and isoG-containing probes in bDNA assays increases target-specific signal amplification without
a concomitant increase in the background signal, thereby greatly enhancing the detection limits without loss of specificity. The detection limit of the third-generation bDNA assay for HIV-1 RNA is 75 copies/ml. bDNA assays for the quantification of hepatitis B virus (HBV) DNA, hepatitis C virus (HCV) RNA, and HIV-1 RNA are commercially available (Siemens Healthcare Diagnostics, Deerfield, IL). The SiemensVersant 440 analyzer for bDNA assays automates the incubation, washing, reading, and data-processing steps.

**Hybrid Capture Assays**

The hybrid capture system is a solution hybridization-antibody capture method that uses chemiluminescence detection of the hybrid molecules (Fig. 3). The target DNA in the specimen is denatured and then hybridized with a specific RNA probe. The DNA-RNA hybrids are captured by anti-antibodies that are used to coat the surface of a tube. Alkaline phosphatase-conjugated anti-antibodies bind to the immobilized hybrids. The bound antibody conjugate is detected with a chemiluminescent substrate, and the light emitted is measured in a luminometer. Multiple alkaline phosphatase-conjugated anti-antibodies bind to each hybrid molecule, amplifying the signal. The intensity of the emitted light is proportional to the amount of target DNA in the specimen. Hybrid capture assays for detection of *N. gonorrhoeae*, *C. trachomatis*, and human papillomavirus (HPV) (14) in clinical specimens are available from Qiagen (Germantown, MD). There are manual and automated (Rapid Capture System) versions of these assays.

**Cleavase-Invader Technology**

Invader assays (Hologic, Bedford, MA) are based on a signal amplification method that relies on the specific recognition and cleavage of particular DNA structures by cleavase, a member of the FEN-1 family of DNA polymerases. These polymerases cleave the 5′ single-stranded flap of a branched, base-paired duplex. This enzymatic activity likely plays an essential role in the elimination of the complex nucleic acid structures that arise during DNA replication and repair. Since these structures may occur anywhere in a replicating genome, the enzyme recognizes the molecular structure of the substrate without regard to the sequence of the nucleic acids making up the DNA complex (15, 16).

In the invader assays, two probes are designed that hybridize to the target sequence in an overlapping fashion (Fig. 4). Under the proper annealing conditions, the probe oligonucleotide binds to the target sequence. The invader oligonucleotide probe is designed such that it hybridizes upstream of the probe with a region of overlap between the 3′ end of the invader and the 5′ end of the probe. Cleavase cleaves the 5′ end of the probe and releases it. It is in this way that the target sequence acts as a scaffold upon which the proper DNA structure can form. Since the DNA

---

structure necessary to serve as a cleavage substrate occurs only in the presence of the target sequence, the generation of cleavage products indicates the presence of the target. Use of a thermostable cleavase enzyme allows reactions to be run at temperatures high enough for a primer exchange equilibrium to exist. This allows multiple cleavage products to form off of a single target molecule. Fluorescence resonance energy transfer (FRET) probes and a second invasive cleavage reaction are used to detect the target-specific products. FDA-cleared assays for detection of pools of high-risk genotypes and types 16 and 18 of HPV in cervical samples are available from Hologic (17, 18).

**TARGET AMPLIFICATION TECHNIQUES**

All of the target amplification systems share certain fundamental characteristics. They use enzyme-mediated processes, in which a single enzyme or multiple enzymes synthesize copies of target nucleic acid. In all of these techniques, the amplification products are detected by two oligonucleotide primers that bind to complementary sequences on opposite strands of double-stranded targets. All the techniques result in the production of millions to billions of copies of the targeted sequence in a matter of hours, and in each case, the amplification products can serve as templates for subsequent rounds of amplification. Because of this, all of the techniques are sensitive to contamination with product molecules that can lead to false-positive reactions. The potential for cross contamination is real and should be adequately addressed before any of these techniques are used in the clinical laboratory. However, the occurrence of false-positive reactions can be reduced through special laboratory design, practices, and workflow.

**Polymerase Chain Reaction**

PCR is a simple, in vitro chemical reaction that permits the synthesis of essentially limitless quantities of a targeted nucleic acid sequence. This is accomplished through the action of a DNA polymerase that, under the proper conditions, can copy a DNA strand (Fig. 5). At its simplest, a PCR consists of target DNA, a molar excess of two oligonucleotide primers, a heat-stable DNA polymerase, an equimolar mixture of deoxyribonucleoside triphosphates (dNTPs; dATP, dCTP, dGTP, and dTTP), MgCl₂, KCl, and a Tris-HCl buffer. The two primers flank the double-stranded DNA (dsDNA) sequence to be amplified, typically <100 to several hundred bases, and are complementary to opposite strands of the target.

To initiate a PCR, the reaction mixture is heated to separate the two strands of target DNA and is then cooled to permit the primers to anneal to the target DNA in a sequence-specific manner. The DNA polymerase then initiates extension of the primers at their 3' ends toward one another. The primer extension products are dissociated from the target DNA by heating. Each extension product, as well as the original target, can serve as a template for subsequent rounds of primer annealing and extension.

At the end of each cycle, the PCR products are theoretically doubled. Thus, after n PCR cycles the target sequence can be amplified 2^n-fold. The whole procedure is carried out in a programmable thermal cycler that precisely controls the temperature at which the steps occur, the lengths of time that the reaction mixture is held at the different temperatures, and the number of cycles. Ideally, after 20 cycles of PCR a 10^6-fold amplification is achieved and after 30 cycles a 10^9-fold amplification occurs. In practice, the amplification may not be completely efficient due to failure to optimize the reaction conditions or the presence of inhibitors of the DNA polymerase. In such cases, the total amplification is best described by the expression (1 + e)^n, where e is the amplification efficiency (0 ≤ e ≤ 1) and n is the total number of cycles.

**Reverse Transcriptase PCR**

As it was originally described, PCR was a technique for DNA amplification. Reverse transcriptase PCR (RT-PCR) was developed to amplify RNA targets. In this process, cDNA is first produced from RNA targets by reverse transcription and then the cDNA is amplified by PCR. As it was originally described, RT-PCR used two enzymes, a heat-labile RT, such as avian myeloblastosis virus RT, and a thermostable DNA polymerase. Because of the temperature requirements of the heat-labile enzyme, cDNA synthesis had to occur at temperatures below the optimal annealing temperatures of the primers. This presented problems in terms of both nonspecific primer annealing and inefficient
primer extension due to the formation of RNA secondary structures. These problems have largely been overcome by the development of a thermostable DNA polymerase derived from *Thermus thermophilus* that under the proper conditions can function efficiently as both an RT and a DNA polymerase (19). RT-PCRs with this enzyme are more specific and efficient than previous protocols with conventional, heat-labile RT enzymes.

**Nested PCR**

Nested PCR was developed to increase both the sensitivity and the specificity of PCR. It uses two pairs of amplification primers and two rounds of PCR. Typically, one primer pair is used in the first round of PCR for 15 to 30 cycles. The products of the first round of amplification are then subjected to a second round of amplification with the second set of primers, which anneal to a sequence internal to the sequence amplified by the first primer set. The increased sensitivity arises from the high total cycle number, and the increased specificity arises from the annealing of the second primer set to sequences found only in the first-round products, thus verifying the identity of the first-round product. The major disadvantage of nested PCR is the high rates of contamination that can occur during the transfer of first-round products to the second tube for the second round of amplification. This contamination can be avoided either by physically separating the first- and second-round amplification mixtures with a layer of wax or oil or by designing single-tube or completely contained amplification protocols. In practice, the enhanced sensitivity afforded by nested PCR protocols is rarely required in diagnostic applications, and the identity of an amplification product is usually confirmed by hybridization with a nucleic acid probe.

**Multiplex PCR**

In multiplex PCR, two or more primer sets designed for amplification of different targets are included in the same reaction mixture (20). By this technique, more than one target sequence in a clinical specimen can be coamplified in a single tube. The primers used in multiplexed reactions must be carefully selected so that they have similar annealing temperatures and lack complementarity. Multiplex PCRs have proved to be more complicated to develop and may be less sensitive than PCRs with single primer sets. Many multiplex assays have been developed, especially for the detection of central nervous system (21, 22), respiratory (23–26), bloodstream (27–29), and gastrointestinal (30, 31) infections. The scale of the multiplexing can range from

---

several to 20 or more targets depending on the method used to identify the individual amplicons. Technological developments in multiplex nucleic acid amplification and detection have allowed an organ system-based approach to molecular microbiology that matches or exceeds the ability of culture methods to provide a comprehensive diagnostic result. One of the first platforms for high-order multiplex PCR analysis was the xMAP system (Luminex Corp., Austin, TX). The xMAP system incorporates a proprietary process to internally dye polystyrene microspheres with two spectrally distinct fluorochromes. By using precise ratios of these fluorochromes, an array is created consisting of 100 different microsphere sets with specific spectral addresses. Each microsphere set can possess a different reactant on its surface. For nucleic acid analysis, oligonucleotide probes would be covalently bound to the microsphere surface by carbodiimide coupling. Since each microsphere set can be distinguished by its spectral address, the sets can be combined, allowing up to 100 different analytes to be measured simultaneously in a single reaction vessel. A third fluorochrome coupled to a reporter molecule quantifies the biomolecular interaction that occurs at the microsphere surface.

Microspheres are interrogated individually in a rapidly flowing liquid stream as they pass by two separate lasers in the Luminex xMAP flow cytometer. High-speed digital signal processing classifies each microsphere based on its spectral address and quantifies the reaction on its surface. Thousands of microspheres are investigated per second, resulting in an analysis system capable of analyzing and reporting up to 100 different reactions in a single reaction vessel in a few seconds.

Multiplex assays run on the Luminex platform typically consist of three major steps: nucleic acid amplification by PCR, target-specific extension, and liquid bead array decod-
Real-Time (Homogeneous, Kinetic) PCR

The term "real-time PCR" describes methods in which the target amplification and detection steps occur simultaneously in the same tube (homogeneous). These methods require special thermal cyclers with precision optics that can monitor the fluorescence emission from the sample wells. The computer software supporting the thermal cycler monitors the data throughout the PCR at every cycle and generates an amplification plot for each reaction (kinetic).

Figure 6 shows a representative amplification plot and defines the terms used in quantitative real-time PCR. The amplification plot shows the normalized fluorescence signal from the reporter at each cycle number. In the initial cycles of PCR, there is little change in the fluorescence signal. This initial signal level defines the baseline for the plot. An increase above the baseline indicates the detection of accumulated PCR product. A fixed fluorescence threshold can be set above the baseline. The cycle threshold ($C_T$) is defined as the cycle number at which the fluorescence passes the fixed threshold. A plot of the log of the initial target concentration versus $C_T$ for a set of standards is a straight line (40). The amount of the target in an unknown sample is determined by measuring the sample $C_T$ and using a standard curve to determine the starting copy number. Alternatively, the cycle number corresponding to the maximal change in fluorescence, the second derivative maximum, has a similar relationship to the initial target concentration.

In its simplest format, the PCR product is detected as it is produced by using fluorescent dyes that preferentially bind to dsDNA. SYBR green I is one such dye that has been used in this application (41). In the dye’s unbound state, the fluorescence is relatively low, but when the dye is bound to dsDNA, the fluorescence is greatly enhanced. The dye binds to both specific and nonspecific PCR products. The specificity of the detection can be improved through melting-curve analysis. As the temperature is slowly raised, the two strands of the amplicon melt apart and the amount of fluorescence decreases. The data are transformed and analyzed by plotting the first derivative of the fluorescence on the y axis and the temperature on the x axis. The specific amplified product will have a characteristic melting peak at its predicted melting temperature ($T_m$), whereas the primer dimers and other nonspecific products should have different $T_m$s or give broader peaks (42).

The specificity of real-time PCR can also be increased by including FRET probes in the reaction mixture. These probes are labeled with fluorescent dyes or with combinations of fluorescent and quencher dyes. In 5′-exonuclease PCR (TaqMan) assays, the 5′-to-3′ exonuclease activity of Tag DNA polymerase is used to cleave a nonextendable hybridization probe during the primer extension phase of PCR (43). This approach uses dual-labeled fluorogenic hybridization probes and is illustrated in Fig. 7. One fluorescent dye serves as a reporter, and its emission spectrum is quenched by the second fluorescent dye. The nucleic degradation of the hybridization probe releases the reporter dye, resulting in an increase in the peak fluorescent emission.
FIGURE 7 5′ Exonuclease chemistry for real-time PCR applications. Modified with permission of Elsevier from reference 219. doi:10.1128/9781555817381.ch6.f7

The increase in fluorescent emission indicates that specific PCR product has been made, and the intensity of fluorescence is related to the amount of the product (44). The specificity is increased because a signal is generated only when the primer and probe are bound to the same template strand.

The use of dual hybridization probes is another approach to real-time PCR (45). This method uses two specially designed sequence-specific oligonucleotide probes (Fig. 8). These hybridization probes are designed to hybridize within 1 to 5 nucleotides apart on the product molecule. The 3′ end of the anchor probe is labeled with a donor dye, and the 5′ end of the reporter probe is labeled with an acceptor dye. The 3′ end of the reporter probe is phosphorylated to prevent extension during PCR. The donor dye is excited by an external light source, and instead of emitting light, it transfers its energy to the acceptor dye by FRET. The excited acceptor dye emits light at a longer wavelength than the unbound donor dye, and the intensity of the acceptor dye light emission is proportional to the amount of PCR product.

Real-time detection and quantification of amplification products can also be accomplished with molecular beacons (46). Molecular beacons are hairpin-shaped oligonucleotide probes with an internally quenched fluorophore whose fluorescence is restored when the probes bind to a target nucleic acid (Fig. 9). The probes are designed in such a way that the loop portion of each probe molecule is complementary to the target sequence. The stem is formed by the annealing of complementary arm sequences on the ends of the probe. A fluorescent dye is attached to one end of one arm, and a quenching molecule is attached to the end of the other arm. The stem keeps the fluorophore and quencher in close proximity such that no light emission occurs. When the probe encounters a target molecule, it forms a hybrid that is longer and more stable than the stem and undergoes a conformational change that forces the stem apart, causing the fluorophore and the quencher to move away from each other, restoring the fluorescence.

Scorpion probes combine a PCR primer with a molecular beacon (47, 48). Intramolecular hybridization of the loop structure to a downstream portion of the amplification product separates the reporter and quencher dyes. The hybridization kinetics of Scorpion probes are generally faster than those of molecular beacons because the primer and probe are located on the same molecule (Fig. 10).

Dark quencher probes are also used in real-time PCR applications (ELITech Group, Princeton, NJ). Dark quencher probes contain a fluorophore on the 5′ end and a nonfluorescent quencher molecule on the 3′ end (49). The fluorescence is quenched when the probe is a random coil and emitted when the probe anneals to the target sequence. Unlike fluorogenic 5′ nuclease probes, these probes are not degraded by the DNA polymerase during target amplification. Since the dark quencher is not fluorescent, it does not contribute to the background signal. This trait has the advantage of improving the signal-to-noise ratio for the detection system, which may improve sensitivity. These probes also incorporate a hybridization-stabilizing compound, known as a minor groove binder. It is a small, crescent-shaped molecule that is covalently linked to the 3′ end of the probe that spans about 3 or 4 nucleotides and snugly fits into the minor groove of DNA, where it forms hydrogen bonds with the template. Minor groove binders increase the $T_m$ of the probe. The minor groove binder allows for the use of shorter probes because of the increased $T_m$s and enables...
improved $T_m$ leveling, which increases the specificity of the detection reaction.

Another approach to detection, characterization, and quantification of real-time PCR amplicons involves the use of a nonstandard DNA base pair constructed from isoG and isoC (50–52). These synthetic bases pair with each other, but not with the natural bases guanine and cytosine, and can be covalently coupled to a wide variety of reporter groups. In the MultiCode-RTx assays (Luminex Corp.), the target is amplified using a forward primer with a single isoC nucleotide with fluorescent label at the 5′ end and an unlabeled standard base reverse primer. Amplification is performed in the presence of isoG coupled to a fluorescence quencher molecule, and site-specific incorporation by the DNA polymerase places the quencher in close proximity to the fluorophore, resulting in a decrease of fluorescence with every PCR cycle. The number of cycles in which the fluorescence change can be detected is dependent on the initial number of target molecules in the reaction. The decrease in fluorescence is easily monitored by a number of different standard real-time PCR instruments. Postreaction amplicon melting-curve analysis can be performed to confirm the identity of the amplicon and to detect sequence variants. MultiCode-RTx ASRs for detection and/or quantification of a variety of bacteria, viruses, fungi, and parasites are available from Luminex.

A novel class of asymmetric, partially double-stranded, linear probes can be used in real-time PCR assays (53). A schematic representation of their design and principles is shown in Fig. 11. The partially double-stranded probe is composed of two complementary oligonucleotides of very different lengths. The long, target-specific strand is 5′ labeled with a fluorophore and is blocked on the 3′ end to prevent extension. The shorter strand is complementary to the 5′ end of the long strand and has quencher dye attached to its 3′ end. In the absence of the target, the quencher oligonucleotide hybridizes to the target-specific oligonucleotide and the duplex does not fluoresce due to the close proximity of the reporter and quencher dyes. When the target is present, the long strand binds preferentially to the target, resulting in increased fluorescence due to separation of the reporter and quencher dyes. Partially double-stranded probes are better able to detect targets with a high level of genetic heterogeneity (e.g., HIV-1 and HCV) than are molecular beacons and TaqMan probes due primarily to their increased length and less stringent hybridization conditions (54). Partially double-stranded probes are used in HIV-1 and HCV viral load assays manufactured by Abbott (Abbott Park, IL).

Real-time PCR methods decrease the time required to perform nucleic acid assays because there are no post-PCR processing steps. Also, since amplification and detection occur in the same closed tube, these methods eliminate the postamplification manipulations that can lead to laboratory contamination with the amplicon. In addition, real-time
PCR methods lend themselves well to quantitative applications because analysis is performed early in the log phase of product accumulation, and as a result, they are less prone to error resulting from differences in sample-to-sample amplification efficiency. However, the multiplexing capabilities of these methods are limited due to the overlapping absorption and emission spectra of available fluorophores, thus restricting the number of multiplexed targets to four or five (55).

Digital PCR

PCR exponentially amplifies nucleic acids and the number of amplification cycles, and the amount of amplicon allows the computation of the starting quantity of targeted nucleic acid. However, many factors complicate this calculation, often creating uncertainties and inaccuracies, particularly when the starting concentration is low. Digital PCR attempts to overcome these difficulties by transforming the exponential data from conventional PCR to digital signals that simply indicate whether or not amplification occurred (56–59). An additional benefit of digital PCR is that it can provide absolute quantification of target nucleic acid without reference standard curves.

Digital PCR is accomplished by capturing or isolating each individual nucleic acid molecule present in a sample within many chambers, zones, or regions that are able to localize and concentrate the amplification product to detectable levels. After PCR amplification, a count of the areas containing PCR product is a direct measure of the absolute quantity of nucleic acid in the sample. The capture or isolation of individual nucleic acid molecules may be done in capillaries, microemulsions, arrays of miniaturized chambers, or on surfaces that bind nucleic acids (Fig. 12). Digital PCR has many applications, including detection and quantification of low levels of pathogen sequences, rare genetic sequences, gene expression in single cells, and clonal amplification of nucleic acids for sequencing mixed nucleic acid samples. Clonal amplification enabled by digital PCR is a key element of many of the “next-generation” sequencing methods described later in this chapter. Digital PCR systems are available from RainDance Technologies (Billerica, MA), Bio-Rad Laboratories (Hercules, CA), Life Technologies (Carlsbad, CA), and Fluidigm Corp. (South San Francisco, CA).

Transcription-Based Amplification Methods

Nucleic acid sequence-based amplification (NASBA) and transcription-mediated amplification (TMA) are both isothermal RNA amplification methods modeled after retroviral replication (60–62). The methods are similar in that the RNA target is reverse transcribed into cDNA and then RNA copies are synthesized with an RNA polymerase. NASBA uses avian myeloblastosis virus RT, RNase H, and T7 bacteriophage RNA polymerase, whereas TMA uses an RT enzyme with endogenous RNase H activity and T7 RNA polymerase.

Amplification involves the synthesis of cDNA from the RNA target with a primer containing the T7 RNA polymerase promoter sequence (Fig. 13). The RNase H then degrades the initial strand of target RNA in the RNA-cDNA hybrid. The second primer then binds to the cDNA and is extended by the DNA polymerase activity of the RT, resulting in the formation of dsDNA containing the T7 RNA polymerase promoter. The RNA polymerase then generates multiple copies of single-stranded, antisense RNA. These RNA product molecules reenter the cycle, with subsequent formation of more double-stranded cDNA molecules that can serve as templates for more RNA synthesis. A $10^9$-fold amplification of the target RNA can be achieved in <2 h by this method.
The single-stranded RNA products of TMA in the Gen-Probe tests are detected by modification of the hybridization protection assay. Oligonucleotide probes are labeled with modified acridinium esters with either fast or slow chemiluminescence kinetics so that signals from two hybridization reactions can be analyzed simultaneously in the same tube. The NASBA products in the bioMérieux (Durham, NC) tests are detected by hybridization with probes labeled with tris(2,2′-bispyridine)ruthenium and electrochemiluminescence. NASBA has also been used with molecular beacons to create a homogeneous, kinetic amplification system similar to real-time PCR (63).

Transcription-based amplification systems have several strengths, including no requirement for a thermal cycler, rapid kinetics, and a single-stranded RNA product that does not require denaturation prior to detection. Also, single-tube clinical assays and a labile RNA product may help minimize contamination risks. Limitations include the poor performance with DNA targets and concerns about the stability of complex multienzyme systems. Gen-Probe has developed FDA-cleared, TMA-based assays for detection of Mycobacterium tuberculosis, C. trachomatis, N. gonorrhoeae, HPV, and T. vaginalis. NASBA-based kits (bioMérieux) for the detection and quantification of HIV-1 RNA and detection of enterovirus and methicillin-resistant S. aureus are commercially available. A basic NASBA kit is also available for the development of other applications defined by the user. In its latest iteration, NucliSSENS EasyQ, NASBA is coupled with molecular beacons for real-time amplification and detection of target nucleic acids (64).

**Strand Displacement Amplification**

Strand displacement amplification (SDA) is an isothermal template amplification technique that can be used to detect trace amounts of DNA or RNA of a particular sequence. SDA, as it was first described, was a conceptually straightforward amplification process with some technical limitations (65). Since its initial description, however, it has evolved into a highly versatile tool that is technically simple to perform but conceptually complex. SDA is the intellectual property of BD Diagnostics.

In its current iteration, SDA occurs in two discrete phases, target generation and exponential target amplification (66). Both are illustrated in Fig. 14. In the target generation phase, a dsDNA target is denatured and hybridized to two different primer pairs, designated as bumper and amplification primers. The amplification primers include the single-stranded restriction endonuclease enzyme sequence for BsoB1 located at the 5’ end of the target-binding sequence. The bumper primers are shorter and anneal to the target DNA just upstream of the region to be amplified. In the presence of BsoB1, an exonuclease-free DNA polymerase, and a dNTP mixture consisting of dUTP, dATP, dGTP, and thiolated dCTP (C₄), simultaneous extension products of both the bumper and amplification primers are generated. This process displaces the amplification primer products, which are available for hybridization with the opposite-strand bumper and amplification primers.

The simultaneous extension of opposite-strand primers produces strands complementary to the product formed by extension of the first amplification primer, with C₄ incorporated into the BsoB1 cleavage site. This product enters the exponential target amplification phase of the reaction. The BsoB1 enzyme recognizes the double-stranded site, but because one strand contains C₄, it is nicked rather than cleaved by the enzyme. The DNA polymerase then binds to the nicked site and begins synthesis of a new strand while simultaneously displacing the downstream strand. This step recreates the double-stranded species with the hemimodified restriction endonuclease recognition sequence, and the iterative nicking and displacement process repeats. The displaced strands are capable of binding to opposite-strand primers, which produces exponential amplification of the target sequences.

These single-stranded products also bind to detector probes for real-time detection. The detector probes are ssDNA molecules with fluorescein and rhodamine labels. The region between the labels includes a stem-loop structure. The loop contains the recognition site for the BsoB1 enzyme. The target-specific sequences are located 3’ of the rhodamine label. In the absence of a specific target, the stem-loop structure is maintained with the fluorescein and rhodamine labels in close proximity. The net effect is that very little emission for the fluorescein is detected after excitation. After SDA, the probe is converted to a double-stranded species, which is cleaved by BsoB1. The cleavage causes physical separation of the fluorescein and rhodamine labels, which results in an increase in emission from the fluorescein label.
SDA has a reported sensitivity high enough to detect as few as 10 to 50 copies of a target molecule (65). By using a primer set designed to amplify a repetitive sequence with 10 copies in the M. tuberculosis genome, the assay is sensitive enough to detect 1 to 5 genome copies from the bacterium. SDA has also been adapted to quantify RNA by adding an RT step (RT-SDA). In this case, a primer hybridizes to the target RNA and an RT synthesizes a cDNA molecule. This cDNA can then serve as a template for primer incorporation and strand displacement. The products of this strand displacement then feed into the amplification scheme described above. RT-SDA has been used for the determination of HIV viral load (67). FDA-cleared tests using SDA for the direct detection of C. trachomatis, N. gonorrhoeae, and herpes simplex virus (HSV) 1 and 2 in urogenital specimens are available from BD Diagnostics. These assays can be run on either a semiautomated (ProbeTec) or fully automated (Viper) system.

The main advantage of SDA is that it is an isothermal process that, unlike PCR, can be performed at a single temperature after initial target denaturation. This eliminates the need for expensive thermal cyclers. Furthermore, samples can be subjected to SDA in a single tube, with amplification times varying from 30 min to 2 h. The main disadvantage of SDA lies in the fact that, unlike those at which PCR is performed, the relatively low temperature at which SDA is carried out (52.5°C) can result in nonspecific primer hybridization to sequences found in complex mixtures such as genomic DNA. Hence, when the target is in low abundance compared to background DNA, nonspecific amplification products can swamp the system, decreasing the sensitivity of the technique. However, the use of organic solvents to increase stringency at low temperatures and the recent introduction of more thermostable polymerases capable of strand displacement have alleviated much of this problem.

**Loop-Mediated Amplification**

Loop-mediated amplification (LAMP) is an isothermal method that relies on autocycling strand displacement DNA
synthesis by Bst DNA polymerase and a set of four to six primers (68). Two inner and two outer primers define the target sequence, and an additional set of loop primers is added to increase the sensitivity of the reaction. The final products of the LAMP reaction are DNA molecules with a cauliflower-like structure of multiple loops consisting of repeats of the target sequence (Fig. 15) (69). The products can be analyzed in real time by monitoring the turbidity in the reaction tube resulting from production of magnesium pyrophosphate precipitate during the DNA amplification. Amplification products can also be visualized in agarose gels after electrophoresis and staining with ethidium bromide or SYBR green.

LAMP has been used successfully in a number of laboratory-developed assays to detect DNA and RNA viruses (70–73) and diagnose mycobacterial infections (74). Since LAMP is an isothermal process and positive reactions can be detected by simple turbidity measurements or visualized directly with the naked eye, it requires no expensive equipment. These attributes make it an attractive technology for resource-poor settings and field use (75). However, primer design for LAMP is more complex than for PCR, with specialized training and software required for their design. Meridian Bioscience, Inc. (Cincinnati, OH) has licensed LAMP technology from Eiken Chemical Company, Ltd. (Tokyo, Japan) for the development of infectious-disease diagnostics in the United States. Meridian currently has FDA-cleared tests for detection of *Clostridium difficile*, *Mycoplasma pneumoniae*, and group A and group B beta-hemolytic streptococci (76).

### Helicase-Dependent Amplification

Helicase-dependent amplification (HDA) is an isothermal process developed by BioHelix (Beverly, MA) that uses helicase to separate dsDNA and generate single-stranded templates for primer hybridization and subsequent extension by a DNA polymerase (77). As the helicase unwinds dsDNA enzymatically, the initial heat denaturation and subsequent thermocycling steps required by PCR can all be omitted. In HDA, strands of dsDNA are separated by the DNA helicase and the ssDNA-coated ssDNA-binding proteins. Two sequence-specific primers hybridize to each border of the target sequence, and a DNA polymerase extends the primers annealed to the target sequence to produce dsDNA. The two newly synthesized products are used as substrates by the helicase in the next round of amplification. Thus, a simultaneous chain reaction proceeds, resulting in exponential amplification of the selected target sequence (Fig. 16).

HDA is compatible with multiple detection technologies, including qualitative and quantitative fluorescence technologies, and with instruments designed for real-time
FIGURE 15  (a) Primer design of the LAMP reaction. For ease of explanation, six distinct regions are designated on the target DNA, labeled F3, F2, F1, B1c, B2c, and B3 from the 5′ end. As c represents a complementary sequence, the F1c sequence is complementary to the F1 sequence. Two inner primers (FIP and BIP) and outer primers (F3 and B3) are used in the LAMP method. FIP (BIP) is a hybrid primer consisting of the F1c (B1c) sequence and the F2 (B2) sequence. (b) Starting structure-producing step. DNA synthesis initiated from FIP proceeds as follows. The F2 region anneals to the F2c region on the target DNA and initiates the elongation. DNA amplification proceeds with BIP in a similar manner. The F3 primer anneals to the F3c region on the target DNA, and strand displacement DNA synthesis takes place. The DNA strand elongated from FIP is replaced and released. The released single strand forms a loop structure at its 3′ end (structure 3). DNA synthesis proceeds with the ssDNA as the template and BIP and B3 primer, in the same manner as described earlier, to generate structure 5, which possesses the loop structure at both ends (dumbbell-like structure). (c) Cycling amplification step. Using self-structure as the template, self-primed DNA synthesis is initiated from the 3′-end F1 region, and the elongation starts from FIP, annealing to the single strand of the F2c region in the loop structure. Passing through several steps, structure 7 is generated, which is complementary to structure 5, and structure 5 is produced from structure 8 in a reaction similar to that which led from structures 5 to 7. Structures 9 and 10 are produced from structures 6 and 8, respectively, and more elongated structures (11, 12) are also produced. Reprinted with permission of Nature Publishing Group from reference 69.
FIGURE 16  HDA amplifies target sequences using two sequence-specific primers flanking the fragment to be amplified and a mixture of enzymes for DNA strand separation and polymerization. In the first step of the HDA reaction, the helicase enzyme loads onto the template and traverses along the target DNA, disrupting the hydrogen bonds linking the two strands. Exposure of the single-stranded target region by helicase allows primers to anneal. The DNA polymerase then extends the 3' ends of each primer using free deoxynucleotides (dNTPs) to produce two DNA replicates. The two replicated DNAs independently enter the next cycle of HDA, resulting in exponential amplification of the target sequence. Reprinted with permission of BioHelix from http://www.biohelix.com/HDA_mechanism.asp. doi:10.1128/9781555817381.ch6.f16

PCR (78). Furthermore, HDA has shown potential for the development of simple, portable DNA diagnostic devices to be used in the field or at the point of care (79–81). FDA-cleared tests for detection of HSV 1 and 2 DNA in oral and genital lesions are available from BioHelix and for detection of C. difficile from Quidel (San Diego, CA).

POSTAMPLIFICATION DETECTION AND ANALYSIS

Gel Analysis
Visualization of amplification products in agarose gels after electrophoresis and ethidium bromide staining was the earliest detection method. After gel electrophoresis, DNA is often transferred onto a nitrocellulose or nylon membrane and hybridized to a specific probe to increase both the sensitivity and the specificity of detection. Membranes with bound radiolabeled probes are placed in proximity to X-ray film, and the hybrids are visualized as dark bands. Enzyme-labeled probes can be visualized through either light or color production after the addition of the appropriate chemiluminescent or chromogenic substrates. Many of these nonisotopic approaches are at least as sensitive as isotopic methods and are faster. In addition, the enzyme-labeled probes are more stable. Although gel electrophoresis and blotting remain important research tools, these techniques are being replaced by faster and simpler methods in the clinical laboratory.

Single-strand conformation polymorphism (SSCP) analysis and restriction fragment length polymorphism (RFLP) analysis have been used to ascertain information about the base compositions of the amplification products visualized in a gel. In SSCP analysis, the PCR product is denatured and then subjected to electrophoresis in a nondenaturing gel (82). Variations in the physical conformations of the PCR products are related to the base compositions and are detected by differential gel migration. This technique has successfully been used to detect mutations causing rifampin resistance in M. tuberculosis (83).

RFLP analysis uses restriction endonucleases to cleave amplification products at specific recognition sites. The fragments are separated by electrophoresis, and the resulting banding pattern provides information about the nucleic acid sequence. When coupled with a hybridization reaction, RFLP analysis can also provide information about the location and number of loci homologous to the probe. Both SSCP analysis and RFLP analysis of short products have largely been replaced by direct DNA sequencing as this technology has improved and the costs have decreased.

Capillary Electrophoresis
Capillary electrophoresis allows for accurate size discrimination of fluorescently labeled nucleic acids from 50 to 1,000 bases with single-base precision. PCR and capillary electrophoresis have been functionally integrated by PrimeraDx (Mansfield, MA) to produce highly multiplexed assays that can simultaneously detect up to 60 targets whose identities
are defined by the specific size of the corresponding amplifica-
tions (84, 85).

PrimeraDx developed a multiplexed assay for the simulta-
neous quantification of cytomegalovirus (CMV), HSV, BK virus, human herpesvirus 6 (HHV-6), and HHV-7 viral loads that integrates PCR and capillary electrophoresis. In this assay, amplification of the nucleic acid targets is monitored by sampling the PCR during sequential cycles and separating and quantifying the PCR products by capillary electrophoresis. These data are used to construct amplification curves. Similar to real-time PCR amplification, a cycle threshold is determined from the amplification curve for each of the targets in the exponential phase of amplification. Unlike real-time PCR, where standards in a separate reaction are used, the PrimeraDx assay uses multiple internal standards in each reaction to generate calibration curves for each individual assay in the multiplex reaction. Qualitative assays for detection of fungal pathogens and respiratory vi-
ruses have also been developed. PrimeraDx’s ICEPlex system is an automated, high-throughput instrument that performs the multiplex real-time PCR and capillary electrophoresis.

Seegene, Inc. (Seoul, South Korea) has developed a wide var-
ety of multiplexed infectious-disease assays, including sexually transmitted disease, HPV genotyping, mycobac-
terial, and respiratory pathogen panels (23, 86). The targets of these multiplexed assays are designed to be discriminated by size and are compatible with several different microfluidic and capillary electrophoresis systems, including the Agilent 2100 Bioanalyzer (Agilent Technologies, Santa Clara, CA) and Applied Biosystems (Foster City, CA) sequencers.

**Colorimetric Microtiter Plate Systems**

Colorimetric microtiter plate (CMP) systems are conven-
ient alternatives to traditional gel and blotting techniques for detection of amplified products. In these systems, the amplified product is captured in microtiter plate wells by specific oligonucleotide probes coating the plastic surface. Bound product is detected by a color change that takes place after addition of an enzyme conjugate and the appropriate substrate. These systems resemble enzyme immunassays and use microtiter plate washers and readers commonly found in clinical laboratories. CMP systems are more practi-
cal and faster than the traditional membrane hybridization techniques described above.

Several variations of CMP systems are commercially available. In one popular approach, biotinylated primers are used to amplify the target, and the biotin-containing PCR product is denatured and added to the microtiter well. After hybridization with a capture probe, the bound product is detected with a streptavidin-enzyme conjugate and a chro-
mogenic substrate (87). Enzyme-conjugated antibodies di-
rected against dsDNA have also been used to detect PCR products in CMP systems (88). Another approach uses digoxigenin-dUTP to label the PCR product and enzyme-
conjugated antidigoxigenin antibodies to detect the captured product (221). With the development and widespread adoption of real-time amplification and detection systems, CMP systems are now used infrequently in clinical labora-
tory settings.

**Allele-Specific Hybridization**

Line probe assays are manufactured by Innogenetics (Ghent, Belgium) for genotyping of HCV, HPV, and HBV; identifi-
cation of mycobacteria; and analysis for drug resistance mu-
tations in HBV and M. tuberculosis (89–94). The HCV line probe assays are distributed by Siemens. In these assays, a series of probes with poly(T) tails are attached to nitrocellu-
lose strips. Biotin-labeled PCR product is then hybridized to the immobilized probes on the strip. The labeled PCR product hybridizes only to the probes that give a perfect sequence match under the stringent hybridization conditions used. After hybridization, streptavidin labeled with alkaline phosphatase is added and binds to the biotinylated hybrids. Incubation with a chromogen results in a purple precipitate. The pattern of hybridization provides information about the nucleic acid sequence of the amplicon. This method is capable of detecting single-nucleotide polymor-
phisms.

A line probe for identification of 37 HPV genotypes is available from Roche Diagnostics (Indianapolis, IN) and is registered for use in the European Union (95). The method employs multiplex PCR with biotinylated primers targeted to the L1 region of the HPV genome and a linear array of L1 sequence-specific probes fixed to a nitrocellulose strip. The pattern of hybridization provides the genotype and is determined as described above.

**Nucleic Acid Sequencing**

The combination of PCR and Sanger dideoxynucleotide chain termination methods can be used to determine DNA sequences in clinical samples (96). The application of capil-
{}
Although direct sequencing of PCR products by capillary electrophoresis is a powerful research tool, its routine use in the clinical laboratory depends on the development of high-throughput systems with integrated databases and data analysis software. Such systems are available for HIV-1 and HCV genotyping and for identification of bacteria and fungi by rRNA gene sequence analysis.

Pyrosequencing (Qiagen) represents an alternative approach to conventional sequencing and is useful for genotyping and short-read-length sequencing (99). Pyrosequencing is based on the luminometric detection of pyrophosphate that is generated during DNA synthesis.

A sequencing primer is hybridized to a single-stranded PCR amplicon and incubated with the enzymes DNA polymerase, ATP sulfurylase, luciferase, and apryrase and the substrates adenosine 5'-phosphosulfate and luciferin. The first of four dNTPs is added to the reaction mixture. DNA polymerase catalyzes the incorporation of the dNTP into the DNA strand. Each incorporation event is accompanied by release of pyrophosphate (PPi) in a quantity equimolar to the amount of incorporated nucleotide. The ATP sulfurylase quantitatively converts PPi to ATP in the presence of adenosine 5'-phosphosulfate. This ATP drives the luciferase-mediated conversion of luciferin to oxyluciferin, which generates light in amounts that are proportional to the amount of ATP. The light produced in the reaction is detected by a charge-coupled device camera. A program is produced in which the height of each peak is proportional to the number of nucleotides incorporated. Apryrase, a nucleotide-degrading enzyme, continuously degrades ATP and unincorporated dNTPs. This degradation switches off the light and regenerates the reaction solution. The next dNTP is added, and the process is repeated.

Pyrosequencing has been used in microbiology to detect drug resistance mutations and to identify and type bacteria, viruses, and fungi (100–103). Unlike conventional sequencing strategies, pyrosequencing provides reliable data for sequences adjacent to the sequencing primer termini. Pyrosequencing provides a simple-to-use platform for short-read-length sequencing.

Multiple new sequencing technology platforms have emerged since 2005 and have greatly surpassed conventional dideoxynucleotide chain termination methods in terms of increased total sequence production and decreased cost. Collectively, these new sequencing methods are referred to as next-generation or massively parallel sequencing, and they have considerable potential for clinical diagnostics (104–106). The major next-generation sequencing platforms as of this writing are the Roche 454 GS-FLX (454, Branford, CT), the Illumina HiSeq and MiSeq (Illumina, San Diego, CA), the ABI SOLiD (Applied Biosystems), and the Ion Torrent (Life Technologies). The sequencing methods, read lengths, depths of coverage, run times, total bases per run, sequence accuracies, usability, and costs vary for each of these platforms.

The Roche 454 platform, using the pyrosequencing technology described earlier to carry out hundreds of thousands of sequencing reactions simultaneously on independent beads, works as follows. Target DNA is first randomly sheared into fragments and then ligated to adapters. Single-stranded template DNA is isolated, mixed with beads, and then subjected to emulsion PCR to clonally amplify the template on each bead. The beads are then distributed into a “picotitter plate” that contains millions of tiny wells. Within each well that receives an individual bead, an isolated environment is created for the sequencing of each template, resulting in massively parallel sequencing of different templates simultaneously.

DNA templates sequenced with the Illumina systems are ligated to adapter sequences that incorporate a sequence complementary to anchor oligonucleotides, which are covalently linked to the surface of a flow cell. After annealing to the anchor oligonucleotides, the template DNA molecules are clonally amplified in a modified isothermal PCR termed a “bridge PCR,” in which the DNA molecules are free to flex and form a bridge with an adjacent anchor oligonucleotide. Bridge amplification generates clusters of amplified template on the solid surface, where each cluster represents a different template. Next, the clusters are denatured to provide a single-stranded template, and a sequencing primer is hybridized to the strand. It uses a unique sequencing chemistry that incorporates fluorescently labeled, reversible terminator nucleotides. These nucleotides are labeled with different-colored fluorophores so that all four nucleotides can be added to the reactions simultaneously. Only one terminator nucleotide can be incorporated into each sequence during one sequencing cycle, and the color of the fluorescent label incorporated into the sequences of each cluster is recorded. Removal of the terminator group on the nucleotide just added enables incorporation of the next complementary nucleotide, and the cycle is repeated.

The ABI SOLiD system chemistry starts with emulsion PCR of adapter-modified ssDNA molecules. After PCR, the templates are denatured and bead enrichment is performed to select beads with extended templates. The template on the selected beads undergoes a 3′ modification to allow covalent binding to a glass slide. The modified beads are deposited randomly on the slide. The sequencing occurs by ligation. Primers hybridize to the adapter sequence within the library template. A set of four fluorescently labeled di-base probes compete for ligation to the sequencing primer. Specificity of the di-base probe is achieved by interrogating every first and second base in each ligation reaction. Multiple cycles of ligation, detection, and cleavage are performed, with the number of cycles determining the eventual read length. Following a series of cycles, the extension product is removed and the template is reset with a primer complementary to the n −1 position for a second round of ligation cycles. Five rounds of primer resets are completed for each sequencing tag. Consequently, each base is interrogated in two independent ligation reactions by two different primers. This dual interrogation provides highly accurate sequences.

The Ion Torrent system employs an integrated circuit to directly perform nonoptical DNA sequencing in a massively parallel fashion (107). Genomic DNA is fragmented and ligated to adapters, and adapter-ligated libraries are clonally amplified onto 2-μm acrylamide beads. Template-bearing beads are enriched through a magnetic bead process. Sequencing primers and DNA polymerase are then bound to the templates and pipetted into the ion chip’s loading port. The chip contains millions of sensor wells. Individual beads are loaded into the individual sensor wells by spinning the chip in a centrifuge. The well depth allows only a single bead to occupy a well.

In ion sequencing, all four nucleotides are provided in a stepwise fashion during an automated run. When the nucleotide in the flow is complementary to the template base directly downstream from the sequencing primer, the nucleotide is incorporated into the nascent strand by the bound polymerase. This increases the length of the sequencing primer by one base, or more if a homopolymer stretch
is directly downstream from the primer, and results in hydrolysis of the incoming nucleotide triphosphate, which causes the liberation of a single proton for each nucleotide incorporated during that flow. The release of the proton produces a shift in the pH of the surrounding solution proportional to the number of nucleotides incorporated in the flow. This is detected by the sensor on the bottom of each well, converted to a voltage, and digitized by off-chip electronics. After the flow of each nucleotide, a wash is used to ensure that nucleotides do not remain in the well. To change raw voltages into base calls, signal processing software converts the raw data into measurements of incorporation in each well for each successive nucleotide flow using a physical model. The use of most widely used technology for constructing integrated circuits allows the manufacturer to produce a more scalable and lower-cost alternative to many of the currently available massively parallel sequencing systems.

Next-generation sequencing will have a major impact on genomics research. In the field of medical microbiology, applications are evolving in the areas of metagenomics, microbial identification, and detection of rare mutations. Ultradeep sequencing can detect rare viral variants consisting of as little as 1% of the population, levels far deeper than those achievable with traditional Sanger sequencing methods, and the detection of these low-abundance drug resistance mutations may significantly affect treatment outcomes in HIV-1 and HCV infections (108–110). The CLSI has recently developed guidelines for nucleic acid sequencing in clinical laboratories (106).

Hybridization Arrays

High-Density Arrays

High-density DNA hybridization arrays are produced by attaching or synthesizing hundreds or thousands of oligonucleotides on a solid support in precise patterns. A labeled amplification product is hybridized to the probes, and hybridization signals are mapped to various positions within the array. If the number of probes is sufficiently large, the sequence of the PCR product can be deduced from the pattern of hybridization (resequencing arrays). A number of manufacturers have developed high-density DNA microarrays and the instrumentation required to acquire and analyze the data, including Affymetrix (Santa Clara, CA), Roche NimbleGen (Madison, WI), and Agilent Technologies. Hybridization arrays have a number of applications in microbiology, including microbial and host gene expression profiling, pathogen identification, antimicrobial resistance detection, viral discovery, molecular surveillance, strain typing, and diagnostic sequencing (111). The CLSI has published a guideline for the use of diagnostic nucleic acid microarrays (112).

One of the most developed approaches brings together advances in synthetic nucleic acid chemistry with photolithography, a process used in the manufacture of semiconductors for the computer industry (Affymetrix). This approach uses light to direct the synthesis of short oligonucleotides (20 to 25 bp) on a silica wafer (113). On a 15-mm-square chip, thousands of individual sites or features can be established. At each feature, specific oligonucleotides are assembled one nucleotide at a time by light-activated chemistry.

NimbleGen’s approach to in situ synthesis of oligonucleotide probes on silica wafers is similar to that of Affymetrix, but photolithographic masks are replaced by virtual or digital masks. The array synthesizer uses an array of programmable micromirrors to create digital masks that reflect the desired pattern of UV light to deprotect the features where the next nucleotide will be coupled with probe size up to 85 bp. Each array contains >106 features. Agilent microarrays use glass slides and ink-jet printing, which eliminates the need for either lithographic or digital masks. The in situ synthesis of 60-mer oligonucleotides is achieved using five-“ink” (four bases plus catalyst) printing of nucleotide precursors combined with coupling and deprotection steps (111). Agilent microarrays are available in a number of formats with up to 244,000 features.

Due to the complex nature of the chemical synthesis and the expense involved in production of in situ-synthesized arrays, this is limited to commercial manufacturers. Consequently, they are not conducive to user-defined or laboratory-developed applications.

Another method of producing DNA hybridization arrays involves the precise micropipetting of premade dsDNA probes (typically 200 to 2,000 bp in length) onto glass slides with a robotic device (114, 115). These arrays are not suitable for mutation detection due to the size and density of the arrayed DNA probes but have facilitated gene expression profiling. DNA libraries of this type can be used to determine the activation states (mRNA levels) of thousands of genes simultaneously. Gene expression profiling of pathogens by use of arrays may provide new insights into pathogenic mechanisms and help identify new therapeutic and vaccine targets.

High-density microarrays coupled with sequence-independent PCR have also been used in the discovery and characterization of pathogens and have the potential to provide rapid, unbiased, differential diagnosis of infectious diseases. Wang et al. described the first microarray designed to detect large numbers of viruses (116). The microarray consisted of 1,600 70-mer oligonucleotides derived from 140 different virus species, with an average of 10 oligonucleotides per virus species. They demonstrated that a wide variety of viruses could be detected by the microarray with sensitivities and specificities similar to those of individual virus-specific PCR assays (117). In addition, this approach has facilitated the discovery of a number of novel viruses from humans and animals, including the severe acute respiratory syndrome coronavirus (118). The current version of the panviral microarray contains 60,000 probes representing all viral species in GenBank. The field of diagnostic microarrays is rapidly developing, with multiple broad-range microarrays described (119–122).

There are a variety of sample preparation methods for the different array types, but all share a few fundamental characteristics. All methods start with extraction of total RNA, poly(A), or genomic DNA that is then converted to either cDNA or cRNA by enzymatic methods that modestly amplify the sample with tagging or incorporating biotinylated or fluoresceinated nucleotides. In expression applications, the amplification must maintain the relative abundance levels of the different transcripts present, whereas for resequencing applications, the relative abundance of information is rarely important. The DNA chip is hybridized in a flow cell with the sample for 2 to 12 h. After hybridization, a scanning laser confocal microscope evaluates the surface fluorescence intensity of the chip. Automated scanning by the microscope takes only a few minutes to acquire an image of the entire surface of the chip, and computer software analyzes the fluorescent image and determines the nucleic acid sequence or gene expression profile of the sample.

High-density microarrays hold much promise for molecular diagnostics. However, the complexity of fabricating the
arrays, limited commercial availability, and high test costs are obstacles to their routine use in clinical laboratories.

Low- to Moderate-Density Arrays
Recent developments of new detection techniques and simplified methodologies have facilitated the transition from expensive high-density arrays to cost-effective low- to medium-density systems for clinical diagnostics. The three microarray systems described in the following paragraphs all are FDA-cleared platforms.

The INFINITI analyzer (AutoGenomics, Carlsbad, CA) is a fully automated, multiplexing platform that uses novel BioFilmChip microarrays for a wide range of molecular diagnostic applications. Fluorescent-labeled PCR amplicons are hybridized to probes immobilized on a BioFilmChip microarray. The microarray is film-based microarray, which consists of multiple layers of thin hydrogel matrices on a polyester solid support. Each spot on the array is scanned with a built-in confocal microscope. The system has integrated controls for all steps and automatically processes and analyzes data. Infectious-disease applications available as research-use-only (RUO) assays include microarrays for detection of drug resistance in M. tuberculosis, respiratory viruses, sexually transmitted disease agents, and nontuberculous mycobacteria (123).

The Verigene system (Nanosphere, Inc., Northbrook, IL) uses gold nanoparticle-labeled probes to detect target nucleic acid hybridized to capture oligonucleotides arrayed on a glass slide. Silver signal amplification is then performed on the gold nanoparticle probes that are hybridized to the captured DNA targets of interest. The Verigene Reader optically scans the slide for silver signal, processes the data, and produces a qualitative result. Tests for the detection of influenza A, influenza B, respiratory syncytial virus, and C. difficile and for the identification of Gram-positive bacteria and selected antimicrobial resistance genes from positive blood culture bottles have been cleared by the FDA for the Verigene system (124, 125). A Gram-negative bacteria panel for positive blood cultures, an enteric pathogen panel, and an expanded respiratory pathogen panel are in the development pipeline.

The eSensor system (GenMark Dx, Carlsbad, CA) uses electrochemical-detection-based DNA microarrays (126). These microarrays are composed of a printed circuit board consisting of an array of 76 gold-plated electrodes. Each electrode is modified with a multicomponent, self-assembled monolayer that includes presynthesized oligonucleotide capture probes. Nucleic acid detection is based on a sandwich assay principle. Signal and capture probes are designed with sequences complementary to immediately adjacent regions on the corresponding target DNA sequence. A three-member complex is formed between capture probe, target sequence, and signal probe based on sequence-specific hybridization. This process brings the 5′ end of the signal probe containing electrochemically active ferrocene labels into close proximity to the electrode surface.

The ferrous ion in each ferrocene group undergoes cyclic oxidation and reduction, leading to loss or gain of an electron, which is measured as current at the electrode surface using alternating-current voltammetry. Higher-order harmonic signal analysis also facilitates discrimination of ferrocene-dependent faradic current from background capacitive current.

The eSensor cartridge consists of a printed circuit board, a cover, and a microfluidic component. The microfluidic component includes a diaphragm pump and check valves in line with a serpentine channel that forms the hybridization channel above the array of electrodes. The eSensor instrument consists of a base module and up to three cartridge-processing towers, each with eight slots for cartridges. The cartridge slots operate independently of each other. The throughput of a three-tower system can reach 300 tests in 8 h. A respiratory pathogen panel for the eSensor system that detects 14 different types and subtypes of respiratory viruses is FDA cleared (127), and an HCV genotyping test is in the development pipeline.

Mass Spectrometry
One of the most exciting developments in clinical microbiology is the application of mass spectrometry (MS) to identification and characterization of pathogens (128, 129). All MS applications are based on direct measurement of two intrinsic properties of the analyte, molecular mass and charge. The mass spectrometer consists of three functional units. The first unit, the ion source, is used to ionize the analyte and transfer it to the gas phase. The second unit is the mass analyzer, which serves to separate the ions by their mass-to-charge ratio, which defines their time of flight (TOF). The analyzer can use a vacuum chamber and a static or dynamic magnetic/electric field to separate the ions. The third unit uses an electron multiplier or fast oscilloscope to detect the ions. A wide variety of ionization methods can be used, but matrix-assisted laser desorption ionization (MALDI) and electrospray ionization (ESI) are used for analysis of proteins and nucleic acids that are too fragile to be ionized by older conventional methods.

MALDI-TOF MS of whole bacterial cells has greatly reduced the time needed to identify bacteria and fungi grown in culture and is increasingly being deployed in clinical laboratories. Two commercially available systems, the MALDI Biotyper (Bruker Daltonics, Billerica, MA) and VITEK MS (bioMérieux), are FDA cleared and are reviewed in chapter 4. MALDI-TOF and ESI MS can also be used to analyze PCR amplicons. Two fully integrated systems for infectious-disease applications are available from Ibis Biosciences/Abbott Molecular (Carlsbad, CA) and Sequenom (San Diego, CA) and are described below.

The T5000 Universal Biosensor/PLEX-ID (Ibis/Abbott Molecular) is a commercially available system capable of identification and characterization of a broad range of pathogens (130). In this system, all nucleic acids present in a clinical sample are extracted and aliquoted into wells of a microtiter plate that each contain one or more pairs of broad-range primers for PCR. The primers are designed to amplify a product from a selected group of microorganisms, for example, all bacteria, specific species, or individual strains. The PCR products produce a mixture of products reflecting the complexity of the original mixture of microorganisms present in the clinical sample.

The PCR products are desalted and sequentially electrosprayed into a mass spectrometer for TOF analysis. The spectral signals are processed to determine the masses of each of the PCR products present with sufficient accuracy that the base composition of each amplicon can be unambiguously deduced. Using the combined base compositions from multiple PCRs, the identities of the pathogens and their relative concentrations in the sample can be determined.

Although it is not immediately intuitive, nucleic acid composition (i.e., the numbers of A’s, G’s, C’s, and T’s) in specific regions of the genome is equally as informative as the nucleic acid sequence. MS is remarkably sensitive and can measure the weight and determine the base composition from small quantities of nucleic acids in complex mixtures essentially instantaneously.
A key element of the Ibis system is a curated database of genomics that associates base counts with primer pairs for thousands of organisms. Broad-range PCRs are capable of producing products from groups of organisms rather than single species. That, coupled with the ability of the mass spectrometer to rapidly and accurately derive base compositions from PCR amplicons, provides high information content and obviates the need to anticipate which pathogen is present in the sample. The Ibis system has been used for the rapid identification and strain typing of a variety of bacteria, viruses, fungi, and protozoa (131). Although the PCR ESI MS system is no longer commercially available, Abbott plans to launch a new platform in 2014.

SeqQuenom developed comparative sequencing by base-specific cleavage and MALDI-TOF MS for automated, high-throughput microbial DNA sequence analysis in its iPLEX MassArray system (132). In this innovative genotyping method, PCR-amplified signature sequences are subjected to in vitro transcription and base-specific RNA cleavage by RNase A. Mass signal patterns of the resulting cleavage and thus by its mass in the resulting mass spectrum, compared with a calculated list of molecular weights derived from an in silico digest of a set of reference sequences in the system database. The simulated patterns of the reference set are used to identify the microorganism by its best match to a reference sequence. Small differences between the best-matching reference and sample sequence show up as a difference between the in silico and detected sample spectra. They can be used to identify and localize sequence differences down to a single base change and identify novel sequences. Depending on the gene target, MALDI-TOF MS can provide high-level discrimination of individual microbial taxa or be used to identify lineages within a species (133–137).

**QUANTITATIVE METHODS**

Many of the methods discussed above can be used to quantify the amount of RNA or DNA in a clinical sample. The most commonly used methods include PCR and RT-PCR, transcription-based amplification, and bDNA assays. The principle of quantitative molecular methods is that there is a linear relationship between the quantity of the input template and the amount of the product or signal generated. Competitive PCR (cPCR) is a reliable and robust method that was the basis of the first generation of viral load assays for HIV-1 and HCV (Amplifiler Monitor System; Roche Diagnostics) that were commonly used in clinical laboratories. These assays, based on conventional standard PCR, are still in use by clinical laboratories but are rapidly being replaced by real-time amplification methods. The basic concept behind cPCR is the coamplification in the same reaction tube of target and calibrator templates with equal or similar lengths and with the same primer-binding sequences (138). Since both templates are amplified with the same primer pair, identical thermodynamics and amplification efficiencies are ensured. The amount of the calibrator must be known, and after amplification, products from both templates must be distinguishable from each other. Different types of calibrators have been used in cPCR, but in general those calibrators similar in size and base composition to the target work most effectively. RNA competitors should be used in quantitative RT-PCRs to address the problem of variable RT efficiency. This competitive amplification approach has also been used effectively with transcription-based amplification methods using RNA targets and RNA calibrators.

For cPCR, the concentration of the target template in the clinical sample can be determined by a simple calculation. The yield of the PCR product is described by the equation $Y = I(1 + e)^n$, where $Y$ is the quantity of the PCR product, $I$ is the quantity of the template at the beginning of the reaction, $e$ is the efficiency of the reaction, and $n$ is the number of cycles. In cPCR, this equation is written for both templates, as follows: competitor, $Y_c = I_c(1 + e)^n$; target, $Y_t = I_t(1 + e)^n$. Since $e$ and $n$ are the same for both the competitor and the target, the relative product ratio, $Y_t/Y_c$, directly depends on the initial concentration ratio, $I_t/I_c$, and the function $Y_t/Y_c = I_t/I_c$ is linear.

Real-time amplification and detection methods are particularly well suited for quantification of nucleic acid because the amount of the fluorescent signal generated is proportional to the concentration of the target DNA or RNA in the original sample. Real-time PCR and transcription-based amplification methods are the most commonly used quantitative methods. For real-time PCR, the fluorescent signal is measured during the exponential phase of amplification, which is where the amplification plot crosses the threshold (Fig. 6). This is in contrast to standard PCR methods that measure the endpoint signal. There are advantages to measuring the fluorescent signal during the exponential phase of amplification; the reaction components are not limiting, and the assay is less sensitive to the effects of inhibitors. As a result, real-time PCR assays are more reproducible than standard PCR assays. Both internal and external calibrators can be used with real-time assays, but the improved precision of real-time assays allows more reliable results to be obtained with an external calibration curve than would be obtained with standard PCR. When external calibrators are used, a calibration curve is generated by plotting the log$_{10}$ concentration of the external calibrator versus the $C_T$, and this plot is used to calculate the concentration of nucleic acid in the sample. The concentration of nucleic acid in the sample is inversely related to the $C_T$: the higher the concentration of the nucleic acid, the lower the $C_T$ (40). In general, quantitative real-time PCR assays are not more sensitive than standard PCR assays; however, they have a much broader linear range, typically 6 to 7 orders of magnitude.

Digital PCR is the next advance in nucleic acid quantification. It can provide a lower limit of detection than real-time PCR methods with better precision at the very low concentrations. As opposed to relative quantification, digital PCR provides absolute quantification with no need for reference standards. Currently, digital PCR is used as a research tool, but it may find applications in clinical laboratories to resolve ambiguous results obtained with quantitative real-time PCR assays or for creating accurate viral reference standards as the technology becomes less costly (139–141). The CLSI has published guidelines for quantitative molecular methods for infectious diseases that address the development and application of quantitative PCR assays and other nucleic acid amplification methods (142).

**AUTOMATION AND INSTRUMENTATION**

Molecular assays consist of three major steps: specimen processing, nucleic acid amplification, and product detection. Sample processing is usually the most labor-intensive step...
and has represented the biggest challenge for manufacturers of automated test systems. However, in the past several years there have been considerable advances in this area with the availability of both semiautomated and fully automated systems. Automation of the nucleic acid extraction process offers laboratories several advantages, including ease of use, limited handling of the sample, improved reproducibility, reduced opportunity for cross contamination, and, for some systems, postelution functions such as adding samples into the master mix. These advantages need to be weighed against the costs of automated systems, the inflexibility of batch size, and the large sizes of many of the automated instruments. The systems vary in the types of nucleic acid extraction methods that they provide and include total nucleic acid, DNA-only, and RNA-only protocols. Other features of automated extraction systems to consider are the availability of protocols for various specimen types and volumes, variable elution volumes, the availability of target-specific and/or generic target extraction methods, and specimen throughput. The available automated systems range from fully automated high-throughput systems such as the MagNA Pure and COBAS Ampliprep systems (Roche), m2000sp (Abbott), and QIAAsymphony (Qiagen) to those designed for a small number of specimens such as BioRobot EZ1 (Qiagen) and NucliSENS (bioMérieux).

There are a wide variety of instruments commercially available for real-time PCR testing. These instruments vary as to speed, capacity of samples per test run, reaction volume, optics, and support for different fluorescence probe types. The time required for analysis depends to a great extent on the time required for thermocycling, and the speed of thermocycling depends on how quickly the instrument can change temperature over time. For example, some instruments can change the temperature at 20°C per s, permitting instrument analysis of up to 32 samples in as little as 30 min. Capacity may offset thermocycling speed. Although a higher-capacity instrument may have a longer thermocycling time than a lower-capacity instrument, potentially more samples may be analyzed by the high-capacity instrument in a specific time period than by the low-capacity instrument.

The reaction mixture volume assayed may also vary from one system to another. If target nucleic acid is present in extremely small amounts in a sample, an instrument that permits higher-volume analysis may be preferred.

Real-time PCR instruments utilize a variety of optics for fluorescence detection. A tungsten source lamp for excitation and selectable filters for excitation and emission wavelength detection are used in a number of instruments. Light-emitting diodes or laser excitation devices coupled with emission wavelength detection may also be used. The new real-time PCR instruments allow up to six different fluorogenic dyes to be used simultaneously in one reaction. The Prism series of sequence detection systems (Applied Biosystems), LightCycler (Roche), SmartCycler (Cepheid, Sunnyvale, CA), and Rotor-Gene (Qiagen) are examples of instruments designed initially for research applications that now find widespread use in molecular diagnostics laboratories. The COBAS TaqMan analyzer (Roche) and the m2000rt system (Abbott) were the first real-time instruments designed specifically for use in clinical laboratories.

Many manufacturers are coupling automated nucleic acid extraction instruments with amplification and detection systems to create high-throughput, fully automated nucleic acid analyzers. The TIGRIS and Panther systems (Hologic Gen-Probe), the COBAS Ampliprep/COBAS TaqMan and COBAS 4800 systems (Roche), the m2000 system (Abbott), and the Viper and BD MAX systems (BD Diagnostics) are examples of fully automated and integrated systems designed to perform sample processing, nucleic acid amplification, and product detection.

The GeneXpert system (Cepheid) represents the other end of the automation spectrum, in which a single sample is added to a disposable fluidic cartridge that fully automates and integrates sample preparation, amplification, and real-time detection. The instrument has a random-access design, amenable to on-demand molecular diagnostic testing. Other examples of simple, sample-in, answer-out systems designed to be performed on demand include FilmArray (BioFire) and AmpliVue (Quidel/BioHelix).

A number of criteria need to be considered before selecting and implementing a new molecular microbiology instrument platform (144). These include vendor support by way of test menu, technical support, pricing, and kit configuration. The functionality of the instrument platform should also be assessed by worklist, reliability, flexibility, and ease of use. Finally, the specifications for the instrument in terms of environmental conditions (e.g., temperature, humidity, and airflow) and utility requirements should be carefully reviewed prior to the final selection.

CURRENT APPLICATIONS

Molecular methods have created new opportunities for the clinical microbiology laboratory to affect patient care in the areas of initial diagnosis, disease prognosis, and monitoring of response to therapy. Over time the methods have become more automated, the cost of testing has decreased, and clinical utility has been proven for the diagnosis and management of a variety of infectious diseases. As a result, molecular testing is now routinely performed in many clinical microbiology laboratories, and clinical applications will continue to expand in the future. A number of near-patient or point-of-care nucleic acid amplification tests for a variety of infectious diseases are commercially available or close to market. These point-of-care tests could extend molecular microbiology into resource-poor settings and potentially drive innovation in global public health programs for control of HIV and M. tuberculosis infections.

Initial Diagnosis

With the development of molecular methods, the clinical microbiology laboratory is no longer reliant solely on the traditional culture methods for detection of pathogens in clinical specimens. Culture-based methods have long been the gold standard for infectious-disease diagnosis, but for several diseases, nucleic acid-based tests have replaced culture as the gold standard. HCV infection, enteroviral meningitis, pertussis, HSV encephalitis, and genital infections due to C. trachomatis and N. gonorrhoeae are some examples of infectious diseases in which nucleic acid-based tests are the new gold standards for diagnosis. In other diseases such as tuberculosis, nucleic acid amplification tests are useful adjuncts to culture that can provide more rapid initial diagnosis and permit timelier public health interventions. This technology has been used to best advantage in situations in which traditional methods are slow, insensitive, expensive, or not available. These techniques work particularly well with fragile or fastidious microorganisms that may die in transit or be overgrown by contaminating biota when cultured. N. gonorrhoeae is an example for which the nucleic acid can be detected under circumstances in which the organism cannot be cultured. The use of improper collection
media, inappropriate transport conditions, or delays in transport can reduce the viability of the pathogen but may leave the nucleic acid still detectable. It is beyond the scope of this chapter to review all of the possible applications or to provide a comprehensive list of methods for detection of various pathogens. The reader is directed to another excellent resource for this information (145).

Opportunities to actually replace culture for bacterial pathogens in routine practice are limited by the need to isolate the organisms for antibiotic susceptibility testing. In those applications in which culture has actually been replaced by nucleic acid testing, the pathogens are of predictable susceptibility and, consequently, routine susceptibility testing is not performed, or the genetics of resistance are well defined and simple to detect, such as methicillin resistance in S. aureus. Since the last edition of this book, most clinical microbiology laboratories have replaced antigen detection with nucleic acid amplification methods for diagnosis of C. difficile-associated disease because the nucleic acid amplification tests have performance characteristics similar to toxigenic culture but with a much shorter analysis time (146).

Molecular methods have had the biggest impact in clinical virology, in which the molecular approaches are often faster, more sensitive, and more cost-effective than the traditional methods. The diagnoses of enteroviral meningitis, HSV encephalitis, and CMV infections in immunocompromised patients are examples of clinically relevant and cost-effective applications of nucleic acid-based tests. There are greater opportunities to replace the conventional methods in virology than in bacteriology because the culture-based methods are costly and antiviral susceptibility testing is not routinely performed. In those situations in which antiviral susceptibility testing is required, such as identification of ganciclovir-resistant CMV, molecular methods (i.e., sequencing) are the method of choice for rapid identification of mutations. The diagnostic role of molecular tests has been further expanded with a new HIV diagnostic testing algorithm proposed by the Centers for Disease Control and Prevention (CDC) (147). In this new algorithm, HIV-1 RNA testing with either the Aptima HIV-1 RNA qualitative assay (Hologic Gen-Probe; FDA approved for HIV diagnosis) or an HIV-1 viral load assay can be used to facilitate prompt diagnosis of acute HIV-1 infection when faced with discordant fourth-generation screening (antigen and antibody combination assays) and supplemental antibody test results to differentiate acute HIV-1 infection from false-positive immunoassay results. Similarly, HCV RNA testing has replaced the recombinant immunoblot assay as a supplemental test for HCV infection (148). Clinical laboratories will be performing more HCV RNA tests with the adoption of the CDC’s amended testing recommendations for one-time HCV testing for all persons born from 1945 through 1965 regardless of risk factors (149).

Until recently a major limitation of molecular tests for infectious diseases was the clinical need for simultaneous identification of multiple pathogens associated with defined syndromes such as respiratory tract infections, sepsis, gastroenteritis, and meningococcal meningitis (150). This syndromic approach to molecular microbiology was facilitated by the technological developments of multiparametric or multiplex analysis described earlier in this chapter. At the time of this writing, there are FDA-cleared highly multiplexed panels for the detection of respiratory, gastrointestinal, and bloodstream infections. It is likely that this trend in development and deployment of syndromic molecular microbiology tests on multiparametric platforms will increase in the future.

Perhaps the greatest impact of molecular methods has been in the discovery of previously unrecognized or uncultivable pathogens. During the past 25 years, a number of infectious agents were first identified directly from clinical material by using molecular methods. HCV, the principal etiologic agent of what was once known as non-A, non-B hepatitis, was discovered in 1989 through the application of molecular cloning techniques by investigators from the CDC and the Chiron Corporation (151). Cloning and analysis of the HCV genome led to production of viral antigens that now serve as the basis of the specific serologic tests used to screen the blood supply and to diagnose hepatitis C. To date, HCV has resisted all attempts at sustained in vitro propagation. As a result, RT-PCR is used to detect, quantify, and genotype HCV in infected individuals.

Tropheryma whippelii, the causative agent of Whipple’s disease, is another example of a microorganism that was initially identified by molecular methods (152). It was discovered by the use of broad-range PCR, in which primers are directed against conserved sequences in the 16S rRNA gene. Sequence analysis of the PCR product and comparison with known 16S rRNA gene sequences were used to characterize the organism and establish its disease association. This approach provides a new paradigm for discovery of unrecognized pathogens that is of value in other diseases with features that suggest an infectious etiology.

Molecular methods are very powerful tools for the identification of emerging pathogens and are covered in detail in chapter 16. RT-PCR with consensus primers and a panviral DNA microarray was used to rapidly identify the etiologic agent of severe acute respiratory syndrome as a coronavirus (153, 154). Within a few months of the recognized outbreak, the virus was identified and sequenced and the molecular assays were developed that played an essential role in diagnosing the infection and defining the epidemiology of the infection.

Similarly, high-throughput shotgun sequencing offers important new opportunities for discovery of microbial pathogens. It was used to identify a novel polyomavirus, Wu virus, from a nasopharyngeal aspirate from a 3-year-old with pneumonia (155). Using a specifically designed real-time PCR assay, this virus has been shown to be present in 0.7 to 3.0% of patients with acute respiratory infections; the majority of patients were coinfected with other respiratory viruses (156). This approach has also been used to detect previously known and unknown viruses in feces of children with gastroenteritis and a novel Old World arenavirus that caused fatal disease in three recipients of organs from a single donor (157).

Identification of Bacteria and Fungi by Nucleic Acid Sequencing

Nucleotide sequence analysis of the 16S bacterial rRNA gene has expanded our knowledge of the phylogenetic relationships among bacteria and is the new standard for bacterial identification. rRNA contains several functionally different regions, with some regions having highly conserved and others having highly variable nucleic acid sequences (158). The sequence of the 16S RNA gene is a stable genotypic signature that can be used to identify an organism at a genus or species level. The 16S gene sequence can be determined rapidly and provides objective results independent of phenotypic characteristics. As discussed in the preceding section, it can also be used to characterize previously unrecognized species. A similar approach that targets the
nuclear large subunit of the rRNA gene can be used for the identification of fungi (159). This gene is universally found in all fungi and contains sufficient variation to identify most fungi accurately to the species level.

The DNA sequencing approach to microbial identification involves extraction of the nucleic acids, amplification of the target sequence by PCR, sequence determination, and a computer software-aided search of an appropriate sequence database. The major limitations of this approach to microbial identification include the high cost of automated nucleic acid sequencers, the lack of appropriate analysis software, and limited databases.

Applied Biosystems has developed ribosomal gene sequencing kits for bacteria and fungi. A sequence from an unknown bacterium is compared with either full or partial 16S rRNA sequences from >1,000 type strains by using the MicroSeq analysis software (160). The software analysis provides percent base pair differences between the unknown bacterium and the 20 most closely related bacteria, alignment tools to show differences between the related sequences, and phylogenetic tree tools to verify that the unknown bacterium actually clusters with the 20 closest bacteria in the database. The MicroSeq fungal identification system is similar to the bacterial identification system but targets D2 large-subunit rRNA (161,162). Continued improvements in automation, refinements of analysis software, and decreases in cost should lead to more widespread use of nucleic acid sequence-based approaches to microbial identification.

More recently, pyrosequencing, or sequencing by synthesis, has been used for the identification of infectious pathogens. Since the length of high-quality sequence generated is limited to 50 to 100 bp, it is very useful for single-nucleotide polymorphism analysis, but it has also been applied to taxonomic categorization of microorganisms. This approach requires identifying a variable region that contains a unique sequence for the different microorganisms within the group. Pyrosequencing has been successfully used to classify mycobacteria and nocardiae into clinically important groups and to identify yeast and filamentous fungi (163, 164). CLSI has published a guidance document focused on interpreting and reporting results for microbial identification by DNA sequencing (165).

DNA-based microbiome studies frequently fall into two categories (166). Targeted amplicon studies focus on one or a few marker genes and use these markers to reveal the composition and diversity of the microbiota. Others use a shotgun metagenomic approach in which genomic sequences are randomly obtained. The gene used most often in targeted amplicon studies is the 16S rRNA gene because of the availability of large databases of reference sequences and taxonomies of bacteria. A variety of sequencing technologies, including massively parallel sequencing, have been used for taxonomic profiling. See chapter 15 for a more complete discussion of the experimental and analytical tools used for studying the human microbiome.

**Disease Prognosis**

Molecular techniques have created opportunities for the laboratory to provide important information that may predict disease progression. Probably the best example is HIV-1 viral load as a predictor of progression to AIDS and death in infected individuals. This predictive value was first demonstrated in 1996 as part of a multicenter AIDS cohort study (167). The investigators showed that the risk of progression to AIDS and death was directly related to the magnitude of the viral load in plasma at study entry. The viral load in plasma was a better predictor of disease progression than the number of CD4 lymphocytes. Subsequent studies have confirmed that baseline viral load critically influences disease progression.

Subtyping of certain viruses by molecular methods may also have prognostic value. Subtyping of respiratory syncytial viruses may provide information about the severity of infection in hospitalized infants, with those infected with group A viruses having poorer outcomes (168). HPV causes dysplasia, intraepithelial neoplasia, and carcinoma of the cervix in women. HPV types 16 and 18 are associated with a high risk of progression to neoplasia, and types 6 and 11 are associated with a low risk of progression (169). The clinical utility of molecular testing for high-risk HPV DNA has been established for managing women with the cervical cytologic diagnosis of atypical squamous cells of undetermined significance. Women with this condition can be referred for colposcopy based on the detection of high-risk HPV DNA (170). HPV DNA testing is approved by the FDA for use as an adjunct to cytology for cervical cancer screening in women aged 30 years or more (171). The most recent consensus screening guidelines for the prevention and early detection of cervical cancer emphasize the importance of HPV testing in women 30 to 65 years of age even in the absence of cervical cytological abnormalities (172).

CMV viral load testing is useful for deciding when to initiate preemptive therapy in organ transplant recipients and distinguishing active disease from asymptomatic infection. The level of CMV DNA can predict the development of active CMV disease (173, 174), with higher viral load values increasing the risk of symptomatic disease. Quantitative assays are also useful in distinguishing disease from infection with other herpesviruses such as Epstein-Barr virus (EBV) and HHV-6.

**Duration of and Response to Therapy**

Molecular methods have been developed to detect the genes responsible for resistance to single antibiotics or classes of antibiotics in bacteria and in many cases are superior to the phenotypic, growth-based methods. The detection of methicillin resistance in staphylococci, vancomycin resistance in enterococci, carbapenem resistance in Enterobacteriaceae, and rifampin resistance in M. tuberculosis provides examples of where molecular methods are used to supplement the growth-based methods (175, 176). However, it is difficult to imagine, given our current state of knowledge of the molecular genetics of antimicrobial resistance and the technological limitations, that a genotypic approach to routine antimicrobial susceptibility testing of bacteria could rival the phenotypic methods in terms of information content and cost in the near future.

Molecular techniques are playing an increasing role in predicting and monitoring patient response to antiviral therapy. The laboratory may have a role in predicting response to therapy by detecting specific drug resistance mutations, determining viral load, and genotyping. Both viral load and genotype are independent predictors of response to combination therapy with pegylated interferon and ribavirin in chronic HCV infections, although genotype is the main predictor of response (177–180). Those patients with high pretreatment viral load values (≥2 million copies/ml or 600,000 IU/ml) or genotype 1 infections have lower sustained response rates compared with those with genotype 2 and 3 infections (177–179). Genotype is also used to determine the duration of therapy, with genotype 1 infection requiring a longer course of therapy than genotype 2 or 3 infections (180, 181). Recent studies have more closely
defined duration of therapy based on the extent of the viral response. Patients who do not reach a ≥2-log₁₀ drop in viral load at 12 weeks after initiating therapy are very unlikely to respond to pegylated interferon and ribavirin. Moreover, patients with a rapid virologic response (HCV RNA level of <50 IU/ml 4 weeks after initiating therapy) may require a shorter duration of therapy, provided they have a low baseline HCV RNA level (<400,000 IU/ml) and minimal hepatic fibrosis (180).

The FDA approval of the first direct-acting antiviral agents for treatment of chronic HCV genotype 1 infections in 2011 changed the paradigm for treatment and monitoring the response to treatment (182). Both drugs, boceprevir and telaprevir, are serine protease inhibitors to be used in conjunction with pegylated interferon and ribavirin. A number of other compounds encompassing at least five distinct drug classes are currently under development or in clinical trials (183). In patients treated with boceprevir, HCV viral load is determined at baseline and at weeks 8, 12, and 24 of therapy. If the HCV viral load is undetectable at weeks 8 and 24, then patients should be treated for a total of 24 weeks. If HCV viral load is >100 IU/ml at week 12 or detectable at week 24, then therapy should be discontinued. The algorithm is similar for patients receiving triple therapy with telaprevir. HCV viral load is determined at weeks 4, 12, and 24. If HCV RNA is undetectable at weeks 4 and 12, then patients should be treated for a total of 24 weeks. If the HCV viral load is >1,000 IU/ml at week 4 or 12 and/or detectable at week 24, then therapy should be discontinued. Currently, there is no clinical indication for viral resistance testing, but that may change as different classes of direct-acting antiviral agents are used for treatment.

Quantitative tests for HIV-1 RNA are the standard of practice for guiding clinicians in initiating, monitoring, and changing antiretroviral therapy. Several commercially available HIV-1 viral load assays have been FDA approved, and guidelines for their use in clinical practice have been published (184). Viral load assays have also been used in monitoring response to therapy in patients chronically infected with HBV (185) and in predicting the risk for developing BK virus-associated nephropathy in renal transplant recipients (186). In organ transplant recipients, the persistence of CMV viral load after several weeks of antiviral therapy is associated with the development of resistance (187).

LABORATORY PRACTICE

The unparalleled analytical sensitivity of nucleic acid amplification techniques coupled with their susceptibility to cross contamination presents unique challenges to the routine application of these techniques in the clinical laboratory. There are special concerns in the areas of specimen processing, workflow, quality assurance, and interpretation of test results. Additional information can be found in the CLSI documents MM3-A2, Molecular Diagnostic Methods for Infectious Diseases; Approved Guideline—2nd Edition (188); MM6-A2, Quantitative Molecular Methods for Infectious Diseases; Approved Guideline—2nd Edition (142); MM13-A, Collection, Transport, Preparation, and Storage of Specimens and Samples for Molecular Methods; Approved Guideline (189); and MM19-A, Establishing Molecular Testing in Clinical Laboratory Environments; Approved Guideline (190).

Specimen Collection, Transport, and Processing

Proper collection, transport, and processing of clinical specimens are essential to ensure reliable results from molecular assays. Nucleic acid integrity must be maintained throughout these processes. Important issues to consider in specimen collection are the timing of specimen collection in relationship to disease state and the proper specimen type. Other factors that come into play include the use of the proper anticoagulant, transport and storage temperatures, and time to processing of the specimen. HIV-1 viral load testing is an example in which the proper conditions for specimen collection, transport, and processing have been well described and has provided insight into the importance of these factors. For HIV-1 viral load testing, the plasma needs to be separated from the cells within 6 h of collection to minimize degradation of RNA. Once the plasma has been separated, it can be stored at 4°C for several days, but ~70°C is recommended for long-term storage (191). Most types of specimens are best stored at ~20 to ~70°C prior to processing.

Molecular methods have several advantages over conventional culture with regard to specimen collection. It may be easier to maintain the integrity of nucleic acid than the viability of an organism. Molecular tests for the detection of C. trachomatis and N. gonorrhoeae are an example in which DNA is stable on dry cervical swabs for a week at room temperature or refrigeration temperatures, which is in stark contrast to the conditions required to maintain organism viability for culture. Nucleic acid persists in specimens after initiation of treatment (192, 193), thus allowing detection of a pathogen even though the organism can no longer be cultured. Also, due to the increased sensitivity of molecular assays, it may be possible to test a smaller volume of specimen or use a specimen that is collected using a less invasive method.

The major goals of specimen processing are to release nucleic acid from the organism, maintain the integrity of the nucleic acid, render the sample noninfectious, remove inhibiting substances, and in some instances concentrate the specimen. These processes need to be balanced with minimizing manipulation of the specimen. Complex specimen processing methods are time-consuming and may lead to loss of target nucleic acid or result in contamination between specimens. Care must be taken to avoid carrying over inhibitory substances, such as phenol or alcohol, from the nucleic acid isolation step to the amplification reaction.

There are several general methods for nucleic acid extraction. Different methods may be used depending on whether the desire is to purify RNA or DNA or both. Another factor to consider when deciding on a nucleic acid extraction method is the type of pathogen sought. Some pathogens, such as viruses, can be very easy to lyse, while mycobacteria, Gram-positive bacteria, and fungi can be very difficult to lyse. Enzyme digestion, harsh lysis conditions, or mechanical disruption may be required to disrupt the cell wall of these organisms.

DNA isolation methods often use detergents to solubilize the cell wall or membranes, a proteolytic enzyme (such as proteinase K) to digest proteins, and EDTA to chelate divalent cations needed for nuclease activity (194, 195). The lysate can be used directly in amplification assays, or additional steps may follow to purify the nucleic acid. These additional steps remove proteins and traces of organic solvent and concentrate the specimen. In order to successfully use a crude lysate, the target DNA must be present in a relatively high concentration and there must be minimal inhibitors of amplification in the sample. If these criteria are not met, additional purification steps should be used.

Another commonly used method of nucleic acid isolation involves disruption of cells or organisms with the chaotropic
agent guanidinium thiocyanate and a detergent (196). After a short incubation, the nucleic acid can be precipitated with isopropanol. Guanidinium thiocyanate denatures proteins and is also a strong inhibitor of ribonucleases, making it a very useful tool for RNA isolation, although it is also used for purification of DNA. The Boom extraction method is also based on the lysing and nuclease-inactivating properties of guanidinium thiocyanate but utilizes the acid-binding properties of silica or glass particles to purify nucleic acid (197).

Detection of target organisms that are present in small numbers in a large-volume clinical sample requires that target organisms be concentrated to a detectable level. One way to accomplish this is to isolate the particular nucleic acid of interest by binding it to a solid phase, which allows the support, with the target bound to it, to be separated from the original sample. These techniques are referred to as target capture. Target capture techniques immobilize nucleic acids on magnetic beads by the use of a capture probe that attaches to the bead and to the target nucleic acid. A magnetic separation device is used to concentrate the target by drawing the magnetic beads to the sides of the sample tube, while the remainder of the sample is washed away and removed. Target capture techniques also remove materials in the sample that might otherwise interfere with amplification.

Over the past several years, various manufacturers have developed commercially available reagents using one of these basic methods or a modification of these methods. Many of these methods rely on the use of spin column technology, are easy to use, and provide a rapid, reproducible method for purification of nucleic acid from a wide variety of clinical specimens. In recent years, further advances have been made with the introduction of magnetic silica particles that are coupled with instruments providing various degrees of automation, thus further simplifying nucleic acid extraction and purification. These reagents tend to be expensive, but the additional cost can be offset by labor savings. Laboratories are increasingly using automated systems for nucleic acid extraction, as they require less hands-on time, may reduce the risk of cross contamination between specimens, and provide more consistent yields. There are now many automated systems available for use in clinical laboratories; they should be thoroughly evaluated because not all isolate nucleic acids with the same efficiency and purity. The quality of the nucleic acid can have a significant impact on the performance of a molecular test.

Tissue samples need to be disrupted prior to the nucleic acid extraction process. This can be accomplished by cutting the tissue into small pieces or mechanically homogenizing the tissue prior to proceeding with one of the above-described extraction methods. Preserved tissue specimens require removal of the paraffin with solvents and slicing into fine sections prior to processing.

Removing inhibitors of amplification is a key function of the nucleic acid extraction process. Simple methods of nucleic acid extraction that involve boiling of the specimen have been used for relatively acellular specimens such as cerebrospinal fluid (CSF). Though the boiling method is fast and easy, there are problems with inhibition of amplification in CSF that are not inactivated by boiling (198). The inhibition rate can be reduced to <1% by using a silica-based extraction method. Similarly, crude lysates of urine and cervical swab specimens are commonly used for the detection of C. trachomatis and N. gonorrhoeae. Specimens containing amplification inhibitors have been reported to range from 1 to 5% for urine to as much as 20% for cervical swabs (199). Common inhibitory substances include hemoglobin, crystals, β-human chorionic gonadotropin, and nitrites. Blood samples are used commonly for detection and/or quantification of a variety of viral pathogens, including HIV-1, HCV, and CMV. HIV-1 viral load testing is an example in which the effects of different anticoagulants have been well studied. HIV-1 viral RNA is most stable when collected in EDTA, and heparin has been shown to be inhibitory to amplification and should be avoided (200). In addition, very small volumes of whole blood (1%) can be inhibitory to Taq DNA polymerase (201). Other compounds such as acidic polysaccharides, which are components of glycoproteins present in sputum and cervical specimens and bile salts found in stool, can also inhibit polymerase (202). Human DNA, when present in the sample in high quantities, for example, tissue or blood, may also interfere with the detection of a low concentration of pathogen nucleic acid. With the recognition of such a wide array of inhibitors of amplification and the availability of simple, reliable, semiautomated, and automated nucleic acid extraction methods, the use of crude lysates for testing becomes more difficult to justify. Regardless of the nucleic acid extraction method employed, the laboratory should monitor inhibition rates for different specimen types and nucleic acid extraction methods (see “Quality Control and Assurance” below).

Contamination Control

Several types of contamination can occur with molecular testing: cross contamination of specimens during the nucleic acid extraction step, contamination of specimens with positive control material, and carryover contamination of amplified products. Contamination with amplified products can occur with DNA or RNA target amplification and with probe amplification methods. It does not occur with signal amplification assays since nucleic acid molecules are not synthesized with these methods. Cross contamination that occurs during specimen processing or handling of positive control material can occur with all amplification methods. The approach to the control of contamination due to amplified products has changed dramatically with the widespread use of real-time amplification and detection methods. Since the reaction tube is not opened after amplification, there is minimal risk of contamination from the amplified product. Many laboratories using real-time methods continue to use a variety of good laboratory practices to control for contamination, but the focus is on minimizing cross contamination between specimens rather than contamination from the amplified product. Refer to CLSI document MM3-A2, Molecular Diagnostic Methods for Infectious Diseases; Approved Guideline—2nd Edition (188), and Molecular Microbiology: Diagnostic Principles and Practice, 2nd ed. (144), for detailed descriptions of good laboratory practices to minimize contamination.

Clinical microbiologists have long been concerned about minimizing contamination between samples with microorganisms during specimen processing. Molecular methods have raised the level of concern considerably, and for good reason, as current methods can detect a few molecules. The previously undetected low levels of contamination that occurred in processing specimens for routine culture can lead to false-positive results in molecular assays. Prevention of contamination due to target DNA or RNA is best done by careful handling of specimens to avoid splashing, opening only one specimen tube at a time, pulse-spinning tubes prior to opening, using screw-top tubes rather than snap-cap tubes to minimize aerosolization, bleaching work surfaces, and
using plugged pipette tips. Some of these approaches can be difficult for high-volume laboratories, which is why automated extraction systems can be very useful. Care must be taken with these systems to ensure that there is no cross contamination during the automated process. This is often done by alternating negative and high-titer specimens in a checkerboard arrangement and monitoring for carryover of sample into the negative specimens. These experiments should be designed with an understanding of the concentration of the organism in the clinical specimen. For example, the concentration of HSV in CSF from patients with meningitis is quite low compared with the concentration of BK virus in the urine of a patient with nephropathy.

Preventing contamination of the laboratory with DNA from a clinical specimen or positive control material is very important, because eliminating contamination with target DNA once it occurs can be very difficult. This is why care should be taken to use a positive control at the lowest concentration that consistently amplifies. The enzymatic and photochemical inactivation methods used to control carryover contamination of amplified products are not effective in preventing contamination with target DNA.

Enzymatic inactivation of amplified products can be accomplished with uracil-N-glycosylase (UNG), a DNA repair enzyme found in a variety of bacterial species. During the PCR, dTTP is replaced with dUTP so that dUTP is incorporated into the newly synthesized DNA products. This allows for a distinction between starting template DNA and amplified products; only newly synthesized PCR products will contain deoxuracil. If UTP-containing amplification products are present as contaminants, the addition of UNG to the reaction mixture will result in the cleavage of deoxuracil residues, thus destroying the contaminating DNA (203). The use of UNG increases the amount of carryover DNA needed to contaminate the reaction mixture by several orders of magnitude (204). When UNG is used, it is important to keep the annealing temperature above 55°C so that the UNG remains inactive, thus avoiding degradation of newly synthesized product. For the same reason, after completion of amplification, the reaction mixture should be held at 72°C (205). UNG can be inactivated at 94°C, but prolonged inactivation at 94°C may also affect the activity of the polymerase enzyme. UNG will not remove uracil from RNA molecules and is therefore ineffective in controlling contamination in RNA amplification assays, such as TMA and NASBA.

When UTP and UNG are used, the PCR reaction conditions should be reoptimized, as the magnesium requirement may increase. The efficiency of amplification may be reduced when UTP is substituted for TTP. This can be overcome by adding a mixture of dUTP and dTTP into the master mix. The efficiency of inactivation using UNG depends on the size of the amplified product and its G+C content. Inactivation may not be effective with amplified products of <100 bp, as maximum UNG efficiency requires the DNA molecule to be 150 bp (206).

Contamination of laboratory work surfaces, equipment, reagents, and clothing of laboratory personnel with previously amplified nucleic acid products is of particular concern for clinical laboratories, since these products can accumulate over time with routine testing and can be inadvertently transferred to subsequent assay reactions, resulting in false-positive test results. To minimize the potential for such amplicon contamination and false-positive results, laboratories performing molecular tests with target amplification methods were designed traditionally to have physical separation of preamplification (i.e., reagent preparation and sample processing), amplification-detection, and postamplification (i.e., DNA sequencing) areas with separate ventilation systems. In addition to the use of dedicated rooms, biological cabinets, and dead-air boxes for various processes involved in specimen testing, laboratories have also typically employed a unidirectional workflow for the movement of specimens, supplies, and personnel from preamplification to postamplification areas through each phase of testing. The physical separation of pre- and postamplification activities and a unidirectional workflow are particularly important for those laboratories performing postamplification analyses in which the reaction vessel is opened and the amplicon transferred to another vessel or device (e.g., sequencing or liquid bead microarrays). The strict separation of pre- and postamplification areas is less important for laboratories using real-time amplification methods, particularly those using fully automated systems that perform nucleic acid extraction, amplification, and detection.

Quality Control and Assurance

“Verification” and “validation” are terms that are often used interchangeably, but it is important to remember that they are different processes (207). Verification is the process by which assay performance is determined; parameters such as sensitivity, specificity, positive and negative predictive values, and accuracy are established. The verification of an assay is completed before the assay is used for patient testing. Validation is the ongoing process of proving that the assay is performing as expected and achieves the intended result or intended use.

The analytical verification of an assay provides information on the performance characteristics of the assay, including the limit of detection, linearity and measuring ranges (quantitative tests), trueness, precision, and specificity, while the clinical verification determines the clinical utility of the assay. The analytical performance characteristics of a test should be well understood prior to determining the clinical utility of a test, and any analytical limitations need to be considered when determining clinical uses. For example, a qualitative HSV DNA test may have adequate sensitivity to detect cases of HSV encephalitis but have inadequate sensitivity to detect the lower levels of DNA found in cases of HSV meningitis.

Determining the clinical utility of a molecular assay can be difficult when the molecular assay is more sensitive than the gold standard. This situation was seen with the commercial assays designed to detect C. trachomatis in genital specimens. Molecular assays proved to be much more sensitive than the gold standard method of culture. An insensitive gold standard can make a molecular assay appear to have a falsely low specificity. In this situation, an expanded gold standard can be used. For C. trachomatis, this included direct fluorescent-antibody testing and/or another molecular method (192, 193, 208). There are additional challenges in determining the clinical utility of molecular assays that detect rare pathogens. These assays are usually laboratory-developed tests (LDTs), and any given medical center may see very few cases of the disease, making clinical verification difficult. Moreover, standards and control material can be difficult to obtain for rare pathogens. Several companies now provide control material for the more common molecular assays, such as those for C. trachomatis, N. gonorrhoeae, HIV-1, HCV, and CMV. A complete list of reference materials and international standards for molecular microbiology tests is maintained by the Genetic Testing Reference Materials Coordination Program, CDC, and can be accessed at http://www.cdc.gov/clia/Resources/GetRM/
The availability of calibrators that are made based on a consensus standard (such as the World Health Organization international standards for HIV-1, HCV, CMV, and EBV) is very important in establishing the clinical utility of viral load tests. The lack of such calibrators makes standardization of LDTs very difficult. This has been particularly problematic for CMV and EBV, for which the presence of latent infection and asymptomatic reactivation leading to low levels of viral replication underscores the need to establish clinical cutoffs for initiating therapy or reducing immunosuppression. With the lack of an international standard, there is poor agreement of viral load values between LDTs (209), so clinically important cutoffs to predict the development of disease need to be determined by the individual laboratory. These standards are now available and should improve the agreement of viral load values between LDTs, which will facilitate the establishment of clinically relevant cutoffs.

A positive control is designed to ensure that the test can consistently detect a concentration of target nucleic acid at or near the limit of detection of the assay. The positive control should be at the lowest concentration that can be reproducibly amplified. A positive control that is significantly greater than the cutoff of the assay may not detect small decreases in amplification efficiency. In addition, use of large amounts of target DNA can increase problems with contamination in the laboratory. For a quantitative test, two levels of positive control are required, a low positive control near the lower limit of quantification and a high positive control near the upper limit of quantification. For real-time methods that have an upper limit of quantification of $10^7$ or $10^8$ copies/ml, it may not be possible to find adequate amounts of control material, so a sample in the range of $10^5$ copies/ml is often used. Depending on the availability of material, the positive control may be purified nucleic acid or lysed or intact organisms. An extraction control tests the ability of the nucleic acid extraction or purification method to successfully release nucleic acid from the organism. The extraction control, which should be intact organisms, can also serve as a positive control if it is used at the appropriate concentration.

Monitoring for the presence of inhibitors in a specimen is important, particularly for complex specimens such as blood or sputum. Several methods can be used to control for inhibition. One method is to amplify two aliquots of a clinical specimen, one directly and the second spiked with an aliquot of positive control DNA. For a specimen to be considered negative for the target analyte, testing results for the direct specimen must be negative and those for the spiked specimen must be positive. If an inhibitor of amplification was present, the spiked specimen would be negative. The concentration of positive control used for the spike must be near the limit of detection of the assay to ensure that low-level inhibition of amplification is detected.

Another approach to monitoring for inhibition of amplification is adding an internal control to the clinical specimen prior to nucleic acid extraction. As discussed in “Quantitative Methods” above, the internal control molecule may be designed with the same primer-binding sites as the target molecule but modified in some manner so as to allow detection separate from the target based on size or sequence. An internal control may be designed that does not share the same primer-binding sites as the target molecule; in this situation a separate set of primers is needed for amplification. An internal control is an effective way to monitor for inhibition, but it may decrease the sensitivity of the assay due to competition for assay components. Amplification of a human housekeeping gene such as the β-globin gene may also be used as an internal control, but the gene should not be present in vast excess of the target molecule or inhibition of amplification of the target molecule can occur without evidence of inhibition of the housekeeping gene. Inhibition controls should be included in assays that use a new specimen extraction method or specimen type. However, a cost-effective approach is to discontinue these controls once the inhibition rate is determined to be <1%. However, discontinuing the use of an internal control limits the ability to detect inhibition due to preanalytical factors, such as collection of the specimen in a tube containing heparin rather than EDTA.

Under certain conditions, there may be a need to determine if there is adequate nucleic acid in a specimen, for example, when using paraffin-embedded tissue or when evaluating the quality of a specimen. In these situations, amplification of housekeeping genes can be used to determine if the specimen contains human DNA. The absence of amplifiable human DNA from the specimen raises concern about whether the specimen quality is adequate.

Negligible controls should be included in all assays and processed in a manner similar to the processing of the clinical specimens. The negative control should be taken through all steps of the assay, including the nucleic acid extraction process. However, lack of target amplification in the negative control does not ensure that there is not contamination in the run, as contamination is often low level and sporadic. Including multiple negative controls in the run may provide additional assurance that there is no contamination, but this approach may be cost prohibitive. Ideally, the negative control should be a clinical specimen that does not contain the analyte of interest. These types of controls may be difficult to obtain, so water or buffer is often substituted.

Currently, the College of American Pathologists (CAP) is the only Centers for Medicare and Medicaid Services-approved proficiency program for molecular testing for infectious diseases. The CAP provides proficiency testing for many common pathogens for which routine tests are done in the clinical laboratory. The Quality Control for Molecular Diagnostics proficiency program, which is jointly sponsored by the European Society for Clinical Virology and the European Society for Clinical Microbiology and Infectious Diseases (Glasgow, Scotland, United Kingdom), also provides testing for a variety of pathogens. When formal external proficiency testing programs are not available, laboratories may split samples with other laboratories, split samples between a new method and an established laboratory-developed method, or clinically validate the test result by clinical diagnosis. When exchanging specimens between laboratories for proficiency testing, it is important that both laboratories use the same method, particularly for quantitative methods, as viral load values may differ substantially among the various assays.

**Reporting and Interpretation of Results**

The interpretation of molecular assays requires a basic understanding of the strengths and limitations of these technologies. There are unique problems in interpreting molecular testing results that are not routinely encountered with traditional microbiological assays, such as culture and serology. Some of the problems that may occur in interpreting molecular assays include recognizing false-positive results, distinguishing viable from nonviable organisms, and correlating nucleic acid detection with the presence of disease.
For interpretation of a positive test result, the issues that need to be considered are assay specificity and contamination. The specificities of most molecular assays are established by the primers and probes used during amplification and detection steps; if the cross-react with other pathogens, then false-positive results are possible. For example, primers designed to detect *M. tuberculosis* from respiratory specimens must not cross-react with organisms that are part of normal oral biota or other common respiratory pathogens, such as *S. pneumoniae*. Although uncommon, problems with primer specificity do occur. Rhinoviruses and enteroviruses are closely related, and finding a conserved gene target that will detect all rhinoviruses and all enteroviruses without some cross-reaction is difficult. This would not be a problem for testing of CSF specimens for enteroviruses since rhinoviruses do not cause meningitis, but it can complicate the interpretation of tests for rhinoviruses in respiratory specimens since enteroviruses can be found in the oropharynx. Problems with primer specificity have also been reported for a commercially available PCR assay designed to detect *N. gonorrhoeae*. The primers used in this assay cross-react with *Neisseria subflava*, a nonpathogenic organism found in the oropharynx (210). False-positive results can also be due to contamination, which may occur during specimen processing or as a result of carryover contamination of previously amplified products.

The interpretation of a negative result requires consideration of assay sensitivity, specimen quality, nucleic acid extraction efficacy, and amplification efficiency. Problems with any of these factors can lead to a false-negative result, which is why measures to control for each of these parameters should be included in assays whenever feasible. Another source of false-negative results is sequence variation, which may prevent binding of either primers or probes. To minimize this problem, one should perform a thorough search of known sequences before designing the assay and occasionally reexamine the available databases after the assay is put into clinical use. False-negative results may also occur when the specimen type is not optimal (throat swab versus nasopharyngeal aspirate for the detection of respiratory pathogens) or when the specimen is collected at an inappropriate time in the disease course.

Molecular assays detect pathogen nucleic acid but cannot determine whether that nucleic acid is found in a viable or nonviable organism. Pathogen nucleic acid can be detected for long periods of time after appropriate treatment is initiated. For example, *C. trachomatis* DNA can be found in the urine of patients for up to 3 weeks after completion of a course of therapy (192). Similar results have been reported for the detection of HSV DNA in the CSF of patients with encephalitis. DNA can persist for 2 weeks or longer after the initiation of acyclovir therapy (211). Due to the persistence of pathogen DNA after initiation of therapy, qualitative molecular assays should not be used to monitor response to therapy. One notable exception is the use of an HCV RNA RT-PCR assay to monitor the response to therapy. In this instance, the absence of detectable viral RNA from plasma is used to define treatment response (178, 179).

The detection of pathogen nucleic acid does not ensure that the organism is the cause of disease. The organism may be present as part of the normal biota, as a colonizer of a particular area, or as a cause of infection. Distinguishing between colonization and infection may be more difficult when molecular techniques that are more sensitive than culture are used. Organisms present in very low concentra-

For interpretation of a positive test result, the issues that need to be considered are assay specificity and contamination. The specificities of most molecular assays are established by the primers and probes used during amplification and detection steps; if the cross-react with other pathogens, then false-positive results are possible. For example, primers designed to detect *M. tuberculosi* from respiratory specimens must not cross-react with organisms that are part of normal oral biota or other common respiratory pathogens, such as *S. pneumoniae*. Although uncommon, problems with primer specificity do occur. Rhinoviruses and enteroviruses are closely related, and finding a conserved gene target that will detect all rhinoviruses and all enteroviruses without some cross-reaction is difficult. This would not be a problem for testing of CSF specimens for enteroviruses since rhinoviruses do not cause meningitis, but it can complicate the interpretation of tests for rhinoviruses in respiratory specimens since enteroviruses can be found in the oropharynx. Problems with primer specificity have also been reported for a commercially available PCR assay designed to detect *N. gonorrhoeae*. The primers used in this assay cross-react with *Neisseria subflava*, a nonpathogenic organism found in the oropharynx (210). False-positive results can also be due to contamination, which may occur during specimen processing or as a result of carryover contamination of previously amplified products.

The interpretation of a negative result requires consideration of assay sensitivity, specimen quality, nucleic acid extraction efficacy, and amplification efficiency. Problems with any of these factors can lead to a false-negative result, which is why measures to control for each of these parameters should be included in assays whenever feasible. Another source of false-negative results is sequence variation, which may prevent binding of either primers or probes. To minimize this problem, one should perform a thorough search of known sequences before designing the assay and occasionally reexamine the available databases after the assay is put into clinical use. False-negative results may also occur when the specimen type is not optimal (throat swab versus nasopharyngeal aspirate for the detection of respiratory pathogens) or when the specimen is collected at an inappropriate time in the disease course.

Molecular assays detect pathogen nucleic acid but cannot determine whether that nucleic acid is found in a viable or nonviable organism. Pathogen nucleic acid can be detected for long periods of time after appropriate treatment is initiated. For example, *C. trachomatis* DNA can be found in the urine of patients for up to 3 weeks after completion of a course of therapy (192). Similar results have been reported for the detection of HSV DNA in the CSF of patients with encephalitis. DNA can persist for 2 weeks or longer after the initiation of acyclovir therapy (211). Due to the persistence of pathogen DNA after initiation of therapy, qualitative molecular assays should not be used to monitor response to therapy. One notable exception is the use of an HCV RNA RT-PCR assay to monitor the response to therapy. In this instance, the absence of detectable viral RNA from plasma is used to define treatment response (178, 179).

The detection of pathogen nucleic acid does not ensure that the organism is the cause of disease. 10. Molecular Microbiology

---

For interpretation of a positive test result, the issues that need to be considered are assay specificity and contamination. The specificities of most molecular assays are established by the primers and probes used during amplification and detection steps; if the cross-react with other pathogens, then false-positive results are possible. For example, primers designed to detect *M. tuberculosi* from respiratory specimens must not cross-react with organisms that are part of normal oral biota or other common respiratory pathogens, such as *S. pneumoniae*. Although uncommon, problems with primer specificity do occur. Rhinoviruses and enteroviruses are closely related, and finding a conserved gene target that will detect all rhinoviruses and all enteroviruses without some cross-reaction is difficult. This would not be a problem for testing of CSF specimens for enteroviruses since rhinoviruses do not cause meningitis, but it can complicate the interpretation of tests for rhinoviruses in respiratory specimens since enteroviruses can be found in the oropharynx. Problems with primer specificity have also been reported for a commercially available PCR assay designed to detect *N. gonorrhoeae*. The primers used in this assay cross-react with *Neisseria subflava*, a nonpathogenic organism found in the oropharynx (210). False-positive results can also be due to contamination, which may occur during specimen processing or as a result of carryover contamination of previously amplified products.

The interpretation of a negative result requires consideration of assay sensitivity, specimen quality, nucleic acid extraction efficacy, and amplification efficiency. Problems with any of these factors can lead to a false-negative result, which is why measures to control for each of these parameters should be included in assays whenever feasible. Another source of false-negative results is sequence variation, which may prevent binding of either primers or probes. To minimize this problem, one should perform a thorough search of known sequences before designing the assay and occasionally reexamine the available databases after the assay is put into clinical use. False-negative results may also occur when the specimen type is not optimal (throat swab versus nasopharyngeal aspirate for the detection of respiratory pathogens) or when the specimen is collected at an inappropriate time in the disease course.

Molecular assays detect pathogen nucleic acid but cannot determine whether that nucleic acid is found in a viable or nonviable organism. Pathogen nucleic acid can be detected for long periods of time after appropriate treatment is initiated. For example, *C. trachomatis* DNA can be found in the urine of patients for up to 3 weeks after completion of a course of therapy (192). Similar results have been reported for the detection of HSV DNA in the CSF of patients with encephalitis. DNA can persist for 2 weeks or longer after the initiation of acyclovir therapy (211). Due to the persistence of pathogen DNA after initiation of therapy, qualitative molecular assays should not be used to monitor response to therapy. One notable exception is the use of an HCV RNA RT-PCR assay to monitor the response to therapy. In this instance, the absence of detectable viral RNA from plasma is used to define treatment response (178, 179).

The detection of pathogen nucleic acid does not ensure that the organism is the cause of disease. The organism may be present as part of the normal biota, as a colonizer of a particular area, or as a cause of infection. Distinguishing between colonization and infection may be more difficult when molecular techniques that are more sensitive than culture are used. Organisms present in very low concentra-
upper limit of the linear range. For values above the limit of detection but below the limit of quantification, results may be reported as detectable or less than the lower limit of detection but below the linear range. For example, if the lower limit of quantification of an HIV-1 viral load assay is 40 copies/ml, a value of 25 copies/ml could be reported as “detectable, <40 copies/ml.” Inclusion of the amplification method and specimen type in the report is particularly important for quantitative assays, as values from different assay types are not always comparable.

**Regulatory and Reimbursement Issues**

The medical needs for new molecular microbiology tests have exceeded the capacity of the diagnostic industry to provide FDA-cleared test kits to fill these needs. A current list of FDA-cleared/approved nucleic acid-based tests for infectious diseases can be found at [http://www.fda.gov/MedicalDevices/ProductsandMedicalProcedures/In Vitro Diagnostics/ucm330711.htm](http://www.fda.gov/MedicalDevices/ProductsandMedicalProcedures/In Vitro Diagnostics/ucm330711.htm).

Notably absent from the list are many tests that have become a standard of care in a variety of infections, including Bordetella pertussis, EBV, varicella-zoster virus, and BK polyomavirus. Many laboratories have developed tests to fill these unmet needs. These LDTs must be appropriately verified and validated as specified in the Centers for Medicare and Medicaid Services final rule for laboratory requirements, 42 CFR part 493 (216). Such tests are eligible for reimbursement by Medicare and other payers if they are determined to be part of a standard of care or to be of proven clinical benefit.

LDTs often utilize a combination of reagents from different manufacturers, some of which are ASRs. ASRs are chemical substances, for example, antibodies or nucleic acid sequences, that are used in diagnostic tests to detect another specific substance in a specimen and are purchased from manufacturers under this label. The value of ASRs is that they ensure the quality of reagents used in LDTs. ASRs do not include a protocol for use or information on analytical performance or clinical indication. The FDA requires a disclaimer on reports for LDTs using ASRs, and it reads as follows: “This test result was developed and its performance characteristics determined by [laboratory name]. It has not been cleared or approved by the U.S. Food and Drug Administration.” This disclaimer was not intended to cover LDTs not using ASRs or the off-label uses of FDA-cleared products.

A laboratory may want to include clarifying statements in the reports of results from LDTs employing ASRs. These statements may point out that FDA clearance is not necessary for these tests and that they are used for clinical purposes. Additional information may include that the laboratory is certified under the Clinical Laboratory Improvement Amendments of 1988 to perform high-complexity testing and that, pursuant to the requirements of the amendments, the laboratory has established and verified the test accuracy and precision.

While the FDA assumes authority for regulating LDTs and is currently exercising enforcement discretion, it has indicated that it will be increasing oversight of these tests in the near future. It is not clear when the FDA will release its guidance on LDTs, but the FDA has stated that the framework for oversight is complete and under review.

The FDA released a draft guidance that clarified the regulatory requirements applicable to in vitro diagnostic products intended for RUO and investigational use only (IUO). In addition, it emphasizes that products so labeled should not be used in clinical diagnosis and patient management ([http://www.fda.gov/MedicalDevices/DeviceRegulationandGuidance/GuidanceDocuments/ucm253307.htm](http://www.fda.gov/MedicalDevices/DeviceRegulationandGuidance/GuidanceDocuments/ucm253307.htm)). RUO and IUO reagents, instruments, and systems have been in use for many years as components of LDTs, and limiting their use would disrupt clinical laboratory testing and as a result negatively affect patient care. The CAP and other professional organizations believe that the FDA should adopt an enforcement discretion policy for RUO/IUO reagents since it is expected that LDTs, which incorporate these components, will soon be under enhanced FDA oversight.

Correct Current Procedural Terminology coding of molecular microbiology tests is essential to coverage and reimbursement by payers. In 1998, many analyte-specific codes for tests using direct probes, amplified probes, and amplified probes with quantification were established in the microbiology section of the Current Procedural Terminology coding manual, and this list of available codes continues to expand (217). The introduction of analyte-specific codes has simplified the coding process and in many cases increased the reimbursement for molecular microbiology procedures, although there continues to be considerable regional variation in reimbursement rates for the codes.

**Credentials**

Staffing a molecular diagnostics laboratory with individuals who have an appropriate knowledge base and skill set remains a challenge. Until recently, molecular diagnostics was not part of the core curriculum in medical technology programs. However, the situation is changing, and the acquisition of credentials in this area is now available for medical technologists and technicians from the American Association of Bioanalysts, the National Credentialing Agency for Laboratory Personnel, and the American Society for Clinical Pathology. The National Credentialing Agency and the American Society for Clinical Pathology merged their credentialing activities in July 2009. Laboratory directors may receive credentials in molecular diagnostics through the American Association of Bioanalysts (physicians and clinical laboratory scientists), the American Board of Clinical Chemistry (physicians and clinical laboratory scientists), and jointly through the American Boards of Pathology and Medical Genetics (physicians only).

**FUTURE DIRECTIONS**

Nucleic acid testing will continue to be one of the leading growth areas in laboratory medicine. The number of applications of this technology in diagnostic microbiology will continue to increase, and the technology will increasingly be incorporated into routine clinical microbiology laboratories as it becomes less technically complex and more accessible. However, now more than ever clinical and financial outcome data will be needed to justify the use of this expensive technology in an era of declining reimbursement and increased cost consciousness.

The clinical utility of molecular testing is now well established, and the gap between the availability of FDA-cleared/approved tests and clinical need is improving. However, the pending enhanced oversight of LDTs and restriction of the use of RUO and IUO reagents and systems by the FDA could limit the ability of laboratories to develop tests to meet clinical needs not met by in vitro diagnostic products. Although there has been considerable progress in recent years, there are other important unmet needs, including the
availability of international standards and traceable and commutable calibrators that can be used for assay verification and validation. These materials, when widely available, should improve agreement of the results between different tests and aid in the establishment of the clinical utility of molecular tests. Another need is for the continued development of effective proficiency testing programs that will help ensure that the results of molecular tests are reliable and reproducible among laboratories.

To a great extent, the future of molecular microbiology depends upon automation. Many of the available tests are labor-intensive, with much of the labor devoted to tedious sample processing methods. Several fully automated systems for molecular diagnostics have been developed for high- and mid-volume laboratories; however, most suffer from a limited test menu. To increase access to molecular tests, simple, affordable, fully automated, random-access platforms with broad test menus are needed, particularly for laboratories that perform low- to mid-volume testing. Nucleic acid testing for infectious diseases at the point of care is beginning to enter clinical practice in developed and developing countries, particularly for applications that require short turnaround times and in settings where a centralized laboratory approach is not feasible (218).

The use of multiplex nucleic acid-based assays to screen at-risk patients for panels of probable pathogens remains a goal for molecular microbiology. Several such tests are currently available, but success to date has been limited by the technical complexity of some systems. The development of simpler, multiparametric technologies is a key to providing molecular tests with the same broad diagnostic range provided by culture and other conventional methods for diagnosis of syndromic infections.

Metagenomic studies have provided new insights into the human microbiome, and alterations in these communities of microorganisms have been linked to a number of disease states. With the continued decrease in the cost of massively parallel nucleic acid sequencing and the increasing availability of the necessary bioinformatics tools, it is likely that our understanding of the human microbiome will result in novel microbiome-related diagnostics and clinical interventions.

Immunoassays for Diagnosis of Infectious Diseases*

ELITZA S. THEEL, A. BETTS CARPENTER, AND MATTHEW J. BINNICKER

By definition, immunoassays are biochemical assays that detect the presence of an analyte, either antibody (Ab) or antigen (Ag), using labeled antibodies as the analytical reagent (1–6). Immunoassays can be adapted for detection of analytes across laboratory disciplines and are often more cost-effective than other diagnostic methods. In the clinical microbiology laboratory, immunoassays often serve as confirmatory tests, and therefore, the results are typically not intended to be used as the sole basis on which a diagnosis is made. However, for certain infectious diseases, including Lyme disease, cryptococcal meningitis, and syphilis, antibody/antigen detection by immunoassays is the primary means by which the infection is established. Due to their ease of use, rapid turnaround time, and generally high specificity, immunoassays are increasingly becoming available for point-of-care testing.

This chapter summarizes the common immunologic testing methods currently used in clinical microbiology laboratories and their application for the diagnosis of infectious diseases. The following discussion emphasizes general assay design, with important caveats relevant to test development and interpretation. While some examples relating to clinical testing are included, for an in-depth, pathogen-focused discussion, the reader is directed to the designated chapters in this Manual.

HISTORIC PERSPECTIVE ON IMMUNOASSAY DEVELOPMENT

The first immunoassays were developed in the early 1940s and were dependent on the visualization of antigen-antibody precipitation bands in various agar preparations. These types of assays, referred to as immunodiffusion assays, were able to detect milligram to microgram quantities of analyte (Table 1) (7–9). Interpretations of immunodiffusion results are notoriously subjective, requiring extensive technician expertise, and assays are labor-intensive to set up and perform. These limitations, along with concurrent improvement in antibody/antigen purification techniques and the introduction of new detection systems, brought about the development of increasingly more sensitive and objective immunoassay methods (1–3, 5, 6, 10).

The first significant improvement of the immunoassay occurred in the clinical chemistry arena in 1959. Solomon Berson and Rosalyn S. Yalow developed a novel radioimmunoassay (RIA) method for detection of human antibodies to insulin and received the Nobel Prize in Medicine in 1977 (11). Using purified antibodies linked to one of a variety of radioisotypes (e.g., $^{125}$I, $^3$H, or $^{13}$C), results from RIAs could be objectively evaluated using a scintillation counter or photographic paper. The RIA dramatically improved sensitivity and greatly expanded the repertoire of analytes available for testing (Table 1). This was also the method after which all future enzyme immunoassays were modeled. The discovery of monoclonal antibodies and the development of antibody-producing hybridomas by Kohler and Milstein in 1975 enabled the production of RIAs with improved specificity and further expanded the repertoire of analytes available for measurement (12). While among the most sensitive of immunoassay techniques, RIAs presented laboratorians with a number of significant challenges, including the needs for safe disposal of hazardous waste and well-trained, attentive laboratory technicians. Due to these concerns, the RIA detection method has subsequently been replaced by avidin-biotin detection assays, chemiluminescence immunoassays (CLAs), and other enzyme-based detection systems.

In recent years, laboratory automation has expanded into the immunoassay arena, with many tests requiring only limited technologist time. As the basic concept of the immunoassay has evolved, there has been increased utilization of different solid-phase matrices for adherence of either antigens or antibodies. While polystyrene test tubes were used as the solid-phase matrix initially, these have largely been replaced by microtiter plates. More recently, with the influx of large, complex automated systems, smaller solid-phase matrices, such as microdisks or spheres, have become increasingly popular. Collectively, immunoassay technology has significantly advanced in both the level of sensitivity of the assays and the breadth of their utilization to the point that immunoassays are now some of the most popular and widely used of all laboratory tests.

DEFINITION OF TERMS

The array of terms used for immunoassays can be a confusing alphabet soup. This chapter discusses some commonly used conventions in terminology; however, the reader may find some references in which the terms are used differently. Overall, most assays utilize the term “immuno-” coupled with a second term, which describes the type of assay or label

*This chapter contains information from chapter 5 by A. Betts Carpenter in the 10th edition of this Manual.
used. For example, immunoprecipitation is an immunoassay utilizing a precipitation reaction. RIA is an immunoassay that utilizes radioactivity as the label. The term enzyme immunoassay (EIA) is a more general term that can be applied to any immunoassay which uses an enzyme label, although EIA is often used to refer to reagent-limited, competitive-type assays. The term enzyme-linked immunosorbent assay (ELISA) can also be used as a general term for any assay utilizing an enzyme label. However, it is most often used to refer to assays in which the antigen or antibody is adhered to a solid-phase matrix and a second, enzyme-labeled antibody is used for detection; this entire method is also referred to as the “sandwich” assay. Finally, “immunometric” is a term generally referring to any reagent used in excess. For the purposes of this chapter, the term EIA is used to refer to any assay using an enzyme, while ELISA refers only to solid-phase sandwich-type assay formats.

### GENERAL CONCEPTS OF ASSAY DESIGN

#### Categorization of Serologic Assays

There are a number of ways to characterize immunoassays. One useful classification scheme stratifies assays based on the amount of available label and reagent (13). There are three major groups of immunoassays: assays that are label free, reagent excess, and reagent limited. Label-free assays rely upon the ability of antigen and antibody to bind and form a detectable agglutination or precipitation reaction. There are many classic agglutination assays used in the diagnosis of infectious disease, including the Widal test for typhoid fever and the Weil-Felix OX-K reaction for scrub typhus. Reagent excess assay formats use solid-phase, adhered antigen or antibody incubated with the sample. Subsequently, excess labeled secondary antibody is added to detect the analyte of interest. These are the most commonly employed immunoassays in clinical microbiology laboratories today. Finally, reagent-limited assays are competitive tests in which sample antigen or antibody competes for binding sites to a solid-phase reagent with an identical enzyme-labeled analyte. The level of enzyme activity is inversely proportional to the level of analyte in the sample. These competitive assays may be performed using classic RIA and EIA formats but are less often used in diagnosis of infectious disease.

Alternatively, immunoassays can be categorized as either heterogeneous (solid-phase assays) or homogeneous (free-solution assays) (1, 3). Heterogeneous assays require the separation of bound from free components, whereas homogeneous assays do not require this separation step. Therefore, heterogeneous assays involve some type of solid phase (e.g., microtiter plate or polyacrylamide bead) to which the immunoreactants are attached. This is in contrast to homogeneous reactions, which occur free in solution and are most often applied for detection of drugs or hormone levels in clinical chemistry laboratories. While the aforementioned classification schemes are useful and can be applied to commonly used immunoassays, the reader should be aware that not all immunoassays strictly fit into either category.

### Determination of Assay Performance Characteristics

When choosing an assay for use in the clinical laboratory, it is critical to understand the concepts of sensitivity, specificity, and predictive values (6). The sensitivity of an assay is defined as the proportion of individuals with the disease that are correctly identified by the particular test of interest; these are the true positives (TP) (Table 2). Conversely, false negatives (FN) are the patients with the disease whose condition is not detected by the test. Formula to determine assay sensitivity is as follows: sensitivity = [TP/(TP + FN)] × 100. The specificity of an assay is defined as the proportion of individuals without the disease that are correctly classified; these are the true negatives (TN). False positives (FP) are the proportion of patients without disease who test positive. The formula to determine the specificity of an assay is as follows: specificity = TN/(TN + FP) × 100. Clinical tests that show high sensitivity ensure that the majority of individuals with the disease will be detected, and thus the number of false-negative results is very low. In contrast, a highly specific test indicates that the majority of individuals without disease will test negative, so the number of false-positive results will be low. When an assay is developed, the diagnostic cutoffs for a positive or negative result can be modified to alter both the sensitivity and the specificity. For example, if one lowers the cutoff, assay sensitivity will increase, with a corresponding decrease in specificity. The gain in sensitivity at the cost of specificity (or vice versa) must be weighed for each individual assay, as optimization of these components will depend on many factors, including (i) disease prevalence in the test population and (ii) whether the test is a screening or diagnostic assay. Finally, it is important to note that when we discuss sensitivity and specificity of an assay compared to a “gold standard” laboratory method, we refer to analytical sensitivity and specificity, which is not the same as clinical sensitivity and specificity. Determination of the clinical performance characteristics requires comparison of assay results to a patient’s clinical diagnosis. Unfortunately, this is not always feasible for the laboratory to determine, and close collaboration with health care providers may be necessary.

The probability of having the disease, given the results of a test, is called the predictivity value of the test. The positive predictive value (PPV) determines the percentage of patients with positive results who have the disease (PPV = [TP/(TP + FP)] × 100), while the negative predictive value

These cells utilize membrane-bound immunoglobulin (Ig) molecules, or antibodies, to recognize a wide array of antigens, which in the case of microbial agents are often expressed on the pathogen surface. Based on their electrophoretic mobility patterns, five different immunoglobulin classes have been identified (IgA, IgD, IgE, IgG, and IgM), though the infectious disease serology field focuses primarily on detection of IgG-, IgM-, and, in some cases, IgA-class antibodies.

The section of the antigen bound or recognized by the antibody is referred to as the “epitope,” and the strength of the antibody-epitope interaction is termed “affinity”; the higher the affinity, the stronger the antibody-epitope bond. Following primary exposure to a novel antigen, immature B lymphocytes are stimulated and differentiate into either plasma cells, which secrete soluble antibody, or resting memory B cells. Due to their prior priming, upon subsequent exposure to the same antigen, resting memory B cells rapidly transition to plasma cells and produce specific antibody much sooner than during the initial exposure. Furthermore, repeat exposure to an antigen leads to an increase in strength of the antibody-epitope bond, a phenomenon called “affinity maturation.” The strength of the antibody-antigen bond is also dependent on the number of antigen binding sites per immunoglobulin (i.e., in IgG, 2 sites; in polymerized IgA, 4 sites; and in IgM, 10 sites), and therefore, the total strength of the complex is much greater than the affinity of a single interaction. This is called “avidity.” Just as with affinity maturation, there is an increase in avidity with additional exposure to an antigen. For example, upon initial interaction with an antigen, IgG avidity is low; however, upon secondary exposure, IgG avidity increases. Measurement of the avidity index can therefore be used as an aid to determine the stage of infection.

There are four phases of antibody response following initial exposure to an infectious agent (i.e., the primary antibody response): (i) an initial lag phase, when there is no antibody detected; (ii) a log phase, when the antibody titer increases in a logarithmic fashion; (iii) a plateau phase, in which the amount of antibody stabilizes; and (iv) a decline phase, during which time the antibody is cleared or catabolized. The actual time course and ultimate maximum antibody titer depend on the antigen and the individual host. The period after initial exposure but before antibody is produced or is at sufficient levels to be detected is called the “window period,” which can vary from as short as 7 days to as long as 6 months, depending on the infectious agent and the patient’s immune status. During a primary exposure, the initial antibody response begins with the production of IgM, which typically appears 7 to 10 days postinfection. IgG antibody production begins approximately 10 days after exposure; however, detectable levels are often much lower than those of the IgM response. Typically, as the IgM antibody level decreases, the IgG level will increase so that by the end of the second to third month, only IgG-class antibody is detectable. If there is a repeat exposure with the same infectious agent, the Ig response kinetics is markedly different: the lag phase typically lasts only 1 to 3 days, and IgG-class antibodies are the primary isotype produced. In the months following antigen exposure, the IgG levels will plateau, at which point the antibody may remain detectable for life, even in the absence of subsequent exposure to the antigen.

Although there is exquisite specificity in the antigen-antibody reaction, a spectrum of antibodies with various affinities and avidities to multiple different antigens can be produced. It is these lower-specificity antibodies that are primarily responsible for the cross-reactions seen between
assays aimed at detecting Ig against closely related microorganisms. Recognition of cross-reactivity is critical in infectious disease testing, as organisms within the same genus, yet causing different disease manifestations, may share multiple antigenic determinants that can potentially lead to nonspecific results. Although current assays are designed to help obviate these problems, laboratorians and clinicians should remain cognizant of the potential for cross-reactivity.

**Specimen Requirements**

Traditionally, the term “serologic assay” has been applied to the use of serum or plasma samples for the detection of antibodies to various infectious disease antigens. This concept has broadened over time and currently refers to the detection of antibody or antigen in a variety of patient sample types, including cerebrospinal fluid (CSF), urine, and other body fluids. While molecular techniques and mass spectrometry (and in the future, microbiome and genomics applications) have dramatically altered the diagnostic field, there remain multiple clinical scenarios in which serological assessment is not only advantageous but also the diagnostic method of choice. Serologic assays are particularly useful for the identification of microbial agents that cannot readily be cultured or when antimicrobials have been administered prior to sampling, which can potentially delay or inhibit organism growth. In these scenarios, determination of antibody titers or detection of antigen can often provide a rapid diagnosis. Furthermore, many of these assays serve as the diagnostic tool, without the requirement of confirmatory testing or microorganism isolation, particularly if an antigen test is positive. A common example is the diagnosis of group A beta-hemolytic streptococcal pharyngitis. If the rapid immunoassay for the detection of the group A streptococcal (GAS) antigen is positive, treatment can be instituted immediately. Only if the rapid antigen test is negative is it necessary to perform a culture, though this is recommended only for children and adolescents (22).

**Use of Serologic Analysis as a Measure of Protective Immunity**

In general, a positive IgG titer is indicative only of exposure to a particular infectious agent at some time in the past. While the following discussion will use the term “immune,” this does not necessarily mean that the level of antibody is protective against reinfection. The actual amount of antigen-specific antibody present in the serum of a particular individual is host determined and is controlled by immune response genes, which are products of the human histocompatibility system. For each infectious agent, the positive/negative cutoff for the serologic assay is usually determined such that a positive result is the minimum amount of IgG antibody present to consider the individual immune. However, this level may not always correlate with the actual level required for protective immunity in each individual.

**Use of Serologic Analysis as a Measure of Recent versus Remote Infection**

A single IgM or IgG serum result should not be used to determine the stage of infection (i.e., acute versus past). While it may be tempting to consider a high IgG titer as indicative of recent infection, antibody levels are largely host specific, and some antigens are more effective than others in stimulating the immune system. Furthermore, the ability of the immune system to respond to antigens can also be affected by a variety of other host factors, such as age, genetic disposition, and comorbidities (18, 19). Ultimately, single-time-point antibody testing typically indicates only that the individual is a high responder to that particular antigen and confirms prior exposure to the infectious agent. There are, however, several ways to differentiate between recent and remote infection using serologic methods.

**IgM-Class Antibodies**

Perhaps the most frequently used method is measurement of IgM-class antibodies specific to the infectious agent. While a positive IgM result to a particular organism is considered evidence of an active (i.e., recently acquired) infection, cautious interpretation is required for certain pathogens, as IgM levels may persist beyond the acute stage (i.e., for months to years following infection). This phenomenon has been described for various organisms, including cytomegalovirus, *Mycoplasma pneumoniae*, hepatitis A virus, *Toxoplasma gondii*, and *Borrelia burgdorferi* (17, 23–25). Conversely, a negative IgM titer does not immediately exclude a recent exposure. It may take 1 to 2 weeks for IgM-class antibodies to develop, and therefore, if a sample is drawn too early in the clinical course, a second specimen may be needed.

**Significant Change in Antibody Titers**

A second technique used to establish the presence of primary infection is to determine acute- and convalescent-phase titers. This requires drawing two serum samples: the first being collected soon after exposure to the infectious agent and the second being collected 2 to 3 weeks later. Evidence of an acute infection is confirmed if there is at least a 4-fold increase in antibody titer between the first and second collections. Drawbacks to this practice include the requirement for multiple return visits and a significant delay between onset of symptoms and confirmation of disease, thus obviating its use for early clinical management. Furthermore, false-negative results are not uncommon in serum samples collected early in disease. Therefore, the diagnostic criteria may include seroconversion (conversion from negative to positive) between acute- and convalescent-phase serum samples. Based on these caveats, serologic testing should not be relied upon for a primary diagnosis in the acute phase of most infectious diseases. Molecular techniques, such as polymerase chain reaction (PCR) and culture-based detection with identification by methods such as mass spectrometry, are the preferred diagnostic methods for early clinical management. The identification of certain microorganisms, however, including those which are not readily detected by molecular methods or easily cultured (e.g., *Leptospira* species, *Treponema pallidum*, *B. burgdorferi*), relies heavily on serologic evaluation.

**Avidity Testing**

Duration of infection can also be determined by measuring the avidity level of IgG-class antibodies for certain diseases (24, 26, 27). Generally, IgG antibodies produced early in infection display low avidity, which subsequently increases with prolonged exposure to the agent. Use of an avidity assay, in conjunction with assessment for the presence of IgG and IgM antibodies, can provide a clearer indication of infection state. Avidity tests are performed by using a standard EIA (defined in detail below); however, samples are tested in duplicate with and without the addition of an IgG dissociation agent (usually high concentrations of urea). Low-avidity antibodies readily dissociate from the antigen in the presence of urea and are removed during subsequent wash steps, whereas high-avidity antibodies remain bound to the antigen despite the presence of urea. Avidity is subsequently estimated by comparing the levels of IgG in treated versus untreated samples. Determination of IgG avidity can
be particularly useful during evaluation of pregnant women for exposure to pathogens associated with pre- and perinatal infections, including toxoplasmosis, rubella, and cytomegalovirus (24, 26). For example, if a pregnant woman presents with symptoms consistent with toxoplasmosis and initial IgG screening results are positive, IgG avidity testing may be recommended. If IgG avidity is high, an acute infection may be ruled out. Alternatively, if the IgG avidity is low and subsequent IgM testing results are positive, acute T. gondii infection can be suspected. Despite the potential utility of avidity testing, certain caveats remain. Importantly, low avidity does not guarantee recent infection, as low-avidity antibodies may persist for months to years depending on the infectious agent and the host immune system. Additionally, few avidity assays are currently FDA approved, and variability in testing may occur due to differences in the applied dissociation agents and the types of reagents used.

**Quantification of EIAs**

At present, many immunoassays report results as absorbance values, optical densities, or international units, making it problematic to apply the concept of a 4-fold increase in titer as discussed above. While it is possible to develop an approximate equivalency between titers and absorbance values, this has to be determined individually for each assay. One method involves collecting multiple pairs of acute- and convalescent-phase reference sera, the titers of which are determined using traditional methods (e.g., immunofluorescence assays). These are subsequently tested by the EIA for the agent in question, and the previously determined titers are compared to the reported EIA value. Assuming that the EIA is linear over the reportable range and that it is able to provide distinct absorbance values between acute- and convalescent-phase sera, this technique can theoretically provide an adequate method to evaluate acute- and convalescent-phase titers.

However, this approach is not commonly performed in clinical laboratories for a number of reasons. First, establishment of the EIA reference range has to be performed separately for each individual assay, which can be both cost-prohibitive and time-consuming. Second, this approach requires access to multiple sets of positive acute- and convalescent-phase paired sera for each organism tested, which may be quite difficult to obtain. Finally, depending on the EIA used and the range of the standard curve, titers may not easily be converted into equivalent and meaningful absorbance values. Therefore, considering the challenges associated with this type of analysis, conversion of titer results to EIA values is generally not recommended. Instead, evaluation for the presence of acute infection should be performed by testing for IgM-class antibodies, by demonstrating seroconversion of IgG-class antibodies, by determining IgG avidity, or, preferably, by direct detection of the organism through molecular and/or culture-based methods.

**SPECIFIC IMMUNOASSAYS**

The spectrum of immunologic assays is discussed in detail in the following sections. Table 1 lists selected assays in order of relative sensitivities and provides approximate levels of detection.

**Precipitation Reactions**

The interaction of soluble antigen and antibodies is best described by a precipitin curve (Fig. 1). When the concentrations of antigen and antibodies are equimolar (i.e., in the zone of equivalence), they bind and form an insoluble antigen-antibody lattice, which can be visualized as a precipitate by a number of different techniques (3, 4). The formation of stable antigen-antibody lattices is less efficient on either side of the zone of equivalence when either antibodies (i.e., prozone) or antigen (i.e., postzone) is in excess. Passive immunodiffusion is the simplest of the precipitation assays and involves placing immune reactants (i.e., antibody and antigen) together in an inert semisolid medium (i.e., agarose gel) and viewing it for the formation of a precipitin band. Antigen and antibody will passively diffuse at a rate dependent on their size, room temperature/humidity, and gel viscosity; this often requires overnight incubation, but the turnaround time can be reduced by the application of an electric current (i.e., immunoelectrophoresis).

There are several variants of the immunodiffusion technique. The Oudin immunodiffusion assay is a single-dimension test in which antibodies are added to liquid agarose, which is then allowed to solidify in a test tube. Antigen is subsequently added to the top of the gel and allowed to diffuse until a precipitin band is formed. Radial immunodiffusion is a modification of the Oudin assay and designed to provide antigen quantification. The antibody-agarose mixture is allowed to solidify in a petri dish instead of a test tube, and antigen is added to a center well and diffuses out radially. The diameter of the resulting precipitin band is compared to the diameters from known antigen concentrations, and the final amount of antigen is quantified. Among laboratories that maintain immunodiffusion protocols, double immunodiffusion, or Ouchterlony analysis, is most common. In this method, immune reactants, typically patient serum and pathogen-specific antigen, are placed in separate wells in an agarose gel and both are allowed to diffuse. At the zone of equivalence, the precipitation line becomes visible, an example of which is shown in Fig. 2.

Overall, immunodiffusion reactions have excellent specificity (some approach 100%), are inexpensive and simple to perform, and can be adapted to a variety of health care settings. Currently, however, these methods are maintained primarily at large hospitals and public health and reference laboratories due to the expertise required to accurately interpret the results. At these facilities, immunodiffusion is most commonly used for detection of antifungal antibodies (e.g., to Coccidioides immitis/Coccidioides posadasii, Histoplasma capsulatum, Blastomyces dermatitidis, and Aspergillus spp.). There
are, however, important limitations to immunodiffusion. First, immunodiffusion generally demonstrates low sensitivity, as microgram quantities of antibody are required for a positive reaction. To overcome this challenge, immunodiffusion assays are performed alongside complement fixation tests (see below). Second, immunodiffusion methods require large amounts of purified antigen, which, depending on the pathogen, may be difficult to acquire from commercial vendors. Third, the interpretation of results can be subjective, and the turnaround time varies from 24 to 48 h. Due to these challenges, smaller clinical laboratories are commonly converting from immunodiffusion assays to rapid, automated enzyme immunoassays.

**Agglutination Reactions**

Agglutination reactions utilize a particulate, insoluble antigen, in contrast to precipitation reactions, which are based on the interaction of soluble antigen and antibodies. Binding of the particulate antigen and the corresponding antibody results in visible clumping and a positive agglutination reaction (3–5, 28). Many varieties of agglutination assays exist and can be classified based on the type of particle to which the antigen or antibody binds. Direct agglutination reactions involve antigens found on naturally occurring particulates (e.g., whole bacterial organisms and red blood cells [RBCs]). This class of agglutination assay continues to be performed for rare pathogens, including Francisella tularensis and Brucella species, by utilizing an inactivated, whole organism mixed with patient sera. Alternatively, indirect or passive agglutination assays utilize antigen coupled to particles or beads composed of an inert material (e.g., latex, colloidal gold, gelatin, or silicates). Indirect agglutination assays are often preferred over direct agglutination reactions due to the enhanced visibility of positive reactions. Finally, soluble antigen can be detected in a patient sample by incubation with antibody-coated particles; this is termed reverse passive agglutination.

IgM-class antibodies are several hundred times more efficient at agglutination than IgG antibodies due to their large pentameric structure. Therefore, if the immune response involves primarily IgG-class antibodies, the reaction may require some type of chemical enhancement or an antiglobulin reagent to bind to the Fc portion of IgG antibodies and enhance their precipitation (Coombs’ test) (29).

Agglutination assays that employ RBCs are termed hemagglutination assays and can be designed in a direct or an indirect format. Direct agglutination of RBCs is commonly used in blood banking for ABO blood group typing. For infectious disease testing, one of the most frequently ordered direct hemagglutination assays is the monospot test. This test detects the presence of heterophile antibody, produced during the early stages of infectious mononucleosis caused by Epstein-Barr virus (EBV). More recently, multiple assays have become available for detection of heterophile antibodies to EBV using indirect hemagglutination assays in which antigen is adsorbed to latex or polystyrene beads. The indirect hemagglutination reaction is a popular assay format due to its improved sensitivity and ease of performance without the need for sophisticated equipment. For these reasons, these assays have been used in many developing countries for testing of a variety of infectious diseases, including human immunodeficiency virus (HIV), hepatitis viruses (A, B, and C), and T. pallidum.

Viral serology uses a unique type of hemagglutination assay, termed hemagglutination inhibition (HI), to detect and quantify anti-influenza virus antibodies. Certain viruses, including influenza virus, have surface proteins (hemagglutinins) that agglutinate RBCs. Taking advantage of this reaction, the HI assay can be used to detect antibodies to influenza virus by incubating RBCs with virus and serum. The presence of anti-influenza virus antibodies will inhibit RBC agglutination, indicative of a positive reaction. The viral antibody titer can also be reported as the last dilution of patient serum still able to inhibit agglutination.

Classic agglutination assays are both straightforward and cost-effective to perform and, therefore, continue to be utilized in a variety of clinical settings, including point-of-care settings. They can be performed either on a card, in a test tube, or in microtiter plates. While typically designed to provide only qualitative results, an antibody or antigen concentration can be obtained through serial sample dilutions. The major limitation to direct agglutination assays is their limited sensitivity, as they detect only microgram to milligram quantities of an analyte. Improved sensitivity can be achieved by variation of the direct agglutination method. For example, microtiter passive hemagglutination assays for infectious disease agents can achieve a sensitivity equivalent to that of a conventional EIA, with a lower limit of detection of approximately 15 to 30 μg/ml. These assays can likewise be reported as endpoint titers, with the caveat that the value has an expected variation of ±1 dilution. Therefore, a reciprocal endpoint titer of 16 is not considered significantly different from endpoint titers of 8 or 32. Finally, agglutination sensitivity may be affected by the prozone phenomenon (Fig. 1). The prozone effect refers to a lack of agglutination due to an excessive amount of antibodies in the patient sample and can readily be overcome by testing serial dilutions of the specimen (1, 3, 4).

Agglutination assays can also display limited specificity, particularly in the presence of rheumatoid factor (RF) (1, 3, 4, 30, 31). This is most commonly observed with assays using IgG-coated latex beads and has been reported as an important limitation of the latex agglutination test for cryptococcal antigen (3, 32). If the patient is known to have RF (of which the laboratory is rarely made aware), there are several measures that can be taken to overcome or identify potentially false-positive reactions. First, if a false-positive reaction is suspected, the sample result can be compared to results from a reaction using control particles coated with normal IgG. If the control reaction is also positive, indicative of a false-positive reaction, then the sample can be treated with a reducing agent, such as 2-mercaptoethanol or pronase, to inhibit RF. Alternatively, the sample can be
pretreated with aggregated IgG to remove the RF. This, however, can result in loss of antigen or specific antibodies and lead to falsely negative results. An alternate test method may be necessary to overcome challenging samples known to be positive for RF.

Complement Fixation

The complement fixation (CF) assay is based on the interaction of immune complexes with components of the classical complement pathway (4). This classic technique is a two-step process used to detect antibodies and determine an endpoint titer. Briefly, patient serum is heated (56°C for 30 min) to inactivate native complement and subsequently incubated with pathogen-specific antigen. During the incubation, Ag-Ab complexes will form if specific antibody is present in the sample. Purified complement is then added, components of which will be bound (“fixed”) by any Ag-Ab complexes in the solution. Hemolysin-sensitized RBCs are added next and act as the final indicator system. If complement was fixed by Ag-Ab complexes, the RBCs are protected from lysis and will pellet to the bottom of the reaction well following centrifugation (i.e., a positive result for the presence of antigen-specific antibodies). If, however, Ag-Ab complexes have not been formed, complement will remain active and lyse the RBCs, resulting in no cell pellet following centrifugation (i.e., a negative result).

CF assays are significantly more sensitive than agglutination, precipitation, and immunodiffusion assays and are relatively inexpensive to perform. However, they are technically demanding and have a long turnaround time, and the required reagents may be difficult to acquire. Therefore, many of these assays have been converted to EIA-based formats. However, a number of laboratories continue to use CF as a confirmatory method for a variety of infectious agents, including C. immitis/C. posadasii, H. capsulatum, adenovirus, herpesvirus, influenza virus, M. pneumoniae, and some rickettsial organisms.

Neutralization Assays

Another classic serologic technique is the neutralization assay, which can be used to detect the presence of antibody able to neutralize viral infectivity (4). This method involves mixing a patient serum sample with live virus and inoculating the solution onto a cell line or a preparation of peripheral blood mononuclear cells. The readout involves evaluation for viral replication by either observation for viral cytopathic effect or performance of an immunoassay for the increased presence of viral protein. Evidence of decreased viral replication confirms the presence of neutralizing antibody in the patient sample. Neutralization assays are often used by reference and public health laboratories to confirm presumptively positive viral serologic results. Additionally, these tests are commonly utilized to assess viral vaccine efficacy, particularly in HIV vaccine studies, in order to demonstrate that the vaccine candidate appropriately induces host antibody production (33). While relatively simple to perform, these assays have a prolonged turnaround time and require cultivation of live virus, and depending on the readout method, the interpretations of the results can be subjective. Furthermore, they can be difficult to standardize, both within and between different laboratories.

Immunofluorescence Assays

Immunofluorescence assays (IFA) use fluorescently labeled antibodies (e.g., labeled with fluorescein or phycoerythrin dyes) to detect either antigen or antibody in serum and other clinical specimens (3–5). There are two main classes of IFA: direct and indirect (Fig. 3).

Direct IFAs use fluorescently tagged monoclonal antibodies to directly detect the analyte of interest in tissue or body fluids. For example, detection of influenza virus in a nasal wash specimen begins by applying the sample to a slide, and then a fluorescently tagged anti-influenza virus antibody is laid over it. The slide is then reviewed using a fluorescence microscope and viewed at the appropriate excitation wavelength for the fluorescent tag. If the tagged antibody has bound influenza antigen present in the sample, fluorescent light will be emitted and observed by the technologist. In contrast, indirect IFAs involve a two-step process. An unlabeled target antigen, antibody, or whole-cell organism is adhered to a microscope slide. Next, the patient sample is added and allowed to incubate. Antigen-antibody complexes will form if the target analyte is present in the sample, and any unbound sample will be washed away. Fluorescently labeled secondary antibody is added, and the slide is observed using a fluorescence microscope.

In general, IFAs are inexpensive tests that are relatively easy to perform. In addition, IFA allows for localization of the analyte to a specific location in the tissue or cell monolayer, which is of particular value for histopathology studies. IFAs also allow for the determination of an endpoint titer, which can be used in some situations to determine the stage of disease or response to therapy. However, IFAs can be tedious and require the purchase of expensive fluorescence microscopy equipment. In recent years, commercially available, automated analyzers that perform IFA slide processing have been developed (34). Additionally, performance of IFAs requires well-trained, experienced laboratory personnel who are able to differentiate between background reactivity and specific fluorescence. Interpreting IFA results is
subjective, and the assays can demonstrate both inter- and intralaboratory variation in results. As with agglutination reactions, acceptable variability between endpoint titers is generally considered ±1 dilution; therefore, seroconversion or at least a 4-fold difference in endpoint titers is required for the change to be considered significant.

**Enzyme Immunoassays**

EIAs are becoming increasingly used in clinical laboratories and continue to be developed for detection of various analytes by many commercial manufacturers (1–3, 5, 6, 35, 36). The RIA has largely been replaced by the EIA in nearly all clinical laboratories, as EIAs offer comparable results without the challenges of radioactive waste disposal. The enzyme label used in EIA can be either fluorogenic, luminescent, or chromogenic in nature, and because a single activated enzyme can catalyze many molecules of the substrate, the detected signal from a single reaction is amplified, leading to sensitivities in the nanogram range. EIAs are also increasingly preferred over IFAs and agglutination reactions, as they often provide more-objective results, are readily adaptable to automation, and have a higher throughput with less technician hands-on time.

**Competitive EIAs**

EIAs can be designed as either competitive or noncompetitive assays (35). Competitive assays are commonly used to measure serum antigen levels and typically utilize unlabeled antibody bound to a solid phase. Briefly, both the patient sample containing the antigen of interest and purified, labeled antigen are added, thereby competing for the adhered antibody bound to the solid phase (Fig. 4). As a negative control, a similar reaction is set up using enzyme-labeled antigen and buffer alone. Following a washing step, the enzyme substrate is added, and the resulting color reaction is assessed. If the patient sample contains the target antigen, it will compete with the enzyme-labeled antigen for binding to the solid-phase antibody and reduce or prevent the color change from occurring. This reaction is then compared to the negative control (buffer plus enzyme-labeled antigen) to determine the specificity of the color change. For competitive assays, the amount of labeled immunoreactant detected is inversely proportional to the amount of antigen present in the sample.

Compared to noncompetitive assays, competitive EIAs often provide greater specificity, though at the cost of lower sensitivity. Competitive assays are ideal for measuring relatively small levels of analyte that can be obtained in large-enough quantities at high purity to be labeled with an enzyme. These assays generally require small amounts of antibody and, therefore, are ideal for use in systems which have a limited sample volume or antibody available.

**Noncompetitive EIAs**

Noncompetitive EIAs have become the mainstay of immunologic testing in the clinical microbiology laboratory, primarily due to their improved sensitivity compared to those of competitive assays. A variety of solid-phase supports can be used and include microtiter plates, nitrocellulose strips, and polystyrene beads. Reaction wells coated with purified antigen bind to specific antibodies in the sample, which will subsequently be detected with an enzyme-labeled secondary antibody (Fig. 5). To identify the specific antibody isotype (e.g., IgM, IgG), isotype-specific, enzyme-labeled anti-Ig antibodies can be used as the secondary antibody. This is perhaps the most commonly used approach for the measurement of immune status with regard to infectious agents and for autoantibody assessment. There are numerous variations of this type of assay, as the captured analyte can be an immunoglobulin, a viral protein, or any antigen with at least two epitopes. This format is often referred to as a “capture” or “sandwich” assay as the sample analyte is “sandwiched” between two antibodies.

**EIA Technical Challenges**

As with any other laboratory test, there are always factors that can affect assay performance. Immunoassays are certainly no exception and have been shown to be adversely affected more often than other routine clinical chemistry and microbiology assays (2, 6, 31, 36–40). There are various
clues that should alert the laboratory to the possibility of an erroneous EIA result, including (i) feedback from a health care provider that results do not correlate with a patient’s clinical presentation, (ii) results for a particular patient that have changed dramatically in a short period of time, (iii) a significant shift in positivity or negativity rates for the test, and (iv) an increase in run failures. These issues should prompt an investigation for potential technical problems associated with the EIA, some of which are discussed below.

**Plate Variability**

There are several issues to consider when performing sandwich EIAs using solid-phase microtiter plates (6, 35, 36). First, there can be variability between readings in adjacent wells of a microtiter plate that are inoculated with the same sample. This variability may be due to the lack of consistency during coating of the wells with capture antigen/antibody. This variability can be expressed as the well coefficient of variation (CV), which manufacturers strive to maintain between 3 and 5% for wells in the same plate. A second consideration is the “edge effect,” which refers to the variability between readings in the outer wells and those in the inner wells for the same sample in a microtiter plate. While plate manufacturing variability may be a possible cause, this occurs primarily due to temperature differences between outer and interior wells, affecting both antigen-antibody and enzyme-substrate reactions. There are several ways to minimize the impact of the edge effect, including the use of single-column microtiter strips and close monitoring of the temperature and light exposure of samples during testing.

**Hook Effect**

The hook effect refers to an unexpected fall in the amount of an analyte at the high end of the dose-response curve, resulting in a gross underestimation of the amount of an analyte. This is equivalent to the prozone effect of agglutination reactions (2, 6, 31, 36–40). The hook effect is particularly problematic in sandwich immunoassays with patient samples that contain an extremely high level of analyte. During testing, the patient sample may give a low to moderately high result when a low dilution is used; however, upon further sample dilution, the result may unexpectedly continue to increase or go beyond the reportable range. Therefore, if laboratories run samples at a single routine dilution, they should be aware of the hook effect and potentially follow up on results that are considered by health care providers to be falsely negative.

Although the explanation for this phenomenon is not completely established, many investigators feel that the hook effect is due to excess antigen, which binds up the majority, if not all, of the antigen binding sites on both bound and unbound, enzyme-labeled detector antibodies. The free-floating antigen-labeled antibody complexes are removed by washing, preventing completion of the sandwich and signal detection. Alternatively, some feel that the hook effect may arise from a combination of the presence of low-affinity antibodies unable to form the sandwich complex, inadequate washing, or suboptimal levels of labeled antibody.

Numerous suggestions regarding ways that laboratories can overcome the hook effect have been made. One obvious strategy is to run all patient samples using 2 dilutions to screen for this phenomenon. If the sample is nonreactive or minimally reactive at the lower dilution but reactive or out of range at the higher dilution, this would alert the technician to the possibility of the hook effect. Although this is an effective approach, many laboratories are concerned about the time, cost, and labor involved with running 2 dilutions for every sample. Alternative strategies to reduce the risk of the hook effect include ensuring that adequate washing is performed between all steps of the EIA, especially following the addition and incubation with each antibody. Automatic plate washers are relatively inexpensive and can simplify this task and minimize potential ergonomic consequences. Additionally, close communication with the kit manufacturers, some of whom have identified a level at which the hook effect may occur, may lessen the frequency of this problem. Also, during new-kit evaluations, it is cru-
cial that the laboratory test specimens with excess antibody levels, as the frequency of the hook effect may vary between different kits. Lastly, open dialogue with the clinician is invaluable, and laboratories are encouraged to discuss the limitations of EIAs with the direct end users, particularly in light of potential false-negative scenarios.

Antibody Interference
There are a number of endogenous antibodies in a patient’s serum that may interfere with the performance of an immunoassay (2, 6, 31, 36–40). There are multiple types of antibody interferences, which can be caused by antibodies binding to the actual analyte (e.g., antipathogen antibodies), binding to components of the detection system (e.g., anti-alkaline phosphatase), or binding to reagent antibodies (e.g., anti-immunoglobulin antibodies). The last category is the most common and involves three types of antibodies. Heterophile antibodies are the first class of these cross-reacting immunoglobulins and are characterized by their weak affinity for immunoglobulins from multiple species, without a known or obviously identifiable immunogen. Second, RF, often found in patients with connective tissue disorders, can have a deleterious effect on a variety of immunoassays, often leading to falsely positive reactions. Finally, there are various types of anti-animal antibodies, the most common of which are the human anti-mouse antibodies (HAMA), which can react with the kit-associated, mouse-derived immunoglobulins (41). A number of techniques have been developed to decrease the interference associated with these cross-reacting antibodies, including heating samples to 70°C to inactivate all antibody in the specimen or precipitation with polyethylene glycol, protein A, or protein G (42). These methods are useful only if the EIA is designed to detect circulating antigen. Close communication with the kit manufacturer is also strongly advised for troubleshooting assistance.

Measurement of IgM
Detection and quantitation of IgM-class antibodies can pose unique technical challenges (3, 6, 26, 35). The most common issue regarding detection of IgM-class antibodies is the development of falsely positive reactions, most often due to the presence of RF in the patient sample. However, false-negative results can also occur due to competitive inhibition of IgM binding in the presence of high levels of specific IgG. Initially, EIAs designed to detect IgM were developed using a standard, indirect solid-phase EIA with an immobilized antigen and an IgM-specific secondary antibody. However, these assays were fraught with both low sensitivity and low specificity.

To obviate these problems, the IgM capture assay was developed (Fig. 6). In this procedure, a polyclonal anti-IgM antibody is bound to the solid phase. Upon incubation with the patient sample, IgM is captured on the plate. The test antigen is then added, binding any specific IgM present on the plate. An enzyme-labeled secondary antibody is subsequently added, and it will bind any immobilized antigen. This assay also obviates the problems with false-negative results due to competitive inhibition, as IgG in the patient sample is removed following the first wash step. False-positive reactions may still occur, however, due to either RF reacting with the IgG conjugate or binding any antigen-specific IgG in the sample. One method to avoid this problem is to use F(ab’)_2-conjugated capture antibodies. These molecules lack the Fc portion of natural antibodies and, therefore, have minimal reaction with RF. Alternatively, the assay can be modified to a direct technique by employing enzyme-labeled antigen in the second step, thus eliminating any Ig which could bind RF. Even with these modifications, problems can still occur with borderline and slightly positive IgM results. For this reason, all IgM-specific antibody results should be evaluated with caution. As mentioned above, in certain clinical scenarios, performing an IgG avidity assay can help with the interpretation of positive IgM results.

Chemiluminescence Immunoassays
The chemiluminescence immunoassay (CLA) is a popular technique widely utilized in a variety of formats (1, 3). Chemiluminescence is defined as the emission of light
when a substrate decays from an excited state to a ground state. In contrast to fluorescence, chemiluminescence derives energy from the chemical reaction itself, most often an oxidation reaction. CLAs display the highest analytical sensitivity among immunoassays, with a lower limit of detection in the attomole ($10^{-18}$) to the zeptomole ($10^{-21}$) level. The antigen or antibody can be tagged directly with the chemiluminescent labels, or the label can be used as the substrate for an enzyme-labeled immunoreactant. Acridinium ester is the most commonly used CLA label due to its high sensitivity. Oxidation of these compounds, typically through the addition of sodium hydroxide or hydrogen peroxide, results in a burst of light that is detectable by a luminometer or by capture on photographic film. Advantages of CLA include label stability, sensitivity, and low cost. Limitations of this method include the requirement for specialized instrumentation and the potential for false-negative results if quenching agents are present in the specimen.

**Western Blotting and Immunoblotting**

Western blotting is a classic solid-phase assay in which pathogen-specific proteins (either a crude lysate or purified derivatives) are separated by denaturing gel electrophoresis and transferred (i.e., blotted) to nitrocellulose filter paper (Fig. 7). The filter paper is subsequently incubated with patient sera, and the presence or absence of antibodies specific to the separated proteins is determined using labeled secondary anti-human antibodies. Notably, most clinical laboratories forgo the initial protein separation step and purchase preblotted nitrocellulose membranes for testing. In addition, numerous platforms enabling the entire blotting procedure (e.g., washing, incubating, and developing) to be entirely automated have been developed, minimizing the amount of technician hands-on time required.

The difference between an immunoblot and a Western blot is that the protein bands on immunoblots are applied directly to the membrane, using purified or recombinant protein, and not transferred from a gel. Immunoblots offer increased specificity and clarity for interpretation, as the potential cross-reactions and background noise due to nonspecific binding are substantially reduced. Regardless of the method, blotting patterns can be read visually, using radiolabeled isotopes or using a CLA substrate, which is then developed on X-ray or photographic film. The presence or absence of a band, however, can be subject to multiple interpretations and may lead to over- or underinterpretation of results. Advances in optical scanning instrumentation which allow for a more objective interpretation of blot results have recently been made.

Western blotting and immunoblotting are most commonly used for confirmatory purposes following an initial screening assay and are typically interpreted by identifying a specific antibody banding pattern. As an example, Western blotting or immunoblotting is currently recommended as a second-tier, confirmatory assay for the presence of antibodies to *B. burgdorferi*, the causative agent of Lyme disease.

**Rapid Immunoassays**

Immunodiagnostic testing has been revolutionized with the development of rapid immunoassays for numerous analytes that were previously performed only at large reference laboratories. CLIA regulations for many of these assays are waived, and they can now be performed as point-of-care tests in as little as 15 to 30 min (4, 16, 43–49). These assays have been designed in a variety of formats and are able to detect antigen, antibody, or even products from nucleic acid amplification tests.

Among the most popular formats is the immunochromatographic method, more commonly referred to as the

---

**FIGURE 7**  Diagram of the Western blot procedure. doi:10.1128/9781555817381.ch7.f7
A lateral-flow immunoassay (LFA). This one-step assay uses a chromatographic pad with three zones: a sample application area, a conjugate pad, and the reaction area (Fig. 8). The sample (e.g., serum, CSF, and urine) is applied to the sample pad and flows laterally by means of capillary action. On the conjugate pad is lyophilized antibody or antigen (depending on the target analyte) tagged with a specific label, which generates a visible signal on the reaction region. Commonly used conjugates include colloidal-gold particles or latex beads. If present, the target analyte will bind to the conjugated detector analyte, and the resulting immune complex will migrate to the reaction pad by capillary action. The reaction area is impregnated with a secondary antibody or antigen specific to the target analyte and a control antibody specific to the conjugated analyte at two distinct locations. Capture of the immune complex leads to concentration of the detector particles and the development of a colored band at both locations, indicative of a positive reaction. The presence of a control band indicates a negative reaction, whereas the absence of a control band invalidates the test.

As variations to this assay format, systems that do not require separate venipuncture or specimen collection procedures have been designed. Often a finger stick device is combined with the one-step lateral-flow assay. Rapid assay formats have been especially useful for HIV testing and have been used extensively in testing for HIV in underdeveloped countries. More recently, LFAs have been developed for detection of bacterial, fungal, and parasitic antigens from various specimen types: Legionella pneumophila serogroup 1 (urine), Streptococcus pneumoniae (urine or CSF) or Cytomegalovirus (serum or urine) (50). Overall, rapid assays are straightforward to perform, are inexpensive, and do not require specialized instrumentation. While LFAs are considered to have lower sensitivity than conventional EIAs, some rapid assays display sensitivities approaching those of traditional assays (44). Limitations of rapid assays include the inability for automation and subjective interpretation.

Automated Technologies

With the continuous expansion of commercially available EIAs, the development and market for automated EIA analyzers have followed suit. It is beyond the scope of this chapter to provide a detailed review of the available instrumentation; however, the reader is referred to the College of American Pathologists’ website (http://www.cap.org), which provides a comprehensive, annual review of each individual, commercially available immunoassay analyzer (51). These instruments are designed as either semi- or fully automated platforms able to process samples in batches or by random access. Automated systems have been adapted to capture the analyte of interest (antigen or antibody) using a variety of solid-phase matrices, including microtiter plates, dyed polyacrylamide or polystyrene beads, magnetic beads, or solid-phase receptacles. Analyte detection can likewise vary depending on the EIA kit, which has necessitated the design of automated systems with the ability to detect colorimetric, chemiluminescent, and fluorescent end products. Currently, these instruments can run a broad range of serological assays to detect both antigens and antibodies for, e.g., HIV, hepatitis (A, B, and C), T. gondii, cytomegalovirus, rubella virus, and Chlamydia trachomatis, provided that an EIA-based kit is available. An increasing number of automated analyzers are also designed to directly interface with the laboratory information system, allowing easier result reporting while minimizing the potential error associated with manual result entry.

An exciting new area of automated immunoassay technology has been the development of multiplex immunoassay systems (52, 53). Many of these instruments combine several technologies, including chemiluminescence, fluorescence immunoassays, flow cytometry, and molecular diagnostics, to allow for rapid and simultaneous analysis of multiple analytes in a single sample. An example of this class of analyzers is the multiplex flow immunoassay, which uses microspheres as the solid-phase matrix, each impregnated with a different fluorescent indicator. The spheres are coated with a unique capture molecule (antigen or antibody) and, depending on the target analytes of interest, can be added in almost any combination to a patient specimen. Following incubation, a secondary, fluorescently labeled antibody specific to the target analyte is added and the microspheres are analyzed by flow cytometry. Each bead, and therefore the associated coating antigen, is identified through its unique dye fluorescence, and the presence of the target analyte is determined based on the presence or absence of fluorescence from the secondary antibody. Using this technology, a recent report described the multiplex detection of IgG-class antibodies to the measles, mumps, rubella, and varicella-zoster viruses in a single reaction (54). Detection of other analytes using this multiplex technology has also been reported (55–57).

A second example of a highly automated system with the potential for multiplexing capabilities is the immunopCR (IPCR) assay. This is a novel technique that combines the traditional EIA format with PCR technology (3, 10, 38, 58–65). It follows a standard EIA protocol in which the secondary antibody is directly linked to a nucleic acid tag rather than an enzyme label. The linker DNA is subsequently amplified by PCR, and the amount
of PCR product is directly proportional to the amount of target analyte present in the sample (66). This is an ultrasensitive technique, in some cases with a limit of detection in the attogram (10^-18 g) range, and has already been applied toward the detection of multiple viral and bacterial agents (e.g., HIV, rotavirus, *Staphylococcus aureus* protein A, norovirus, and Shiga toxin) (66, 67). IPCR also gained recognition for its ability to detect prion proteins, which are difficult to identify with currently available methods (39, 64). Despite the potential benefits of IPCR, many challenges with this technology must be overcome prior to its broad implementation in clinical laboratories. These challenges include issues with high background reactivity due to nonspecific interactions, the general multistep, complicated assay protocol, which may lead to performance errors, instrumentation cost, and, finally, the potential for cross-sample contamination with amplified PCR products. Development is ongoing to resolve these potential pitfalls.

**SUMMARY**

The role of immunodiagnostics in clinical microbiology is a rapidly advancing and evolving area. There has been significant progress made in the performance of serologic tests for infectious diseases, and automated platforms now allow testing laboratories to increase sample throughput. In addition, automated instruments reduce hands-on time, provide better standardization, and increase efficiency while decreasing turnaround time to result reporting. Furthermore, in the current era of cost reduction, automated instruments are more commonly being designed to process and test samples across clinical laboratory disciplines. Despite these advantages, automated instrumentation can present clinical laboratories with a number of challenges, including a high upfront purchase cost, which may be difficult to overcome in smaller laboratory settings. Additionally, some of these platforms have large footprints, and instrument errors can occur. Finally, as automated platforms continue to have more-expansive test menus, the potential for both improper test utilization and incorrect interpretation of results will likely increase. This results in an even greater need for clinical laboratories to work closely with health care providers to guide proper test utilization and provide accurate result interpretation for the diagnosis of infectious diseases.

**REFERENCES**

Health care-associated (or nosocomial) infections (HAIs) represent one of the most common complications of health care delivery, affecting an estimated 1.7 million persons admitted to acute-care hospitals in the United States each year (1). The World Health Organization reports that millions more worldwide suffer each year from infections acquired in the health care setting, estimating the pooled HAI prevalence among hospitalized patients worldwide to be 10.1% (2). Every health care facility should therefore have an infection prevention program (IPP) charged with monitoring, preventing, and controlling the spread of infections in the health care environment. Because infection prevention requires the ability to detect infections when they occur, the clinical microbiology laboratory (CML) is inextricably linked to any comprehensive IPP. In this chapter, we discuss the impact of HAIs, outline the organization of the hospital IPP, and describe the important roles of the CML in the prevention of HAIs.

HEALTH CARE-ASSOCIATED (OR NOSOCOMIAL) INFECTION

Definition
An HAI is one that is acquired in a hospital or health care facility (i.e., the infection was not present or incubating at the time of contact with the health care environment). For most bacterial infections, an onset of symptoms more than 48 h after admission is evidence for health care acquisition. To determine whether some infections, such as legionellosis, are health care associated, one must consider the usual incubation periods and determine whether the patient was exposed to the health care environment during that time period. Because hospital stays are getting shorter and more patients are being treated in the outpatient setting, many HAIs are not recognized during hospitalization or may be associated with health care environments other than acute-care hospitals (e.g., ambulatory surgery centers, dialysis, and long-term care). IPPs must therefore devise strategies for effective outpatient surveillance in order to accurately monitor HAI rates (3).

Infection Rates, Infection Sites, and Predominant Pathogens
At least 5 to 10% of patients admitted to acute-care hospitals acquire an infection during hospitalization (2, 4, 5). The urinary tract is the most commonly involved site, comprising 30 to 40% of all HAIs. Surgical wound and lower respiratory tract infections are the next most frequent, with each accounting for about 15 to 20% of HAIs, followed by bloodstream (5 to 15%) infections. The vast majority of HAIs are associated with medical devices (e.g., urinary tract catheters, endotracheal tubes in ventilated patients, and central venous catheters). For this reason, and as a way to adjust for risk when comparing rates over time or between similar units in different facilities, the Centers for Disease Control and Prevention (CDC) recommends calculating HAI rates in the intensive care unit (ICU) using device days as the denominator (see Table 1 for definitions of common epidemiology terms) (6).

Table 2 lists the five most common bacterial pathogens isolated from various infection sites in U.S. hospitals (7). However, the spectrum of organisms causing HAIs is continuously changing, and organisms may vary from region to region or even from hospital to hospital (8). From the 1970s through 2000, the spectrum of nosocomial pathogens shifted from Gram-negative to Gram-positive organisms, and Candida spp. emerged as a major problem (9). The incidence of nosocomial infections caused by staphylococci and enterococci increased as these organisms became increasingly resistant to antimicrobial agents (10, 11). More recently, multidrug-resistant Gram-negative rods (MDR-GNRs; defined by in vitro resistance to at least three of the antimicrobial classes used for treatment) have become increasingly prevalent in many hospitals (12–14). For example, 2009–2010 data from the National Healthcare Safety Network (NHSN) reveals that multidrug resistance (including carbapenem resistance) was reported in more than 60% of Acinetobacter species among most HAI types (7), and a recent CDC report documented a 4-fold increase in the proportion of carbapenem resistance among Enterobacteriaceae (CRE) in U.S. hospitals, from 1.2% in 2001 to 4.2% in 2011 (15).

Morbidity, Mortality, and Cost
HAIs cause or contribute to thousands of deaths annually (1, 2, 4). Because patients with the most severe underlying illness are also those most vulnerable to HAI, it is very difficult to estimate the proportion of crude or overall mortality that is directly attributable to HAIs. Studies that attempt to address this by carefully controlling for many potentially confounding variables are called attributable mortality studies. Estimates of the attributable mortality associated with health care-associated bloodstream infections have ranged from

doi:10.1128/9781555817381.ch8
106
14% for infections caused by coagulase-negative staphylococci (16), 31% and 37% for infections caused by vancomycin-resistant enterococci (VRE) (17, 18), respectively, and 38 to 49% for infections caused by Candida spp. (9, 19, 20) (Table 3).

HAIs also increase hospital costs and lengths of stay (LOS); a recent CDC report estimated the annual direct medical costs of HAIs in U.S. hospitals at between $28.4 and $33.8 billion (21). At the University of Iowa, the median excess LOS for nosocomial bloodstream infections caused by coagulase-negative staphylococci and Candida spp. were 8 and 30 days, respectively (16, 20). Health care-associated bloodstream infections in the ICU were associated with an excess LOS of 24 days and excess hospital costs of $40,000 per survivor (22). Kirkland found that surgical-site infections increased LOS by more than 6 days and increased hospital costs by over $3,000 per infection (23). Surgical-site infections after major orthopedic surgery (e.g., hip replacement) are associated with an even greater increase in length of stay and costs (24).

The premise upon which IPPs operate is that many of these life-threatening and costly HAIs are preventable. The landmark Study of the Efficacy of Nosocomial Infection Control (SENIC) indicated that the presence of an active IPP was associated with a 32% decrease in HAI rate, while the absence of such a program was associated with an 18% increase in HAI rate (25). During the 1990s, the CDC National Nosocomial Infections Surveillance (NNIS) system of hospitals reported a reduction in risk-adjusted infection rates in ICUs for all monitored infection sites (urinary tract, bloodstream, lung). The elements that were critical for reducing rates included targeted surveillance in high-risk populations (using standard definitions), adequate numbers of trained infection preventionists (IPs), who inform health care providers of their infection rates, and prevention efforts designed to address issues identified during evaluation of infection rates (26). More recently, hospitals using combinations (“bundles”) of evidence-based prevention strategies have demonstrated greater reductions in device-associated HAIs than previously thought possible (27, 28). For example, a collaborative study involving over 100 ICUs in Michigan demonstrated a two-thirds reduction in rates of central-line-associated bloodstream infection (CLABSI), with a reduction of the median CLABSI rate to zero among participating ICUs (27). Thus, although it is not known what proportion of all HAIs are truly preventable, an effective IPP clearly improves patient care, saves lives, and decreases health care costs.

### HOSPITAL INFECTION PREVENTION PROGRAM

#### Structure, Personnel, and Responsibility

The responsibilities of the hospital IPP include surveillance and prevention of HAIs, continuing education of medical
staff, control of infectious disease outbreaks, protection of employees and visitors from infection, and advice on new products and procedures. The program is generally directed by a physician/epidemiologist and enforced by the infection prevention committee. Every hospital must also have a working infection prevention staff, comprising one or more infection preventionists (IPs). The IPs coordinate surveillance and prevention activities, including clinical microbiology, and should meet every 1 to 3 months to review hospital-specific HAI data and to formulate policy. The members bring the needs and perspectives of their departments to the committee and, in turn, take back important information about infection prevention initiatives and policies. Other responsibilities of the committee include reviewing technical information about new products, devices, or procedures pertinent to infection prevention and instituting all necessary control measures in the event of an outbreak or other infection-related emergency.

The clinical microbiologist, or the microbiology supervisor, in an institution that does not have a doctoral-level microbiologist, is an integral component of the infection prevention team and thus must be an active member of the infection prevention committee. Because the infection prevention committee frequently bases its decisions on the results of microbiological tests, the clinical microbiologist must instruct members of the committee how to integrate culture results and which microbiological approaches can be used to solve specific infection prevention problems. The microbiology laboratory can benefit if the infection prevention staff understands the routine processes in microbiology, e.g., timelines for the processing of blood, wound, or urine cultures and related techniques (29). Specimen processing timelines enable infection prevention staff to understand various expectations of turnaround times (TATs) for specific results and time constraints of microbiology test services and can educate them as to when they can expect follow-up information for routine cultures, thus minimizing premature phone calls to the laboratory requesting culture information. Conversely, while serving on the committee, the microbiologist will learn about the problems confronting infection prevention personnel and thus will be better able to organize the laboratory’s response to such problems.

In addition, the microbiologist should inform the committee about changes in methods, reagents, or instrumentation that may substantially affect the laboratory’s ability to detect and characterize HAI pathogens. These include changes in the sensitivities and specificities of diagnostic methods and changes in antimicrobial susceptibility testing (AST) interpretive criteria, as well as taxonomic changes that may create confusion. An example of changes in testing and reporting criteria that directly affect infection prevention efforts is the recent change in the interpretive breakpoints for cephalosporins and carbapenems against the Enterobacteriaceae enated by both the Clinical and Laboratory Standards Institute (CLSI) (30) and the European Committee on Antimicrobial Susceptibility Testing (EUCAST) (31). The new (lower) breakpoints are intended to obviate the need for extended-spectrum β-lactamase (ESBL) confirmatory testing or modified Hodge testing (confirmation of carbapenemase) for clinical use. The result of this change in testing and interpretive criteria has been the loss of considerable epidemiologic data available from routine testing, as isolates with ESBL production may no longer be confirmed or flagged as such (32), and in some instances, this has led to an increase in the number of isolates characterized as resistant to these agents and therefore potentially MDR, with major implications for infection prevention (33–36). One institution recently reported that this change resulted in a 35% increase in the number of MDR-GNRs identified and a concomitant increase in the hospital’s use of contact precautions (33).

Members of the infection prevention team must communicate with each other to accomplish their goals. Communication can be enhanced if the infection prevention staff members regularly make rounds in the laboratory to ask questions, review microbiological and molecular testing results, and discuss current problems and views. Likewise, the microbiology staff should attend conferences at which infection prevention personnel discuss epidemiological principles and contemporary topics. Unfortunately, several ongoing trends challenge these valuable personal interventions between microbiology and infection prevention personnel (34). Consolidation of CML services, off-site relocation of microbiology laboratories, and total reliance on electronic medical records to the exclusion of first-hand observation (e.g., review of plates or Gram stains) too often keep clinicians and infection prevention personnel out of the microbiology laboratory and keep microbiologists confined to the laboratory.

HAI Surveillance

Active HAI surveillance programs are associated with reduced rates of infection and their consequent morbidity and mortality (25, 37); national and state accrediting agencies require hospitals to do HAI surveillance, and public reporting of certain HAI rates is now a requirement for U.S. hospitals that participate in the Medicare program (38). Thus, systematic surveillance of HAIs is the IPP’s most important activity. Surveillance is also the IPP’s most costly and time-consuming activity. Surveillance allows the IPP to monitor the frequency and types of HAIs, detect outbreaks, evaluate compliance with infection prevention guidelines, provide data for policy development, and monitor the effect of infection prevention interventions on HAI rates. To accomplish the overall goal of decreasing infection rates, the IPP must provide surveillance data to clinic units as soon as possible, accompanied by suggestions for improvement and reminders of existing infection prevention practices. IPPs can compare their hospital rates with national benchmarks compiled and reported by the CDC NHSN system (39). Figure 1 is a simple format for comparing infection rates in an ICU with national benchmark data. The IPP should provide infection rates, recommendations for reducing rates, and assistance in implementing interventions to unit personnel, such as medical directors, nurse managers, and clinicians.

The IPP should design a surveillance system that is compliant with state and federal mandates, appropriate for the specific needs of the hospital, and feasible based on their budget. Because surveillance consumes more resources than any other infection prevention activity (40), IPPs must design the most efficient surveillance system possible. The most complete and accurate surveillance program would require an IP to review charts of all hospitalized patients daily, but this approach obviously is not practical in any but the smallest of hospitals. IPPs should focus limited resources in the highest-risk areas (e.g., intensive care, hematology/oncology, burn, and organ transplant wards) and use various screening techniques to increase surveillance efficiency. IPs can use a variety of data sources (e.g., microbiology reports, nursing care plans, antibiotic orders, radiology reports, vital signs, and discharge diagnoses) to determine which charts should be further reviewed.

Review of microbiology data is probably the most common single method for case finding, and it compares favorably in some circumstances with more-comprehensive ward-based surveillance (41, 42). For example, Yokoe and colleagues reported that review of microbiology data alone was both more resource efficient than and as effective as applying the CDC’s definition of health care-associated bloodstream infection (43). Such laboratory-based surveillance allows the IP to efficiently review a large amount of data. Moreover, medical information systems can enhance laboratory-based surveillance further by linking laboratory data with data from many other sources (44, 45), including pharmacy (antimicrobial use), radiology, billing (diagnostic codes), patient census data, and nursing notes (vital signs, care plans).

Although reviewing microbiology reports is an essential part of surveillance, these data alone may not detect all HAIs or all outbreaks. The sensitivity and specificity of laboratory-based surveillance depend upon both the

**FIGURE 1** Rates of central venous catheter (CVC)-associated infection in a medical ICU (MICU). Sample chart format for reporting nosocomial infection rates in an ICU compared with CDC NHSN benchmarks. doi:10.128/9781555817381.ch8.f1
frequency with which clinicians obtain cultures and the quality of the culture specimens received by the lab. In addition, while laboratory-based surveillance may quickly detect outbreaks due to unusual pathogens, or infections at unusual sites, outbreaks or clusters due to common pathogens at common sites (e.g., Escherichia coli urinary tract infection) may go undetected for longer periods of time. An optimal surveillance program will include data from multiple sources to help IPs determine which charts deserve further review. The University of Iowa previously validated a surveillance strategy using primarily microbiology reports and nursing care plans and found the sensitivity and specificity to be 81% and 98%, respectively (46). More recently, we introduced and validated a computer-based screening algorithm that provides for each IP each day a list of all patients in their units that had specific abnormalities in vital signs or white blood cell counts, positive microbiology findings, or different combinations of tests ordered within a 24-h period (e.g., chest radiograph and culture of respiratory secretions or cultures from two or more body sites). After reviewing this list, the IPs review the medical records of a smaller percentage of patients, thereby reducing the amount of time required for surveillance.

The overall approach to surveillance in each health care facility should be monitored and adjusted by the infection prevention committee based on the types of patients treated, the procedures performed, the resources available for surveillance, prevailing infection rates, state and federal mandates, and other factors. The surveillance approach should be re-evaluated each year during an annual risk assessment performed by the IPP and approved by the infection prevention committee. In addition, the infection prevention committee, in consultation with CML personnel, should decide the mechanism by which the CML provides specific information needed for surveillance (e.g., all positive results and selected or sorted reports).

Increasing public disclosure of HAI rates (38, 47–50) and increasing pressure for hospitals to demonstrate reductions in HAIs have important implications for surveillance. If interhospital comparisons of HAI rates are to have any meaning, all hospitals must use the same methods for surveillance and risk adjustment (47, 49) and HAI definitions must be as objective as possible so that they are not subject to “gaming” (38). Unfortunately, methods for HAI surveillance vary widely among hospitals, and validated methods for risk-adjusting rates are not available (51). So although public disclosure of HAI rates is a laudable goal and is now reality in the United States, much work needs to be done to ensure that such reporting improves, rather than hinders, efforts to prevent HAIs (48, 52).

Process Surveillance
Several recent studies clearly demonstrate that implementing evidence-based infection prevention practices, such as good hand hygiene (53, 54), and the guidelines for placement and care of central venous catheters (27, 55) can dramatically reduce HAI rates (27, 54). The obvious implication of these studies is that health care workers do not routinely adhere to the safest processes of care. For this reason, IPs must perform surveillance not only for important outcomes (infections) but also for important processes (e.g., rates of hand hygiene performance, use of maximal sterile barriers during central venous catheter placement, and elevation of the bed of the bed to 30 degrees for ventilated patients). Process measures can help infection prevention personnel understand some of the variation in HAI rates.

In addition, reporting adherence rates to personnel may improve practice and reduce HAI rates.

Antimicrobial Stewardship
Every hospital in the United States must now have an antimicrobial stewardship program (ASP), guidelines for which have been published by the Infections Disease Society of America (IDSA) and the Society for Healthcare Epidemiology of America (SHEA) (56). Antimicrobial stewardship efforts are directly dependent on reports from the CML, so good communication between the laboratory, pharmacy, infection prevention personnel, and a stewardship team is essential. For guiding empirical antimicrobial therapy, unit-specific and tailored antibiograms should be updated on a regular basis and provided to clinicians for use at the bedside. Such antibiogram data can also be used for evaluation of trends in important antimicrobial resistance rates and for education of clinicians regarding optimal antimicrobial use. Directed antimicrobial therapy requires patient-specific culture and susceptibility data. This allows for a prospective audit of antimicrobial use with feedback to the prescriber.

A major challenge to effective stewardship is the ability to obtain antimicrobial susceptibility data from the laboratory in a timely and efficient manner. Efforts to reduce the analytical turnaround time are helpful; however, the data must then be incorporated rapidly into antimicrobial management. The task of the ASP is made considerably more difficult if laborious chart reviews are required for each patient on antimicrobial therapy. The use of a computer decision support system can streamline this process by automatically analyzing patient data from multiple sources (pharmacy, laboratory, electronic medical record, unit census) and generating a variety of alerts for the ASP (e.g., bug-drug mismatch, allergy, drug interactions, duplicative coverage, and the opportunity to convert from intravenous to oral drug administration) (57, 58). One ASP projected that a computer decision support system could save the institution over $600,000 annually compared to the ASP without the decision support system (58).

ROLE OF THE CML IN INFECTION PREVENTION
With this overview of the structure and activities of the hospital IPP in mind, we will now focus on the most important specific roles played by the CML in the day-to-day practice of infection prevention.

Specimen Collection and Transport
Many HAI pathogens (e.g., coagulase-negative staphylococci) also commonly colonize patients’ skin or mucous membranes and can easily contaminate cultures if specimens are not collected or handled properly. If contaminants are mistakenly considered to be infecting organisms, IPs may inadvertently count these as HAIs, thereby inflating the infection rates (29, 59, 60). Consequently, the laboratory must provide guidance for acceptable collection and transport of clinical specimens (see chapter 18). Enforcement of rejection criteria and a quality assurance program with monitors for blood culture contamination rates and specimen transport time help to optimize the preanalytical phase of testing.

Accurate Identification and Susceptibility Testing of HAI Pathogens
Commercial identification and susceptibility testing systems allow most laboratories to identify microorganisms to the
species level and to perform antimicrobial susceptibility testing (AST) (see chapters 4 and 72). However, the expanding spectrum of organisms that colonize and infect seriously ill patients challenges the ability of the CML to identify and characterize HAI pathogens accurately. Consequently, the laboratory frequently must update the methods used to identify and characterize HAI pathogens. For example, the introduction of matrix-assisted laser desorption ionization–time of flight mass spectrometry (MALDI-TOF MS) as an identification method provides the opportunity for more precise (and more rapid) characterization of some previously difficult to identify HAI pathogens (see chapter 4).

The degree to which organism identification is routinely conducted can be important to HAI control efforts. Infection prevention involves a constant search for evidence that a common organism has spread from patient to patient (34, 61). The ability to detect such events is enhanced by identifying the organism to the species level. Laboratories that identify HAI pathogens to the species level may find outbreaks that would otherwise have gone undetected because clusters of unusual organisms or unusual clusters of organisms may be clues to outbreaks. Furthermore, incorrect or incorrect identification of organisms may obscure real problems and make retrospective epidemiologic investigation impossible. For example, a report of the “Klebsiella Enterobacter group” fails to distinguish between two genera (Klebsiella and Enterobacter) that may have different epidemiologic patterns of infection within the hospital.

Unusual microorganisms, or common microorganisms with atypical phenotypic properties, often cannot be reliably identified by commercial systems and may require the use of molecular or proteomic methods to obtain an accurate identification. As pathogens continue to evolve and taxonomic classifications are revised, microbiologists must pay attention to the manufacturers’ communications about products, such as letters, notices, or test exclusions regarding the accuracy of the test methods, as well as the published literature describing the potential problems encountered by others using these identification systems. Prompt notification of infection prevention personnel of such issues will avoid confusion.

New antimicrobial resistances continue to emerge, and existing resistances are increasing in frequency. To guard against significant AST errors for some organism-antimicrobial combinations, laboratories must supplement automated systems with other methods (see chapters 70 to 73). AST errors are most likely for organisms that display heteroresistance, inducible resistance mechanisms, or mechanisms for newly emerging resistance. For example, automated systems did not perform well in the detection of vancomycin resistance in staphylococci or of carbapenem resistance among Klebsiella species when these phenotypes first emerged (62, 63), necessitating the use of additional or confirmatory test methods. If the laboratory uses methods that do not accurately identify organisms or particular resistance patterns, the infection prevention program may not identify serious problems or even outbreaks. Conversely, infection prevention personnel may investigate spurious problems, thereby diverting and wasting precious resources. The CLSI M100 document provides an important annual update to guidance regarding susceptibility testing methods and evaluation of unexpected susceptibility results (30).

Laboratories that recognize problems with commercial automated AST or identification systems should bring them to the manufacturers’ attention so that they can improve the instrumentation, panels, or software programs to improve accuracy. This process of ongoing independent evaluation of automated systems and feedback to responsive industry representatives is extremely important. Unfortunately, in an era of shrinking laboratory resources, fewer laboratories have the ability to perform rigorous internal evaluations of new technology. The most important resistances emerging in nosocomial pathogens include those to ESBLs (most notably the carbapenemases) among Enterobacteriaceae (15, 64), to vancomycin among enterococci (10) and Staphylococcus aureus (65–67), to methicillin in S. aureus (68), and to multiple drugs among nonfermenters, such as Pseudomonas aeruginosa, Acinetobacter spp., and Stenotrophomonas maltophilia (69).

The infection prevention program must implement measures to prevent the spread of important multidrug-resistant organisms (MDROs), and the CDC has published a comprehensive guideline to assist in this effort (70). However, the success of any program to control MDROs depends upon the ability of the laboratory to detect these organisms. Laboratory directors must read current literature regarding automated systems’ ability to detect emerging resistances and implement if necessary additional methods to detect or confirm particular resistance patterns. The CDC website provides fact sheets summarizing current recommendations for detecting these resistances (http://www.cdc.gov/HAI/settings/lab/lab_settings.html). They are also reviewed in chapters 73 and 77 of this Manual.

Laboratory Information Systems

An information system that can perform prospective data mining and interface with other parts of the computerized patient record could help IPs perform surveillance, monitor patient-to-patient spread of pathogens, and detect outbreaks early (44, 45, 71, 72). Thus, persons choosing a laboratory information system (LIS) must consult with both laboratory and infection prevention personnel before purchasing the best system for the hospital.

Rapid Diagnostic Testing for Infection Prevention and Antimicrobial Stewardship

During the past decade, numerous rapid diagnostic tests that use molecular or immunologic methods have been developed. For example, a variety of methods are now available for rapid detection of respiratory viruses (73), Clostridium difficile (74), Mycobacterium tuberculosis (75), and Legionella pneumophila serogroup 1 (76). Rapid methods for detecting important antimicrobial resistances have also been developed, with most of the current focus being on rapid detection of methicillin-resistant S. aureus (MRSA) and vancomycin-resistant enterococci (VRE), with increasing need for rapid and accurate detection of the MDR-GNRs (77, 78). A positive result from any of these tests may allow for early intervention to improve infection prevention (e.g., earlier implementation of appropriate isolation precautions to prevent the spread of MDROs or faster investigation and mitigation of health care facility water sources to curb Legionella transmission).

Of course, if clinicians order the tests indiscriminately or the laboratory has poor quality control, rapid diagnostic tests can lead to errors, including falsely positive tests that lead to inappropriate treatment and isolation of the patients. Erroneous results may also cause the infection prevention program to waste time investigating a pseudo-outbreak (79).

As mentioned previously, more-rapid detection of pathogens (and their susceptibility patterns) is also critically important to good antimicrobial stewardship (80). Specific approaches to more-rapid detection of organisms and their
resistance determinants are discussed in chapters 4 and 70 to 77 of this Manual.

Reporting Laboratory Data to the Infection Prevention Program

Culture and AST results are an important data source for infection prevention and are usually reviewed daily by IPs. Thus, routine microbiology laboratory results should be readily accessible to IPs. In addition to having microbiology data available in real time, both clinicians and IPs benefit from periodic summaries of selected microbiology results, such as an antibiogram specifically for HAI pathogens. These results can be presented in a table that includes the antibiograms of the most common HAI pathogens by anatomical site and hospital service and also includes antimicrobial cost information. This information will help clinicians choose empirical antimicrobial therapy for patients with health care-associated infection. The CLSI has developed guidelines for antibiogram preparation (81).

Outbreak Recognition and Investigation: Epidemic versus Endemic Infections

Most nosocomial infections are not associated with outbreaks; they are endemic rather than epidemic infections. If HAI rates are consistently defined by prospective surveillance, infection prevention personnel may occasionally identify HAI outbreaks—increases in rates of infection beyond the expected during a defined time period—by reviewing these rates. However, more often, infection prevention personnel learn about potential outbreaks while interacting with personnel on the ward, in clinics, or in the laboratory.

When the infection prevention team detects a cluster or outbreak of health care-associated infection, they must act promptly to identify the etiologic agent if it is not known, define the extent of the outbreak, learn the mode of transmission for the pathogen, and institute appropriate control measures. The CML must provide appropriate laboratory support during this time. Table 4 outlines recommended steps in an outbreak investigation and points out the important role of the CML at each step.

Because the demands on the laboratory may be great during outbreaks, the laboratory staff should prepare in advance. Laboratory personnel should ask IPs what types of outbreaks have occurred in the past or can be anticipated in the future and what laboratory resources would be required should similar outbreaks occur. Laboratory staff should also anticipate the extra costs associated with outbreak investigations so that they can work with hospital administrators to include funds for these efforts in annual budgets. Costs should not be borne by the laboratory or charged to individual patients involved in the outbreak.

Some problems and potential pitfalls of outbreak investigation are pertinent to the CML and bear specific mention. Foremost among these is the problem of determining when to proceed with an outbreak investigation in the first place. The number of cases necessary to constitute an outbreak depends upon the organism, the patient population, and the institution involved. For example, while numerous cases of Escherichia coli urinary tract infection in a long-term care facility may not constitute an outbreak, even a single nosocomial case of group A streptococcal surgical-wound infection or VRSA infection merits an outbreak investigation. Laboratories should consider implementing computer decision support systems that recognize clusters of pathogens within the hospital (82, 83). Organisms that appear to be part of a cluster could be further characterized to evaluate whether they are genetically related, which would suggest patient-to-patient spread or exposure to a contaminated common source. Investigators at the hospital of Northwestern University implemented such a system and noted that their rates of HAIs decreased in temporal association with this intervention (82).

A second important problem is that of a pseudo-outbreak. A pseudo-outbreak has occurred when an apparent outbreak turns out not to be an outbreak after all. The usual cause of a pseudo-outbreak is either misdiagnosis (e.g., infection has not actually occurred) or misinterpretation of epidemiologic data (e.g., infections have occurred but clustering or epidemic transmission has not). The microbiology laboratory can be the source of pseudo-outbreaks (84–90). Problems in the laboratory that lead to pseudo-outbreaks include contamination of reagents for stains (85), false antimicrobial susceptibility test results (84), and contamination of culture specimens (often from construction or renovation projects [87] or cross-contamination during specimen processing [90]). Careful attention to quality control, sterile techniques in specimen processing, and preventive measures during construction and renovation projects can decrease the likelihood of pseudo-outbreaks that originate in the laboratory.

Molecular Typing to Support Infection Control Activities

Outbreaks of nosocomial infection often result when hospitalized patients are exposed to a common source or a reservoir of a pathogenic agent (e.g., water from a hot water tank colonized with Legionella spp.). The organisms causing such outbreaks usually derive from a single strain (i.e., they are clonally related). The infection control program may, therefore, request that the microbiology laboratory characterize isolates that may be associated with outbreaks to determine whether they are genetically related. In the appropriate clinical setting, species-level identification and AST results (antibiogram) may provide strong evidence for an epidemiological link. However, more-sensitive methods
of strain delineation are often necessary. In this setting, genotypic or DNA-based typing methods have replaced phenotypic typing methods (e.g., AST, biochemical profiles, bacteriophage susceptibility patterns), which discriminate poorly among isolates (91, 92).

Genotypic typing methods provide meaningful data and are cost-effective only when they are used for well-defined epidemiologic objectives. These objectives include (i) determining the source and extent of an outbreak, (ii) determining the mode of transmission of HAI pathogens, (iii) evaluating the efficacy of preventive measures, and (iv) monitoring transmission of pathogens in high-risk areas (e.g., intensive care units), where cross-infection is a recognized hazard.

The ideal genotypic typing system should be standardized, reproducible, stable, sensitive, broadly applicable, readily available, and inexpensive. The typing method should also have proven value in previous epidemiologic investigations. Further discussion of the relative advantages and disadvantages of the many available typing systems is beyond the scope of this chapter, and the discussion has been summarized in published reviews (91, 92) and in chapter 10 of this Manual.

Organism Banking and Storage
Of course, the CML cannot provide the infection prevention program with supplemental testing, such as molecular typing, if the appropriate isolates have not been saved. The laboratory should plan ahead and be sure to save all epidemiologically important isolates (see chapter 11). Laboratory and infection prevention personnel should decide which isolates should be banked and how long they should be stored based upon their epidemiological importance and the available resources. We recommend that all isolates from normally sterile sites (e.g., blood, cerebrospinal fluid [CSF]), important MDROs (e.g., MRSA, VRE, ESBL producers, CRE) from any site, and other epidemiologically important pathogens (e.g., Mycobacterium tuberculosis) be saved for a period of 3 to 5 years.

Surveillance Cultures from Patients, Hospital Personnel, and the Environment
The clinical microbiology laboratory is often called upon to detect potential pathogens that may be colonizers of patients, health care workers, and the hospital environment. For example, several U.S. states (as well as the VA health care system) have mandated the routine use of “active surveillance and isolation” (using culture or molecular methods to identify patients that are MRSA colonized but not clinically infected, in order to place them in contact isolation and/or attempt decolonization), a process that remains controversial (93). As more-extensive experience with MRSA active surveillance accumulates, there is also interest in how best to apply active surveillance to prevent the transmission of other MDRs, including VRE and MDR-GNRs.

A major reason for careful consideration before launching into large-scale active surveillance efforts is the fact that such measures are complex and resource intensive. Indeed, the prospect of performing active surveillance cultures for a large number of diverse MDRs (which requires that culture samples be obtained from several different

*Adapted from reference 6.*
anatomic sites of each patient) threatens to overwhelm and divert the resources of CMLs, IPPs, and hospital units. In addition, recent data suggest that the “horizontal” infection prevention approaches (those approaches that target all infection types and are applied to an entire population, such as hand hygiene) are preferred over a focus on “vertical” approaches (those that target a specific pathogen, such as active surveillance of MRSA) (94). For example, a recent cluster-randomized trial demonstrated that universal decolonization of all ICU patients was more effective than active surveillance in reducing rates of bloodstream infection and positive MRSA clinical cultures (95). In our view, active surveillance culture for MDROs should be limited to (i) new introduction of problematic pathogens, (ii) continued transmission of an MDRO despite implementation of standard and enhanced IP practices, and (iii) outbreaks. In these settings, active surveillance should always be seen as an adjunct to, not a replacement for, those well-established horizontal IP practices (e.g., hand hygiene and bundled practices for prevention of device-associated infection).

Health care workers are also occasionally screened for carriage of epidemiologically significant organisms. The most common organisms for which screening is performed are the MDROs, most often MRSA, usually as one aspect of an outbreak response. Screening for other organisms (e.g., group A streptococci) may also be performed as part of an infection or outbreak investigation. Finally, hand cultures may be performed as part of educational efforts in support of a hand hygiene campaign or to confirm the mechanism of cross-infection during an outbreak investigation (96).

For some organisms (e.g., MRSA), screening methods are standardized and well established, while for others (e.g., MDR-GNRs), such methods are evolving and will continue to evolve as more-complex resistance phenotypes emerge (78). Table 5 outlines current approaches to screening patients and health care workers for organisms of epidemiologic significance (97–100).

Laboratory and infection prevention personnel should weigh two important factors before deciding to culture specimens from hospital personnel during an outbreak investigation. Finding the outbreak strain on the hands or in the nares of a health care worker does not establish the direction of transmission or definitively implicate a health care worker as the source or reservoir for the outbreak, and culturing hospital personnel indiscriminately can lead to confusing results and can generate ill will toward the infection prevention program. In general, only health care workers epidemiologically linked to cases should be cultured. We recommend that infection prevention programs obtain cultures of hospital personnel only after consulting with a hospital epidemiologist experienced in outbreak investigation.

At one time, the hospital environment was felt to be the major source of HAI pathogens. Since then, it has been recognized that patients most often acquire infection from

</table>

\(^{a}\)Such cultures should be done only for the following reasons: (i) as part of an outbreak investigation to seek carriage of an organism among patients or health care workers who are epidemiologically linked to cases, (ii) to seek carriers of MDROs as part of enhanced MDRO control strategies, or (iii) to identify S. aureus carriers in order to proceed with a decolonization strategy to decrease the risk for acquisition of *S. aureus* infection during a period of vulnerability (e.g., the perioperative period).

\(^{b}\)The “gold standard” method includes overnight broth enrichment and confirmation of species identification and antimicrobial susceptibility, which can increase the TAT to 96 h. Most conventional agar-based screens (e.g., mannitol salt agar with or without oxacillin), without broth enrichment, provide TATs of approximately 48 h.

\(^{c}\)The nares provides the best sensitivity and specificity of any single site for detection of *S. aureus* (including MRSA) detection (97). However, several studies have demonstrated that sampling of additional sites, including the oropharynx and perirectal sites, may increase yield by 10 to 40% (98–100).

\(^{d}\)Positive results for chromogenic agar medium can be reported at 18 to 24 h, but negative results are reported at 48 h.

\(^{e}\)Currently available real-time PCR assays are FDA approved only for nares samples but have been used in some studies for oropharyngeal, skin, and perirectal samples.

\(^{f}\)Several modifications of culture methods may enhance recovery by increasing medium selectivity for MDROs (e.g., addition of ceftazidime for ESBL-producing Enterobacteriaceae, levofloxacin for fluoroquinolone-resistant *E. coli*, imipenem or meropenem for carbapenem-resistant GNRs, etc.). Chromogenic agar is now commercially available, and the CDC has guidance for detection of carbapenem-resistant *Enterobacteriaceae* (http://www.cdc.gov/hai/pdfs/labsettings/klebsiella_or_ecoli.pdf). Laboratory-developed molecular methods for more-rapid detection of specific resistance determinants (e.g., *blaKPC*; \(^{g}\)) are in use in some centers, and multiplex assays to detect multiple resistance determinants are now commercially available.

\(^{g}\)The sample site(s) should be guided by likely reservoirs, with gastrointestinal (e.g., *Enterobacteriaceae*) and respiratory (e.g., *Acinetobacter*) being most common.
their own colonizing biota (101, 102). Nonetheless, the hospital environment can serve as a source of this colonizing biota, which is transmitted to patients on the clothing and hands of health care personnel. Thus, there are specific circumstances in which environmental sampling for quality assurance or for detection of potential pathogens is necessary. Routine sampling for quality assurance should be limited to biologic monitoring of sterilization processes and monthly cultures of water and dialysate for hemodialysis. Rarely, it may be useful to perform a short-term evaluation of the effectiveness of hospital cleaning and disinfection (for example, sampling surfaces for VRE or Clostridium difficile after terminal room cleaning to evaluate the effectiveness of cleaning practices). Likewise, sampling the hospital potable water for Legionella spp. is indicated after diagnosis of a nosocomial legionellosis case or as part of a comprehensive program to decrease the risk of nosocomial legionellosis (101, 103, 104). Air sampling for mould spores can also be an important step in identifying the source of fungal disease transmission in highly immunocompromised patients. Rarely, sampling of other inanimate objects or surfaces may be indicated, if such objects or surfaces are implicated in pathogen transmission. Table 6 outlines current approaches to screening the hospital environment for organisms of epidemiologic significance.

As a general rule, routine, undirected cultures of health care workers or the hospital environment should not be performed; such cultures are labor-intensive, nonstandardized, and difficult to interpret, and they rarely provide useful information (101). Except as previously outlined, such sampling should be done only as part of an epidemiologic investigation in consultation with the hospital epidemiologist. When such an epidemiologic investigation reveals a common organism in patient and/or environmental samples, the laboratory should also provide access to epidemiologic typing methods, as previously discussed.

### Emerging Issues and Trends in Health Care Infection Prevention

The landscape of health care infection prevention is ever changing. At the time of this writing, the emerging issues of greatest import (at least in the U.S. health care system) include (i) the growing perception that every HAI is preventable and therefore that the only acceptable HAI rate is zero and (ii) the starkly increased stakes for health care facilities to demonstrate HAI elimination, given the impact of greater transparency and increased financial consequences for HAIs (38). These trends provide both challenges and opportunities for the CML.

While many HAIs are preventable by use of current best practices, there are still gaps in our knowledge that result in HAI risks for severely immunocompromised patients who require invasive devices that breach normal host defenses (38, 105). However, improved prevention approaches have resulted in HAI reductions that are greater than previously thought possible (27). As HAI rates get lower, each HAI is scrutinized more carefully than ever; in some institutions, HAIs may be subject to adjudication by consensus panels or individual clinicians (106). For HAIs that include a microbiology laboratory test result as part of the definition,

</tbody>
</table>

<sup>a</sup>With the exception of water and dialysate cultures for monitoring of hemodialysis and potable water cultures for Legionella spp., environmental cultures should be performed only when an epidemiologic investigation suggests that the environment may be involved in pathogen transmission.

<sup>b</sup>Large-volume air samplers are preferred for air sampling for mould spores; settle plates should not be used for this purpose.

<sup>c</sup>There are no standards for acceptable levels of bacteria in air samples, nor is there any evidence correlating bacterial burden to infection risk. Air sampling for bacteria should be performed only rarely, as part of either an outbreak investigation or a research protocol.

<sup>d</sup>Legionella spp. do not grow on routine aerobic culture media. Buffered charcoal yeast extract (BCYE) agar is the most common medium used for Legionella isolation.

<sup>e</sup>A large volume (1 liter) is preferred. If the water source is chlorinated, 0.5 ml of 0.1 N sodium thiosulfate should be added to each liter of sample to neutralize the chlorine. Water samples are filter concentrated. Swabs should be immersed in 3 to 5 ml of water taken during sampling of the same site to prevent drying.

<sup>f</sup>The role of waterborne fungi in infection transmission in the hospital environment remains poorly described, but cultures may be indicated as part of a search for environmental sources during an outbreak of invasive fungal infections in an immunocompromised patient population.

<sup>g</sup>Standards of the Association for the Advancement of Medical Instrumentation (AAMI) govern microbiological monitoring of hemodialysis.

<sup>h</sup>The sterile swab or sponge should be moistened (e.g., with nutrient broth, sterile saline, etc.) prior to sample collection.

For C. difficile, the contact agar plate should be optimized for anaerobic recovery (selective, preinoculated media, promptly placed in an anaerobic environment).
this scrutiny places increased pressure on those diagnostic tests to provide unrealistic levels of accuracy. For example, the more successful an institution is at reducing its rate of health care-associated C. difficile, the greater the likelihood that a positive result from a highly sensitive PCR-based assay will be falsely positive (107). This increases the importance of enforcing strict criteria for testing submitted samples (e.g., no testing of nondiarrheal stool, no repeat testing, no “test of cure”) and also makes clear that no institution will demonstrate “elimination” of health care-associated C. difficile, if only because some falsely positive results will undoubtedly result in misclassification. The same concepts hold for any HAI definition that relies heavily on microbiology results. As the stakes rise for each HAI, labs will undoubtedly be called upon to defend the accuracy of their diagnostic approach, if not to become involved in adjudicating individual HAI s. The Healthcare Infection Control Practices Advisory Committee (HICPAC) of the CDC has recently published guidance for the use of surveillance data in this new, high-stakes environment (38).

This high-stakes environment, resulting from financial consequences and public disclosure about HAI rates, also provides an opportunity for the CML to play a more active role in HAI prevention. Once health care system leaders realize that the CML is an integral component of any effective IPP, they will understand how shortsighted it is to cut resources for CMLs. While such cuts may appear to save money in the short term, they will undoubtedly increase long-term costs and, more importantly, morbidity and mortality related to elevated HAI rates and uncontrolled outbreaks due to insufficient CML support of IP activities.

CONCLUSION

The CML is an essential element of the infection prevention program in every health care facility, playing critical roles in surveillance, outbreak detection and management, antimicrobial stewardship, risk assessment and planning, and education. The development and application of new technologies in the clinical laboratory can greatly enhance infection prevention efforts. Close collaboration between CML and infection prevention personnel is required to ensure optimal HAI prevention, which saves money and lives.

INVESTIGATION/DEFINITIONS
A disease outbreak (or cluster) is the occurrence of a disease in excess of what would otherwise be expected. Outbreaks can have a major impact on health care expenditure whether they occur in a restricted area or result in cases over a wide geographic spread. The time period may be limited or may last for years. To classify an outbreak, it is vital to know the epidemiology of the implicated infectious agent. A single case in an unrecognized area or community, as in the case of smallpox, can be considered an outbreak and should be investigated. Whether the cases are few in number or enter into the hundreds or thousands, outbreaks can be fear and anxiety provoking for large populations and divert a large amount of public resources.

Recognizing an increase in the number of cases relative to the ongoing background of diseases is difficult. Increasing the specificity of the case definition by describing outbreaks in terms of time, place, and person can minimize this challenge. This involves collecting detailed information on the similarities of clustered cases as well as identifying the important outliers. Geography was traditionally a major clue as to the source of the outbreak. However, as a result of the globalization of the world economies as well as increases in travel and trade, pathogens have expanded beyond their typical geographical ranges. Both people and foodstuff now regularly travel far distances and challenge prior demarcations for infectious agents. Public health officials must have the knowledge and flexibility to be prepared for presentations of disease in uncommon locations and the ability to trace back a source across continents. It is easy to see in today’s world how an outbreak can become a pandemic, an epidemic spreading to several countries, even with a limited number of cases. The spread of severe acute respiratory syndrome (SARS) in 2003 is a good example of this. Originating as a small cluster of cases from the Guangdong Province in southern China, the outbreak lasted approximately 6 months and spread to 29 countries and regions (http://www.who.int/csr/sars/country/table2004_04_21/en/).

Outbreaks are usually triggered when individuals travel into an area of endemicity or when a new infectious disease is introduced into a susceptible population. Thus, host factors in addition to behavior play a key role. In the 21st century, the population of persons vulnerable to an outbreak is growing due to the number of people living with chronic, immunologically debilitating conditions, such as malnutrition, cancer, and HIV.

In addition to host immunity, new or unusual behavioral, sexual, cultural, or political changes can make populations particularly at risk. An example of this is the migration of refugees during wartime. In 2012, there were around 6.5 million newly displaced persons, largely associated with large-scale population movements due to armed conflict (3). This is the highest global figure ever reported. There are also voluntary mass movements, such as international sporting events or pilgrimages to religious places. In 2012, nearly 700,000 people traveled to the United Kingdom for the Olympics, 66,000 of those from the United States (http://www.ons.gov.uk/ons/rel/ott/travel-trends/2012/sty-visits-to-the-uk.html). In the same year, over 3 million people performed the Hajj pilgrimage, with 14,567 visas issued for persons in the United States (http://www.saudiembassy.net/latest_news/news10271201.aspx).

The modern response to outbreaks can be vastly different than in years past due to advances in the understanding of infectious disease pathogenesis. Many outbreaks are identified and investigated retrospectively. In these cases, the cause may be difficult to identify, as the investigation is remote from the event and the source of the outbreak may no longer be present. The laboratory, which has always been integral to an outbreak investigation, has become even more central now that advancements in microbial identification, even in cases of novel pathogens, are more likely to be identified at the time of the outbreak.

This chapter will review concepts associated with infectious disease outbreaks, including disease surveillance, mechanisms used to detect outbreaks, and the epidemiological steps used to investigate an outbreak. Since this Manual is largely for laboratorians, this chapter focuses (i) on routine and novel laboratory detection that can be used in outbreak settings and (ii) on examples of situations in which laboratory testing played a key role in the investigation of an outbreak. In past editions of this Manual, the focus was largely foodborne outbreaks; this chapter expands the focus to include many different types of pathogens and settings for outbreaks.

DISEASE SURVEILLANCE
Outbreak (or epidemic) intelligence is the process used to detect, verify, analyze, assess, and investigate signals that may represent a threat to public health (4). Around the world, this effort is coordinated by international health organizations that receive information from national public
health agencies, which in turn rely on local authorities. Improved coordination has been shown to be highly effective and necessary in large-scale epidemics. Comparing the largest influenza pandemic of the last century with the first pandemic of the 21st century, the average numbers of secondary cases generated by contact with one infected individual, “R,” were similar (5, 6). However, while the 1918 pandemic affected almost a half a billion persons and killed 3% of the world’s population, the SARS epidemic was limited to fewer than 10,000 persons thanks to the coordinated responses of public health agencies worldwide (http://www.who.int/csr/sars/country/table2004_04_21/en/).

At every level, multidisciplinary teams that are comprised of epidemiologists, laboratory personnel, environmentalists, and other technical staff are involved. Table 1 illustrates the vast types and levels of organizations that work hand in hand to address infectious disease outbreaks in the United States. Most of the investigations and most of the legal authority to conduct those investigations are at the state or local level. Basic laboratory testing and interviews of a select number of individuals may provide sufficient information to identify the source and take appropriate measures. This is well within the means of the local authorities and can usually be performed with public cooperation without a public health mandate. Outbreak investigations provide a unique opportunity for enhanced education and awareness, making local authorities that have insight into their area particularly suited.

Federal agencies usually become involved only when outbreaks involve multiple states, coordination across multiple agencies is needed, or specific expertise is requested. In the United States, there are a variety of federal agencies that assist in setting standards and coordinating efforts, such as the Centers for Disease Prevention and Control (CDC), Federal Drug Administration (FDA), U.S. Department of Agriculture (USDA), and U.S. Department of Health and Human Services (HHS). The CDC, for example, regularly collects surveillance data from health departments in the 50 states, five territories, New York City, and the District of Columbia. Important for laboratories to note is that in addition to information regarding the pathogens, patient data are collected. Reporting is typically done through the National Electronic Disease Surveillance System (NEDSS), and a list of the diseases involved in mandatory reporting is included in Table 2 (7). This consistent data source allows for agencies to easily identify spikes in case numbers. For example, in the United States in 2011, an increase to 222 measles cases and 17 outbreaks marked a significant change from a median of 60 cases and 4 outbreaks reported annually during 2001 to 2010 (8). Even though the cases were reported from 31 states, the increase could be identified through mandatory reporting of a predetermined laboratory and clinical case definition.

Internationally, the World Health Organization (WHO) has a 24-h global alert and response system for epidemics and health emergencies and supports member states in their preparedness for epidemics by pooling the resources of existing entities with particular expertise. The 2005 International Health Regulations published by the WHO provides a framework for the climate under which member nations develop and maintain surveillance capabilities. Any nation with knowledge of a disease outbreak of international concern is obligated to report it to the WHO within 24 h (http://www.who.int/ihr/global_alert/en/). It is then the role of larger, international agencies to collect and disseminate information to local agencies and keep them current on the global perspective.

### OUTBREAK DETECTION

The investigation of an outbreak is initiated for many reasons, but in general, potential outbreaks come to the attention of health authorities through one of three ways: direct reporting, active pathogen surveillance, and syndromic surveillance (http://www.cifor.us/documents/CIFORGuide linesforFoodborneDiseaseOutbreakResponse.pdf).

Direct reporting is when the public notifies health authorities of cases of which they have an immediate knowledge through a notification or complaint system. Reporting via notification has been important to the identification of outbreaks since the inception of public health agencies. Typically, an individual will call in to report an illness, perhaps after a group function or event. A physician caring for that individual may also report one or more cases. Reporting via this route enables identification of cases caused by any organism, not just those under active monitoring, such as norovirus, and is usually timely. However, notification-based systems require that the public and clinicians be aware of them and rely on a high degree of resources to appropriately triage and investigate these reports. As described earlier, each state and local area defines a list of specific infectious diseases that are considered reportable. This usually

<table>

</tbody>
</table>

includes language that allows for reporting any “unusual clusters” or “pathogens that may take on some unexpected significance.” In addition, since reporting from the public and clinicians is passive, most states and local areas have a dual system whereby laboratories report similar lists of pathogens/conditions in parallel. Lab-based reporting can be electronic and is likely to be more reliable but will not have the specifics of a clinical presentation. Thus, these forms of reporting are complementary.

Second, authorities regularly conduct pathogen-specific surveillance to look for clusters cases or numbers previously not seen in certain geographical areas using predetermined case definitions. In order to identify an increase in the number of illnesses that define an outbreak, public health officials must routinely collect data to serve as a predetermined case definition. By collecting routine data, there are often predetermined thresholds that are set for an alert and a response based on known epidemiology.

Sometimes outbreaks come to the attention of health authorities as a combination of direct reporting and surveillance. For example, at the end of June 2011, the French Institute for Public Health Surveillance was informed of eight cases of bloody diarrhea or hemolytic uremic syndrome (HUS) in adults living in southwest France (9), but authorities were already on high alert because of known cases of HUS in Germany in that year that resulted in 3,816 identified Shiga toxin-producing Escherichia coli (STEC) infections and 54 deaths (10). The cause was identified as sprouts in both outbreaks.

Finally, public health authorities actively engage in syndromic surveillance by looking at nonspecific health indicators. An example of this is the CDC’s practice of looking at diagnosis codes in all emergency departments around the time of notable events, such as the Olympics. This allows epidemiologists to look for cases of intentional food poisoning or biological terrorism (11). It is important to note that

evidence collected by any of these methods may include false positives, and case definition becomes vital in the development of a reporting threshold at which action is taken.

**EPIDEMIOLOGICAL APPROACHES TO AN OUTBREAK INVESTIGATION**

Once an outbreak is suspected, the decision to perform a full investigation can be initiated. The purposes of an outbreak investigation can be multiple, including but not limited to, identifying the etiologic agent responsible, finding the source of the infection, determining the specific attack rate, and formulating recommendations to prevent further transmission. Speed and accuracy are two key components that must be utilized, and a systematic framework is vital to ensure that neither is sacrificed for the other. The basic steps of an outbreak are listed in Table 3 (http://www.cdc.gov/excite/classroom/outbreak/steps.htm) (12). These steps serve as a guide to stay organized, work systematically, and allow for planning. In the urgency of an outbreak investigation, many of these steps can occur concurrently or be rearranged but must not be overlooked and should serve as a mental checklist. The extent and scope of the investigation may change based on resources, timing, the clinical or public health significance of the outbreak, and whether the outbreak is ongoing.

Depending on the nature of the outbreak, a team of experts knowledgeable in the area should be brought together. In order to verify that an outbreak is occurring, the observed number of cases must exceed the expected number. Unrelated cases of clinically similar illnesses but different diseases and sporadic and unrelated cases of the same disease may confound the investigation and must be ruled out. The diagnosis must be confirmed by testing or through the collection of laboratory specimens to be analyzed at a later time point (in cases where the pathogen is unknown). An initial case definition should be established. This involves classifying cases as (i) confirmed, i.e., laboratory test positive, (ii) probable, i.e., displaying clinical features without lab confirmation, and (iii) suspect, i.e., displaying only some clinical features. This allows for an accurate case count and allows for some evolution in case definition and diagnosis.

The next step in an outbreak investigation is to perform some simple epidemiologic analyses. Creating a line listing of cases, some early demographic factors, and potential exposures will start to identify patterns in those affected and possible sources or exposures that might be causing the outbreak or at least be related to the source. Creating a histogram at this stage is key to representing the number of cases that occurred over time in order to determine how they were propagated relative to the exposure. A point source outbreak is a cluster of cases around the time of the exposure, while person-to-person spread results in cases that cluster around the exposure (the primary cases) and then in secondary cases (household contacts, school contacts, etc.) that occur when the epidemic is propagated (Fig. 1).

It is important that laboratory data, including any additional specimens not originally collected when propagation was unknown, continue to be collected as the cases are identified. It is important to develop a hypothesis of the source agent early on but to revise the theories as information becomes available. Included in this hypothesis should be the mode of transmission and the likely mechanism of exposure.

Once a hypothesis is developed, control measures should be implemented to contain the outbreak. These measures may be revised and should become more permanent existing measures as needed to protect vulnerable populations or prevent the occurrence of a repeat or similar outbreak. The investigation does not end with the outbreak. Ongoing surveillance must be conducted to ensure that there are no

new cases that are linked or that exceed a normal threshold for that particular disease. Public compliance is key to the establishment of new control measures; health officials can effectively educate the public and ensure compliance to new measures. The WHO provides guidelines for communicating with the public during an outbreak, but most communications should be handled by local health departments, which have experience in outreach. Monitoring after an outbreak may need to be enhanced, and more-permanent active surveillance measures may need to be put in place.

In some outbreaks, additional, more sophisticated, epidemiological, comparative, or other studies may be considered (e.g., case-control studies, cohort studies, and practice observations). Situations where this may be appropriate include when resources are available, when the outbreak is associated with high mortality or severe disease, with new or unusual pathogens or methods of transmission, and/or with outbreaks which continue despite implementation of control measures. Discussion of these more advanced studies is beyond the scope of this chapter but can be found in Epidemiology by Gordis.

ROLE OF THE LABORATORY IN OUTBREAKS

Routine

Although outbreaks may last decades (as in the case of AIDS), some last mere hours (bacterial food poisoning). Laboratory investigation and specimen collection are key at every juncture, and the team should be prepared with the tools and the materials needed to collect, process, and transport specimens at the time of an outbreak investigation. After the suspected pathogens are determined, the appropriate clinical specimens can be determined, and laboratories with the capability of handling specimens should be contacted and informed. The logistics required for the collection, processing, and storage of each specimen should be considered prior to collection.

Specimens obtained in the acute phase of the disease, preferably prior to the administration of any treatments (i.e., antimicrobials) are much more likely to yield the infective pathogen. The specimens should be collected in sufficient quantity and should not be contaminated by other specimens or sites. Protective clothing must be worn if indicated, and specimen collection sites should be cleaned and decontaminated as necessary. All specimens should be correctly labeled with a patient identifier, the location of the specimen, and the time of collection. Additionally, in cases in which bioterrorism is suspected, chain of custody may need to be maintained. The CDC and WHO have guidelines for general as well as disease-specific specimen collection; they are summarized in Table 4. Culture is the mainstay of outbreak investigation, and although newer techniques have emerged, it remains the gold standard for testing therapeutics (i.e., drug susceptibilities).

In outbreak cases in which fatalities have occurred, it is important to save tissue specimens for current examination and also for possible later reference analysis, including, but not limited to, skin biopsy specimens, liver biopsy specimens, and brain, cornea, and/or neck biopsy specimens if indicated. Once the disease is known, specimen collection can be limited to only those required to confirm the diagnosis of the disease.

Current and Novel Lab Detection Methods (Illustrative Examples)

It is an exciting time in which the rate at which pathogens are discovered through the use of increasingly powerful technology is rapidly growing. These modern techniques for identifying pathogens have become integral to both surveillance activities and sporadic case investigations and have advanced the speed at which outbreak investigations can be conducted. Once the etiology of an outbreak is known, the focus can shift from pathogen detection to intervention. Resources can then be directed toward employing treatments, such as antimicrobials, therapeutic antibodies, and vaccines. Thus, a method for rapid and accurate organism detection is highly desirable. Table 5 discusses some examples of the use of the laboratory in selected outbreaks in this modern era of molecular microbiology. Molecular techniques are discussed in detail in chapter 10, but select examples of their use in outbreak investigations are discussed below.

Genomic sequencing is a technology that involves identifying sequential nucleotides from a template strand. It is often employed to identify new pathogens in which the etiology is unknown. This was the case in the identification of West Nile virus, which caused an outbreak of human encephalitis in New York City in 1999, along with the death of birds. Necropsy samples from the birds were inoculated into embryonated chicken eggs for viral isolation, and the entire viral genome was sequenced and subsequently identified through phylogenetic analysis. Sequencing (either in whole or in part) is becoming more available due to declining costs and the increases in taxonomy databases. The total time in which an organism, even a novel one, is sequenced has vastly decreased. In fact, the challenge is how to best analyze the output. Another complication surrounding sequencing and the availability of the genetic code revolves around the potential to weaponize pathogens. Although there have been no recent examples of bioterrorism, the accessibility of techniques to synthesize whole synthetic genomes may allow for the mass production of current or modified pathogens and explains why outbreak surveillance for eradicated diseases, such as smallpox, is ongoing.

Once the nucleotide sequence is known, target amplification, usually by PCR technology, can also be used as a detection method. This was seen in the 2012 novel coronavirus (CoV) outbreak in which the CDC developed a novel PCR assay to qualitatively detect Middle East respiratory syndrome CoV (MERS-CoV) RNA in respiratory specimens in patients that met the clinical criteria. For the detection of pathogens with known sequences, PCR is typically highly sensitive and specific but is dependent on adequately obtained specimens. In some investigations, these are difficult to obtain. In the case of MERS-CoV, specimens of the lower respiratory tract are required.

In order to test for multiple pathogens simultaneously, multiplex PCR can be used. It is best employed in an outbreak to narrow the differential when a patient presents with a common complaint (e.g., respiratory panel for common respiratory pathogens, gastroenteritis panel, etc.). The nosocomial implications of this technology are particularly important, and these methods can be used to monitor baseline levels and outbreak clusters within health care institutions, particularly when platforms with more-specific identifications (i.e., Rous sarcoma virus type A [RSV A] versus

RSV B) are used. These more commercial platforms usually rely on the fact that the organism and its sequence are both known and suspected; however, they may also be used to employ degenerate, genus-wide primers to discover novel pathogens (28).

In another promising technology, DNA microarray, millions of genetic probes are bound to glass or silicon wafers and tested for their capacity to bind complementary sequences (29). The binding is detected by measuring tagged fluorescent molecules. This adds increased specificity and has the potential to allow technicians to survey multiple microbes simultaneously and even identify antibiotic resistance markers. It has shown some promising results, but sensitivity is currently low and processing is cumbersome, so use in outbreak investigations is still limited (30, 31).

With any of these laboratory methods, it is key that appropriate controls are established and that methodology is validated. Remember that the laboratory can be the cause of a pseudo-outbreak or the presumption of an outbreak when there is none. It must be considered that an uptick in the rate of infection may be a lab artifact rather than clinical reality.

---

**SELECT EXAMPLES OF OUTBREAK SCENARIOS: HEALTH CARE AND FACILITIES, CONTAMINATED PRODUCTS, AND FOODBORNE ILLNESSES**

Outbreaks in health care facilities are discussed in detail in chapter 8. As in other locations, mandatory reporting in health care facilities exists in order to aid in ongoing baseline surveillance. The increased number of reportable health care-associated infections places a particular burden on the lab to constantly monitor and report certain infections. In addition, some facilities require ongoing environmental surveillance to be performed by their laboratory, depending on that location's infection control needs. It is important to let the epidemiology guide the investigation, as sporadic environmental cultures may either overestimate or underestimate the pathogens present and infection may still occur (32, 33).

Another area in which outbreak investigations are becoming increasingly important is in the preparation, handling, and distribution of medications. In one case, an outbreak of *Serratia marcescens* and *Enterobacter cloacae* bacteremia in a surgical intensive care unit was traced to
### TABLE 6 Steps of an outbreak investigation using fungal meningitis cases linked to contaminated steroid injections from a 2012 multistate outbreak

<table>
<thead>
<tr>
<th>Step in the outbreak</th>
<th>Specific illustrative finding(s)</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Prepare to investigate</td>
<td>The Tennessee Department of Health was aware of baseline data, including the uncommon nature of fungal CNS infections and the known association of infection with epidural injections.</td>
</tr>
<tr>
<td>2. Verify the diagnosis</td>
<td>The index case was confirmed to be <em>Aspergillus fumigatus</em> by CSF culture, and a Gram stain of the L4 L5 space on autopsy yielded branching hyphal elements consistent with <em>A. fumigatus</em>.</td>
</tr>
<tr>
<td>3. Establish a case definition</td>
<td>In response to a single reported case of <em>Aspergillus</em> meningitis in a patient who had a recent epidural injection, active surveillance for additional cases was performed. Cases were defined as patients with fungal meningitis, posterior circulation stroke, spinal osteomyelitis, or epidural abscess that developed after epidural or paraspinal glucocorticoid injections that were administered after 21 May 2012 in Tennessee.</td>
</tr>
<tr>
<td>4. Find cases</td>
<td>Additional cases were identified on active surveillance. Initially, cases from the same clinic were investigated, including those that received methylprednisolone injections. After the index case, 21 additional patients had laboratory confirmation of infection, all with <em>Exserohilum rostratum</em>.</td>
</tr>
<tr>
<td>5. Describe the epidemiology</td>
<td>Detailed chart reviews captured patient data and other factors including common products used in the procedures.</td>
</tr>
<tr>
<td>6. Develop a hypothesis</td>
<td>Based on the finding of an association with single-dose vials of methylprednisolone injections, the Massachusetts Department of Health contacted the supplier, the New England Compounding Center (NECC).</td>
</tr>
<tr>
<td>7. Evaluate the hypothesis</td>
<td>Cerebrospinal fluid, isolates, and tissue obtained from clinical specimens were sent to the CDC for identification of the pathogen with the use of PCR amplification of fungal DNA and genomic sequencing. The FDA also analyzed unopened vials of methylprednisolone that had been collected from NECC and were later found to be positive. Patients who received injections of other medications at the same clinic did not manifest disease.</td>
</tr>
<tr>
<td>8. Refine the hypothesis and carry out additional studies</td>
<td>Based on the distribution of the methylprednisolone vials from the manufacturer, 2 additional clinics were quickly included in the investigation in Tennessee, and over 65 patients were identified.</td>
</tr>
<tr>
<td>9. Implement control and prevention measures</td>
<td>In October 2012, NECC recalled all products compounded at and distributed by its facility in Framingham, MA.</td>
</tr>
<tr>
<td>10. Communicate findings</td>
<td>The CDC regularly received reports of and communicated rates of fungal infections due to NECC products. The FDA advised follow-up with patients who were administered products from NECC and advised withholding any products still in circulation.</td>
</tr>
</tbody>
</table>

*See references 26 and 27.*

Extrinsic contamination of the parenteral narcotic fentanyl by likely tampering by a health care worker. The laboratory was key in analyzing patient, environmental, and drug samples, in ruling out environmental causes, and in showing similarities between the fentanyl and blood isolates (34).

In another case involving a multistate outbreak of fungal meningitis, the laboratory was key in confirming cases that met the case definition and in investigating the contaminated product, particularly in the identification of which lots were infected. Table 6 reviews this investigation and how the laboratory played a role at the key steps in the outbreak investigation. Using Table 3 as a template, we show how a multistate outbreak of fungal meningitis was recently linked to cases from Tennessee and extrinsic contamination from a compounding pharmacy (35, 36). By adding clear associations between products and infection, the laboratory provides evidence to warrant change either at the level of an individual institution (as in the removal of the implicated health care worker in the outbreak of *Serratia* bacteremia or in the move to revise legislation...
involve the regulation of compounding pharmacies, as with the cases of fungal meningitis).

Due to the critical supply of our food network and distribution chain, monitoring of foodborne diseases is one of the most active, coordinated surveillance systems in the United States, involving local and reference laboratories. FoodNet is a sentinel surveillance system undertaken at 10 participating sites in the United States in collaboration with the CDC, USDA, and FDA. It concentrates on laboratory testing and documented diseases and gives a baseline incidence of foodborne and diarrheal diseases and their distribution in the United States. Together, these sites survey about 15% of the U.S. population (37).

Foodborne illnesses can cause outbreaks at any time and are monitored regularly. It is estimated that there are 9.4 million domestically acquired foodborne illnesses each year caused by over 30 pathogens. This results in an estimated 55,961 hospitalizations and 1,351 deaths annually (38). In recent years, changes in the American diet to include undercooked foods, imported foods, and mass-produced foods add to the challenge of investigating foodborne outbreaks. It is not uncommon in today’s market to find food that is processed in a variety of locations distributed over multiple states or multiple countries.

In addition to FoodNet, PulseNet is a national subtyping network of over 80 state and local public health laboratories and federal food regulatory laboratories that perform molecular surveillance of foodborne infections. They analyze DNA fingerprints through testing with pulse-field gel electrophoresis (PFGE) and routinely detect and report on subtypes of eight bacteria, including Escherichia coli O157:H7, Listeria monocytogenes, and Salmonella serotypes. Isolate subtypes are constantly being uploaded, and in 2012, participating laboratories reported over 60,000 isolates to PulseNet, providing baseline data on infections down to the molecular level (http://www.cdc.gov/pulsenet/).

One example of PulseNet at work is its handling of the Listeria monocytogenes multistate outbreak in 2011. On 2 September 2011, the Colorado Department of Public Health and Environment (CDPHE) reported to the CDC seven cases of listeriosis since 28 August 2011, whereas on average, they would report two cases annually in August. All patients were interviewed, and three reported eating cantaloupe marketed as “Rocky Ford.” Outbreak strains were analyzed with PFGE, and PulseNet picked up an additional PFGE pattern that emerged as a multistate cluster. A sample of cantaloupes collected from the implicated farm also had that PFGE pattern. Although two serotypes and five widely differing PFGE pattern combinations were found, both ongoing surveillance and outbreak investigations were able to identify cases that spanned 28 states. The accuracy of detection also meant that by 9 September 2011, the CPDHE could inform the public that cantaloupes were the likely cause of the illness and instruct consumers not to eat them, and by the next day, distribution was stopped and grocery stores were instructed to remove the product. Despite the rapid action taken by public health authorities, the case number, at 147 infected persons and 33 deaths, was the largest listeriosis outbreak since the CDC has been keeping record (http://www.cdc.gov/listeria/outbreaks/cantaloupes-jensen-farms/index.html) (39).

RESOURCES TO STAY INFORMED AND CONNECTED IN GLOBAL OUTBREAKS

With the rise of Internet-based surveillance and other social media tools, the way that we identify, communicate during, and react during an outbreak is being revolutionized. In the last few decades, the WHO has often responded to outbreak investigations that have been triggered by what had previously been considered nontraditional sources, such as media surveillance systems (40). Even with national and transnational public health organizations engaging in continual information gathering, often the most vulnerable countries have no infrastructure for reporting or alerting populations (41). Internet or mobile resources can support high-risk areas that may be the most susceptible to disease but the most lacking in epidemic infrastructure. A sample of some widely used and cited resources is listed here. Many of these systems track not only human but also zoonotic infections, as many outbreaks originate in domestic animals or wildlife and animals are critical to comprehensive surveillance.

GeoSentinel (http://www.istm.org/geosentinel/main.html) is a worldwide communication and data collection network for the surveillance of travel-related morbidity. The International Society of Travel Medicine (ISTM) and the CDC initiated it in 1995 as a network of ISTM members travel/tropical medicine clinics. Its members are connected through e-mail, which can be linked to a network to quickly communicate with public health officials. They can informally provide leads when they encounter any unusual diagnosis or exposure and be surveyed to assess rates of background disease (42, 43).

ProMED-mail (http://www.promedmail.org), established in 1994 by Joshua Lederberg after a meeting of the Federation of American Scientists and the WHO, is a free e-mail alert system about new or evolving outbreaks (44). A panel of experts in each field selects and reviews ongoing member submissions. They then provide expert commentary and supply literature references before disseminating reports to a >60,000-member subscriber base in over 180 countries. It served as an early warning system in the SARS outbreak and has served as a communication network among laboratories. The Global Public Health Intelligence Network (GPHIN) is a fee-based subscription service run by the Public Health Agency of Canada that scans news services in real time and posts to its members in six languages (45). Posts are not verified or tied to references, and more than 60% of the initial reports come from informal sources, but the WHO has incorporated the GPHIN into its Global Outbreak Alert Response Network and works to verify the epidemic reports (http://www.who.int/csr/alertresponse/epidemicintelligence/en/). Google Flu Trends uses Google search queries to track and map influenza globally (46) and was found to perform well during the 2009 H1N1 pandemic (47).

HealthMap (http://healthmap.org), developed by Boston Children’s Hospital, is a multistream surveillance program that integrates Google News, ProMED-mail, Eurosurveillance, and official documents from the WHO, among other sources, into a user-friendly map that is updated in real time (48). Users can be updated on a mobile app or can report outbreaks using their smart phone. InSTEDD (Innovative Support to Emergencies, Diseases, and Disasters) is a growing number or nonprofits that work to develop open-source technology that specifically serves vulnerable populations. It currently develops local media tools and hopes to eventually aggregate medical services data to promote awareness in areas of need and create sustainable approaches to health problems (http://instedd.org).

For those investigating health care-associated outbreaks, the Outbreak Database (http://www.outbreak-data-base.com) can be used. It is an open-access resource maintained by physicians at the Charité University Hospital
(Berlin, Germany) and contains updated articles related to worldwide nosocomial outbreaks. It can provide relevant literature pertaining to an acute outbreak and literature to address science-oriented questions or to aid in the development of successful infection prevention policies. It can be particularly valuable for laboratory personnel by identifying molecular diagnostics that were used in similar outbreak settings and to locate reference laboratories that may be used in an ongoing investigation (49).

CONCLUSIONS

This chapter has reviewed concepts associated with outbreaks, including how to approach an epidemiological investigation, routine and novel laboratory methods, and infectious disease reporting. Examples of routine and novel laboratory testing that have been used in outbreak settings and examples where laboratory testing played a key role in the investigation of an outbreak have been reviewed.

The rise in globalization highlights the importance of thinking about the world health community when responding to an outbreak. Local clinicians, laboratory technicians, and public health practitioners remain the stalwart members of the outbreak team. However, they must interface with state, national, and international authorities and professional organizations in order to act fast, precisely define, and stem the tide of an outbreak. Pathogen identification is becoming crucial and likely expanding role in the investigation of an outbreak have been reviewed. Laboratory testing that have been used in outbreak settings and larly valuable for laboratory personnel by identifying molecular diagnostics that were used in similar outbreak settings and

REFERENCES

Our knowledge and understanding of infectious diseases have increased dramatically in recent decades primarily from observations drawn from the interconnected fields of clinical microbiology and epidemiology. In the context of infectious diseases, epidemiology is the study of the transmission of human pathogens, including their risk factors for and control of infectious disease in human populations (1). The epidemiology of infectious diseases has, since the discovery of microbial pathogens, been closely linked to the laboratory sciences. Until the introduction of molecular techniques in the 1970s, infectious disease epidemiology was driven mostly by discoveries in classical microbiology, with the development of culture and phenotypic identification methods, subtyping techniques, like bio-, sero-, and phage typing, and antimicrobial susceptibility testing. These methods were used to discover pathogens and study their reservoirs, transmission routes, geographical distribution, infection dynamics (including outbreak detection and investigations), vaccine efficacy, and other disease prevention measures.

Since the 1970s, molecular methods have been introduced and, with increased frequency, continue to replace phenotypic methods in the microbiological laboratories. The emergence of these new methods led to the creation of a new discipline: molecular epidemiology. In its simplest form, molecular epidemiology can be defined as the application of molecular (i.e., nucleic acid- or protein-based) tools to answer epidemiological questions. With the introduction of molecular epidemiology, the study of the epidemiology of infectious diseases has reached new heights. Molecular epidemiology is no longer a science for the elite; molecular biological devices and reagents are widely available, and almost any clinical or research laboratory has the expertise and the equipment required for performing molecular studies. We are now obtaining deeper recognition of the molecular mechanisms that form the basis of the virulence of microbial pathogens, and as time passes, the subtyping methods used to trace them are becoming faster, more discriminatory, and therefore more powerful. The etiologies of many infectious diseases may now be diagnosed without culture in minutes or hours, thereby enabling a fast specific therapeutic response and in some instances also a rapid public health response.

Molecular epidemiology is often confused with another related but distinct microbiology discipline: molecular taxonomy. Taxonomy is the discipline that studies the classification, identification, and naming of microorganisms. A subdiscipline of taxonomy is phylogeny, which is the study of the evolutionary relationships of microorganisms. Before the introduction of molecular methods, phylogeny was based solely on phenotypic traits and, as a result, was imprecise and often yielded erroneous information. The use of nucleic acid hybridization techniques and the analysis of housekeeping gene sequences have greatly improved our understanding of microbial evolution. Compared to taxonomy and phylogeny, molecular epidemiology focuses on the study of more recent population dynamics. In addition, taxonomy and phylogeny describe interactions between the organisms themselves, whereas epidemiology describes interactions between the organisms, their hosts, and the surrounding environment. The same molecular methods may be used in both disciplines; it is their application that determines if they are used for taxonomy or epidemiology.

In molecular epidemiology, molecular methods are used for detection, identification, virulence characterization, and subtyping to generate isolate-specific molecular markers (or fingerprints) for assessment of epidemiological relatedness (1). This chapter is an introduction to molecular epidemiology and important concepts associated with this discipline. Some terms commonly used in molecular epidemiology are provided in Table 1. A nonexhaustive list of subtyping methods that are commonly used now or are under development and are anticipated to supplement or replace the currently used ones is provided. Key characteristics and applications of these methods are summarized in Table 2. Strategies for the development of molecular subtyping tools, including validation and quality control, will be discussed. Criteria for the selection of methods to be used in the different contexts of epidemiology and how the choice of the method influences the interpretation of data will also be addressed.

### SUBTYPING METHODS

#### Subtyping Method Characteristics

**Typeability**

An ideal typing method should be able to produce data that can lead to the establishment of subtypes for the majority, if not all, of the strains of the pathogen being studied. The degree with which a method achieves this can be expressed, in mathematical terms, as the percentage of typeable isolates among the total number of isolates being subtyped. All molecular subtyping methods (except plasmid profiling with some organisms) show very high typeability with the organisms that they target.

### Definitions commonly used in molecular epidemiology

<table>
<thead>
<tr>
<th>Term</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>Isolate</td>
<td>A population of microbial cells from a pure culture derived from a single colony on an isolation plate.</td>
</tr>
<tr>
<td>Strain</td>
<td>An isolate or group of isolates exhibiting phenotypic and/or genotypic traits which are distinctive from those of other isolates of the same species.</td>
</tr>
<tr>
<td>Clone</td>
<td>A group of isolates descending from a common ancestor as part of a direct chain of replication and transmission from host to host or from the environment to host. The term “outbreak strain” is often used with this meaning in the context of epidemiologic subtyping.</td>
</tr>
<tr>
<td>Subtype</td>
<td>A specific pattern or set of markers displayed by a strain when a particular typing system is used.</td>
</tr>
<tr>
<td>Typeability</td>
<td>The proportion of strains for which a subtype may be generated by a given subtyping method.</td>
</tr>
<tr>
<td>Reproducibility</td>
<td>Same as repeatability. The ability of a subtyping method to produce the same results upon repeated testing. Usually stated as the proportion of strains in a given population that displays the same subtype upon repeated testing.</td>
</tr>
<tr>
<td>Stability</td>
<td>The ability of a subtyping method to assign the same subtype to epidemiologically related strains, e.g., as part of the same single-strain outbreak or originating from the same patient or from serial passage in vitro or in vivo. Usually stated as the proportion of epidemiologically linked strains showing the same subtype.</td>
</tr>
<tr>
<td>Discriminatory power</td>
<td>The ability of a subtyping method to differentiate between epidemiologically unrelated strains.</td>
</tr>
<tr>
<td>Epidemiological concordance</td>
<td>Subtyping results generated in the same or in very few experiments in the same laboratory may be compared due to poor interexperiment reproducibility.</td>
</tr>
<tr>
<td>Comparative subtyping</td>
<td>The ability of a subtyping method to link epidemiologically related strains.</td>
</tr>
<tr>
<td>Definitive subtyping</td>
<td>Subtyping results generated in different laboratories and/or at different times may be compared and stored in a reference library.</td>
</tr>
<tr>
<td>Library subtyping</td>
<td>Subtyping results generated by definitive subtyping are stored in a database (library). Sometimes used synonymously with definitive subtyping.</td>
</tr>
<tr>
<td>Cluster</td>
<td>The occurrence of clinical isolations of microbes with a particular subtype greater than would otherwise be expected in a particular time and place with no further supporting epidemiological information.</td>
</tr>
<tr>
<td>Outbreak</td>
<td>Same as an epidemic. The occurrence of disease greater than would otherwise be expected in a particular time and place.</td>
</tr>
<tr>
<td>Sporadic</td>
<td>Antonym to outbreak. Occurring with no clear relation to an outbreak.</td>
</tr>
<tr>
<td>Endemicity</td>
<td>Constant presence of a disease at a significant frequency; typically restricted to, or peculiar to, a locality or region.</td>
</tr>
</tbody>
</table>

### Reproducibility and Stability

Reproducibility refers to the ability of a method to assign the same type to an isolate tested on independent occasions separated in time and/or place. It may be calculated as the percentage of strains that, upon repeated testing using the same parameters, yield the same result. This term is sometimes also referred to as the repeatability. Typically, there is a direct correlation between the reproducibility and robustness of a method and the quality of the data being generated. Reproducibility may be influenced by many steps in the procedure, such as preparation of materials (growth conditions, DNA extraction), different batches of reagents, different types of instruments, and, finally, bias in observing, analyzing, and interpreting results. Some methods have such a poor reproducibility that it is not possible to compare results generated in different experiments. Such methods are said to be comparative. Other methods are so reproducible that it is possible to recognize the same subtypes even though they have been generated at separate times and/or in separate places. Such methods are considered definitive subtyping methods.

Reproducibility has both intralaboratory and interlaboratory dimensions. As will be discussed later, some subtyping methods, e.g., amplifed fragment length polymorphism (AFLP) analysis, show excellent reproducibility when performed on the same instrument in one laboratory (i.e., they have good intralaboratory reproducibility) but poor or suboptimal reproducibility when testing is performed in different laboratories (i.e., they may have a poor interlaboratory reproducibility).

Reproducibility is also indirectly affected by the stability of the genetic markers being targeted by the method. The assessed markers should remain stable during outbreaks and among multiple individual patient isolates not varying to a

degree that confuses the epidemiological picture. The genetic fingerprints generated by a method should also not be affected by in vitro manipulations, such as freeze-thaw cycles and serial passages.

**Discriminatory Power**

Discriminatory power is defined as the ability of a method to distinguish between unrelated strains. An objective measure of discriminatory power can be obtained by calculating Simpson's index of diversity (DI) (2), which is an estimate of the probability that two epidemiologically unrelated strains will display different subtypes. The formula reads

$$\text{DI} = 1 - \frac{1}{N(N-1)} \sum_{j} a_j$$

where $N$ is the number of unrelated strains tested and $a_j$ is the number of strains with a subtype that is indistinguishable from the $j$th strain. The DI value of 1.0 indicates that all strains can be differentiated from each other. A value above 0.95 is a desirable cutoff for subtyping methods to be used for outbreak investigations.

The DI is a function of both the number of subtypes in the strain population (richness) and the proportion of strains representing each subtype, i.e., the evenness of the distribution of the isolates among the different subtypes. It is not possible to determine the contribution of the richness or the evenness of a subtyping method to the DI from the number per se. This should also be taken into consideration when comparing different subtyping methods. Several other diversity indices have been devised for this purpose, among which Shannon's index ($H$) (3) is the most commonly cited. However, the maximal size of this index is a direct function of the number of subtypes generated within a given strain population, and it is therefore difficult to interpret differences in the sizes of the index unless the populations studied generate the same number of subtypes. An easier and more comprehensible way to judge the richness of a subtyping method is to create a histogram showing the distribution of different subtypes. The results of a hypothetical experiment of subtyping the same population of 100 strains by two different methods are shown in Fig. 1A and B. Method A has a slightly higher DI than method B. However, the difference between the methods becomes obvious when one observes the histograms: method A has a higher richness than method B. The 100 strains are differentiated into 74 subtypes, with all containing 5 or fewer strains by method A, whereas the 6 most common subtypes by method B contain half of the strains, and overall, only 43 subtypes are generated by this method.

An ideal method should have such a high discriminatory power that it is capable of discriminating all epidemiologically unrelated isolates from each other (i.e., it has a high specificity). However, the method should also be able to group together isolates that are associated with the same source (i.e., it has a high sensitivity). In other words, a method with high sensitivity and specificity generates epidemiologically relevant data. The ability of a method to group together epidemiologically related isolates is sometimes also referred to as the epidemiological concordance.

**Convenience Parameters**

There are many convenience parameters to be considered, including speed of analysis, cost, technical demands, accessibility of the method, and ease of data analysis. The
ability of a method to generate data rapidly is affected by the throughput of the method, the number of steps involved, the amount of hands-on technical time required to perform the method, and whether the method is amenable for automation. Ideally, typing results should be available within a single working day. The cost of performing a method depends on numerous factors, such as the initial investment in equipment and infrastructure, the price of reagents and consumables, and the number and skill level of staff needed. Cost is usually also the most critical factor affecting the accessibility of the method to general microbiology laboratories. Ease of use encompasses technical simplicity, high throughput, and ease of scoring the results. For easy analysis, data should be objective, amenable for computerized analysis, and easily disseminated between laboratories.

Another convenience parameter rarely considered is the universal applicability of the method; can the same method be used to subtype a broad range of organisms while maintaining a universally high typeability, reproducibility, and discriminatory power? The broader the range of microbial species that can be studied, the more central the position of the method in the general typing laboratory will be.

**Non-Target-Specific Methods**

A short description of the principle of some non-target-specific methods is shown in Fig. 2.

**Plasmid Profiling**

Plasmids are circular extrachromosomal autonomous self-replicating genetic elements that are found in bacteria and some eukaryotes. Their sizes range from approximately 1 kb to >1 Mb. Besides carrying genes regulating their own replication and transmission, plasmids may carry genes that confer specific properties in the host organism, e.g., antimicrobial resistance or toxins. Plasmid profiling was the first widely used nucleic acid-based bacterial subtyping method dating back to the 1970s. The rationale for using plasmid profiling for subtyping is that bacterial strains typically differ in the numbers and sizes of plasmids that they carry. The isolates are lysed using a method that disrupts chromosomal DNA while retaining the integrity of the plasmid, e.g., alkaline lysis (4), followed by separation of the plasmids by agarose gel electrophoresis (5), staining using a fluorescent dye, e.g., ethidium bromide, and visualization of the plasmids under UV light.

The advantages of this method are that it is universal (i.e., it may be used to characterize any organism that contains plasmids by using the same basic procedure) and that it is inexpensive, rapid, and simple, with no requirements for special equipment. The typeability of the method is variable, the discriminatory power varies between organisms, and the reproducibility is in general good, but since plasmids may be lost during strain propagation in vivo and in vitro, the stability is suboptimal. Additionally, plasmids can be unintentionally nicked, causing changes in their conformational structure (from supercoiled to a relaxed or linear form), impacting their migrating properties and resulting in an incorrect profile. These changes may happen if the purification process is performed too harshly. Two or all three conformations may be present at the same time in significant amounts and be visible as two or three bands in the gel, and since they have different migration properties in agarose, interpretation of the profiles may be difficult. In addition, large plasmids, those >100 kb in size, are poorly

---

**FIGURE 2** Procedural principles of some commonly used non-target-specific subtyping methods.

separated by ordinary agarose gel electrophoresis. Unrelated plasmids with similar sizes may not be differentiated in an agarose gel. However, if they are digested with a restriction enzyme before electrophoresis, it will often be possible to differentiate between them.

Plasmid profiling has been used in numerous epidemiological investigations of a wide range of community-acquired or nosocomially acquired infections (6, 7) and is still used as an adjunct in investigations of outbreaks of foodborne infections in some countries (8). Plasmids may spread between different organisms and cause outbreaks of, for example, antimicrobial resistance. Plasmid profiling is the first step in the investigation of such outbreaks (9, 10).

Restriction Fragment Length Polymorphisms

A restriction endonuclease is an enzyme that recognizes a short DNA sequence and cuts it at a specific location within the restriction site. Genomic DNA from a single microorganism will always be cut into fragments of the same size and number if it is digested by the same restriction enzyme. The restriction fragments may be separated according to their size by electrophoresis using agarose or a similar medium as a matrix, followed by staining and visualization under UV light to reveal the DNA fingerprint or restriction profile of that organism. Since different strains have different genomic contents, even strains of the same species that are epidemiologically unrelated to each other will usually show different restriction profiles. Subtyping methods that explore the polymorphisms of restriction profiles are called restriction fragment length polymorphism (RFLP) methods, and the process is called restriction endonuclease analysis (REA). The method was introduced in the late 1970s and the 1980s for subtyping of viruses, parasites, fungi, and bacteria (11–14) using high-frequency cutting enzymes, which resulted in DNA fingerprints containing up to 500 restriction fragments ranging in size from <1 kb to 30 kb. Although the method had universal applicability, was simple, and required few resources, the resulting fragments were often difficult to resolve and the DNA fingerprints too complex to analyze accurately, especially for organisms with large genomes, e.g., bacteria, fungi, and parasites. For this reason, ways to simplify the RFLP DNA fingerprints while maintaining the discriminatory power of the method were sought. This was achieved by reducing the number of restriction fragments in the fingerprints by (i) reducing the number of fragments generated during the restriction reaction or (ii) reducing the number of fragments being visualized. Pulsed-field gel electrophoresis (PFGE) falls within the former category. There are numerous examples of the latter technique, among which IS6110 fingerprinting will be mentioned herein. Finally, optical mapping or whole-genome mapping (WGM), which does not involve electrophoresis but visualizes high-frequency RFLP fingerprints on a glass surface with the restriction fragments in the order that they occur in the chromosome, will be described.

Pulsed-Field Gel Electrophoresis

In pulsed-field gel electrophoresis (PFGE), the DNA fingerprint is simplified by using rarely cutting restriction enzymes with the goal of reducing the number of restriction fragments to be analyzed (macrorestriction). The resulting fragments usually range between ~20 kb and >1 Mb in size. Because organisms differ in the guanine and cytosine (GC) contents of their DNA, the optimal restriction enzymes for PFGE vary between organisms (15). The optimal restriction enzyme(s) generates between approximately 8 and 25 DNA fragments that are well separated and evenly distributed throughout the gel from each strain tested.

Large DNA fragments cannot efficiently be purified in a liquid suspension because this will cause random shearing. To avoid that, the genomic DNA is released and purified from cells that have been embedded in a solid agarose plug. The plug stabilizes the DNA against breaking or shearing as the cells are lysed chemically. The intact genomic DNA is then digested with an infrequently cutting restriction enzyme. Large restriction fragments cannot be resolved with conventional agarose gel electrophoresis, which works best for separation of fragments smaller than approximately 30 kb. This limitation is overcome by subjecting the plug with the macrorestriction DNA to electrophoresis in an alternating or pulsing electric field using an agarose gel as the separation matrix. Since its introduction in 1984 (16), several different PFGE platforms have been developed (17–19). In all formats, the electric field alternates in direction in a predefined manner throughout the course of the electrophoresis. During PFGE, smaller DNA fragments reorient (i.e., make a directional change) in the electrical field faster than larger fragments and therefore move more rapidly through the gel, resulting in separation of the fragments in a size-dependent manner. In some platforms, the interval of time that the electrical current is applied in one direction before it is switched to another direction may be changed. Usually the switch times are set to be short in the beginning of the electrophoresis and are then increased or ramped up during the course of the run.

PFGE has been performed since the 1980s and still remains the gold standard for bacterial molecular subtyping due to its universal applicability, virtual 100% typeability, high discriminatory power, good reproducibility, and stability. By nature, all electrophoresis-based methods are comparative; i.e., only isolates investigated in the same experiment may be compared. However, this problem may be overcome by rigorous standardization of the procedure, with the choice of restriction enzyme, type and brand of agarose, and electrophoresis running conditions being critical. Since 1996, PulseNet USA, the national molecular subtyping network for foodborne disease surveillance, has used PFGE as the preferred method for molecular surveillance, thereby proving its utility as a library subtyping method (20). The drawbacks of the method are that special electrophoresis equipment is required and that the procedure is rather labor-intensive. Up to 20 isolates may be subtyped within 2 working days by one person.

IS6110 Fingerprinting

IS6110 fingerprinting is an RFLP fingerprinting method used for subtyping of strains of the Mycobacterium tuberculosis complex. It was the first RFLP method to become standardized internationally (21), and it remains the gold standard for the molecular surveillance of tuberculosis (TB). The principle of the method includes whole-genomic-DNA restriction by a high-frequency cutting endonuclease, e.g., PvuII, followed by standard agarose gel electrophoresis, transfer of the DNA fragments onto a nitrocellulose or nylon membrane by Southern blotting (22), hybridization of the labeled probes containing IS6110 insertion sequences to membrane-bound fragments, and visualization of the hybridized fragments (23). Only strains of M. tuberculosis and Mycobacterium bovis contain this insertion sequence (24), with M. tuberculosis strains containing between 10 and 12 copies and M. bovis only between 1 and 3 copies. Because of the low number of copies of IS6110 in M. bovis, the method is not optimal for subtyping this species.
The strength of the method is that it has enabled the monitoring of the global spread of *M. tuberculosis* and tracing outbreaks to their sources because of its high typeability, reproducibility, and discriminatory power. The drawbacks of the method are that it may be used only for surveillance of tuberculosis and that it is complicated and labor-intensive.

### Whole-Genome Mapping

Whole-genome mapping (WGM) or, as it was initially called, optical mapping is a technique where single DNA molecules are stretched out on a glass surface, after which they are subjected to restriction endonuclease analysis; the resulting fragments are visualized by fluorescence microscopy in the order that they occur in the genome (25, 26). The generated restriction maps of complete genomes can be compared using specialized software. The technology is a powerful tool for subtyping that can facilitate genome assembly from whole-genome shotgun sequences and that can perform comparison of the sizes and contents of genomes from related organisms, e.g., virulence genes and phages (25, 27–31). However, the technology is complex and costly. It has been automated and commercialized by the company OpGen (Gaithersburg, MD), but the cost is still prohibitive for large-scale use for public health purposes, particularly when the current cost of whole-genome sequencing (WGS) is equal to or, with some sequencing platforms, less expensive than that of whole-genome mapping.

### PCR-Based Subtyping Methods

Numerous subtyping methods employing PCR alone or in combination with restriction analysis have been described previously. These techniques vary in amplification approach and/or in the genomic regions that they interrogate. Following amplification and restriction, if this is part of the method, the resulting fragments are separated by electrophoresis and visually shown following staining with ethidium bromide. Since the fragments generated by PCR usually are small, capillary electrophoresis using a DNA sequencer may also be used to visualize the amplicons if the primers are fluorescently labeled.

#### Random Amplification of Polymorphic DNA/ Arbitrarily Primed PCR

In random amplification of polymorphic DNA/arbitrarily primed PCR (RAPD/AP-PCR), small genomic fragments are amplified using short primers (less than approximately 14 bp) with a random sequence under low-stringency conditions (32, 33). Because of the low-stringency PCR conditions, the primers will bind to genomic regions with perfectly matching sequences as well as regions with a few mismatches. The result is a number of unevenly amplified fragments of different sizes yielding a profile that, theoretically, should be specific to each strain. The method is universally applicable, and it has a typeability of virtually 100%, a discriminatory power that is good but typically less than that of PFGE. Because of the problems with reproducibility, it is comparative and best suited for subtyping of a limited number of isolates during a short time span, but some laboratories have succeeded in creating small libraries of rep-PCR patterns. The reproducibility problems encountered with manual rep-PCR seem to have been alleviated.

Thus, rep-PCR, like RAPD, is a universal and simple subtyping method for most pathogens with a high typeability and a discriminatory power that in general is good but typically less than that of PFGE. Because of the problems with reproducibility, it is comparative and best suited for subtyping of a limited number of isolates during a short time span, but some laboratories have succeeded in creating small libraries of rep-PCR patterns. The reproducibility problems encountered with manual rep-PCR seem to have been alleviated.

#### PCR Ribotyping

In PCR ribotyping, the region between the genes encoding 16S and 23S rRNA is amplified. The method takes advantage of the fact that the genomes of most organisms contain more than one rRNA gene operon and that the size of the amplified region between the 16S and the 23S rRNA gene sequences often varies both within the same strain and between different strains (45). The method is rapid, simple, inexpensive, and in general universally applicable; the typeability is virtually 100%, the reproducibility is good, but the discriminatory power is moderate. Although PCR ribotyping protocols have been described for numerous organisms, the method has gained general acceptance for the subtyping of mainly one organism, *Clostridium difficile* (46, 47).

### Combined RFLP and PCR-Based Methods

#### Amplified Fragment Length Polymorphism

AFLP is a patented fingerprinting technique that is based on the selective amplification of a subset of DNA fragments between interspersed repetitive DNA elements is amplified. Repetitive elements are present in many copies of the genomes of most organisms and conserved among phylogenetically related genera. If they are located close to each other in the genome, the sequence in between them may be amplified by PCR. Usually, several amplicons will be generated, and their numbers and sizes will often vary between strains. Many different repetitive elements have been identified. The most commonly used are the repetitive extragenic palindromic (REP) elements, which are 33 to 40 bp in length (35, 36), the enterobacterial repetitive intergenic consensus (ERIC) elements, which are 124 to 127 bp in length (36, 37), and the BOX element, which is a 154-bp repetitive sequence composed of three subunits, BoxA, BoxB, and BoxC, that may be present in different combinations (38). Theoretically, it is possible to perform highly reproducible and specific rep-PCRs due to the lengths of the primers used. However, in practice, rep-PCR suffers from the same reproducibility problems as RAPD, and when performed manually, results generated in different laboratories or with different PCR equipment and analysis platforms cannot be readily compared (39, 40).

A commercial semiautomated platform for rep-PCR, the DiversiLab system (bioMérieux, Marcy l’Etoile, France), is now available. In this system, quality-controlled reagents are provided in a kit format with Internet-based computer-assisted analysis, reporting, and data storage (41). This way, the reproducibility problems encountered with manual rep-PCR seem to have been alleviated.

Thus, rep-PCR, like RAPD, is a universal and simple subtyping method for most pathogens with a high typeability and a discriminatory power that in general is good but typically less than that of PFGE. Because of the problems with reproducibility, it is comparative and best suited for subtyping of a limited number of isolates during a short time span, but some laboratories have succeeded in creating small libraries of rep-PCR patterns. The reproducibility problems encountered with manual rep-PCR seem to have been alleviated.
generated by restriction enzyme digestion (48). The method involves three steps. First, the genomic DNA is restricted with one or two restriction enzymes, followed by ligation of oligonucleotide adapters to the ends of the restriction fragments. Then a subset of the fragments are amplified by PCR using primers that are complementary to the adapters extending 1 to 3 bases into the restriction fragments, thereby reducing the number of fragments that are amplified by selection of those that are complementary to the extra (selective) bases. Finally, the amplicons are separated by polyacrylamide electrophoresis or, if the primers are fluorescently labeled, in an automated DNA sequencer using capillary electrophoresis (49). Typically, 50 to 100 fragments are amplified, thereby ensuring the high discriminatory power of the method. The method is universally applicable and has been used to study numerous organisms. Its typeability is very high, the discriminatory power is in general of the same magnitude as that of PFGE, and the reproducibility is good if the procedure is standardized (e.g., the same equipment is used in all experiments). However, even if the protocol is standardized, AFLP profiles may not be comparable if different detection platforms or different models of the same brand of DNA sequencer are used (50). Therefore, the intralaboratory reproducibility of the method may be excellent but the interlaboratory reproducibility rarely is, rendering this approach unsuitable for the creation of large-scale surveillance libraries involving multiple laboratories. Finally, the method is fairly complicated, as is the analysis of data generated by it.

Target-Specific Methods
A short description of the principles of some of the target-specific methods is shown in Fig. 3.

**PCR-RFLP**
In PCR-RFLP, a short DNA fragment containing the whole or part of a gene or an operon is amplified, followed by digestion of the amplicon with a suitable restriction enzyme. The resulting fragments are then separated and visualized in an agarose gel. In this way, information about the content of the amplified fragment may be generated without sequencing it. These methods with a few exceptions do not provide much discrimination beyond the species level but may assist in the grouping of isolates at a higher level and in the identification of virulence determinants. For example, several protocols have been described for subtyping of Shiga toxin type 2 (Stx2) in Shiga toxin-producing Escherichia coli (STEC) (51). Toxin subtype information is useful, since there seems to be a correlation between the Stx2 subtype and severity of disease (52). A recently described PCR-RFLP method for further subtyping STEC organisms by targeting the region located upstream from stx genes on the stx phage appears promising, though the resolution was somewhat less than that of PFGE (53).

Another PCR-RFLP application is amplified ribosomal DNA restriction analysis (ARDRA). In this method, the 16S rRNA gene in prokaryotes and the 18S rRNA gene in eukaryotes is the amplification target. Isolates of closely related but different bacterial and fungal species will usually be differentiated, whereas the variation of the restriction patterns is low below the species level. For this reason, this method is an easy way to identify bacterial species that are difficult to differentiate phenotypically, e.g., Acinetobacter genomospecies (54) or mycobacteria (55).

Finally, PCR-RFLP has been used to assist in the rapid identification of Salmonella and STEC O157 flagellar antigens by targeting the fljB and/or the flaC genes (56, 57).
Similarly, a PCR-RFLP protocol for subtyping thermotolerant Campylobacter spp. has been developed. In this protocol, the flagellar gene flaA is targeted (58). The discriminatory power of the method is good albeit less than that of PFGE (59, 60), but due to its simplicity, it is a useful screening tool and a supplement to other methods.

Gene Sequencing

Multi-locus Sequence Typing/Multivirulence Locus Sequence Typing

Multi-locus sequence typing (MLST) was one of the first DNA sequence-based subtyping methods. It was originally introduced by Maiden et al. (61) for Neisseria meningitidis as a sequencing-based counterpart to the phenotypic method multilocus enzyme electrophoresis. MLST detects variation due to mutations or recombination by direct nucleotide sequencing of 350- to 600-bp fragments typically in 5 to 10 housekeeping genes. Innovative technologies, such as electrospray ionization-mass spectrometry (MS), can also be used to determine the base composition instead of direct sequencing (62). When a gene has a base pair change, the new gene sequence is considered a separate allele type. The allele types for each of the gene sequences are combined to define the multilocus sequence type (ST) to characterize the genetic relatedness of the strains. Additionally, MLST results can be analyzed using clustering techniques, such as the eBURST algorithm, which is able to divide isolates based on their STs into clonal complexes (CCs). With eBURST clustering, isolates with a high level of genetic similarity (such as those having six of seven identical alleles) are combined as members of a CC (63). Thus, isolates in different CCs are less closely related to one another than those within the CC.

Since housekeeping genes are under little selective pressure, the accumulation of changes occurring is typically slow. Because the original MLST approach often had a limited discriminatory power in many organisms for it to be an effective epidemiological tool, other similar systems targeting more rapidly evolving genes, such as virulence-associated genes or genes encoding outer membrane proteins, have been developed. This use of virulence factors in an MLST scheme has been referred to as multivirulence locus sequence typing (MVLS). The experience so far has been mixed. Noller et al. (64) used a combination of seven housekeeping genes (arcA, avrE, dnak, mdh, gnd, gapA, pgi) and two membrane protein genes (espA, ompA) to subtype a collection of STEC O157:H7/H8 strains with highly diverse PFGE patterns. Overall, they found a lack of diversity in all housekeeping genes, as well as in espA, and only minimal diversity inompA. In contrast, an MLST scheme developed by Zhang et al. (65) for subtyping Listeria monocytogenes exclusively targeted virulence genes (prfA, inlB, ilcC) and virulence-associated genes (ddl, lisR, cfp) and was able to discriminate between sporadic isolates that were indistinguishable by PFGE. An MLST assay targeting only two genes, the por gene, encoding the outer membrane protein porin, and the thiB gene, encoding the transferring binding protein subunit B, has been proven to be a highly discriminatory method for subtyping of Neisseria gonorrhoeae while still being able to accurately identify sexual contact pairs (66). While MLST can be used for epidemiological surveillance for some organisms with plastic genomes, such as Neisseria species, the key application for it in general is studying the phylogeny and evolution of population lineages (67). MLST may also be used to study differences in host preference or virulence potential in human infection between clonal complexes (68).

One key advantage of MLST over gel-based techniques, such as PFGE, is that the sequence data are nonambiguous, regardless of the type of the instrument used to generate it, and can readily be compared between laboratories through the curated MLST websites, such as http://pubmlst.org, http://www.mlst.net, and http://www.pasteur.fr/mlst. MLST also has a 100% typeability and a high reproducibility. However, sequencing both directions of the DNA strands in multiple loci is rather labor-intensive and expensive compared to some other technologies, such as fragment analysis.

Other Gene Sequencing Applications

The Lancefield M protein is an important virulence factor in group A streptococci (GAS) that is also used for serotype classification. The protein is encoded by the emm gene, and the M serotype may be predicted from its sequence (69). The complete set of emm sequences and the sequencing protocol are available at http://www.cdc.gov/streplab/M-ProteinGene-typing.html. emm typing has made M serotyping available to the broader scientific community while retaining the historical and pathogenic information generated in a relatively few reference laboratories in the course of many years of research using the traditional method. Since there is more variation in emm sequences than is apparent from the M type, emm typing provides additional discrimination of GAS compared to the classical M serotyping method (70).

Similarly, the capsular type is an important virulence factor for pneumococci. This capsule is encoded by the cps gene, and the cps sequences of all the pneumococcal serotypes are available at http://www.sanger.ac.uk/Projects/S_pneumoniae/CPS/. A recent study described a single PCR sequencing strategy based on a primer pair spanning the regulatory gene cpsB that could putatively amplify 84 out of the 92 serotypes studied and differentiate 46 of them (71). A protocol using sequential nested PCRs has been developed to identify the 29 most common pneumococcal serotypes without sequencing the whole gene (72).

Methicillin-resistant Staphylococcus aureus (MRSA) contains a large heterogeneous mobile genetic element, the staphylococcal chromosomal cassette mec, SCCmec, carrying the mecA gene, the central element of methicillin resistance, and the ccr locus, which encodes recombinases (ccrAB or ccrC) involved in SCCmec mobility. SCCmec types are defined by combining the information on the genetic organization of the mec complex with the ccr type and with subtypes defined by variations in the junkyard (J) regions. So far 11 major types (I to XI) have been identified (73). The up-to-date nomenclature and guidelines for reporting novel SCC elements are available on the SCCmec website curated by the International Working Group on the Classification of Staphylococcal Cassette Chromosome Elements (http://www.sccmec.org). Determining the SCCmec type is epidemiologically particularly relevant, since different SCCmec types are associated with hospital and community MRSA infections (74, 75).

Molecular epidemiologic approaches have been used to study the transmission patterns of numerous viruses. The most common approach is to perform sequence analysis on a defined region of the viral genome that contains sufficient genetic diversity to make valid conclusions based on sequence comparison and phylogenetic analyses. The lengths of these sequence “windows” vary with each viral species. Typical windows include hypervariable regions or genes which are often flanked by relatively conserved regions that
make convenient PCR targets. For the purpose of molecular epidemiology, viruses are usually assigned to clades, genotypes, or clusters, represented by established reference strains. In particular, RNA viruses have high mutation rates, which increase the amount of sequence variation in the genome (76, 77).

Variable-Number Tandem-Repeat Analysis
Many microbial genes and intergenic regions contain loci of repetitive DNA which may be varied among strains with respect to the number of repeat units present or their individual structure. These so-called variable-number tandem-repeat (VNTR) regions have been identified in essentially all pro- and eukaryotic species and have been successfully used for subtyping purposes (78, 79). Slipped-strand mispairing (SSM) is the molecular model that best explains the variability of short sequence repeats (80). Stretches of relatively short arrays of repeat units, when being copied by DNA polymerase, may engage in illegitimate base pairing. This forces the polymerase to introduce or delete individual repeat units. The evolutionary clock speeds of different repeat loci are varied; some loci evolve very slowly and others so fast that they are too unstable to be considered epidemiological markers. Therefore, some loci are better suited for epidemiological tracing than others (81). In the simplest form, VNTR analysis may include only a single locus (82). When multiple loci are targeted, the technology is often referred to as multiple-locus VNTR analysis, or MLVA (83).

VNTR loci can be identified from a partial or complete reference genome sequence by using free-of-charge software available on the Web, such as Tandem Repeats Finder (http://tandem.bu.edu/trf/trf.html) or TRedD (http://tandem.sci.brooklyn.cuny.edu/). Tandem-repeat databases (http://minisatellites.u-psud.fr; http://tandem.bu.edu/cgi-bin/trdb/trdb.exe) have also been developed to assist in identifying VNTRs from published sequences using various parameters and query tools (84). A typical MLVA protocol involves a multiplex PCR amplification of VNTR targets, followed by fragment sizing using high-resolution capillary electrophoresis (85). The use of multiple fluorescent dyes to label the forward primers facilitates multiplexing targets with overlapping fragment sizes. The observed fragment size for each VNTR defines the allele type (either a copy number or an arbitrary number), and the string of allele types constitutes the MLVA type.

The key application of MLVA is in the field of epidemiological surveillance used either alone or in combination with other techniques. Since MLVA targets fast-evolving repeat sequences, the discriminatory power of the method can be quite high for many highly clonal organisms that show low diversity with other methods. For example, a MLVA scheme targeting eight VNTRs was able to differentiate laboratory contaminants and non-outbreak-related strains during the 2001 anthrax outbreak in the United States (86). Other organisms that show relatively high diversity with other commonly used methods, such as PFGE, may have clonal subpopulations that can be differentiated using MLVA. This is the case for strains belonging to the Salmonella enterica serotype Typhimurium-defective type 104 (DT 104) complex that, until MLVA was introduced, could not be differentiated efficiently by any subtyping method (87, 88). The downside of targeting fast-evolving genetic elements, such as VNTRs, is that patterns can evolve during an outbreak, complicating data analysis and compromising epidemiological concordance. For example, single- and even double-locus variants have been detected during STEC O157 and S. enterica serotype Typhimurium outbreaks (89, 90).

The advantages of MLVA are its high throughput, low labor intensity, and relatively low per-sample cost. As with many other PCR-based techniques, MLVA is vulnerable to PCR and fragment analysis artifacts, such as minus-A, stutter peaks, and fluorescence carryover, which can interfere with the data analysis. Robustness and reproducibility of the method can be affected by instrument- and reagent-related issues, which in turn can have an impact on the portability of the method and interlaboratory data sharing. For example, significant sizing discrepancies are known to occur between different capillary electrophoresis platforms (91). However, all these issues can be overcome by the proper assay design and optimization, strict adherence to standard operating procedures, and staff training. When different instrument platforms are employed, interlaboratory data sharing can be facilitated by a calibration strain set that is used to normalize the allele types to be comparable to the actual sequenced copy number (92). The overall main weakness of MLVA is that the assays are typically specific to the organism(s) even the sensitivity for which they were developed. Only a few published assays have attempted to cover multiple serotypes or species (93–95). On the other hand, the specificity may also be an advantage, since virtually all strains are typeable and a fingerprint can also be generated without a pure culture from a primary enrichment sample (unpublished PulseNet USA data).

Clustered Regularly Interspaced Short Palindromic Repeat Analysis
Clustered regularly interspaced short palindromic repeats (CRISPRs) represent the most widely distributed family of DNA repeats in prokaryotes. They were initially discovered in E. coli (96) and have recently been identified in approximately 90% of archaeal and 40% of bacterial genomes (97). Most CRISPR-containing prokaryotes possess multiple CRISPR clusters (from 2 to 20 loci), each of which is organized as a tandem array of up to 100 short (21- to 47-bp) and highly conserved direct repeats (DRs) regularly separated by stretches of variable sequences called spacers. Many CRISPR loci are flanked by an AT-rich leader sequence and CRISPR-associated (cas) genes. Spacers are derived from foreign nucleic acids, such as phages or plasmids, and can bestow on the host bacteria protection from subsequent infection by homologous phages or plasmids (98, 99).

As a bacterial immune system, CRISPRs evolve rapidly in response to changing phage pools. CRISPRs evolve by either deletion or acquisition of units (a DR and a spacer). In the majority of cases, new units are added at one end of the CRISPR adjacent to the leader, whereas motif depletions can occur randomly (100).

CRISPR loci can be identified from partial or complete genome sequences and their structures characterized using the CRISPRFinder program available at http://crispr.u-psud.fr/Server/CRISPRFinder.php (101). The extracted CRISPRs are stored in a public database (CRISPRdb), which is also automatically updated from published genomes. The first CRISPR application developed was spoligotyping of M. tuberculosis, which consisted of detection of the presence or absence of a range of spacers after PCR by hybridization on a membrane (102). Nowadays, a typical CRISPR protocol involves PCR amplification of CRISPR loci followed by either Sanger sequencing of the PCR products or detection of the presence or absence of spacers using oligonucleotide probes coupled on a DNA microarray (103, 104). The free-of-charge Web resource CRISPRcompa
CRISPR analysis can be used for epidemiological surveillance either alone or in combination with other targets. CRISPR analysis and MLST of two virulence genes have been successfully used to subtype Salmonella strains, with particularly promising results for serotype Enteritidis, which is highly clonal by other methods (105, 106). It remains to be seen how effective CRISPR analysis is as an attribution tool, but given that different phages are known to be unique to specific niches, the spacer composition may give clues about the source of a particular strain (107).

WGS

The introduction of high-throughput, next-generation sequencing (NGS) technologies resulted in a dramatic decrease in the per-base cost of genomic sequencing over the course of the past decade, with a corresponding increase in the volume of data output. The earliest NGS platforms were based on massively parallel pyrosequencing (108, 109), and subsequent generations of the technology have either refined this approach or applied new advances, such as ligation chemistry (110), semiconductor-based detection (111), single-molecule sequencing (112), and engineered protein nanopores (113). There are currently four main commercial platforms for NGS, namely, 454 GS FLX+ (Roche Diagnostics, Branford, CT), Ion Torrent PGM and Proton (Life Technologies, Guilford, CT), MiSeq and HiSeq (Illumina, San Diego, CA), and PacBio RS/RS II (Pacific Biosciences, Menlo Park, CA). With the exception of PacBio RS/RS II, which can perform single-molecule, long-read sequencing of libraries >10 kb, all of these systems generate between several hundred thousand and several billion short-read sequences between 100 and 800 bp long. Despite this similarity, there are nonetheless important differences in read length, sequence output, turnaround time, accuracy, error model, and cost (114–116). Each of these factors must be considered when selecting an appropriate sequencing strategy for specific objectives and applications. To further complicate matters, as NGS technologies continue to mature, the hardware, software, chemistries, and consumables are all subject to intense development and innovation, with improvements to sample throughput and data quality, and continual decreases in per-isolate sequencing costs.

WGS represents the ultimate tool in molecular epidemiology, as it allows the identification of single genomic changes between two isolates. The technology has not yet been widely used for real-time surveillance and outbreak investigations at the community level, though it has proven its power in a few recent investigations in health care settings (117–119). WGS has been widely used to develop new diagnostic tests for known and emerging pathogens (120), and it has become an important tool in pathogen discovery and characterization and in studying pathogen evolution and transmission. A recent example is the analysis of the complete genome of the swine origin H1N1 strain that emerged in 2009, which showed that the virus had been circulating in humans for an extended period as the result of a single introduction. The new strain had genome segments derived from swine, human, and avian strains (121). Similarly, in the 2011 German outbreak of E. coli, WGS played a key role in understanding the determinants and modeling the evolutionary events that led to a hypervirulent strain (122, 123).

As the cost and complexity of sequencing continues to decline, the management and analysis of the massive volumes of output data have emerged as a significant challenge to the routine use of NGS for infectious disease surveillance, outbreak detection, and response. In order to be useful for public health intervention, raw whole-genome sequence data from suspected pathogens must be analyzed, assembled, interpreted, and compared in a timely fashion, so that action may be taken to prevent or minimize disease-associated morbidity and mortality. In the case of a small outbreak investigation, these data may represent tens of gigabytes of raw sequence, but for large molecular surveillance efforts, such as the PulseNet network for foodborne disease surveillance (124), the expected raw sequence output could easily surpass a hundred terabytes of raw genomic sequence data each year. The challenge of genomic “big data” will require the development of a dedicated informatics infrastructure to support NGS and other high-throughput laboratory technologies and the incorporation of genomics, bioinformatics, and data science skill sets by the public health workforce. Since most end users of the technology will be microbiologists in clinical and public health laboratories with limited informatics skills, it is critical that user-friendly and intuitive bioinformatics tools be developed for most sequencing-related surveillance activities. Equally important for global health is the development of clear and concise international consensus standards on sequence quality; data compression, storage, and transmission; sequence-associated metadata; and analytical methods for outbreak detection and response. Work to address these issues has already been initiated through the Global Microbial Identifier (GMI) network (http://www.globalmicrobialidentifier.org/), which consists of approximately 200 experts from at least 30 countries, including clinical, food, and public health microbiologists and virologists, bioinformaticians, epidemiologists, representatives from funding agencies, data hosting systems, and policymakers from academia, public health, industry, and governments.

Whole-Genome SNP Typing

Whole-genome single nucleotide polymorphism (SNP) typing involves mapping sequence reads from each query (or test) isolate against a reference genome to identify and compare positions of single nucleotide variations. The reference sequence is typically selected from among closely related, finished genomes from public repositories or from a high-quality de novo assembly of an epidemiologically important internal reference isolate (e.g., an index case or putative source) in cases where an external reference sequence is either not available or not appropriate for the investigation. An example of the latter case is illustrated in Fig. 4.

The initial pool of candidate SNPs can vary greatly in number between organisms according to their genome sizes, their complexity and plasticity, their population diversity, and the quality and coverage of mapped sequence reads. Candidate SNPs identified from each mapping are typically
### TABLE 3 Definitions commonly used in bioinformatics

<table>
<thead>
<tr>
<th>Term</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>Annotation</td>
<td>The identification and functional determination of genes and genetic elements within a sequence.</td>
</tr>
<tr>
<td>Genome assembly</td>
<td>Process by which many short DNA sequence fragments, such as those generated by next-generation sequencers, are reassembled into a representation of the original genomic sequence.</td>
</tr>
<tr>
<td>Contig</td>
<td>Contiguous consensus sequences derived from the assembly of many short, overlapping DNA fragments.</td>
</tr>
<tr>
<td>Coverage (read depth)</td>
<td>Avg number of reads representing a given nucleotide in the reconstructed sequence.</td>
</tr>
<tr>
<td>De novo assembly</td>
<td>Genomic assembly without an a priori reference sequence to inform the genomic structure.</td>
</tr>
<tr>
<td>High-confidence SNP</td>
<td>Single nucleotide polymorphism that has been verified using specific criteria, such as sequence coverage, sequence quality, and population and allelic frequency. While these parameters will vary depending on the context and application of the SNP calling, the typical minimum criteria are 10 to 20× coverage, &gt;Q20 (see below for definition), and 100% frequency.</td>
</tr>
<tr>
<td>Indel</td>
<td>Insertion or deletion of nucleotides, which results in a net change of the total number of nucleotides.</td>
</tr>
<tr>
<td>k-mer</td>
<td>Oligonucleotide of length “k.”</td>
</tr>
<tr>
<td>N50 statistic</td>
<td>Commonly used as a rough assessment of genomic assemblies. It represents the contig length for which all contigs of that length or greater include at least half of the total base pair length of the sequence set.</td>
</tr>
<tr>
<td>Open reading frame</td>
<td>Uninterrupted reading frame in a given sequence that may be used for gene prediction.</td>
</tr>
<tr>
<td>Per-base sequence quality</td>
<td>The sequence quality score for each individual base position in a sequence. Typically, Phred scores are used, where Q = −10log(error probability). A Q30, for example, means a 1-in-1,000 likelihood of an incorrect base call at that position.</td>
</tr>
<tr>
<td>Read</td>
<td>A unit of continuous DNA sequence derived from target DNA.</td>
</tr>
<tr>
<td>Reference-mapped assembly</td>
<td>Assembly of a genome by aligning new sequence reads against a preexisting and similar reference sequence.</td>
</tr>
<tr>
<td>Suffix array</td>
<td>An array of all substring suffixes of a longer string. For example, the sequence ATGCATGC, represented as an array (A[i]), includes suffixes of ATOCATGC, ATOCATG, ATGCAT, ATGCA, ATGC, ATC, AT, and A.</td>
</tr>

filtered according to sequence quality; the position, genomic distribution, and functional impact of variant alleles; and population-level considerations, such as allelic frequency, genetic convergence, homoplasy, and linkage disequilibrium. With sufficient bioinformatics expertise and computational resources, the distillation from reference mappings to a minimum set of high-confidence, parsimoniously informative loci can be completed relatively quickly. Once validated, sets of high-confidence canonical SNPs can be used as targets for the analysis and subtyping of subsequent isolates or as the basis for high-throughput surveillance says using real-time PCR or other lower-cost molecular technologies (125, 126).

There are several circumstances in which SNP-based strain typing may perform suboptimally, primarily due to its dependence on consistent reference mapping. For some organisms, there are no circularized reference genomes necessitating the use of de novo assemblies as references. Even when a closed reference genome exists, genomic plasticity in the population may be sufficiently high in species such as Neisseria gonorrhoeae or Burkholderia that mapping to historical reference strains may be inefficient or result in
important gaps in genomic coverage. Similarly, in organisms where critical virulence and diversity factors are carried by plasmids, transposons, or other mobile genetic elements, information about important discriminatory loci may be absent from the available reference sequences. One strategy is to construct composite reference sequences from the microbial chromosome, with major plasmids or transposons of interest appended as a pseudoassembly. While this approach allows for the consideration of these extrachromosomal sequences, the limited stability of many mobile genetic elements and important differences in selective pressure between chromosomal and extrachromosomal alleles may present important problems. Some organisms also contain mutational hot spots (clustered mutations) from which SNP calls need to be assessed carefully, with the natural error rate of Taq polymerase kept in mind. A final consideration relates primarily to fungi and parasites, where the ploidy (number of sets of chromosomes) of the organism and the presence of complex or heterogenous alleles may impact the number and quality of high-confidence, discriminatory SNPs that are useful for subtyping and analysis.

**WGS, MLST, and Binary Typing**

As the sequencing, assembly, and annotation of large numbers of microbial genomes become increasingly cost-effective and feasible, it is possible to define and query large-scale MLST or binary typing schemes, which include dozens or even hundreds of different genes or sequences of interest. This approach can be applied to both microbial subtyping and characterization, as important differences in gene complement may be associated with the mobilization of plasmids, transposons, bacteriophages, or horizontal gene transfer from other organisms and may signal phenotypic differences in levels of virulence or antimicrobial susceptibility. Publicly available database schemas and software, such as the Bacterial Isolate Genome Sequence Database (BIGSdb) [http://pubmlst.org/software/database/bigsdb/](http://pubmlst.org/software/database/bigsdb/), allow bacterial genomes to be catalogued and systematically compared across many different MLST targets (127). Other measures, such as BLAST (Basic Local Alignment Search Tool) score ratios (BSR), provide a more general assessment of the functional similarity of two genomes, based on the pairwise comparison of all open reading frames (ORFs) (128).

Although gene-based comparisons are emerging as an important strategy for strain typing and characterizing bacteria and other pathogens using WGS data, current limitations with short-read next-generation sequencing and bioinformatic analysis may impact their usefulness, particularly for large-scale comparisons. The reliance of these techniques on high-quality genomic assemblies and the consistent prediction or annotation of open reading frames present challenges in terms of the technical complexity and throughput of the analysis. Draft bacterial genomes may include hundreds of contigs, and the interpretation of complex MLST schemes will invariably be affected by breaks, duplications, or misassemblies of important sequences or reading frames. Differences in assembly or gene prediction algorithms may also impact the throughput of the assay and interpretation of results, and the development of standardized bioinformatic methods and workflows is critical, particularly as sequence databases scale to hundreds or thousands of genomes with many different alleles.

**Binary typing data** for the presence or absence of genes or genetic variants may also be used to provide useful information for microbial characterization, particularly when used in conjunction with other strain typing methods. Interrogating sets of known resistance and virulence markers can provide important information during an outbreak investigation or response, and these features can often be used to support strain type identification or to correlate with transmission or patient outcomes.

**K-mer Analysis**

Recently, a number of different k-mer-based approaches have emerged to analyze and compare large genomic data...
sets in a computationally efficient manner. In general, these algorithms deconstruct genomic sequences or unassembled raw reads into large sets of k-mers, or oligonucleotides of length “k,” for comparison by means of suffix arrays. The k-mers are then sorted, deduplicated, and compared to other k-mer sequence sets to identify variations (SNPs and indels) that can be used for clustering and comparison (129).

Unlike traditional SNP-mapping approaches, which take into consideration the genomic context of the variant position and the underlying sequence quality of the reads that support its identification, k-mer-based SNP analysis focuses on the putative SNP position and the 10 to 12 bases of surrounding sequence, without consideration of quality scores. These are important limitations, which may restrict the ability of k-mer-based methods to reliably detect closely spaced SNPs or indels and result in limited resilience against low sequence quality or sequencing errors. Even so, k-mer methods have significant advantages in terms of speed and implementation, since they do not require assembly or alignment of sequences and can be equally applied to whole-genome sequence sets and unassembled sets of short reads.

k-mer-based algorithms continue to improve, and recent implementations for strain typing can assess horizontal gene transfer, annotate SNP positions based on a known reference, demonstrate missing alleles and reveal evolutionary convergence, and they are easily adapted to new applications, such as the metagenomic analysis of complex samples (129). During outbreak investigations in particular, k-mer-based SNP analysis is an excellent tool for initial genomic comparison and clustering, since it provides actionable strain typing information quickly and can be used to guide the application of more-resource-intensive downstream bioinformatics analyses, which may take several days to complete.

DNA Microarrays
A DNA microarray is a molecular platform in which a few hundred to thousands of specific DNA oligonucleotides or short sequences (capture molecules) are bound to a matrix. The array is used to detect specific DNA sequences (target sequences) in a test sample of fluorescently labeled DNA, with or without amplification, by hybridization followed by detection of the array-bound test DNA. Two types of arrays, planar and liquid, are used.

Analysis with planar microarrays is typically performed by deposition of DNA probes complementary to the genome targets of interest on a glass slide (solid matrix). Probes are typically synthetically produced oligonucleotides (9 to 100 bp) or PCR products (100 to 1,000 bp). They can target ORFs amplified from the sequenced reference isolates or ORFs amplified from the sequenced reference isolate or the sequenced reference genome. From this, ORFs can be used to detect a large number of viral pathogens and can quickly identify the etiologic agent in unknown sources (139). When the amount of target is abundant (138), the disadvantage of this approach is that there is a practical limit to the number of primer sets that can be included in the PCR. Instead of coupling PCR amplification and DNA array detection, applying direct detection to extracted DNA or RNA is achievable when the amount of target is abundant (138). The primary goal in this case is to avoid amplification biases associated with PCR.

Several DNA microarrays have been developed for rapid identification of viruses, including the ViroChip and the GreeneChip (139–141). These arrays have the capacity to detect a large number of viral pathogens and can quickly identify the etiologic agent in unknown source outbreaks (142, 143). In some cases, the arrays are designed to detect specific groups of viruses, such as respiratory pathogens (144–146). The most comprehensive pathogen detection
arrays reported to date were designed by a team at the Lawrence Livermore National Laboratory. The Lawrence Livermore microarray detection assay (LLMDA) can detect over 6,000 viruses and 15,000 bacteria as well as fungi and protozoa (147, 148). The array contains both “discovery” probes, which match conserved genome regions that are unique to a taxonomic family or a subfamily but shared by species within that family, facilitating detection of novel species within a family, and “census” probes, which target highly variable regions unique to an individual species or a strain and can hence be used for forensic purposes.

Microarrays have also been used to genotype viral and bacterial agents based on SNPs occurring on specific sequence regions. In many cases, though, whole-genome sequence analysis may be the more cost-effective means of obtaining a viral or bacterial genotype. Nevertheless, there are numerous examples of the use of microarrays for viral genotyping, including human rotavirus (149), human and avian influenza viruses (150, 151), hepatitis B virus (152), HIV (153), varicella-zoster virus (154), measles virus (155), human papillomavirus (156, 157), polioviruses (158), and neoroviruses (142, 143). Similarly, microarrays have been utilized for bacterial subtyping by polymerase chain reaction (PCR) electrospray ionization mass spectrometry to identify select organisms (159), SNP analysis (160, 161), and binary typing (162) and for detection of the presence or absence of antimicrobial resistance genes (163, 164) or specific mutations conferring antimicrobial resistance (165, 166).

Microarrays, besides being used for pathogen identification and genotyping, have been used for resequencing the complete genomes of viral agents (167, 168) and partial bacterial genomes (169, 170); however, the development of next-generation sequencing methods has made array-based sequencing impractical.

Mass Spectrometry

In recent years, matrix-associated laser desorption ionization–time of flight (MALDI-TOF) MS systems have become increasingly common in clinical and public health microbiology laboratories throughout the world. In contrast to earlier generations of mass spectrometry equipment, which were complex, costly, and difficult to maintain, these newer instruments offer simpler workflows for many genus- and species-level microbial identification tasks, with high throughput, accurate and fast results, and a low overall per-test cost (171). While a few proof-of-concept studies have demonstrated the feasibility of MALDI-TOF for strain- and subspecies-level identification of select organisms (172–175), standardized or generalizable methods have yet to be developed, and in most cases, the current level of resolution of MALDI-TOF, when used alone, remains at the genus or species level. Attempts have been made by some commercial companies to combine mass spectrometry with other technologies and typing approaches. The PLEX-ID (Abbott Laboratories, Abbott Park, IL) system uses PCR and reverse transcription-PCR (RT-PCR) electrospray ionization mass spectrometry to identify and/or type viruses, bacteria, and fungi. For most bacterial species, the level of resolution is generally equivalent to that of MLST, with the inclusion of other important multiplexed targets for further confirmation or characterization (176).

Another system, the Agilent MassCode PCR system (Agilent Technologies), uses highly multiplexed PCR panels and identifies/subtypes microorganisms through the detection and measurement of cleavable mass tags using atmospheric-pressure, chemical-ionization, quadrupole mass spectrometry (177). Other platforms, such as the Sequenom MassArray (Sequenom Inc., San Diego, CA), use PCR MALDI-TOF to interrogate thousands of SNPs through a single primer base extension and can be used for high-resolution SNP-based strain typing using standardized sets of canonical targets (178). However, these applications remain under active development and in most cases do not currently provide the discriminatory power needed for epidemiologically relevant high-resolution strain typing.

APPLICATIONS

Molecular Surveillance

Molecular Serotyping

Serotyping is a subtyping method in which specific antigens on the surfaces of microorganisms are detected by antigen-antibody reactions using diagnostic antisera. The method is definitive but only moderately discriminatory. It has nevertheless proven to be extremely useful for epidemiologic classification of a number of pathogens and has for this reason been a mainstay in the surveillance of different infectious diseases for more than 70 years. It is a cumbersome method that requires the availability of high-quality antisera and substantial expertise to perform the assay and interpret the results. More convenient, rapid, and reliable molecular alternatives to serotyping are being developed. These molecular serotyping methods are designed to generate data that are in close or complete agreement with conventional serotyping in order not to lose the connection to the historical data. In the previous sections, molecular flagellin typing of Campylobacter (flaA typing), M serotyping (emm typing) of GAS, and capsular (cps) typing of pneumococci have been mentioned.

In the genus Salmonella, more than 2,500 serotypes are currently recognized (179). Two types of molecular serotyping approaches have been used; in one, a molecular subtyping method is correlated with the serotype, and in the second, the genes actually encoding the serotype are targeted directly. In this latter case, for O antigens the genes are within the rfb gene cluster, and for the flagellar antigens the flaC and flaB genes encode phases 1 and 2, respectively. Some examples of subtyping methods that correlate with serotyping are MLST, PFGE, ribotyping, and rep-PCR (180); the correlation between subtyping methods is never perfect, and ideally, serotypes determined this way should be confirmed by traditional serotyping or a molecular serotyping method targeting the serotype-encoding genes. Regarding the latter, the U.S. Centers for Disease Control and Prevention (CDC) has developed an assay that reliably identifies the vast majority of the serotypes involved in human infections using a combination of PCR amplification of the rfb genes, flaC, and flaB, with detection of the amplimers using a liquid microarray (159, 181). This assay was recently commercialized by Luminex. With the advances in sequencing technology, it is also becoming increasingly cost-efficient to determine the serotype directly from the sequences of the serotype-encoding genes (182). The methods targeting rfb, flaC, and flaB are directly compatible with the Kaufman-White scheme, which contains the phenotypic descriptions of all Salmonella serotypes (179), and the results will not need to be confirmed by traditional serotyping.

Cluster Detection/Outbreak Investigations

Subtyping methods that are used for community-wide routine surveillance to detect disease case clusters and to support outbreak investigations need to be rapid, highly dis-

Source Attribution

Source attribution is the epidemiological science that studies the relative contributions of different sources to the burden of infectious diseases. Strictly speaking, outbreak investigations are source attribution analyses, but the term is more commonly used in a broader sense encompassing both outbreak-related and sporadic disease. Molecular methods may be used to study the geographic distribution of sources and spread of microbial strains, and this is discussed in a section below.

For highly infectious viruses, such as measles virus, transmission can occur anywhere. Molecular techniques have been used to identify the source of the infections when standard case investigations have failed to identify a source (191).

Source Attribution

Source attribution is the epidemiological science that studies the relative contributions of different sources to the burden of infectious diseases. Strictly speaking, outbreak investigations are source attribution analyses, but the term is more commonly used in a broader sense encompassing both outbreak-related and sporadic disease. Molecular methods may be used to study the geographic distribution of sources and spread of microbial strains, and this is discussed in a section below.

The combination of molecular epidemiologic techniques and standard case classification and reporting provides a very sensitive means of describing the transmission pathways of many viruses. In particular, analysis of the sequence data can help to confirm the source of a virus or suggest a source for cases in which the source was unknown. Molecular data can be used to establish epidemiologic links, or lack thereof, between various cases and outbreaks. Molecular techniques have been particularly useful for the study of outbreaks of foodborne viruses, such as norovirus (188). In these cases, sequence data were used to identify the source and to trace the transport and distribution of contaminated food (189, 190).

For highly infectious viruses, such as measles virus, transmission can occur anywhere. Molecular techniques have been used to identify the source of the infections when standard case investigations have failed to identify a source (191).
distribution of each source to the burden of human disease (192). This approach was introduced in the United Kingdom to attribute the sources of Campylobacter jejuni and Campylobacter coli to predominantly chicken meat, with ruminants being another important source (193), and has since been used in many countries to attribute the sources of campylobacteriosis and to guide and to demonstrate the effect of intervention measures (194, 195).

The limitation of the model is that it will attribute only to sources for which there are data available; i.e., if no isolates are included from a potential major source, no estimates for this source will be generated. Subtyping methods used for source attribution do not need to be as discriminatory or reproducible as those used for outbreak investigations, as long as they clearly differentiate isolates from different sources. Choosing a subtyping method with an unnecessarily high discriminatory power will increase the complexity of the analysis of the data set. In regard to Campylobacter, PFGE is the gold standard for outbreak investigations, whereas the less discriminatory method MLST works well for attribution. Theoretically, subtyping methods that provide phylogenetic information are more useful for source attribution than methods that do not provide this information, since the data collected from each source are likely not to be all-inclusive. Even if some subtyping information is missing, the data may still be useful, since strains that are related phylogenetically to each other are more likely to originate from the same source.

Dynamics of Infectious Disease

Pathogen Evolution

Molecular techniques have made enormous contributions to our understanding of the evolution of pathogens, but a detailed description of these studies is beyond the scope of this chapter. Molecular techniques have been used to monitor the distribution of circulating strains of various pathogens, to monitor the stability of antigenic sites that are important for diagnostics and as vaccine targets, and to assess susceptibility to antimicrobial drugs.

Improvements in computational molecular biology resources and new analytical methods such as BEAST (Bayesian Evolutionary Analysis and Sampling Trees) (196) incorporate sample date and allow the evolutionary dynamics of a population to be inferred from sequence data. These approaches are called phylodynamics (197). With these approaches, sequence information from infectious agents can be used to infer the transmission patterns of that agent over time. Analysis of hepatitis C virus sequences from Egypt suggested an exponential increase in the number of cases in 1990 and 1995, when unsterile needles were used to distribute an antischistosomal therapy (198). Similar studies documented the episodic transmission of HIV into London during the late 1990s (199). More recently, these methods were used to investigate the origins of the swine origin influenza A H1N1 (2009) viruses that were associated with the influenza pandemic in 2009 and 2010 (200).

Geographic Spread

The ability of a molecular technique to identify the source of an infectious agent can be applied on a global scale, and the information can be used to monitor the spread of the pathogen. The sensitivity of this approach depends on the level of surveillance activity and the availability of a global database of genetic information. Sequence analysis was used to identify the source of the West Nile virus that was introduced into the United States in 1999 and to track the spread of this lineage of virus across the entire country (201, 202), as well as to track the global spread of various genetic variants of HIV (203).

Sustained Transmission in Areas That Are Destined for Elimination

Molecular surveillance for viral diseases that are prevented by vaccination is especially beneficial when it is possible to observe the change in viral genotypes over time in a particular country or region. This information, when analyzed in conjunction with standard epidemiologic data, has helped to document the interruption of transmission of endemic viruses and provides a means to measure the success of vaccination programs.

Molecular characterization of measles viruses has provided a valuable tool for measuring the effectiveness of measles control programs. In general, three patterns of measles genotype distribution have been described. In countries that still have endemic transmission of measles, the majority of cases are caused by several endemic genotypes that are distributed geographically. In these cases, multiple cocirculating lineages within the endemic genotype or genotypes are present. In countries that have eliminated measles, the small numbers of cases are caused by a single or different genotypes that reflect various sources of imported virus and suggest the lack of sustained transmission of an endemic genotype or genotypes. The third pattern occurs in countries or regions that have had very good measles control but are experiencing an increase in the numbers of susceptible individuals because of failure to maintain high rates of vaccination coverage. In this situation, reintroduction of measles usually results in a large outbreak associated with a single genotype of virus with nearly identical sequences (191, 204–206).

Pathogen Discovery/Identification

Molecular methods are sometimes crucial for the discovery of new pathogens, especially viral pathogens, and to determine if a pathogen is truly new or has arisen from known pathogens through recombination or other genetic events. For example, coronaviruses have the ability to recombine with other coronaviruses as well as to incorporate cellular genes into their genomes (207). The initial analysis of the complete genome sequence of the coronavirus associated with severe acute respiratory syndrome (SARS-CoV) confirmed that the virus was a novel coronavirus and not a recombinant between previously described coronaviruses (208, 209). In 2012, rapid WGS of a novel coronavirus causing acute respiratory syndrome in humans (HCoV EMCoV) showed that the new virus was a new variant of Betacoronavirus that was closely related to a bat coronavirus and more distantly related to SARS-CoV (210–212).

Vaccination Issues

Live attenuated vaccines are used to control a number of viral diseases. In some cases, these vaccines can cause symptoms that are similar to those caused by infection with the wild-type virus. When the risk of exposure to disease is very low, these vaccine reactions can be identified by temporal association with vaccination. However, when vaccination is used as part of an outbreak response, it may be difficult to distinguish vaccine reactions from symptoms caused by the wild-type virus. Since serologic techniques usually lack the sensitivity to distinguish between antibodies directed at the vaccine or the wild-type strain, genetic characteriza-
tion of the viruses is usually the only means available to clearly classify the case as vaccine associated or due to a wild-type infection. Of course, this approach requires that appropriate specimens for virologic detection be collected from the suspected cases and that sequence information be available for the vaccine strains.

The availability of molecular methods that can clearly identify vaccine reactions, as described above, has contributed to our knowledge about the safety of live attenuated vaccines. In addition, molecular techniques now play an important role in the postlicensure evaluation of live attenuated viral vaccines. Here, genetic characterization is used to monitor the stability of vaccines in the field and to clearly identify vaccine reactions. In one example, PCR and RFLP analysis were used to monitor the safety of varicella-zoster vaccine by classifying vesicular rash or zoster cases as being associated with wild-type varicella-zoster virus of the Oka vaccine strain (213). Additionally, some viruses have the capacity to recombine or reassort their genomes, and in these cases, WGS is an important component of molecular epidemiologic studies. The live attenuated strains used in the WHO poliomyelitis program replicate in the human gut and can be excreted for several weeks after immunization. If the attenuating mutations in the vaccine strains revert, the vaccine may cause vaccine-associated paralytic poliomyelitis in vaccinees or result in transmissible, neurovirulent, circulating vaccine-derived poliovirus strains which have been associated with outbreaks of poliomyelitis (214, 215). The vaccine-derived polioviruses often contain mosaic genomes that result from recombination between the vaccine strains and other lineages of poliovirus or other enteroviruses (215, 216), and these variants can be detected only by full-genome sequencing.

In some cases, data from molecular surveillance of viral and bacterial pathogens are used to decide on the most appropriate formulation for vaccines. The geographic distribution of strains may affect the efficacy of the vaccines if the genetic changes are accompanied by changes in antigenicity. Therefore, for agents with variable antigenic properties (e.g., rotavirus and influenza virus), careful monitoring of the strains associated with cases in vaccinated populations is necessary (217–219).

**Forensic Microbiology**

Sometimes infectious disease incidents are criminally investigated if there is a suspicion that they may be the result of deliberate actions or criminal gross negligence. HIV-infected individuals have been imprisoned for spreading the virus intentionally (220) or through negligence (221), and anthrax has been spread through the mail (86, 222). Numerous outbreaks of foodborne infections occur each year, and some have been the result of intentional contamination of the food supply (223). Forensic molecular epidemiology comes into play when regulators and laymen, judges, and lawyers have to decide if an infection (or infections) is a result of criminal action. In principle, criminal microbiological investigations are not different from outbreak investigations, except that in criminal investigations, the link between the infection(s) and its (their) source(s) needs to be proven beyond reasonable doubt. In outbreak investigations, the precautionary principle is relatively often used when deciding on public health actions, since the aim of an outbreak investigation is to stop the outbreak from spreading as soon as possible. This is in contrast to criminal investigations, where the precautionary principle is not used since an offender is presumed innocent until proven otherwise. Subtyping methods that may quantify the probability that two microbial strains are related are therefore preferred over methods that do not yield direct quantifiable information. Non-target-specific methods are therefore not ideal for criminal investigations because DNA fragments of the same size may have completely different sequence contents; e.g., it is not possible from the PFGE pattern to tell if two isolates are identical, hence the use of the term “indistinguishable” for PFGE patterns that cannot be differentiated from each other. In contrast, differences observed with a target-specific method may be quantifiable if the prevalence of the detected alleles is known in the relevant microbial populations.

**SUBTYPING METHOD SELECTION, VALIDATION, AND DATA INTERPRETATION**

**Method Selection**

All too often, it appears that the selection of subtyping methods is guided only by convenience criteria, in particular, the accessibility of a method to the laboratory. This has led to numerous studies in which an inappropriate method was used to study an organism (1). When selecting a subtyping method, one should first of all consider the epidemiological context in which it is going to be used; i.e., what is the question that the typing data should answer? A method that is appropriate for long-term surveillance is most likely not appropriate for a short-term investigation of a nosocomial outbreak. Careful consideration should also be given for the genetic makeup of the target organisms, including the clonality, mode of transmission, and outbreak potential.

**Factors That Impact the “Clonality” of a Given Population**

The clonal relatedness of isolates is manifested by their display of a significantly higher level of similarity in their genotype and/or phenotype than can be expected from randomly sampled and epidemiologically unrelated isolates of the same species (1). The simplest explanation for a genetically monomorphic pathogen is that the population size of the ancestors of all extant organisms was so strongly reduced during a recent bottleneck that genetic diversity was abolished. One possibility that can result in such a bottleneck is a crucial genetic event that happened only once, such as a change in ecological niche due to the acquisition of two plasmids by the progenitor of *Yersinia pestis* (224). In the case of STEC O157, it has been suggested that clonality can be explained by source-sink evolution dynamics (225–227). According to this theory, mutations in microbes that reside mainly in reservoirs (the source, e.g., cattle) in which they are not pathogens confer on a small subset a phenotype that results in injury to an accidental host (the sink, e.g., humans). Alternatively, it has been argued that a strong selective advantage conferred by a mutation enabled certain strains of STEC O157 to flourish in cattle, making them more available for spillover into humans (227). On the other hand, some host-restricted pathogens, such as *S. enterica* serotype Typhi, are under relatively little selection pressure from their host or environment and therefore do not diversify through point mutations, recombination, or acquisition of new sequences (228). Finally, a sampling bias may also contribute to the appearance of population clonality. Sampling from one part of the phylogenetic tree will overlook much of the variation present in the population and collapse all isolates outside the studied population into a single type (229). In order to be able to adequately discriminate clonal organisms, subtyping methods targeting fast-evolving genetic elements, such as VNTRs or SNPs, are usually preferred (230, 231). With some organisms, optimal results...
Method Validation

Once a proper method or approach has been selected, it must be subjected to the highest scrutiny possible to ensure that it meets the criteria discussed at the beginning of this chapter. This includes validation using a population of strains and isolates that originate from the epidemiological context to which the method is going to be applied. Techniques that will be applied in local investigations need to be validated on a strain collection from the same locality, whereas methods that will be used for community-wide surveillance need to be validated on a collection of strains reflecting the diversity in the whole community. When a subtyping method that has been validated for use in one given epidemiological context is to be used in a different one, it may be necessary to validate it in the new context before it is implemented. This supplementing validation may not need to be as thorough as the original validation, depending on how similar the two contexts are.

Unlike methods developed in isolation (for use by one laboratory), methods to be used in multiple laboratories for the generation of data archived in reference libraries must be particularly carefully tested, evaluated, and validated. All methods need to go through four phases of validation: initial development, internal validation, external validation, and, finally, postimplementation evaluation. The first two phases often overlap. Additionally, before the new method is implemented, a quality assurance and quality control (QA/QC) program needs to be established.

The goal of the initial development is to identify the optimal conditions or parameters to ensure that the protocol is robust and reproducible and generates highly discriminatory and epidemiologically concordant data on all strains. Ten to 50 isolates that represent the diversity in the study population at large is typically used in this phase.

During the internal validation, the method is tested by individuals not involved in the method development in order to ascertain the robustness of the protocol in the hands of laboratorians with no prior experience with it. The panel of test isolates is expanded to include the full genetic diversity of the study population and should contain both sporadic and outbreak-related isolates in order to test the true discriminatory power and the epidemiological concordance of the method. Duplicate isolates of the same strain and multiple isolates from single-source outbreaks need to be included to evaluate the reproducibility and stability of the method. The test panel will usually contain 250 to 500 isolates. The isolates need to be selected from a collection of strains with a known subtype if a gold standard subtyping method exists for the organism in order to be able to evaluate the performance of the new method against this gold standard.

During the external validation, the robustness and portability of the method is further tested typically by 5 to 10 external partner laboratories, ideally with different levels of subtyping expertise and access to different types or brands of equipment and reagents. The assay is evaluated using 10 to 50 isolates selected by the laboratory that developed the method. The interlaboratory reproducibility of the method is also assessed during this phase. Sometimes the external validation is further expanded to include a prospective or retrospective testing of up to 50 isolates from each laboratory’s own collection.

Following the successful completion of these phases, the method may be implemented. However, even after its implementa-

mentation, the performance of the assay needs to be assessed on a regular basis to detect problems not identified during the initial validation and to assess emerging situations, such as the impact of introduction of new brands of reagents that may have become commercially available.

Quality Assurance/Quality Control

A quality assurance program needs to be in place before any molecular subtyping technique is implemented to ensure consistently high quality and reproducibility of the data generated. At a minimum, subtyping should be performed only by personnel trained in working with the procedure; a written standard operating procedure should be in place, and a strain with a well-established stable subtype should be included in all experiments in order to detect procedural failures. For library subtyping systems involving multiple laboratories, participation in an external quality assessment (EQA) program that includes an initial certification and annual proficiency testing is mandatory.

Data Interpretation

When interpreting subtyping results, one must consider the epidemiological context and all other available data, such as associated demographic and other epidemiological information, and other subtyping information, e.g., biochemical reaction profiles, serotype, phage type, antimicrobial susceptibility profiles, and the presence of virulence factors; reliance on a single parameter for characterization should be avoided whenever possible. Knowledge of the subtyping method, including the quality of the data, the diversity of the organism, and the history of the subtypes encountered, should also be considered (233).

Quality of the Data

Even when a carefully standardized procedure is followed, artifacts may occur, which may lead to erroneous conclusions about relationships between profiles. It is therefore important to know the nature of these artifacts in order to recognize and correct them. In this, the role of the database curator is extremely important. In PFGE, the artifacts include, among other things, ghost bands caused by incomplete restriction and subtle differences in band resolution (one thick band versus two thinner bands) (233). In PCR-based methods, such as RAPD and rep-PCR, differences in band intensities are a huge problem, and in MLVA, PCR, and fragment analysis artifacts, such as minus-A and stutter peaks and fluorescence carryover, can confuse data interpretation (234). Also, Sanger sequence trace files should be routinely checked for quality either manually or by using software (e.g., Phred/Phrap, http://www.phrap.org). Most major sequence databases require the submission of the raw sequence trace files from the laboratory when a new allele type is proposed (235). The quality of the next-generation WGS data can be assessed using various quality metrics that are based on the raw reads (e.g., per-base sequence quality, sequence length distribution, sequence duplication level, and sequence coverage) or assemblies (e.g., N50 and the number of contigs) and can be generated by using either the software built into the sequencing system or external software packages. It is important to recognize that the quality of the genome assemblies reflects the quality of the sequencing technology used but also of the analysis software employed for assembly and annotation (236).

Diversity of the Organism

Optimal interpretation of the differences (or lack thereof) between subtypes of two isolates depends largely on the
variability of the organism being typed. Large databases should provide sufficient data to make reasonable determinations of diversity. If an organism displays little diversity, one should be cautious in assuming that closely related patterns, or even indistinguishable patterns, indicate a high likelihood that they originate from a common source. In this case, additional data from other typing methods and other available information should be considered. If the organism shows substantial diversity, one must still consider whether there are clonal subpopulations within a nonclonal organism. On the other hand, when an organism demonstrates extreme variability, any pattern matches may be significant.

Epidemiological Context
If the epidemiological setting from which the isolates are derived appears to be a point source outbreak without continued transmission, only very minor differences are likely to be observed, because the outbreak strain has very little time to undergo genetic changes. In contrast, when there is ongoing transmission, such as prolonged hospital or community outbreaks, with strains being passed from person to person, more variability should be expected. Additionally, the amount of variation seen during an outbreak will depend on the stability of the genetic markers targeted by the typing method. Fast-evolving genetic markers, such as VNTRs, tend to change slightly even during shorter outbreaks (90).

During investigations of known outbreaks, it is fairly easy and often helpful to designate patterns that differ slightly from the primary outbreak pattern as subpatterns or variants. However, when performing surveillance for cluster/outbreak detection, accepting such variations may mislead the epidemiological investigation (183), especially if one of the variants represents a common pattern.

It is also important to consider how the laboratory results fit together with the epidemiologic and environmental investigations. The fact that common subtypes exist for many organisms demonstrates that indistinguishable subtypes alone do not unequivocally prove an epidemiologic connection. It is always possible that two individuals were infected with the same strain from different sources. On the other hand, clearly differing subtypes do not prove that isolates are epidemiologically unrelated, since multiple strains can be associated with the same outbreak (237) and some strains contain genetic elements, e.g., prophages, which are incorporated into the genome in an unstable manner and therefore may affect the subtype of different colonies picked from the same pure culture of the organism (238).

LIBRARIES FOR MOLECULAR EPIDEMIOLOGY
International travel, migration, and the food trade are the main factors that have contributed to the worldwide spread of microbes. Therefore, the need for international databases with standardized type nomenclature and information on epidemiologically relevant strains has emerged. Building such databases relies upon standardization of typing methods and on regular ring trials for all participating laboratories to guarantee consistently comparable data.

Strain Catalogues
Strain catalogue databases are mainly public access websites with limited access components in some of them. Their main function is to standardize subtype nomenclature and facilitate easy data sharing. Most of them are curated but typically contain minimal epidemiological or demographic information about the strains and are therefore not very useful for real-time epidemiological surveillance. The laboratories that contribute data to strain catalogues use protocols that vary in their levels of standardization from none (MLVA) to medium (spa typing).

The best-known examples of strain libraries are the three MLST databases that are hosted on Web servers located at Imperial College London (http://www.mlst.net) (235), Oxford University (http://pubmlst.org) (239), and the Institut Pasteur (http://www.pasteur.fr/mlst). On http://www.mlst.net and the Institut Pasteur websites, species-specific information, including limited epidemiological data, can be accessed on each of the species websites, whereas http://pubmlst.org software enables multiple client databases to query a single species-specific profile database, so that the information on isolates can be kept private for security or confidentiality reasons. Each species-specific database holds the sequences of all known alleles at each of the MLST loci and through the curator assigns new allele numbers and sequence types. The websites also provide clustering tools to explore the relationship of the query strain with other strains in the database.

SeqNet (http://www.seqnet.org/), coordinated by the Münster University Hospital and Robert Koch Institute in Wernigerode, Germany, is an example of a non-MLST-based strain catalogue. SeqNet is an initiative of 60 national reference laboratories and university laboratories from 29 European countries to establish a network of sequence-based typing of microbial pathogens (240). SeqNet currently has only a database for S. aureus spa types through the curated spa server. Unlike the three MLST databases, SeqNet has a QA/QC aspect built in it in the form of a one-time certification and annual ring trials.

The ccrB typing tool (http://www.ccrbypting.net) is a public online resource for storage and automatic analysis of MRSA ccrB sequences (241). The user’s sequence is assigned to an allele based on 100% homology with an existing allele or to a new allele if a homology between 90% and 100% is found to any of the available alleles. In the case of a new allele, the most similar allele is indicated. Based on the allele assignment, a prediction of the ccrAB allotype and SCCmec type is also provided.

International databases for MLVA data have also been recently established. MLVAbank (http://mlva.u-psud.fr), hosted by the University of Orsay, France, has both public and private databases available for a few organisms (94). The public databases have been derived from published data, sometimes by merging publications from different groups. Since the VNTR markers used by different groups are not always the same because of the current lack of standardization, different data sets may be available for different sets of isolates. Since different sets of primers are sometimes used for the same marker by different groups and since there are sizing discrepancies between different capillary electrophoresis platforms, the data are not always directly comparable even though they are uploaded to MLVAbank as repeat copy numbers.

The TB database (http://www.tbdb.org) is an integrated database for tuberculosis (TB) research that houses annotated genome sequence data for several M. tuberculosis strains, microarray and RT-PCR expression data from in vitro experiments, and TB-infected tissues (243). Experimental data may be deposited into the database by any TB researcher prior to publication, providing prepublication access to tools for the analysis, annotation, visualization, and sharing of data. The data are then made public at the author’s request or following publication. The database
curators also actively search the literature for publications containing relevant TB or host microarray data and then obtain the raw data from the researchers and load them into the database.

**Surveillance Databases**

Surveillance databases are restricted-access curated databases for real-time sharing of subtyping data and detailed demographic information associated with the strains. The main function of surveillance databases is to rapidly detect and define clusters of disease in order to initiate and support epidemiological investigations that are aimed at tracing the source and limiting the scope of outbreaks. Laboratories contributing data to surveillance databases typically are required to follow highly standardized protocols and comply with an extensive QA/QC program to ensure the reproducibility and the high quality of data.

PulseNet, the national and international surveillance network for foodborne disease, is the most successful example of a surveillance database. PulseNet USA was established in 1996 (20), and similar networks later followed in Canada, the Asia Pacific region, Latin America, the Middle East, and Europe, and the latest is in Africa (244) (www.pulsenetinternational.org). The participating laboratories perform PFGE on all foodborne organisms that they receive from clinical and food specimens in real time. The generated patterns are analyzed locally using highly customized software and uploaded to the central databases of each region via the Internet. The database managers confirm the quality of the patterns, name them according to a standardized scheme, and compare them against the patterns submitted to the database within the previous 60 days (120 days for Listeria). The epidemiologists are alerted if a new cluster of indistinguishable isolates is detected. Until now, much of the work in PulseNet International has focused on establishing the infrastructure of the network, but eventually each regional network will be able to log on to the server of any other international network, query the databases for matches to pathogen subtypes of interest, and, if matches are found, access the epidemiological information on matching isolate patterns (244). Such collaboration is already taking place between PulseNet USA and PulseNet Canada.

Other PulseNet-like surveillance databases include the CaliciNet network in the United States (245) and the Foodborne Viruses in Europe (FBVE) network (246), dealing mainly with norovirus. The virological networks employ primarily DNA sequence analysis. A number of virus-specific, curated databases have been established. These can be identified by an Internet search, though many may have restricted access.

**CONCLUSIONS AND FUTURE TRENDS**

Molecular methods have improved our understanding of the epidemiology of infectious diseases and the well-known emerging or reemerging pathogens causing them during the past 4 decades. Molecular methods have been used not only to subtype and otherwise characterize the pathogens following their culture but also to identify and detect nonculturable or slowly growing organisms (247–249). The emergence and increased use of a plethora of culture-independent diagnostic tests (250, 251) in clinical laboratories in the last few years has resulted in decreased availability of cultures for further characterization in public health laboratories. This trend may place culture-dependent surveillance networks such as PulseNet in serious jeopardy. However, with the rapid evolution of next-generation sequencing technologies, including metagenomics (252), it is to be expected that these methods will be used to an increasing extent for rapid nonculture diagnostics of infectious diseases directly from a clinical sample, providing detection, virulence characterization, and subtyping of the organisms at the same time, thereby creating the potential for detection of public health events, e.g., outbreaks, in real time, with no delays caused by isolating and growing the organisms as pure cultures. Before this can be accomplished, some formidable challenges need to be tackled, such as building comprehensive sequence reference libraries for metagenomics containing a representative diversity not only of pathogenic microbes but also of the human microbiome (253). Additionally, a significant investment in public health informatics infrastructure is needed to ensure that the users of the data are alerted to and know how to use the growing information flowing from clinical laboratories.

**REFERENCES**

The text on the page contains references and citations as follows:

Long- and short-term preservation of microorganisms for future study has a long tradition in microbiology. As early as the 1880s, it was observed that bacteria survived well in ice and that freeze-thaw cycles damaged the cell wall (1). By the 1900s, researchers had optimized methods to preserve tissues, viruses, and bacteria for later use by freezing and drying. It had become apparent to early researchers that preserving microorganisms allowed them to be studied at a later time and to remain viable when transported to others (2). Indeed, culture collections of microorganisms are valuable resources for scientific research in microbial diversity and evolution, patient care management, epidemiological investigations, and educational purposes. Preserved individual strains of microorganisms serve as permanent records of microorganisms’ unique phenotypic profiles and provide the material for further genotypic characterizations. Such reference collections can encompass rare infectious agents unique to an individual or catalog the history of disease caused by common pathogens such as those responsible for community outbreaks.

There are multiple methods for microbial preservation. Effective storage is defined by the ability to maintain an organism in a viable state free of contamination and without changes in its genotypic or phenotypic characteristics. Secondly, the organism must be easily restored to its condition prior to preservation. Microbial preservation methods have been evaluated extensively over the past 60 years, and often, optimal methods for preservation depend on a microorganism’s taxonomic classification. Review articles, monographs, and books have been published that provide detailed information about the storage of various types of microorganisms (3–7). For clinical microbiology laboratories, simple and broadly applied methods are necessary to maintain organisms for short- and long-term recovery. This chapter presents methods that can be used for the storage of bacteria, protozoa, fungi, and viruses.

OVERVIEW OF PRESERVATION METHODS

Short-Term Preservation Methods

Direct Transfer to Subculture

The simplest method for maintaining the short-term viability of microorganisms, most often used for bacteria, is periodic subculture to fresh medium. Although simple, if microorganisms are saved for >1 week, this method is potentially labor-intensive, requires extensive laboratory space, and may compromise a microorganism’s phenotypic profile. Each transfer to a new subculture increases the likelihood of mutation with undesirable changes in a microorganism’s characteristics. Furthermore, plasmids may be lost with subculturing.

The interval between transfers varies among organisms. Additionally, the rate of mutation is quite variable. Some organisms appear stable indefinitely with repeated transfer, and others may change phenotypic traits after as few as two or three passages. The actual rate of mutation, however, has not been studied until recently using sequencing technology (8, 9). Issues that must be addressed with direct transfer include the medium to be used, the storage conditions, and the frequency of transfer.

Maintenance Medium

The medium should support the survival of the microorganism but minimize its metabolic processes and slow its rate of growth. Extreme environments should be avoided because microorganisms have the unique ability to adapt through mutation events in order to survive in suboptimal surroundings. A medium with too high a nutrient content will induce rapid replication that requires more frequent transfers. The optimal medium for maintaining microorganisms has not been clearly defined and most likely varies from one species to another and may even depend on the individual strain. Media that have been used include distilled water, tryptic soy broth, and nutrient broths, all of which may be used with or without cryopreservatives.

Storage Conditions

Many laboratories store organisms, most often bacteria, for short periods on routine agar media at the workbench. Cultures kept in this fashion are subject to drying. A better method is to transfer organisms into an agar slant tube with a screw top and to store them in an organized location away from light and significant temperature changes. To prevent drying, caps can include rubber liners, or film can be wrapped over the top of the tube before or after the cap is screwed on. Storage at lower temperatures (3 to 8°C) slows metabolic processes and maintains viability for longer periods.

Frequency of Transfer

There is no set protocol for the frequency of transfer since storage conditions, media used, and types of microorganisms
vary among laboratories. Individual laboratories may conduct studies for each category of microorganism to determine optimal intervals between transfers under their conditions used for storage. Such studies would involve performing series of tubes at scheduled times until the laboratory identifies an acceptable interval between transfers at which a microorganism can reliably and reproducibly be recovered. (When transfers are performed, 5 to 10 representative colonies should be used to avoid the possibility of introducing an altered genotypic or phenotypic characteristic.) For the passage and storage of quality control organisms for antimicrobial susceptibility testing, published standards should be followed (10).

Quality Control Procedures
Although it is not necessary with each transfer, the status of the specimen should be assessed periodically. Ongoing viability, stability of phenotype, microorganism identity, and the rate of contamination of specimens should be determined and noted in a log.

Immersion in Oil
An alternative to capping tubes is to add a layer of mineral oil to the top of the specimen. Many bacteria and fungi can be stored for periods of up to 2 to 3 years by this method, and transfers are not needed as frequently. Microorganisms are still metabolically active in this environment, and mutations can still occur. Mineral oil should be medicinal-grade oil with a specific gravity of 0.865 to 0.890. Contamination of the specimen can occur if the mineral oil is not adequately sterilized. For sterilization, it should be heated to 170°C for 1 to 2 h in an oven (4). Autoclaving is not considered acceptable. Sterile mineral oil is also commercially available.

To prepare the specimen, an inoculum of 5 to 10 colonies of the microorganism should be placed on an agar slant or in tubed broth media. Once growth is identified, a layer of mineral oil at least 1 to 2 cm deep is added, and the agar must not be exposed to air. As with the simple transfer method, tests for viability should be performed to determine the optimal transfer schedule that will ensure microorganism recovery. Transfers will be less frequent than those of microorganisms stored without oil; however, oil is more difficult to add to vials and to clean up in the event of spills.

Freezing at −20°C
Refrigeration or freezing in ordinary freezers at −20°C may be used to preserve microorganisms for periods longer than those that can be accomplished by repeated transfers. Viability may be maintained for as long as 1 to 2 years for specific microorganisms, but overall damage caused by crystal formation (6) and electrolyte fluctuations (4) results in poor long-term survival. The medium used for storage appears to be important, since preservation times vary from a few months to 2 years depending upon which medium is used (6, 11, 12). Modern self-defrosting freezers with freeze-thaw cycles must be avoided because cyclic temperature fluctuations will destroy the microorganism.

Drying
Although most microorganisms do not survive drying, molds and some spore-forming bacteria may be dried and stored for prolonged periods. Soil has been described as a storage medium if it is autoclaved and air dried, but it is not a standardized, defined, and consistent product for use over long periods (4). Instead, commercial silica gel can be used in small cotton-plugged tubes after being heated in an oven to 175°C for 1.5 to 2 h (6), with moderately successful recovery of fungi. Alternatively, a suspension of 10^8 microorganisms can be inoculated onto sterile filter paper strips or disks. The paper is dried in air or under a vacuum and is placed in sterile vials. These vials can be stored in the refrigerator for up to 4 years, and then single strips or disks can be removed as needed (4). This method is commonly used for quality control organisms.

Storage in Distilled Water
Most organisms do poorly in distilled water, but some survive for prolonged periods. Many fungi and Pseudomonas spp. survive for several years in distilled water at room temperature (6, 13). McGinnis et al. found that with the exception of fungi that do not easily sporulate, 93% of yeasts, molds, and aerobic actinomycetes can be easily and inexpensively preserved this way (14).

Long-Term Preservation Methods
Whereas the methods described above may be used to store microorganisms for periods of up to a few years, ultralow-temperature freezing and freeze-drying (lyophilization) are recommended for long-term storage. Although the initial investment in ultralow-temperature freezers and lyophilization may be costly, these methods are less labor-intensive over time, require less laboratory space (e.g., a cryovial versus broth or agar media), and reduce the chances of mutation events. Of course, mutations and loss of mobile genetic elements can still occur, and this phenomenon was observed in Staphylococcus aureus strains that lost the meCA gene during long-term preservation at −80°C (15). Similar to those with other preservation methods, survival rates after freeze-drying vary with species. Evaluating microorganisms over a 10-year period, Miyamoto-Shinohara et al. found that survival rates after freeze-drying for Brevibacterium spp. and Corynebacterium spp. approached 80%, whereas those for Streptococcus mutants decreased to 20% after 10 years (13).

Ultralow-Temperature Freezing
Microorganisms can be maintained at temperatures of −70°C or lower for prolonged periods. Systems for achieving these temperatures include ultralow-temperature electric freezers and liquid nitrogen storage units. With either system, unwanted heating can occur due to the loss of electrical power or liquid nitrogen. Close observation of the system and an adequate alarm mechanism are essential, since any increase in temperature will reduce viability. In the event that the temperature does rise, restoring power and returning to the target storage temperature as quickly as possible are essential. The presence of a cryopreservative such as glycerol may reduce the risk to microorganisms upon short exposure to higher temperatures (16). If thawing does occur, there are no guidelines for rapid restoration of the storage condition. Refreezing of the sealed vials as described below may be considered.

For long-term storage, temperatures below −130°C are recommended for fastidious cells, such as fungal hyphae and protozoa. Cellular activity and chemical reactions cease at these low temperatures, but at −70°C they may still continue to a limited extent. Hence, for long-term cryopreservation of certain organisms, storage in liquid nitrogen (−196°C) or liquid nitrogen vapor (−150°C) is recommended (3).
Storage Vials
Storage vials must be able to withstand very low temperatures and maintain a seal for their contents. Plastic (polypropylene) or glass (borosilicate) tubes may be used. Plastic vials with screw tops and silicone washers are much easier to use than glass vials that must be sealed with a flame and then scored and broken open. Several commercial suppliers stock acceptable vials, e.g., Fisher Scientific Products (Pittsburgh, PA), VWR Scientific (Radnor, PA), Wheaton Science Products (Millville, NJ), and Becton Dickinson and Co. (Franklin Lakes, NJ). Vials come in a variety of sizes. Half-dram vials are available from several suppliers and can be conveniently packaged in a 12-by-12 grid so that 144 vials are stored in one box or layer.

Cryoprotective Agents
To protect microorganisms from damage during the freezing process, during storage, and during thawing, cryoprotective agents are often added to the culture suspension. Whereas most bacteria, fungi, and viruses survive better with such additives, studies have shown that cryoprotective agents significantly damage others. The reader is referred to detailed references for specifics (Table 1) (3, 6). Rapid freezing without additives may still be acceptable for the long-term survival of protozoa, although freeze-drying may be preferred.

There are two types of cryoprotective agents: those that enter the cell and protect the intracellular environment and others that protect the external milieu of the organism.

</tbody>
</table>
Glycerol and dimethyl sulfoxide (DMSO) are most often used for the former; sucrose, lactose, glucose, mannitol, sorbitol, dextrose, polyvinylpyrrolidone, polyglycol, and skim milk are used for the latter. Combinations of agents as well as detergents (e.g., Tween 80 and Triton WR 1339), other carbohydrates (e.g., honey), and calcium lactobionate have also been used. The most universal cryoprotectant is DMSO; however, the optimal cryoprotectant often varies with the microorganism. For example, glycerol appears to be best suited for the preservation of bacteria. A current and comprehensive review of protectant additives used in the cryopreservation of microorganisms is provided by Hubalek (17).

Glycerol is typically added at a concentration of 10% (vol/vol), and DMSO is added at 5% (vol/vol). Prior to use, glycerol is sterilized by autoclaving. Once prepared, it can be stored at room temperature for months. DMSO must be filter sterilized and can be stored in open containers for only 1 month prior to use.

Of the external products, skim milk is the most often used. Dehydrated skim milk is purchased from medical product suppliers, e.g., Becton Dickinson and Co. and Hardy Diagnostics (Santa Maria, CA). It is autoclaved and used in a final concentration of 20% (wt/vol) in distilled water (3). This is double the concentration suggested by the manufacturers if the intent is to make a reconstituted equivalent of regular milk.

Preparation of Microorganisms for Freezing

Microorganisms are inoculated into a medium that adequately supports maximal growth. Cultures are allowed to mature to the late growth or stationary phase before being harvested. Broth specimens are centrifuged to create a pellet of microorganisms. The pellet is withdrawn and resuspended in 2 to 5 ml of broth with the appropriate concentration of cryoprotectant additive. For agar specimens, broth containing the cryoprotectant is placed on the surface of the agar. The surface is scraped with a pipette or sterile loop to suspend microorganisms, and then the broth mixture is pipetted directly into freezer vials. Alternatively, the agar surface can be scraped with a sterile loop. The microorganisms can then be transferred directly into the vial of cryoprotectant and emulsified into a final dense suspension. The volume of the aliquots to be frozen is typically 0.2 to 0.5 ml.

Freezing Method

The American Type Culture Collection (ATCC) recommends slow, controlled-rate freezing at a rate of 1°C per min until the vials cool to a temperature of at least −30°C, followed by more rapid cooling until the final storage temperature is achieved (3). This protocol is best achieved using a controlled-rate freezer. As an alternative, the ATCC suggests the use of an insulated freezing chamber, such as one commercially available or simply an appropriate polystyrene box packed with insulating materials. Studies in the 1970s showed that uncontrolled-rate freezing may be acceptable for most organisms and is much less expensive or labor-intensive (6). When organisms are stored in liquid nitrogen, however, it is still recommended that vials be placed initially in a −60°C freezer for 1 h and then transferred into the liquid nitrogen. When organisms are stored permanently at −60 to −70°C, the vials can be placed directly into the freezer.

Vials with small glass beads or plastic beads can also be used for freezing microorganisms, e.g., CryoBank (Copen Diagnostics, Murrieta, CA) or Microbank (Pro-Lab Diagnostics, Round Rock, TX) systems. The culture suspension will coat the beads, and then the excess culture suspension is aspirated from the vial. Individual beads can then be removed from storage for reconstitution without thawing the entire sample (18).

Thawing

Damage to microorganisms occurs as they are warmed from the frozen state. Critical temperatures appear to be between −40 and −5°C. Studies suggest that rapid warming through these temperatures improves recovery rates. For optimal results, stored culture vials should be warmed rapidly in a 35°C water bath until all ice has disappeared (3, 6). Once a vial is thawed, it should be opened and the organism should be transferred to an appropriate growth medium immediately. Great care must be exercised during the thawing phase, since rapid temperature changes and resulting air pressure changes inside vials can cause the vials to explode. Protective clothing and eyewear must be worn during this process.

For most practical purposes in the clinical laboratory, however, thorough thawing of stored bacteria or yeast in a water bath is not practical or necessary. The frozen vial can be thawed at room temperature and plated with good results for most routine organisms. If the organism vial must be saved for reuse at a later date, one may scrape off a small portion of the frozen contents with a sterile loop or pipette tip and then inoculate the appropriate media. The vial may be returned to frozen storage immediately without thawing and may be reused at a later date with limited damage to the organism.

Specialized Storage Systems

Computerized technology can facilitate the organization and database management of large storage collections. Some laboratories have developed their own tracking system, while other products are commercially available, e.g., Freezerworks (Dataworks Development, Inc., Mountlake Terrace, WA) and FreezerPro (Ruro Inc., Frederick, MD). These kinds of software allow the user to enter data regarding each sample in a repository, and the data are stored in a highly organized, searchable fashion. Radio-frequency identification (RFID) labeling may also be used for compact storage of information associated with each sample, e.g., ColdTrack vials (BioTillion LLC, Skillman, NJ) or FreezerPro RFID kit.

Freeze-Drying (Lyophilization)

Freeze-drying is considered to be the most effective way to provide long-term storage of most bacteria, yeasts, sporulating molds, and viruses. Better preservation occurs with freeze-drying than with other methods because freeze-drying reduces the risk of intracellular ice crystallization, which compromises viability. Removal of water from the specimen effectively prevents this damage. Among bacteria, the relative viability with lyophilization is greatest with Gram-positive bacteria (sporeformers in particular) and decreases with Gram-negative bacteria (6, 19), but overall, the viability of bacteria can be maintained for as long as 30 years. In addition, large numbers of vials of dried microorganisms can be stored with limited space, and organisms can be easily transported long distances at room temperature.

The process combines freezing and dehydration. Organisms are initially frozen and then dried by lowering the atmospheric pressure with a vacuum apparatus. Freeze-drying has been extensively reviewed in the past (5), and
the required equipment includes a vacuum pump connected in line to a condenser and to the specimens. Specimens can be connected individually to the condenser (manifold method) or can be placed in a chamber where they are dehydrated overnight in a dry air space (chamber or batch method). Alexander et al. and Heckly have both published detailed descriptions of equipment options (3, 5).

Storage Vials
Glass vials are used for all freeze-dried specimens. When freeze-drying is performed in a chamber, double glass vials are used. In the chamber method, an outer soft-glass vial is added for protection and preservation of the dehydrated specimen. Silica gel granules are placed in the bottom of the outer vial before the inner vial is inserted and cushioned with cotton. For the manifold method, a single glass vial is used. For both methods, the vial containing the actual specimen is lightly plugged with absorbent cotton. The storage vial in the manifold method or the outer vial in the chamber method must be sealed to maintain the vacuum and the dry atmospheric condition. All vials are sterilized prior to use by heating in a hot-air oven.

Cryoprotective Agents
Research concerning cryoprotective agents has been extensively reviewed (5). In general, the two most commonly used agents are skim milk and sucrose. Skim milk is used most often for chamber lyophilization, and sucrose is used most often for manifold lyophilization. Skim milk is prepared by making a 20% (vol/vol) solution of skim milk in distilled water. The solution is divided into 5-ml aliquots and autoclaved at 116°C, with care taken to prevent overheating and caramelization of the solution. The preparation is then used in smaller volumes as described above for freezing. Sucrose is prepared in an initial mixture of 24% (vol/vol) sucrose in water and added in equal volumes to the microorganism suspension in growth medium to make a final concentration of 12% (vol/vol).

Preparation of Microorganisms for Lyophilization
As with simple freezing, maximum recovery of organisms is achieved by using microorganisms in the late growth or stationary phase from the growth of an inoculum in an appropriate growth medium. High concentrations of microorganisms are considered to be important. The ATCC recommends a concentration of at least 10⁸ CFU/ml (3), and Heckly suggests a concentration of 10¹⁵ CFU/ml or higher (6).

Freeze-Drying Methods
In the chamber method, inner vials with the microorganism suspension are placed in a single layer inside a stainless steel container. This container is placed in a low-temperature freezer at −60°C for 1 h. The container is then transferred to a chamber containing a low temperature bath, e.g., dry ice in ethyl Cellosolve or other solvent, and covered with a sealed vacuum top, which is connected in sequence to a condenser reservoir also filled with the dry ice-solvent mixture and to a vacuum pump. The vacuum is maintained at a minimum of 30 μm Hg for 18 h. At the same time, the outer vials are prepared by being heated in an oven overnight, filled with silica gel granules and cotton, and placed in a dry cabinet (with <10% relative humidity). The freeze-dried inner vials are inserted into the outer vials, and the outer vials are heat sealed. Multiple different strains or species should probably not be processed in the same batch.

Cross contamination rates vary from 0.8 to 3.3% when two different microorganisms are placed on opposite sides of the same container and are as high as 8.3 to 13.3% when microorganisms are intermingled (20).

In the manifold method, a rack of individual vials is used rather than a single container. The rack is placed in a dry ice bath. After the freezing process, the vials are connected by individual rubber tubes in sequence to the condenser container filled with the dry ice-solvent mixture and to the vacuum pump. As in the method described above, the vacuum is maintained at 30 μm Hg for 18 h and then the individual vials are sealed.

Storage
Individual vials need to be appropriately labeled and sorted. Storage at room temperature does not maintain viability and is not recommended. Storage at 4°C in an ordinary refrigerator is acceptable, but survival rates may be improved at temperatures of −30 to −60°C (3, 5).

Reconstitution
Care must be taken when opening vials for reconstitution because of the vacuum inside the vial. Safety glasses should always be worn, and vials should be covered with gauze to prevent injury if the vial explodes when air rushes in. Reconstitution should also be conducted in a closed hood to avoid dispersal of microorganisms. The surface of the vial should be wiped with 70% alcohol, and then the top of the glass vial can be scored and broken off or punctured with a hot needle. A small amount (0.1 to 0.4 ml) of growth medium is injected into the vial with a needle and syringe or a Pasteur pipette, the contents are stirred until the specimen is dissolved, and then the entire contents are transferred with the same syringe or a pipette to appropriate broth or agar media. A purity check must be done on each specimen because of the possibility of either cross contamination or mutation during the preservation process.

Newer Technologies
The long-term preservation methods previously described are specifically designed for recovery of microorganisms for further cultivation. Culture-independent tests based on antigen or nucleic acid technologies are in widespread use and do not require viable microorganisms. In this regard, storage of microorganisms to preserve their antigens or nucleic acids is also important for clinical laboratories. The use of Whatman Flinders Technology Associates (FTA) matrix cards (Whatman International Ltd., Maidstone, United Kingdom) or other filter paper-based products is a novel approach for long-term storage of microbial DNA that is safe (microorganisms are inactivated), inexpensive, and fast (21, 22). Bacterial and/or fungal cell suspensions are applied directly to dry FTA paper. The FTA cards are impregnated with buffers, free radical trap and protein denaturants that lyse cell membranes on contact, entrap DNA, and protect DNA from degradation. This technology has been successfully applied to a variety of bacteria and fungi and serves as a reusable DNA archiving system. Although beyond the scope of this chapter, direct specimens such as blood can be preserved using a dry blood spot on filter paper or with a non-paper-based matrix for future antibody or nucleic acid testing to detect HIV (23–25), hepatitis B virus (23), hepatitis C virus (23, 25), Rickettsia typhi, and Orientia tsutsugamushi (26).
Procedures for Specific Organisms

Procedures for specific organisms are described below and summarized in Table 1.

Bacteria

All of the material presented in this chapter applies primarily to the preservation of bacteria. Simple transfer, storage under mineral oil, drying, or freezing at −20°C can maintain bacteria for short periods; freezing in ultralow-temperature electric freezers at −70°C or in liquid nitrogen at −196°C or freeze-drying can provide long-term preservation. A summary of the studies of bacterial preservation has been published (6). In general, serial transfer will preserve bacteria for up to a few months, storage under mineral oil or with drying will last 1 to 2 years, freezing at −20°C will preserve bacteria for 1 to 3 years, freezing at −70°C will preserve bacteria for 1 to 10 years, and freezing in liquid nitrogen and freeze-drying will preserve bacteria for up to 30 years (4). For fastidious bacteria such as Streptococcus pneumoniae, Neisseria spp., and Haemophilus spp., the optimal methods are lyophilization and freezing at −70°C by using Trypticase soy broth with glycerol as a preservation medium (27–29). Stock cultures of quality control microorganisms can be maintained in a cryopreservative suspension for up to 1 year at −20°C or indefinitely at −70°C.

Protozoa

Information concerning the preservation of protozoa is limited, in keeping with the infrequent need for such a process in clinical microbiology laboratories. Variable methods for individual genera are described. In general, freezing appears to be preferred to freeze-drying. Storage in liquid nitrogen is recommended for many of the protozoa below, although cryopreservation up to several months may be successful at −70°C (1). Cryopreservation of other parasites such as helminths is rarely done in clinical laboratories, and methods for storing and preserving viability for various parasites are reviewed elsewhere (30). All of the following procedures are as described by the ATCC (3).

Acanthamoeba spp., Leishmania spp., Naegleria spp., Trichomonas spp., and Trypanosoma spp. can be handled as described above for ultralow-temperature freezing with 5% (vol/vol) DMSO as the cryoprotective agent. These organisms should be stored in liquid nitrogen.

Acanthamoeba spp. and Naegleria spp. can also be dried at room temperature onto filter paper. Aliquots of a microorganism suspension (0.3 ml) are pipetted onto the paper in a shell vial and dried in air for 14 days at room temperature and then in a vacuum desiccator for an additional week. The vials are sealed and stored in liquid nitrogen.

Entamoeba spp. are stored frozen at −40°C. Specimens should be suspended in a mixture of growth medium containing 12% (vol/vol) DMSO and 6% (vol/vol) sucrose. Leishmania spp. may also be prepared by inoculation of the organism into an animal host. At the peak of infection, the spleen is harvested and homogenized in half the final volume of ATCC medium 811 salt solution. Freezing is completed with 10% glycerol as the cryoprotectant.

Plasmodium spp. can be stored from infected blood samples. At the height of parasitemia, blood is obtained and anticoagulated with the following preparation: 1.33 g of sodium citrate, 0.47 g of citric acid, 3.00 g of dextrose, 200 mg of heparin (sodium), and 100 ml of distilled water. The final concentration of anticoagulant added to blood is 10%. To this anticoagulated blood, 30% glycerol in 0.0667 M phosphate buffer is added to a final concentration of 10% (vol/vol) glycerol. Freezing should occur in liquid nitrogen.

Trypanosoma spp. must be harvested from an animal host. At the peak of parasitemia, blood is withdrawn into heparinized tubes and diluted 1:1 in Tyrode’s solution (8.0 g of NaCl per liter, 0.02 g of KCl per liter, 0.2 g of CaCl2 per liter, 0.1 g of MgCl2 per liter, 0.05 g of NaH2PO4 per liter, 1.0 g of NaHCO3 per liter, and 1.0 g of glucose per liter) with 1 to 5% phenol red added. Then 5% DMSO is added as the cryoprotectant, and the specimen is stored in liquid nitrogen.

Yeasts and Filamentous Fungi

All of the techniques described above have been applied to the storage of yeasts and fungi (4, 6, 7, 31). The individual method employed depends on the species to be preserved and whether or not it sporulates.

Subculturing. Subculturing is the simplest method of maintaining living fungi and involves serial transfer to fresh solid or liquid media. Storage is accomplished usually at room or refrigerator temperature. Fungi may be maintained by subculturing for a number of years. Care must be taken to avoid aerosolization and contamination of the laboratory or other specimens.

Storage under oil. Whereas species of Aspergillus and Penicillium have remained viable under oil for 40 years (7), many species have shown deterioration after 1 to 2 years and must be transferred periodically. Taddei et al. also reported the successful storage and recovery of actinomycetes stored under paraffin oil for 10 to 30 years (32).

Water storage. Many fungi can be stored successfully for prolonged periods in distilled water (13, 33). A simple method is to pipette 6 to 7 ml of sterile distilled water onto 2-week-old culture slants in screw-cap tubes. The spores and fragments of hyphae are dislodged by scraping with the pipette, and the suspension is transferred to a sterile 1-g vial, which is tightly capped and stored at 25°C. Fungi are revived by subculturing. Storage is accomplished usually at room or refrigerator temperature. Fungi may be maintained by subculturing for a number of years. Care must be taken to avoid aerosolization and contamination of the laboratory or other specimens.

Drying. Drying as described above has been used for fungi. Only 6 of 16 genera of fungi stored in this fashion survived for 4 years (36). The greatest success is reported for sporulating fungi stored in silica gel or in soil.

Freezing. Fungi have been successfully preserved by storage in liquid nitrogen by using glycerol or DMSO as a cryopreservative. Yeasts may also be stored at ultralow temperatures in skim milk. Both cultures containing nonpathogenic fungi are disrupted in a Waring blender and suspended in equal parts of DMSO or glycerol to achieve final concentrations of 5 or 10%, respectively. Pathogens should not be disrupted in a mechanical blender because of the potential biohazard associated with aerosolization. Histoplasma, Paracoccidioides, and Blastomyces species should be frozen in the yeast phase, and Coccidioides species should be frozen in the early mycelial phase to minimize exposure of laboratory personnel. Otherwise, procedures for freezing are as described above.
Freeze-drying. Most spore-forming fungi can be preserved by freeze-drying. Cultures to be stored by freeze-drying should be grown on agar or broth media to the point of maximum sporulation (3) and processed as described above. Survival in storage for many years has been demonstrated (37, 38), but this is true only for sporulating organisms. Young vegetative hyphae of fungi do not survive freeze-drying (7).

Viruses

Ultralow-temperature freezing is effective in a number of situations. In addition to cryoprotectants described above, sucrose-phosphate-glutamate containing 1% bovine albumin (SPGA) (6, 39) and hypertonic sucrose are particularly effective, the latter for storing labile viruses such as respiratory syncytial virus (40). If ultralow-temperature freezing is employed, the rate of freezing should be as high as possible, using small-volume suspensions (0.1 to 0.5 ml). In addition to freezing of pure isolates, stool specimens known to contain viral enteric pathogens have been maintained at −70 to −85°C for 6 to 10 years with reasonable recovery and no change in the morphological characteristics of astroviruses, small round structured viruses, enteric adenoviruses, rotaviruses, and caliciviruses (41).

Gallo et al. evaluated five types of media for storage of HIV-infected peripheral blood lymphocytes and concluded that freezing peripheral blood lymphocytes in RPMI 1640 containing 10% fetal bovine serum and 10% DMSO and storing them at −60°C is acceptable for HIV isolation (42).

Freeze-drying is probably the optimum method for preserving viruses for extended periods. A detailed review of acceptable procedures has been published (43). Virus suspensions freeze-dried in medium supported with SPGA appear to survive better (6, 44). Lyophilization of polioviruses and other enteroviruses works best when electrolytes are removed by dialysis or ultrafiltration (6).

Select Agents

In response to the Public Health Security and Bioterrorism Preparedness and Response Act of 2002, federal regulations require laboratories that store select agents to register and comply with the standards established by the act (45). A current and complete list of microorganisms considered to be select agents can be found at http://www.selectagents.gov. Regardless of the method for long-term preservation, laboratories must register with the Federal Select Agent Program if they wish to use, possess, or transfer select agents or toxins. In order to minimize risk to public health and safety, select agents must be stored in a highly secured area with restricted access and appropriate safeguards. Only registered individuals who have completed training for handling select agents can access and retrieve these microorganisms from storage. An accurate and current inventory of select agents held in long-term storage must be maintained. Further guidance on storing select agents is available from the Centers for Disease Control and Prevention (http://www.selectagents.gov/resources/Long_Term_Storage_version_3.pdf).

Disaster Preparedness

Especially in light of recent natural disasters like Hurricanes Katrina and Sandy (22), laboratories should consider the value of their organism collection and have a written emergency plan for the biorepository. For valuable or large collections of microorganisms in long-term storage, the International Society for Biological and Environmental Repositories provides guidance on emergency preparedness (http://www.isber.org). It is good practice to maintain backup copies of written or electronic data linked to the stored organisms. A laboratory may consider dividing irreplaceable collections of microorganisms between containers or laboratory locations if these options are feasible. Liquid nitrogen storage containers do not require constant electrical power for operation. They may be filled up prior to an anticipated evacuation in order to maximize their temperature stability. For electric-powered freezers, laboratories should consider connection to a backup energy source such as an uninterruptable power supply or motor generator.

Future Directions

The field of microbiology is rapidly evolving, especially in the era of genomics and proteomics. Scientific research in human genetics, health care epidemiology, global health, antimicrobial resistance, microbial taxonomy, and infectious diseases relies heavily on carefully curated repositories of microorganisms. Clinical laboratories have various levels of resources for the preservation of microorganisms and their long-term storage, but anyone can contribute to national or international culture collections. Additionally, scientific advancements of pathogen discovery, genomics, and proteomics are supported by collecting and storing biological specimens such as human blood and urine, particularly from patients with noncultivable pathogens or ill-defined clinical syndromes. Scientific protocols have been developed to preserve the integrity of these biological specimens for long-term storage, up to 30 years (47, 48). All should partner with the scientific community (e.g., regional research centers of excellence or government-sponsored projects) by contributing to both specimen and microorganism repositories. The answers to many future questions lie in our clinical laboratories of today.

Prevention of Laboratory-Acquired Infections

MICHAEL A. NOBLE

Laboratory biosafety is the active, assertive process based on evidence-based principles to ensure safety from microbial contamination/infection or toxic reaction for workers, the public, and the environment as a result of the active manipulations of live microorganisms or their products during academic, research, industrial, and clinical investigations. Laboratory accidents, injuries, and infections not only impact laboratory workers but can have consequences that impact laboratory coworkers, the institution, the community (including workers’ families and friends), and the environment. Active laboratory biosafety addresses not only the prevention of laboratory-acquired infections in workers but also the potential accidental release of live agents, which could endanger humans, animals, and plants.

EPIDEMIOLOGY

The characterization of a person’s infection as laboratory acquired is usually retrospective and is based on the assumption that the only likely exposure occurred while the person was in a laboratory. A trivial laboratory event may be considered the possible exposure because no other circumstance outside the laboratory could account for infection (1).

It is, however, important to appreciate that the total laboratory testing cycle begins well before the sample actually reaches the laboratory (the preanalytical phase of laboratory testing) and that exposures during the collection and transport of the sample should also be considered. In the past, infections acquired during the collection of some samples were included if it could be ascertained that the collection was solely for the purpose of a laboratory investigation. Infections experienced by phlebotomists as a result of needle stick injuries are now routinely included as laboratory-acquired infections (2). In contrast, phlebotomist infections, such as influenza and chicken pox acquired while collecting samples in patients’ rooms, are not included (3).

Although difficult to date precisely, the first microbiology laboratories of Pasteur and Koch were active by 1840 to 1860. The first report of a laboratory-acquired infection, Mediterranean fever, was in 1899 (4).

Various compilations of laboratory-acquired infection have been published over the past 60 years. In 1953, the first survey published was of 5,000 American laboratories by Sulkin and Pike. These authors provided additional updates in 1961, 1965, and 1976. The authors cited 3,921 laboratory infections dating between 1930 and 1974, with a mortality of 4.1%. Of note, 2,307 (58.8%) of the infections were reported from research facilities, 677 (17.3%) were from diagnostic facilities, 134 (3.4%) were from the generation of biological products (industry), and 106 (2.7%) were from teaching facilities. The sources of the remaining 697 (17.8%) were unspecified.

Four series performed in the United Kingdom between 1971 and 1991 revealed that within clinical facilities, the majority of infections were reported from workers in the microbiology laboratory, followed by the autopsy service. Over the 20-year period, the number of infections reported dropped over 80%, from 104 to only 17.

Compiled information tends to be limited to events that are reported in the literature or specific databases. Thus, while uncommon community infections, such as those associated with Brucella species, are reported commonly as laboratory acquired, very common infections with Staphylococcus aureus (including methicillin-resistant S. aureus [MRSA]) are rarely identified (5) as being acquired in the laboratory. It is assumed that even complete listings reflect an immeasurable minority of infections that actually occur (6).

More recently, Internet-based discussion groups have worked to create information-gathering approaches (7, 8). While these newer surveys have challenges similar to those of former retrospective compilations, they demonstrate their potential for rapidly gathering important information on laboratory safety and infection.

Formal reporting programs have been implemented as part of patient and worker safety initiatives (9).

Two hundred cases of laboratory-acquired infections with parasites resulting from laboratory accidents from 1929 through 1999 have been previously published (1, 10). While the distribution of cases changed from decade to decade, the number of cases identified in each decade (19 to 28) remained relatively constant. Sharps-related injuries (e.g., needles and glass) were common factors and were often associated with the manipulation of research animals and the production of blood smears for malaria.

LABORATORY BIOSAFETY PROGRAM

Laboratory safety is an integral component of active programs that address the convergence of quality, safety, and risk (11). It involves all aspects of laboratory activity starting from before microorganisms arrive in the facility and progressing through the training of personnel, the establishment and monitoring of safe working practices, the proper use of reagents, materials, and equipment, the safe storage...
and transport of agents, and ultimately the terminal sterilization and destruction of microorganisms.

In those countries where laboratories are certified or accredited to ISO requirements, these documents are considered essential standards. ISO 15190:2003 addresses a range of topics relevant to medical laboratory safety, including management responsibility, the role of the safety manager, the need for a safety manual, implementation of a safety program, education, training, and competence, and performance of audits and review. It states that laboratory management is responsible for the safety of all employees and visitors to the laboratory and that ultimate responsibility rests with the laboratory director. The laboratory must identify an appropriately trained and experienced laboratory safety officer to assist the laboratory director and managers with safety issues. The laboratory safety officer must have the authority to stop activities that are deemed unsafe. The laboratory safety officer is responsible for designing and maintaining the laboratory safety program and is responsible for monitoring its effectiveness.

The elements of a laboratory safety program include development of the laboratory safety manual, safety audits, inspections (see Table 1 for audits required by ISO 15190:2003), risk assessments, and the maintenance of records. For further details, ISO 15190:2003 is available through the International Organization for Standardization website (www.iso.ch) or the Clinical and Laboratory Standards Institute (www.clsi.org).

LABORATORY SAFETY AND PERSONAL ATTRIBUTES

A small but still-relevant matched case-control study of 33 laboratory workers who experienced a laboratory-associated injury over a 2-year period was previously described (17). Accident-involved persons were significantly more likely to have had a laboratory accident or laboratory infection prior to the 2-year study period and were significantly more likely to have a low opinion of laboratory safety programs. When the conditions surrounding the accidents were examined, 36% occurred when the employee was working too quickly, either just before lunch or at the end of the day. In 30% of accidents, the employee acknowledged a breech in safety regulations. This is consistent with the observation that organizational human error is most commonly the consequence of actions by well-meaning and usually well-informed people caused by slips and mistakes (18). One recent questionnaire-based study suggested that hospital laboratory workers may have less regard for an organizational safety culture and commitment than other hospital workers (19).

These observations continue to have relevance today. Laboratories continue to evolve with increasing samples and complexity. At the same time, the workforce is shrinking, and those that remain are older; this combination of circumstance is likely to result in increased stress and time pressures, two factors that contribute to medical laboratory error (20, 21).

In a study in which laboratory practices were directly observed and then related to laboratory environmental contamination with hepatitis B virus (HBV), contamination was strongly related to a flawed technique and high workload. Unsafe work practices were also related, but to a lesser degree (22).

Over time, laboratory workers have learned that even conventionally accepted practices can result in serious infection. Mouth pipetting, marking of blood spots, transport of samples to the laboratory in corked or sheathed sharps, recapping of needles, eating, and smoking were all at one time commonly practiced in properly run medical laboratories.
All of these practices are now appreciated as risky and are prohibited. Injuries with sharp objects continue to be identified as an area of concern. Examination of bacterial culture plates with an eyeglass and sniffing plates to help identify organisms are now controversial (23). Laboratory safety requires diligent review and ongoing critique of current conventional practice, as well as openness to change when new risks are identified.

RISK-BASED CLASSIFICATION OF MICROORGANISMS

As a foundation for determining environmental requirements and best laboratory practices, the international community has developed a common risk classification of microorganisms. Group 1 biological agents are unlikely to cause human disease. Group 2 biological agents can cause human disease and might be a hazard to workers but are unlikely to spread to the community; there is usually effective prophylaxis or treatment available. Group 3 biological agents cause severe human disease and present a serious hazard to workers; they may present a risk of spreading to the community, but there is usually effective prophylaxis or treatment available. Group 4 biological agents cause severe human disease and are a serious hazard to workers; they may present a high risk of spreading to the community, and there is usually no effective prophylaxis or treatment available. A partial list of microorganisms by category is shown in Table 2.

While there is general consistency in classification of organisms by different countries, there are some examples where the same organism can be classified differently. This can have implications with respect to certification of the laboratory or to regulations surrounding transportation of these agents. Laboratories need to be aware of both domestic and international requirements prior to transport.

Increasingly, the emphasis has been to rely less on the classification of organisms and to focus more on the levels of safety with respect to containment and practices. For example, this approach allows for recommendations to contain organisms using the requirements of biosafety level 2 but to increase the caution by using a higher level of safety practices.

### BIOSAFETY AND CLINICAL LABORATORY DESIGN

Knowledge of the classification of microorganisms flowing into a laboratory aids in the design of containment equipment and facilities. For research laboratories where the microorganism load is known, the process of matching risk and containment is straightforward. In the clinical laboratory, the content of samples is more likely to be unknown and may in certain situations contain microorganisms across the spectrum of classification. That being said, most isolates recovered from clinical samples can be categorized within biosafety level 1 or 2; thus, most facilities require containment level 2 (Table 3). The design elements required for containment level 2 laboratories are described in Table 4.

Laboratories that process viral cultures or investigate mycobacterial cultures should be designed to accommodate biosafety level 3. For many clinical laboratories, biosafety level 3 is considered beyond the scope of their practice.

In the wake of the 2001 terrorist attacks in New York and the anthrax mail scares that happened shortly afterwards, the interest in laboratory biosafety measures as a component of bioterrorism defense was brought to the fore. Specific funding has been allocated for construction of new national and regional biocontainment laboratories. Laboratories with increased levels of containment and security not only are of benefit for bioterrorism and biosecurity but also provide facilities to address potential epidemics, such as severe acute respiratory syndrome (SARS) and potential

¹See reference 138.

In order to protect workers, the public, and the environment, laboratories need to ensure that access to their facilities is controlled, that procedures for specimen receiving and disposal are controlled, that incident reporting and emergency response plans are in place, that stored agents are under high security, and for research facilities, that animal tracking and trace back systems are accurate. Caution needs to be taken to ensure that the needs for confidentiality and information containment do not interfere with the open communications necessary for laboratory safety and public health.

Handling of exotic pathogens of risk group 4 requires high containment level 4 facilities. Discussion of these facilities is beyond the scope of this chapter.

The essential practice standards for microbiology laboratories are cited in Table 5.

SAFETY EQUIPMENT AND THE CLINICAL LABORATORY

Splashguards

Splashguards made of clear glass or plastic represent the minimum level of equipment for protecting workers. They are more likely to protect workers from gross splashes than from aerosols. They can be an appropriate alternative to biosafety cabinets for opening vacuum blood tubes. They should be of sufficient size and be cleanable to remove the occasional blood splatter. The effectiveness of splashguards depends on appropriate placement with respect to both workflow and worker height. It is inappropriate to obscure vision by using splashguards as a convenient location for taped memos and procedures.

Biosafety Cabinets

Biosafety cabinets can protect the laboratory worker and the laboratory environment from splashes and aerosols and also reduce the risk of sample contamination. Biosafety cabinets are enclosed units with variable degrees of openness and access and which control exhausted air. Class 1 cabinets have an open front but work under negative pressure and exhaust their air through a HEPA filter. Exhausted air usually is returned to the work area. Class 2 cabinets increase the level of safety by including a HEPA-filtered downward-flow air curtain designed to increase the degree of separation between room air and interior cabinet air. Class 2 cabinets may exhaust air back into the room (class 2A) or outside the building environment through an exhaust system (class 2B). Class 2B cabinets can be further subclassified based on additional features. Class 3 cabinets are completely enclosed, providing gas-tight containment. They are accessible only through front-end glove ports. Class 3 cabinets provide the most suitable containment for working with exotic pathogens. Class 3 cabinets must be vented through ductwork supplemented with double HEPA protection and incineration. Because class 1 and class 2A units exhaust to the laboratory air, they are unacceptable for use with volatile chemicals and reagents. Biological safety cabinets cannot be used as alternatives to chemical fume hoods.

Many institutions require that safety cabinets be tested and certified to the National Sanitation Foundation standard NSF/ANSI 49:2009 (Biosafety Cabinetry: Design, Construction, Performance, and Field Certification) by a qualified person on a regular basis to ensure that they maintain their required face velocity and negative pressure.

Chemical Fume Protection

A fume hood is a mechanically ventilated, partially enclosed workspace where harmful volatile chemicals and reagents can be handled safely. The primary function of a fume hood is to contain and remove gases and vapors.
Most fume hoods use ducts and a fan to ensure that heat and airborne contaminants are captured, transported out of the work area, and eventually discharged into the atmosphere outside the building. Chemical fume hoods differ from biosafety cabinets in that they are usually all ducted. They must be constructed of noncombustible materials, and they must also be explosion-proof.

Nonducted or recirculating fume hoods are of limited use in the laboratory and should not be considered acceptable substitutes for ducted fume hoods for containment of volatile chemicals (31). Special fume hoods are designed to protect workers from specific highly corrosive reagents or chemicals, such as perchloric acid and radioisotopes.

**Installation of Biological Safety Cabinets and Chemical Fume Hoods**

These large pieces of safety equipment protect users and the environment through the use of negative air pressure drawing air away from the user and through the equipment. This requires air to move at sufficient volume and velocity without developing turbulence. This can be measured using the ASHRAE 110 tracer gas test. Airflow can be negatively affected by overcrowding the cabinet or stacking of equipment against either the front or the back grill. This will disrupt the airflow, resulting in backwash out the front of the unit, and impair dexterity (32, 33).

Cabinets that are improperly positioned in relationship to each other or in relationship to room space and ventilation outlets can result in airflow imbalance and reversal (34), thereby increasing rather than decreasing the risk to the user. When airflow is being measured, the tester should not only test individual pieces of equipment but also ensure that airflow is not hampered when more than one cabinet is being used at the same time. Installation of equipment must take into consideration the proximity of equipment as well as timing of use.

*Adapted from Biosafety in Microbiological and Biomedical Laboratories, 5th ed (30), and The Laboratory Biosafety Guidelines, 3rd ed. (146).*
Centrifuges

Although the safety centrifuge was first described in 1975 (35), accidental contamination of the laboratory and personnel is regularly reported (36, 37). While other equipment may result in greater aerosol dispersal, the commonness of centrifuge use increases its potential impact on laboratory risk (38). Accidents occur because of lack of tight seals on containers and rotors. Centrifuges can be susceptible to contamination because prolonged use without regular inspection can lead to worn O-ring container seals (39). Plastic centrifuge tubes can crack or distort and result in increased risk (37). Accidents can be avoided when centrifuges are included in preventive maintenance and are used safely. Lids must be closed at all times during operation. The centrifuge should not be left until full operating speed is attained and the machine is running safely without vibration. If vibration does occur, the centrifuge should be stopped immediately and load balances checked. Swing-out buckets should be checked for clearance and support. It is recommended that rotors and cups be cleaned and disinfected after each use with noncorrosive cleaning solution because of unrecognized leaks (40). (Cleaning and disinfection after each use may be a difficult regimen for all laboratories. A less frequent but regularly established routine may be an acceptable alternative.) All spills and breakage should be reported to the laboratory safety officer and should be cleaned immediately, after first vacating the laboratory to give time for aerosols to settle. Depending on the materials involved in the spill and the air handling in the facility, aerosols may remain suspended for over 35 min (38). In the context of quality control, a log should be maintained and include the rotor serial number, speed in revolutions per minute, the duration of spin, times of use, and the operator’s name.

Sharps Protection

Scalpels, needles, and broken glass, as well as other sharps, are commonly associated with wound injuries and laboratory-acquired infections (41). To the extent possible, the use of sharps should be eliminated or safety barriers implemented (5, 43). Sharps may be contaminated with infectious or cytotoxic agents or both. All sharps should be considered potentially infectious and be securely discarded in an appropriate sharps container.

Sharps containers used in medical laboratories should be specifically designed for the containment and disposal of needles, syringes with needles, scalpel blades, clinical glass, or other items capable of causing cuts or punctures (43). If containers are not resistant to penetration or compression, they pose a health risk to those involved in their handling and disposal.

The characteristics of well-designed containers are that they are leakproof and puncture resistant, do not degrade in autoclaves, either require no assembly or are easy to assemble, are appropriately labeled, and are available in a variety of sizes. Within this framework, manufacturers can implement a variety of designs. Sharps containers should be stable enough to resist toppling over and durable enough to withstand being dropped onto a hard surface (44). They should be constructed in a manner that ensures sufficient puncture resistance. International standards recommend a thickness able to resist a puncture pressure of 15 to 20 N (45, 46).

Using locally available tin cans or other containers in lieu of designed containers is inappropriate, as they do not address important aspects of containment.

Sharps containers must have a prominently displayed universal biohazard symbol. In addition, sharps containers intended for sharps contaminated with cytotoxic agents must display the cytotoxic hazard symbol. The international color code is yellow for biohazardous medical sharps and red for cytotoxic medical sharps.

Containers should not be filled to more than three-quarters of their maximum capacity to avoid accidents from overfilling, and sharps should never be forced into the container. Properly designed containers have a designated fill line.

Most sharps containers are designed for single use only. Once filled, they are securely and irreversibly closed for containment. Following autoclave treatment, the containers should be disposed of in accordance with local requirements. Containers with cytotoxic sharps or probable prion proteins should not be autoclaved but rather should be incinerated.

To reduce the challenges associated with disposal of single-use containers, reuse container services can provide collection and transport to an offsite location for secure reopening, emptying, and decontamination prior to redistribution for reuse.

Medical Waste as an Infection Hazard

Medical facilities generate large volumes of waste that can be hazardous to workers and the community (47). Liquid medical laboratory waste, such as urine, in many jurisdictions can be disposed of directly through a drain leading to the sanitary sewer system, although some jurisdictions require prior decontamination using a product such as 10% bleach. The remainder of medical waste requires sterilization.

In a recent survey, most university hospitals in the United States continue to use autoclaves to sterilize medical waste. Autoclaves effectively sterilize biological waste at a temperature of 121°C and with pressure at 100 kPa for 15 min. The more densely packed the autoclave is loaded, the longer it can take to reach these conditions in the middle of a load. Many organizations do not monitor autoclave effectiveness appropriately with biological indicators (48).

Contractual arrangement with biomedical waste management organizations may be an economic or environmental alternative. Alternatives, including microwave inactivation, can be considered if the necessity of required rigorous conditions is recognized (49). In some areas where economic or environmental issues are of extreme concern, solar disinfection (50) of biomedical waste may be a viable consideration. In rare circumstances when zoonotic outbreaks are addressed and, more commonly, in resource-limited regions, incineration of medical waste continues to be performed, even though it has been demonstrated to be harmful to health and the environment (51).

SAFETY AS A QUALITY MANAGEMENT INITIATIVE

Safety Preparedness and the Material Safety Data Sheet

Guidelines for the protection of laboratory workers describe the preparations required in case of accidents. In the event of an accident, a prompt and appropriate response requires preparedness, rapid access to critical information, and equipment. Every laboratory should have a written and prepared plan in case of emergency. Routes for evacuation in case of fire or spill should be planned and practiced on a regular basis. Personnel trained in first aid should be readily available to respond to the needs of laboratory workers.
available. Up-to-date material safety data sheets (MSDS) for all chemicals and microorganisms should be available. The locations of emergency equipment, including showers and eyewash stations, should be known to all and should be tested on a regular basis to ensure functionality at the time of need. Equipment and materials for containment of spills, including personal protective equipment, absorbent, and disinfectant (bleach or accelerated hydrogen peroxide), should be readily available and their locations known. Accident preparedness should be the subject of a regular internal safety audit program.

MSDS for chemicals should be obtained from the supplier or may be available from a variety of commercial and free Internet sites. A list of appropriately formatted MSDS for microorganisms is available through the Public Health Agency of Canada website (http://www.phac-aspc.gc.ca/msds-ftss/).

Every incident must be reported to appropriate management and the required authority. Every incident should be internally investigated for details of the accident, root causes, and the steps necessary to prevent similar events. Recommendations for required changes should be the subject of safety audits to ensure that they have been acted upon in a timely manner.

**Hand Washing and the Use of Personal Protective Equipment**

Hand washing is the single most useful technique to stop the transmission of microorganisms and acquisition of infection in medical laboratories (52). Hands can be contaminated during sample collection, handling of sample containers, handling of contaminated equipment, and touching of sample storage units.

While contamination can be reduced by the use of gloves, gloves alone are not completely effective. Hand hygiene can be performed with running water and either plain or antimicrobial soaps. Nonmedicated detergent-based soap products and water alone do not disrupt normal skin microbiota but can have some effect on the reduction of transient hand microbiota, including both bacteria and viruses (52, 53). The efficacy is directly related to the duration of hand washing. Plain soaps, like other products, can be associated with detrimental effects, including skin drying and irritation.

It is less clear whether soaps containing antimicrobial products are essential for the vast majority of hand-washing situations, even in the microbiology laboratory. For example, hand washing with plain soap is as efficacious as washing with antiseptic soap for removing *Clostridium difficile* (54), nonenveloped viruses, and *Bacillus anthracis* (55). The two product types are equally efficacious for the removal of common bacterial pathogens (53, 56).

Most laboratories continue to regularly use antiseptic soaps. Selection of an appropriate product for the laboratory depends upon both the types of organisms in specimens processed by the laboratory and issues such as fragrance, consistency, and potential for irritation and skin drying. Commonly used products contain chlorhexidine, iodophors, triclosan, or related compounds. Other ingredients, such as tea tree oil, are acceptable alternatives (57).

Waterless alcohol-based (60 to 62%) products can be a rapid and convenient alternative to conventional hand washing, especially when a sink with running water is not immediately accessible (53, 58). Used correctly, alcohol-based hand gels are as active as traditional 70% alcohol for removing MRSA, *Serratia marcescens*, and *Candida albicans* from contaminated hands (59). Alcohol-based products have reduced efficacy when hands are contaminated with spore-forming organisms, including *C. difficile* or *B. anthracis* (53) and nonenveloped viruses (53). In addition, alcohol-based products should not be relied upon when hands are visibly soiled, contaminated with proteinaceous materials, or contaminated with materials that have a high microbial load.

It is common in many laboratories to place alcohol-containing bottles by hand wash sinks. Others have noted that health care workers are more compliant with hand care when agents are close to the site of contamination (60). Accordingly, laboratories might consider having containers of alcohol-containing hand gel closer to workstations.

**Gloves**

Gloves can provide an important barrier within the laboratory, provided that they are used appropriately. Clearly, gloves are essential to prevent damage when hands are exposed to heat, cold, and toxic materials. Insulated gloves are essential when taking materials out of −70°C freezers or autoclaves or when hands are exposed to liquid nitrogen. In the microbiology laboratory, gloves create a protective barrier to reduce the risk of hand exposure to pathogens and their products.

General-purpose utility gloves ("kitchen" or "rubber" gloves) provide ample protection for clearing up biological spills, for cleaning, and for decontamination. Utility gloves can be cleaned and reused, although they should regularly be examined for cracks, tears, and peeling. Damaged utility gloves should be discarded. Utility gloves may be inappropriate when handling chemical solvents and should not be used. Chemical-resistant gloves should be available in all laboratories that handle chemical solvents and other toxic chemicals and dyes.

The degree of protection that gloves can provide depends upon many factors, including composition, size, fit, grip, and thickness, all of which can affect user dexterity. Latex-containing gloves may provide superior fine finger dexterity, which might be associated with fewer spills or accidents (61).

Disposable gloves of latex, vinyl, or nitrile can provide an effective barrier, especially when handling blood, body fluids, and excrement. This is especially true since open abrasions on hands may often go unnoticed (62). In specific settings, gloves of increased length (to the elbow or shoulder) may be appropriate. Gloves are easily torn. In-use durability studies indicate that vinyl gloves may tear as often as 40% of the time, depending upon the presence of powder and the length of the user’s fingernails (62). Latex gloves are more durable but may be associated with atopic reactions.

Disposable gloves do not provide significant protection against needle stick injury. If sharps exposure and the risk of injury are possible, double gloving can provide some protection. Cotton undergloves provide more protection than a second vinyl or latex glove. In the morgue, use of chain mail gloves may be appropriate.

Gloves provide an important protective barrier; however, they may also be a source of harm. Using vinyl, latex, or cotton undergloves can reduce the contact irritation noted with rubber gloves. Excessive glove use can result in moisture damage to skin (63–65). Surveys of dentists wearing gloves for 6 h daily indicated that many, especially young women with preexisting eczema, suffered from glove intolerance (66). In addition, contaminated gloves often result in contamination of equipment (67) and can also contribute to transmission of serious infection (68).
While it has become common for phlebotomists to wear gloves during specimen collection, this may not be essential if the risk of exposure to blood and body fluids is considered sufficiently low and gloves of an appropriate size or material are not readily available.

A common concern in the microbiology laboratory is the appropriateness of regular glove use while working on the bench in a routine laboratory. In the accessioning area, where original sample containers are handled, gloves are appropriate because it is not uncommon to have sample on the outside of the container.

There is little evidence to support or reject glove use while handling culture plates. On the one hand, gloves may provide a layer of protection in case a plate is dropped or mishandled. On the other hand, poorly fitting gloves can reduce dexterity and increase risk. Glove use may be a topic of personal preference or local policy.

Wearing gloves is appropriate when protecting an existing hand injury; however, prolonged glove use can induce further moisture-associated skin injury. If gloves are worn, it is critical for the user to remove them at the end of the task or when the task is interrupted and whenever he or she leaves the bench in order to reduce the risk of laboratory contamination.

Regardless of the type of gloves and their compositions, it is essential that the user always wash his/her hands as soon as gloves are removed, either with running water and soap or, in many settings, with alcohol-containing hand hygiene products.

Respirator Masks
For health care workers with direct exposure to patients, including phlebotomists, it is a common recommendation to require wearing an N95 mask while performing certain tasks. Many institutions require that people wearing an N95 mask pass a qualitative-fit test or quantitative testing (69, 70), which can be time-consuming, costly, and subjective.

An alternative protection may be provided by use of a surgical mask. Surgical masks are not fit tested, are less uncomfortable (71), and provide an equal level of protection (71–73). While caution and reasonable practices have been developed to contain outbreaks, effective influenza immunization in conjunction with personal protective equipment is required for optimal protection.

Ultimately the choice of usage will be governed by regulatory requirements.

Immunization
Immunization provides protection against some laboratory-acquired infectious diseases but should be considered secondary to mental alertness and good laboratory practices. Immunization may not prevent infection but can protect against serious illness. All adults, including pregnant women, should have a complete primary immunization with tetanus and diphtheria toxoids and should receive a booster every 10 years (74).

Laboratory workers, especially those with direct patient exposure, should receive annual influenza immunization (75). Similarly, those with direct patient exposure, especially to children and infants, should consider an immunization booster for pertussis (75). All staff with possible occupational exposure to human blood and body fluids should receive hepatitis B vaccine (75). The value of meningococcal immunization for laboratory workers has been discussed (76–78). Cases of meningococcal illness possibly linked to laboratory exposure have been published, and it has been recommended that microbiologists routinely exposed to meningococci, especially if aerosolized, should consider meningococcal immunization. Laboratorians working with specific pathogens and in specific situations should consider additional immunizations, for example, human diploid cell rabies vaccine, typhoid vaccine, and vaccinia vaccine (79, 80).

In the past, Mycobacterium bovis BCG vaccination has been considered of value for health care workers. However, it is no longer recommended as a primary tuberculosis (TB) control strategy because the protective efficacy of the vaccine in health care workers is uncertain and immunization with BCG may cause difficulty in the interpretation of tuberculin skin test responses caused by true infections with Mycobacterium tuberculosis. In laboratory and other health care workers with positive tuberculin skin tests, the new interferon gamma release assays can help differentiate likely TB exposure (positive) from BCG vaccination (negative).

Notable Laboratory-Acquired Infections
While the variety of microorganisms associated with laboratory-acquired infection is broad, certain ones have stood out over time as being of increased concern.

(i) Brucella Species
Brucellosis is a frequent cause of laboratory-acquired infection, especially in laboratories in regions of endemicity (81, 82) or in research facilities. In the clinical laboratory, infrequency and lack of familiarity with Brucella species is a risk factor, especially if relevant clinical information does not accompany the sample. Brucella species are pathogenic, even with very low inocula. The route of laboratory-acquired infection is often speculative, but direct exposure to hands and procedures that increase aerosols are thought important (83–85).

Often, small Gram-negative bacilli recovered from blood, joint fluid, cerebrospinal fluid (CSF), or pleural fluid are not appreciated as possible Brucella species (86), and work may continue on an open workbench, increasing the risk of exposure. Early action may be impeded as a result of biochemical misidentification as Moraxella species (87) or Ochrobactrum anthropi (88, 89).

Once the possibility of a Brucella isolate present on an open bench is raised, laboratories should transfer all work to a more secure laboratory environment with a properly working biological safety cabinet. In the event of a suspected or documented accident leading to possible exposure to Brucella species, laboratory workers can be monitored for seroconversion or clinical illness. In high-risk situations, prophylaxis with doxycycline, rifampin (90), or trimethoprim-sulfamethoxazole with or without rifampin (87) should be considered. Immunization with a Brucella vaccine is currently unavailable, although much progress is under way (91).

(ii) Francisella tularensis
Francisella tularensis is a Gram-negative cocobacillus associated with zoonosis-associated pneumonia (30, 92–95) and potentially with bioterror events (96). Because of its infrequency, delayed identification may occur among laboratory workers (94). This reinforces the value of taking a cautionary approach toward the isolation of small Gram-negative bacteria. Potential exposure to Francisella tularensis should raise the consideration of doxycycline (97) for prophylaxis in laboratory workers.

(iii) Burkholderia pseudomallei
Meliodosis is a significant cause of fatal sepsis (98). It is caused by Burkholderia pseudomallei, which is commonly
found as an environmental saprophyte in Southeast Asia (30, 98, 99) and northern Australia but is also found in the Caribbean (100) and in Central America (101). Laboratory exposures can potentially result from many routine practices and result in serious infection. While definitive human data are lacking, animal studies strongly suggest that prophylaxis with co-trimoxazole, started as soon as possible after exposure, can be highly effective in preventing clinical infection (101–103).

(iv) Mycobacterium tuberculosis
Mycobacterium tuberculosis is internationally accepted as a risk group 3 bacterium (Table 3). Although there are no statistics readily available, it is likely the most common risk group 3 microorganism to which clinical laboratory workers are exposed. Tuberculosis is one of the 10 most commonly reported laboratory-acquired infections (104). Because of the silent and delayed nature of conversion and frequency of tuberculosis in the community, it can be difficult to trace skin test conversion to laboratory exposure. The organism is most commonly in spumtum or urine samples, which may or may not specify or request examination for possible M. tuberculosis infection. Handling samples, especially sputum, under a biological safety cabinet can reduce exposure to aerosols (104). It is most commonly transmitted through aerosol production. Clinical laboratory worker exposure may be difficult to trace (104), although exposure to aerosols and autopsy (105, 106) are recognized. Laboratory workers with frequent direct patient exposure are also at risk (107). Laboratory workers should have annual skin tests.

(v) Coccidioides Species
Coccidioidomycosis is a lung infection associated with Coccidioides immitis or Coccidioides posadasii, commonly regionally located (30). In 60 to 65% of cases, this infection is asymptomatic (108). Laboratory workers are potentially at risk due to culture exposure (109) or exposure during autopsy (110). Coccidioides immitis has been previously identified as a potential agent for bioterror (109), although it was removed from the list of select agents and toxins in 2012. While respiratory exposure to Coccidioides species by laboratory workers would be concerning, most infections are asymptomatic or self-limited. Immunocompetent individuals may be at greater risk (111). The value of prophylaxis with antifungal agents is unproven but may be recommended (112, 113).

(vi) Laboratory-Acquired Viral Infections, Including HIV, Hepatitis B, and Hepatitis C
A broad range of surveys and case reports describe viral infections in laboratory workers (104, 114–120). Over the last 75 years, the variety and frequency of laboratory-acquired viral infections have progressively increased, perhaps reflecting greater awareness and improvements in diagnosis. Most are reported from research and/or veterinary laboratories. When reported, the most probable routes of infection include percutaneous infection (sharps), aerosol (fomite) inhalation, and oral ingestion, indicating the importance of laboratory safety practices. The incidence of new cases of human immunodeficiency virus (HIV) in the United States has stabilized to between 40,000 and 50,000 new cases per year (121). There are no recent reported cases in laboratory workers in the United States, but that may not be true for all countries (122–124). Following a deep tissue exposure injury, such as with a needle or scalpel, it is recommended that workers consider postexposure prophylaxis (PEP), even though PEP does not always prevent HIV infection following an exposure (125).

Laboratory workers are at risk of blood-borne infections, such as hepatitis C virus (HCV), HBV, and HIV. However, the safeguards introduced into medical laboratories have decreased the risk to laboratory workers.

There is little information on the prevalence of hepatitis C in health care workers, although it is estimated by the National Center for Infectious Diseases (126) that after needle stick or sharps exposure to HCV-positive blood, about 2 (1.8%) health care workers out of 100 will get infected with HCV (range, 0% to 10%). A recent review of a 14-year prospective study did not find health care workers at a heightened risk of HCV as a consequence of sharps injuries (127). Following the introduction of hepatitis B vaccine in 1982, the incidence of hepatitis B infection was reduced by over 95% (5).

While blood-borne infection information may be thought to be well established, recent knowledge surveys of health care workers have demonstrated that education sessions to update existing staff and inform new staff are regularly required (128).

(vii) Influenza and Other Severe Viral Respiratory Infections
Influenza and other severe outbreaks are a common event in many communities. Study of influenza outbreaks (129–131) has pointed out potential gaps in biosafety protection for laboratory workers. Although laboratory workers may be at risk (132), the level of risk is low because in-laboratory containment is easily addressed (133, 134). Laboratory workers are among those with the lowest incidence of illness or serological conversion (132). That being said, phlebotomists and microbiology and accessioning laboratory workers receiving respiratory samples, especially via vacuum tube delivery systems, were deemed to be at increased risk. Laboratories equipped and designed to biosafety level 2 should use practices more consistent with biosafety level 3, which require all samples to be opened and handled only under a biosafety cabinet (30, 133). In addition, centrifugation of samples should be performed only with sealed safety buckets that are opened within a cabinet. Frequent hand washing with either soap and running water or alcohol-based hand gels should be required (131).

(viii) Laboratory-Acquired Infections and External Quality Assessment
Infections acquired in the clinical laboratory are not always associated with clinical samples. Documented clusters of bacterial infections have been associated with samples sent to laboratories for proficiency testing (135). Contamination of other samples by quality control organisms has also been documented (136), although no in-laboratory infections resulted. Regardless of source, all viable microorganisms processed within a clinical laboratory must be handled with full awareness of appropriate biosafety practices.

(ix) Prions
Samples from patients with Creutzfeldt-Jakob disease (CJD) may be submitted to a laboratory for investigation. To date, there are no known cases of laboratory-acquired CJD, and there is no evidence that laboratory workers are at increased risk of developing CJD. That being said, the progressive deteriorating nature of CJD raises concerns for those handling samples from patients with CJD, especially those of neurological origin (137). This represents a special problem in medical laboratories because of the difficulty of inactivating the underlying prions.
Current precautions while handling tissue samples (brain, spinal cord, dura mater, pituitary, and eye samples) require full use of personal protective equipment to protect the worker and the workspace (138, 139). All tissue samples must be discarded as medical waste. No special precautions are required for disposal of body fluids.

Equipment that has been exposed to CJD patient tissues should either be discarded or, if tolerant to heat, be autoclaved at 134°C for 18 min (prevacuum sterilizer) or 121°C to 132°C for 1 h (gravity displacement sterilizer). Autoclaving in water may be more effective than autoclaving in its absence (140). Equipment may also be soaked in 1 N NaOH for 1 h (140, 141). Work surfaces should be cleaned with a 1:10 dilution of sodium hypochlorite.

Milder chemical treatments based upon combinations of enzymes, including proteinase K and pronase, in conjunction with detergents, such as alkaline cleaners or SDS, have been shown to experimentally reduce PrPSc material to levels below detection and to prevent infectivity. The advantages of these methods are described as being inexpensive, noncorrosive, and nonhazardous to staff (140, 141). In vitro studies suggest that maintaining equipment in a moist environment reduces the adhesion of PrPSc materials to surgical stainless steel and can increase the efficacy of decontamination (142).

Safety and Point of Care

Medical laboratories are responsible for all aspects of laboratory testing throughout the total testing cycle, even when the testing is performed outside the laboratory itself. Increasingly, medical laboratories are responsible for point-of-care testing (POCT), such as blood glucose monitoring, coagulation, and oxygenation. Despite improvements in equipment and hygiene protocols, cases of hepatitis B and C continue to be associated with point-of-care devices. Prevention of transmission requires strict adherence to infection control protocols for equipment cleaning (143).

Safety Considerations Associated with MALDI-TOF Mass Spectrometry

Matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) analysis is a new process that provides rapid identification of microorganisms through mass spectrometry of microbial proteins. The procedure includes application of the microbial target onto the sample plate, where it can be exposed to laser light. When addressing organisms, particularly those of risk group 3, in order to reduce potential biohazardous exposure, the sample can be rapidly (30 min) inactivated by exposure to trifluoroacetic acid (TFA), with minimal risk of altering the protein mass spectrometry peak fingerprint (89). Regardless of prior treatment, upon completion, all samples should be considered biohazardous waste and be treated accordingly.

Transportation of Samples

Laboratories have a responsibility to prevent exposure to infectious agents in laboratory samples to the highest extent possible. This responsibility includes during the transport of samples to and from the laboratory. For local transport within a clinic or hospital, the laboratory should ensure that leakproof containers are available and that the sample is transported in secure outer packaging, such as a sealable plastic bag, preferably emblazoned with the international biohazard label. For transport outside the facility, especially by road, rail, ship, or air, local and federal regulations apply. Even for short distances, it is appropriate that samples be transported in secure, firm outer containers with sufficient absorbent materials inside in case of a spill. In most jurisdictions, transport of samples with infectious agents by postal services is prohibited.

Air transport is under the authority of federal regulations directed by the requirements of the International Civil Aviation Organization (ICAO) as adopted by the International Air Transport Association (IATA). ICAO specifies the packaging and labeling requirements, including the proper shipping name and appropriate UN number, for samples known to contain infectious agents based on the source of the sample and the likely pathogens contained. Every laboratory that transports samples is required to have at least one person certified as knowledgeable with respect to packaging and transport requirements, including the completion of shipping documents.

For additional information, direct reference can be made to the International Civil Aviation Organization technical instructions for the safe transport of dangerous goods by air or to federal requirements (144).

Postexposure Management for Accidents Involving Infectious Agents

It is beyond the scope of this chapter to address the specifics of medical management following accidents that involve infectious agents. However, it is important that the following steps always be undertaken or considered. Every accident or injury, including those that are seemingly trivial (1), should be reported to the appropriate safety officer or supervisor. Scratches and puncture wounds should be cleaned immediately. For some injuries, especially those involving blood exposures, time may be a critical factor (145). If it is deemed appropriate to seek medical attention, it is important to indicate that the accident was laboratory acquired. If the likely or probable agent is known, bringing the microorganism MSDS can be helpful and save time. In research or animal facilities, preparation of information sheets on specific organisms and the availability of standardized investigation and treatment protocols in the event of an accident can be invaluable.

Decontamination, Disinfection, and Sterilization
CONSTANZE WENDT, RENO FREI, AND ANDREAS F. WIDMER

Decontamination, disinfection, and sterilization are basic components of any infection control program. Patients expect that any reusable instrument or device used for diagnosis or treatment has undergone a process to eliminate any risks for cross-infection. However, the infection control literature documents many reprocessing failures, including numerous reports of transmission of nosocomial pathogens from contaminated endoscopes (1–5). Before 1990, it was very difficult to prove a causal relationship between a contaminated device and a subsequent nosocomial infection. Today, state-of-the-art clinical epidemiology supported by molecular typing tools such as pulsed-field gel electrophoresis, PCR, and genome sequencing can enable the hospital epidemiologist to prove a causal relationship between the use of a contaminated device and a consequent infection. Molecular epidemiology has thus provided scientific tools that can identify the limitations of the available disinfection and sterilization methods and can provide the impetus to improve reprocessing technologies. Despite those advances, little research has been done that will lead to major breakthroughs in disinfection and sterilization in the near future. Thus, we believe the key issues instead will be to standardize and optimize our applications of current knowledge.

Clearly, more research is needed in this field, but resources for such work have been limited. In fact, most disinfectants were introduced to the market more than 30 years ago, and little is known about their modes of action and the mechanisms of resistance. Excellent reviews on this topic have been published by Block (6) and by Russell and coworkers (7, 8). In addition, few basic procedures in decontamination, disinfection, and sterilization have been tested in randomized clinical trials. In this chapter, we have tried to cite the highest level of evidence available. However, given the dearth of studies, we have often had to cite results of observational studies, animal models, in vitro tests, and expert opinion because higher levels of evidence were unavailable.

Despite the lack of resources, reprocessing techniques, disinfectants, and general infection control practice have garnered more attention recently than in the past. This is due in part to the increasing frequency of multiresistant bacterial pathogens at a time when pharmaceutical companies have shifted from developing antimicrobial agents to designing drugs for chronic diseases (9). Moreover, new pathogens, such as the viruses causing severe acute respiratory syndrome (SARS), avian influenza (10), and swine flu (11) or the prions causing Creutzfeldt-Jakob disease (CJD) and variant CJD (vCJD), are emerging, for which there are few if any treatments. Consequently, the medical community needs better knowledge on disinfection and sterilization to prevent the spread of these pathogens.

PRINCIPLES, TERMINOLOGY, AND BACKGROUND

There is no uniform terminology for antiseptics, disinfec-
tion, and sterilization, and many problems arise as a result. Many terms are ill defined even within the United States or Europe. In addition, the testing procedures for disinfectants are not as far advanced and well defined as MIC testing based on the recommendations of the Clinical and Laboratory Standards Institute (CLSI). However, there currently are efforts to standardize and harmonize the terminology on an international level. For example, the International Organization for Standardization (ISO) norms for sterilization were published in 2004 and included in the new guidelines published in 2010 (12). In addition, manufacturers now must provide specific data on how to reprocess their medical devices. In the past, such information was frequently missing in the user's manuals.

For this chapter, we will use the term antiseptics for chemical compounds that are used to disinfect living tissue. The term disinfection will be used for compounds or methods that reduce microorganisms to a level at which the treated product cannot cause infection. In contrast to disinfection, sterilization will be used for procedures that will lead to a product that is free of microorganisms.

ANTISEPTICS

Compounds that disinfect living tissue are called antiseptic agents. They must meet many more requirements than compounds used to disinfect inanimate surfaces because they have to come in direct contact with the skin or mucous membranes. In addition, some of the agents are considered drugs and, thus, are regulated by the U.S. Food and Drug Administration (FDA). The antimicrobial spectra of commercially available agents are summarized in Table 1. The choice of the agent should be based not only on the desired effect but also, like antimicrobial agents, on side effects. Antiseptics rarely cause serious side effects, and most agents on the market have excellent safety profiles. Nevertheless, health care workers (HCWs) must remember that these
agents can cause side effects such as anaphylactic shock in patients who have had contact with chlorhexidine, mainly patients originating from the Far East (13, 14).

Common Antiseptic Compounds

Alcoholic Compounds

Alcohol is the most important skin antiseptic. For centuries, alcohols have been appreciated for their antimicrobial properties. Alcohol is defined by the FDA as having one of the following active ingredients: ethyl alcohol, 60% to 95% by volume in an aqueous solution, or isopropyl alcohol, 50% to 91.3% by volume in an aqueous solution. Ethyl alcohol (ethanol) and isopropyl alcohol (isopropanol) are the alcoholic solutions most often used as surface disinfectants and antiseptic agents in health care institutions because they possess many qualities that make them suitable both for disinfection of equipment and for antisepsis of skin. They are fast acting, minimally toxic to the skin, nonstaining, and nonallergenic. Alcohols evaporate readily, which is advantageous for most disinfection and antisepsis procedures. The uptake of alcohol by intact skin and the lungs when alcohol is used topically is below toxic levels for most recent guidelines published in 2009, and Muslims, for example, are allowed to use alcoholic compounds for hand hygiene. Therefore, preparations for hand disinfection should contain emollients.

The exact mechanism by which alcohols destroy microorganisms is not fully understood. The most plausible explanation for the antimicrobial action is that alcohol coagulates (denature) proteins (e.g., enzymatic proteins), impairing specific cellular functions (18). Ethyl and isopropyl alcohols at appropriate concentrations have broad spectra of antimicrobial activity that include vegetative bacteria, fungi, and viruses. In fact, their antimicrobial efficacies are enhanced in the presence of water, with optimal alcohol concentrations being 60 to 90% by volume.

Alcohols (i.e., 70 to 80% ethyl alcohol) rapidly (i.e., within 10 to 90 s) kill vegetative bacteria, such as Staphylococcus aureus, Streptococcus pyogenes, Enterobacteriaceae, and Pseudomonas aeruginosa in suspension tests (17). Isopropyl alcohol is slightly more bactericidal than ethyl alcohol (18) and is highly effective against vancomycin-resistant enterococci (19). It also has excellent activity against fungi, such as Candida spp., Cryptococcus neoformans, Blastomyces dermatitidis, Coccidioides immitis, Histoplasma capsulatum, Aspergillus niger, and dermatophytes, and mycobacteria, including Mycobacterium tuberculosis. However, alcohols generally do not destroy bacterial spores. In fact, spores of Clostridium difficile are stored in ethanol in the microbiology laboratory. In addition, fatal infections due to Clostridium spp. occurred when alcohol was used to sterilize surgical instruments. Both ethyl and isopropyl alcohols inactivate most viruses with a lipid envelope (e.g., influenza virus, herpes simplex virus, and adenovirus). However, several investigators found that isopropyl alcohol had lower virucidal activity against naked, nonenveloped viruses (20). In the experiments by Klein and DeForest, 2-propanol, even at 95%, could not inactivate the nonenveloped poliovirus type 1 and coxsackievirus type B in 10 min (21). In contrast, 70% ethanol inactivated these enteroviruses (21). Neither 70% ethanol nor 45% 2-propanol killed hepatitis A virus (HAV) when their activities were assessed on stainless steel disks contaminated with fecally suspended virus. Among 20 disinfectants tested, only 3 reduced the titer of HAV by greater than 99.9% in 1 min.

\(d\): Not available in the United States.

Ethanol at >95% is highly effective against viruses; isopropanol has limited effectiveness against small or nonlipid viruses. Data from references 30, 69, and 334. Symbols: ±, poor; +, fair; ++, good; ++++, excellent.
Chlorhexidine

Chlorhexidine gluconate, a cationic bisbiguanide, has been recognized as an effective and safe antiseptic for nearly 40 years (29, 30). Chlorhexidine formulations are extensively used for surgical and hygienic hand disinfection (see previous discussion). Other applications include preoperative showers (or whole-body disinfection), antisepsis in obstetrics and gynecology, management of burns, wound antisepsis, and prevention and treatment of oral disease (plaque control, pre- and postoperative mouthwash, and oral hygiene) (29, 30). When chlorhexidine is used orally, its bitter taste must be masked and it can stain the teeth. Intravenous catheters coated with chlorhexidine and silver sulfadiazine are used to prevent catheter-associated bloodstream infections (31). In fact, an infection control program to prevent catheter-associated bloodstream infections included hand hygiene, chlorhexidine site care, and full-barrier precautions in a large clinical study in intensive care units: these interventions led to an infection rate close to zero (32). Today, chlorhexidine compounds are considered the gold standard for catheter site care (33). Chlorhexidine is most commonly formulated as aqueous solutions and used to disinfect catheters. However, alcoholic preparations have been demonstrated in numerous studies to have better antimicrobial activity than detergent-based formulations (34). Bactericidal concentrations destroy the bacterial cell membrane, causing cellular constituents to leak out of the cell and cell contents to coagulate (29). The bactericidal activity of chlorhexidine gluconate against vegetative Gram-positive and Gram-negative bacteria develops within minutes. In addition, it provides a persistent antimicrobial action that prevents the regrowth of microorganisms for up to 6 h. This effect is desirable when a sustained reduction in the microbiota reduces infection risk (e.g., during surgical procedures). Chlorhexidine has little activity against bacterial and fungal spores except at high temperatures. Mycobacteria are inhibited but are not killed by aqueous solutions. Yeasts and dermatophytes are usually susceptible, although the fungicidal action varies with the species (35). Chlorhexidine is effective against lipophilic viruses (e.g., HIV, influenza virus, and herpes simplex virus types 1 and 2), but viruses such as poliovirus, coxsackievirus, and rotavirus are not inactivated (29). Unlike what occurs with povidone iodine, blood and other organic materials do not affect the antimicrobial activity of chlorhexidine significantly (36). However, inorganic anions and organic anions such as soaps are incompatible with chlorhexidine, and its activity is reduced at extreme acidic or alkaline pH and in the presence of anion- and non-ion-based moisturizers and detergents. Microorganisms can contaminate chlorhexidine solutions (37), and resistant isolates have been identified. For example, Stickler found chlorhexidine-resistant Proteus mirabilis after chlorhexidine was used extensively over a long period to prepare patients for bladder catheterization (38). The chlorhexidine resistance among vegetative bacteria was thought to be limited to certain Gram-negative bacilli (such as Pseudomonas aeruginosa, Burkholderia cepacia, Proteus mirabilis, and Serratia marcescens) (39). However, genes conferring resistance to various organic cations, including chlorhexidine, have been identified in S. aureus clinical isolates (40, 41). Chlorhexidine has several other limitations. When absorbed onto cotton and other fabrics, it usually resists removal by washing. If a hypochlorite (bleach) is used during the washing procedure, a brown stain may develop (29). Long-term experience with the use of chlorhexidine has demonstrated that the incidence of hypersensitivity and skin irritation is low. However, severe allergic reactions including anaphylaxis have been reported (13, 42). Although cytotoxicity has been observed in exposed fibroblasts, no deleterious effects on wound healing have been demonstrated in vivo. There is no evidence that chlorhexidine gluconate is toxic if it is absorbed through the skin, but ototoxicity can occur when chlorhexidine is instilled into the middle ear during operative procedures. High concentrations of chlorhexidine and preparations containing other compounds (e.g., alcohols and surfactants) may damage eyes (43). In the report “Strategies to Prevent Central Line-Associated Bloodstream Infections in Acute Care Hospitals,” it has been acknowledged that no recommendations with regards to chlorhexidine gluconate antiseptic can be made for infants less than 2 months of age due to incomplete safety data in this population (44). In fact, 51% of participants in a survey who used chlorhexidine in their neonatal intensive care unit reported adverse reactions. All were skin reactions and included erythema (32%), erosions (7%), or burns (61%). Of the reported skin burns, 13 of 17 (76%) were reported to have occurred in neonates with a birth weight of less than 1,500 g (45).

Iodophors

Iodophors essentially have replaced aqueous iodine and tincture as antiseptics. Iodophors are chemical complexes of iodine bound to a carrier such as polyvinylpyrrolidone (PVP) iodine (also known as povidone iodine) or ethoxylated nonionic detergents (poloxamers). These complexes gradually release small amounts of free microbical iodine. The most commonly used iodophor is PVP iodine. Its preparations generally contain 1 to 10% PVP iodine, which is equivalent to 0.1 to 1.0% available iodine. The active component appears to be free molecular iodine (I2). A paradoxical effect of dilution on the activity of PVP iodine has been observed. As the dilution increases, bactericidal activity increases up to a maximum and then falls (46). Commercial PVP iodine solutions at dilutions of 1:2 to 1:100 kill S. aureus and Mycobacterium chelonae more rapidly than do stock solutions (47). S. aureus can survive a 2-min exposure to full-strength PVP iodine solution but cannot survive a 15-s exposure to a 1:100 dilution of the iodophor (47). Thus, iodophors must be used at the dilution stated by the manufacturer. The exact mechanism by which iodine destroys microorganisms is not known. Iodine may react with microorganisms’ amino acids and fatty acids, destroying cell structures and enzymes (46). Depending on the concentration of free iodine and other factors, iodophors exhibit...
a broad range of microbicidal activity. Commercial preparations are bactericidal, mycobactericidal, fungicidal, and virucidal but non-sporidical at the dilutions recommended for use. Prolonged contact times are required to inactive certain fungi and bacterial spores (20). Despite their bactericidal activity, PVP iodine and poloxamer-iodine solutions can become contaminated with B. cepacia or P. aeruginosa, and contaminated solutions have caused outbreaks of pseudomembranous colitis, iritis, and pseudophakic cystoid macular edema (48, 49). In fact, B. cepacia was found to survive for up to 68 weeks in a PVP iodine antiseptic solution (50). The most likely explanation for the prolonged survival of these microorganisms in iodophor solutions is that organic or inorganic material and biofilm may mechanically protect the microorganisms. Iodophors are widely used for antisepsis of skin, mucous membranes, and wounds. A 2.5% ophthalmic solution of PVP iodine is more effective and less toxic than silver nitrate or erythromycin ointment when used as prophylaxis against neonatal conjunctivitis (ophthalmia neonatorum) (51). In some countries, PVP iodine alcoholic solutions are used extensively for skin antisepsis before invasive procedures (32). Iodophors containing higher concentrations of free iodine may be used to disinfect medical equipment. Solutions designed for use on the skin should not be used to disinfect hard surfaces because the concentrations of the antiseptic solutions are usually too low for this purpose (20). The risk of side effects, such as staining, tissue irritation, and resorption, is lower for iodophors than for aqueous iodine. Iodophors do not corrode metal surfaces (46). However, a body surface treated with an iodine or iodophor solution may absorb free iodine. Consequently, increased serum iodine levels (and serum iodide levels) have been found in patients, especially when large areas were treated for a long period (46). For this reason, hyperthyroidism and other disorders of thyroid functions are contraindications for the use of iodine-containing preparations. Likewise, iodophors should not be applied to pregnant and nursing women or to newborns and infants (53). Because severe local and systemic allergic reactions have been observed, iodophors and iodine should not be used in patients with allergies to these preparations (54). Iodophors have little if any residual effect. However, for a limited time, they may have residual bactericidal activity on the skin surface because free iodine diffuses into deep regions but also back to the skin surface (46). The antimicrobial efficacy of iodophors is reduced in the presence of organic material such as blood.

Triclosan and PCMX

Triclosan (Irgasan DP-300 or Irgacare MP) has been used for more than 30 years in a wide array of skin care products, including hand washes, surgical scrubs, and consumer products. A review of its effectiveness and safety in health care settings has been published (55). A concentration of 1% has good activity against Gram-positive bacteria, including antibiotic-resistant strains, but less activity against Gram-negative organisms, mycobacteria, and fungi. Limited data suggest that triclosan has a relatively broad antiviral spectrum, with high-level activity against enveloped viruses, such as HIV type 1, influenza A virus, and herpes simplex virus type 1. However, the nonenveloped viruses proved more difficult to inactivate. Clinical strains of S. aureus with low-level resistance to triclosan have been identified, but the clinical significance of this remains unknown (56). Triclosan is added to various soaps, lotions, deodorants, toothpastes, mouth rinses, commonly used household fabrics, plastics, and medical devices. Moreover, the mechanisms of triclosan resistance may be similar to those involved in antimicrobial resistance (57), and some of these mechanisms may account for the observed cross-resistance of laboratory isolates to antimicrobial agents (58). Consequently, concerns have been raised that widespread use of triclosan formulations in non-health-care settings and products may select for biocide resistance and even cross-resistance to antibiotics. However, environmental surveys have not demonstrated an association between triclosan usage and antibiotic resistance (59). Triclosan solutions produce a sustained residual effect against resident and transient microbials, which is minimally affected by organic matter. Numerous studies have not identified toxic, allergenic, mutagenic, or carcinogenic potential. Triclosan formulations may help control outbreaks of meticillin-resistant S. aureus (MRSA) when used for hand hygiene and as a bathing cleanser for patients (55). However, some MRSA isolates have reduced triclosan susceptibility. Triclosan formulations are less effective than 2 to 4% chlorhexidine gluconate when used for surgical scrub solutions; properly formulated triclosan solutions may be used for hygienic hand washing. PCMX (chloroxylenol) is an antimicrobial used in hand-washing products. It is available at concentrations of 0.5 to 3.75%. Its properties are similar to those of triclosan. Nontoxic surfactants may neutralize PCMX.

Octenidine

Octenidine dihydrochloride is a novel bispyridine compound which is an effective and safe antiseptic agent. The 0.1% commercial formulation favorably compared to other antiseptics with respect to antimicrobial activity and toxicological properties. In vitro and in vivo it rapidly killed both Gram-positive and Gram-negative bacteria as well as fungi (60, 61). Octenidine is virucidal against HIV, HBV, and herpes simplex virus. Similar to chlorhexidine, it has a marked residual effect. No toxicological problems have been found when the 0.1% formulation was applied according to the manufacturer’s recommendations. The colorless solution is a useful antiseptic for mucous membranes of the female and male genitals and the oral cavity (62), but its bad taste limits its use orally. In a recent observational study, the 0.1% formulation was highly effective and well tolerated for care of central venous cannula insertion sites (63).

The results of this study have also been supported by a randomized controlled clinical trial (64). Octenidine is not registered for use in the United States.

Hygienic Hand Washing and Hand Disinfection

Hand hygiene is the single most important infection control measure (65). However, it remains difficult to motivate HCWs to perform this simple procedure faithfully (66). The Centers for Disease Control and Prevention (CDC) has published detailed guidelines on hand hygiene (65), and in 2006, the WHO launched a global effort to improve hand hygiene in health care facilities with a reference book published in 2009 (http://whqlibdoc.who.int/hq/2009/WHO_IER_PSP_2009.07_eng.pdf). In-depth reviews have been published by several authors (67–69). Microorganisms on the hands can be classified into three groups (70): (i) the transient biota, which consists of contaminants taken up from the environment; (ii) the resident biota, which consists of permanent microorganisms on the skin (69); and (iii) the infectious biota. Resident bacteria, most of which are on the uppermost level of the stratum corneum, have low pathogenicity and infectivity, and persons with normal immune systems who do not have implants or foreign bodies rarely acquire infections with these organisms. The density of resident bacteria on the skin ranges between 10^2 and 10^3.
CFU/cm², and these resident bacteria limit colonization with more pathogenic microorganisms (i.e., colonization resistance). During their daily work, HCWs can contaminate their hands with pathogens. If they do not practice good hand hygiene, they can transmit these organisms to susceptible patients. Several studies indicated that pathogens such as S. aureus (71), Klebsiella pneumoniae (72), Acinetobacter spp., Enterobacter spp., or Candida spp. can be found on the hands of >20% of HCWs. Moreover, numerous epidemics have been traced to HCWs’ contaminated hands (73–77). The goal of hand hygiene outside the operating room is to eliminate the transient biota without altering the resident biota. Hand washing for 15 and 30 s kills 0.6 to 1.1 and 1.8 to 2.8 log units, respectively (78). However, HCWs are very busy and frequently wash their hands for less than 10 s, which is insufficient to kill the transient biota (68, 69). One major advantage of the alcohol-based hand rub is that performance with these products takes about 25% of the time required for hand washing (68, 69). Moreover, compliance with hand-washing procedures does not exceed 40% even under controlled study conditions (67, 68). More recent studies have shown that compliance with using the alcohol-based hand rubs exceeds that of hand washing (79). Furthermore, other studies have demonstrated that rubbing one’s hands with an alcohol-based hand rub kills bacteria and most viruses more effectively than hand washing with a medicated soap (80, 81). Of note, investigators have not determined whether the level of killing is associated with the efficacy of preventing nosocomial infections. Alcohol-based hand rubs have several other practical advantages for hand hygiene over washing with soap and water. Compared with sinks, dispensers for the alcohol-based products are inexpensive, and they can be installed at locations that are more convenient for HCWs. Furthermore, unlike sinks (82), the dispensers have not been associated with outbreaks. Given the numerous advantages of these products, CDC’s current hand hygiene guidelines recommend that health care facilities consider introducing alcohol-based hand rubs as the primary mode of hand hygiene (65). Most U.S. institutions promote hand hygiene using an alcoholic hand rub as standard of care, driven by the theoretical advantage, but there are no data from controlled clinical trials proving that the incidence of surgical site infections is lower when this product is used. The WHO has issued a guideline for surgical hand antisepsis (www.who.int) with an executive summary published (90, 91).

Alcohol-based surgical rubs have several advantages over traditional surgical scrubs. Alcoholic preparations are more effective than any medicated soap for the surgical scrub, and they do not alter the skin as much as chlorhexidine washes do. Moreover, the water supply in an operating room could harbor Pseudomonas spp. that might contaminate the hands of surgical personnel after they perform their surgical scrub (92). Brushes, which are used during a surgical scrub, may do more harm than good, and they should be used only to clean the fingernails, not to clean the skin. Given the advantages of the alcohol-based preparations, the presurgical scrub has been replaced in many European countries by the alcohol-based surgical rubs (68), and the WHO guidelines recommend the surgical hand rubs. Alcoholic gels are frequently promoted, but most of them are significantly less effective than liquids and should not be used in the operating room (93). A very rapid protocol (1.5 min) for the surgical hand rub has been proposed and was rapidly accepted by surgeons at the author’s institution (94). The results of this investigational study were confirmed in a clinical trial (91, 95). However, few commercially available products have been successfully tested, and quite a few failed. Therefore, a 1.5-min surgical hand antisepsis is only acceptable if the product is cleared for such a short exposure to the hands.

Of note, both routine hand hygiene and surgical hand preparations must balance removing unwanted bacteria from HCWs’ hands and maintaining the integrity of the HCWs’ skin because damaged skin is more likely than normal skin to become colonized with pathogenic organisms. Therefore, either hand hygiene products should contain emollients or health care facilities should provide moisturizing hand lotions that do not damage latex for their staff so that their skin does not become dry, cracked, and irritated.

Surgical Hand Washing (Scrub) or Surgical Hand Disinfection (Rub-In)

In contrast to hand hygiene outside the operating room, the surgical hand scrub aims to eliminate both transient biota and resident biota so that if the surgeon’s gloves are punctured or torn, bacteria from his or her hands do not contaminate the surgical site. Tiny holes are observed in ≥30% of surgeons’ gloves after operations, even when high-quality gloves are used. Cruse and Foord found that the incidence of surgical site infection was three times higher if the surgeon’s gloves were punctured than if they were intact after the procedure (5.7 and 1.7%, respectively) (86). An experimental study demonstrated that the level of bacterial leakage through pinholes ranged between 10³ and 10⁴ CFU (87). Recently, a clinical trial clearly demonstrated that the presence of holes in a surgical glove without adequate antimicrobial prophylaxis increases the risk of postoperative surgical site infections fourfold (88). Moreover, a persistent antimicrobial effect is required after washing or disinfection to limit bacterial regrowth underneath the gloves (89). Thus, antiseptic preparations intended for use as surgical hand preparation are evaluated for their ability to reduce the number of bacteria released from hands (i) immediately after scrubbing, (ii) after wearing surgical gloves for 6 h (persistent activity), and (iii) after numerous applications over 5 days (cumulative activity). Immediate and persistent activities are considered the most important. Guidelines in the United States recommend that agents used for surgical hand preparation should significantly reduce microorganisms on intact skin, contain a nonirritating antimicrobial preparation, have broad-spectrum activity, and be fast acting and persistent. Agents, such as chlorhexidine, that have a prolonged postexposure effect are preferred because of this theoretical advantage, but there are no data from controlled clinical trials proving that the incidence of surgical site infections is lower when this agent is used. The WHO has issued a guideline for surgical hand antisepsis (www.who.int) with an executive summary published (90, 91).

Alcohol-based surgical rubs have several advantages over traditional surgical scrubs. Alcoholic preparations are more effective than any medicated soap for the surgical scrub, and they do not alter the skin as much as chlorhexidine washes do. Moreover, the water supply in an operating room could harbor Pseudomonas spp. that might contaminate the hands of surgical personnel after they perform their surgical scrub (92). Brushes, which are used during a surgical scrub, may do more harm than good, and they should be used only to clean the fingernails, not to clean the skin. Given the advantages of the alcohol-based preparations, the presurgical scrub has been replaced in many European countries by the alcohol-based surgical rubs (68), and the WHO guidelines recommend the surgical hand rubs. Alcoholic gels are frequently promoted, but most of them are significantly less effective than liquids and should not be used in the operating room (93). A very rapid protocol (1.5 min) for the surgical hand rub has been proposed and was rapidly accepted by surgeons at the author’s institution (94). The results of this investigational study were confirmed in a clinical trial (91, 95). However, few commercially available products have been successfully tested, and quite a few failed. Therefore, a 1.5-min surgical hand antisepsis is only acceptable if the product is cleared for such a short exposure to the hands.

Of note, both routine hand hygiene and surgical hand preparations must balance removing unwanted bacteria from HCWs’ hands and maintaining the integrity of the HCWs’ skin because damaged skin is more likely than normal skin to become colonized with pathogenic organisms. Therefore, either hand hygiene products should contain emollients or health care facilities should provide moisturizing hand lotions that do not damage latex for their staff so that their skin does not become dry, cracked, and irritated.

Presurgical Skin Disinfection

The aim of skin disinfection is to remove and kill the skin biota at the site of a planned surgical incision rapidly. However, currently available antiseptics do not eliminate all microorganisms at the incision site. In fact, coagulase-negative staphylococci can be frequently isolated even after three applications of agents such as iodine-alcohol to the
skin (96). The FDA defines a skin disinfectant as a “fast-acting, broad-spectrum, and persistent antiseptic-containing preparation that significantly reduces the number of microorganisms on intact skin” (97). Spore-free alcohols are well suited for this purpose, but they lack persistent activity. Iodine is frequently added for this purpose (98). PVP iodine continuously releases free iodine, which results in a limited prolonged antimicrobial effect. Chlorhexidine, with its profound prolonged effect after application, seems to be favorable compared to PVP iodine; however, PVP excelled against chlorhexidine according to a clinical trial (99). The WHO guideline on “safe surgery” recommends PVP iodine or chlorhexidine as a reasonable choice for preoperative skin preparation (http://www.who.int/patientsafety/safesurgery/en). A recent randomized controlled clinical trial indicates a preference for chlorhexidine-alcohol over iodophors (100), but the addition of alcohol may be the reason for the favorable effect rather than chlorhexidine, as shown in a similar trial favoring iodophor in alcohol (99). A recent study also showed that microorganisms causing surgical site infection (SSI) did not all correlate with remaining bacteria after standardized three-step disinfection with povidone iodine-alcohol (101).

A Cochrane review found some evidence that preoperative skin preparation with 0.5% chlorhexidine in alcohol was associated with lower rates of SSIs following clean surgery than alcohol-based povidone iodine paint. However, the authors stated that further studies are needed that evaluate the iodine-containing and chlorhexidine-containing solutions relevant to current practice as well as the type of solution used (alcohol versus aqueous) (102).

Before a patient’s skin is prepared for a surgical procedure, the skin should be free of gross contamination (i.e., dirt, soil, or any other debris) (103). Although preoperative showering has not been shown to reduce the incidence of surgical site infections (104), this practice may decrease bacterial counts and ensure that the skin is clean (105). The antiseptics used to prepare the skin should be applied using sterile supplies and gloves or by a no-touch technique, moving from the incision area to the periphery (103). The person preparing the skin should use pressure because friction increases the antibacterial effect of the antiseptic. For example, alcohol applied without friction reduces bacterial counts by 1.0 to 1.2 log CFU compared with 1.9 to 3.0 log CFU when friction is used. In comparison, alcoholic sprays have little antimicrobial effect and produce potentially explosive vapors (106).

Decolonization
The term “decolonization” when used in the context of MRSA carriers refers to measures primarily aimed at reducing the number of MRSA colonies present on the skin and mucous membranes or even at eradicating (i.e., eliminating) the microorganism completely. In contrast to medical treatment, decolonization of MRSA can also be indicated in the absence of infection. In most situations, complete MRSA eradication will be attempted; however, in many circumstances, the decreased risk of infection or decreased rates of transmission may be considered a desirable outcome.

Antiseptics have long been used on MRSA-colonized intact skin for decolonization. However, until now, no randomized controlled clinical studies on the efficacy of skin antiseptics used as monotherapy have been published, and the efficacy of several antiseptic agents has been demonstrated in experimental laboratory studies only (107–109).

Chlorhexidine is the most extensively investigated antiseptic agent. It has been used for many years all over the world to decolonize the MRSA-colored skin. As early as 1977, Davies et al. (110) noted that chlorhexidine produced a significant decrease of the local skin flora in comparison with soap baths and other antiseptic agents (PVP iodine and hexachlorophane) (111, 112). This observation was confirmed by several other studies (112, 113). In the 1980s, chlorhexidine added to shower or bath water preoperatively with the aim of preventing SSIs was investigated with inconclusive results (105, 111, 112–115). Subsequently, chlorhexidine was repeatedly used for decolonization of MRSA patients (116–118); however, these investigations conducted in the setting of an outbreak were essentially observational in nature and did not include control groups. In two randomized placebo-controlled trials of whole-body washing with chlorhexidine in addition to nasal mupirocin, the superiority of chlorhexidine could not be demonstrated (112, 119). Although MRSA may not be completely eradicated by chlorhexidine, Sandri et al. (120) observed in a 5-year prospective study that the incidence of nosocomial MRSA infections was diminished following the administration of chlorhexidine plus nasal mupirocin ointment for all patients in an intensive care unit. Furthermore, in a multicenter study, it was demonstrated that universal decolonization of all patients in intensive care units was more effective than targeted decolonization or screening and isolation in reducing rates of MRSA clinical isolates and bloodstream infection from any pathogen (121).

Due to the limitations of chlorhexidine, other antiseptics have been used as part of decolonization bundles. Various case reports, but no controlled studies, are available for octenidine dihydrochloride. A significant reduction in numbers of bacteria on the skin was demonstrated for several body sites (122, 123), but side effects that led to discontinuation of treatment in 14% of patients were described (123). Further antiseptics that have been proposed for eradication of MRSA skin carriage include povidone iodine (PVP iodine) (124), polyhexanide, triclosan (125), hexachlorophane (126, 127), undecylenamidopropyltrimonium methosulfate 4%, a quaternary surfactant, and phe noxyethanol 2% (128). However, none of these drugs has been studied in controlled trials. Povidone iodine (PVP iodine) is not recommended for application to extensive body surface areas due to systemic absorption (129, 130). Triclosan 0.3% added to hand or bathing soap was able to stop a MRSA outbreak affecting a neonatal unit (125), but it has been shown that MRSA strains can develop resistance to triclosan (131–133). Results on efficacy of hexachlorophane are inconclusive, and they are derived from an outbreak setting alone (126).

Since antiseptic agents may be applied to extensive surfaces of the body, depending on the indication, it is advisable to select antiseptic products with low absorption to limit the risk of adverse effects.

Although MRSA carriage in the throat is not uncommon (116, 134, 135), no studies have been reported that focused on eradication of MRSA from this location. Antiseptic agents potentially suitable for oropharyngeal MRSA decolonization include octenidine, triclosan, and chlorhexidine (136–140). The main difficulty consists of achieving a sufficiently long contact time between the throat and the antiseptic agent. Mouth rinses and gargling do not ensure adequate contact times, and administration of lozenges does not lead to sufficient distribution of the antiseptic. Hence, sprays may be more suitable for oropharyngeal administration (140). However, eradication of MRSA from the throat remains a largely unresolved issue and has been treated by tonsillectomy in extreme cases (141). Difficulties
CLEANING AND DECONTAMINATION

In Europe, decontamination basically means cleaning an item to remove organic material, protein, and fat. In the United States, the term describes a cleaning step and any additional step required to eliminate any risk of infection to HCWs while they handle a device without protective attire. The CDC guideline defines cleaning as the removal of visible soil (e.g., organic and inorganic material) from objects and surfaces by using water with detergents or enzymatic products. Thorough cleaning is essential before high-level disinfection and sterilization because inorganic and organic materials that remain on the surfaces of instruments interfere with the effectiveness of these processes. Decontamination removes pathogenic microorganisms from objects so they are safe to handle, use, or discard (142). The FDA defines the cleaning process as including all steps necessary to remove, inactivate, or contain contamination, beginning immediately after an item has been used for clinical purposes, continuing with the steps to decontaminate, clean, and package a device up to the first step of the sterilization process and ending with quality control tests.

Regardless of regulations, cleaning is always the initial step of the decontamination process on both continents. In this chapter, we use the term “decontamination” to describe the removal of debris, blood, proteins, and most microorganisms. This process usually, but not necessarily, renders the device “safe to handle” by HCWs who are not wearing protective attire. Basic definitions are outlined in Table 2.

The first step in reprocessing used medical devices is for HCWs to prevent debris from drying on the item. Research on prion diseases demonstrated that removal of debris is seriously impaired if the debris is allowed to dry on a medical device (143). Therefore, the reprocessing cycle should start as soon as possible: the item should be kept wet if delays in reprocessing are anticipated (144, 145). Cleaning can be done physically or chemically; it can also be done manually, by sonication, or with washers. In the United States, cleaning is

<sup>a</sup>Examples of standards for sterilization methods: ethylene oxide, ISO 11135 (industrial facility use) and ANSI/AAMI ST 41 (health care facility use); moist heat, ISO 11134 (industrial facility use) and ANSI/AAMI ST 46 (health care facility use).
frequently performed manually with water and a detergent. In Europe, many countries rely primarily on washer-disinfectors that rinse items with cold water and then with warm water plus a detergent. The cycle is completed with hot water at ≥90°C. Items such as bedpans and urinals can be cleaned and disinfected by putting the items into a machine, pushing a button, and removing them after a 2- to 5-min procedure. All sterilization techniques other than steaming have been shown to fail in 1 to 40% of sterilization cycles if residual proteins and/or salts are not removed by a proper cleaning process (146). Even steam sterilization at 134°C for 18 min, recommended by the WHO to inactivate prions, can fail to prevent cross-transmission if the device does not undergo a cleaning process beforehand (143–145).

For floors, surfaces, and noncritical items, cleaning with a detergent is sufficient in most situations, and a disinfection process adds little if any additional effect (147). In addition, disinfectants may interfere and even lose activity with residual proteins and debris that escape the cleaning process (147). Routine disinfection of environmental surfaces in patient care areas is recommended in the United States to add a step of additional safety in cases of unrecognized body fluids, but it is restricted to intensive care units and emergency rooms in Europe (148).

DISINFECTION

Disinfection is the second critical step in reprocessing medical devices. To be effective, disinfection must be preceded by thorough cleaning and must be done properly. Staff members must check the disinfectant’s concentration regularly if it is diluted at the place of use, even if it is diluted with an electronically monitored dilution device. Failures of the valve or other critical parts of the device can result in an insufficient final concentration, which usually cannot be detected by checking either the appearance or the odor of the disinfectant. Many manufacturers provide test strips to check for the appropriate concentration. Of note, numerous outbreaks have occurred when staff members have not followed appropriate protocols (149). For example, Klebsiella oxytoca caused an outbreak after an infection control committee allowed staff members to decrease the concentration of a glutaraldehyde-based surface disinfectant because they didn’t like the odor. The outbreak stopped after staff resumed using the disinfectant at the recommended concentration (150). An outbreak of 58 cases of Mycobacterium xenopi infection occurred when instruments used for discectomy operations were rinsed with tap water after they were disinfected (151).

Definitions and Terms (Adapted from FDA and Environmental Protection Agency [EPA] Definitions)

Since the FDA regulates the most critical part of disinfection and sterilization, FDA definitions are used throughout the chapter unless stated otherwise. The most important definitions are given in Table 3.

Principles and Antimicrobial Activities of Compounds

The antimicrobial spectrum of disinfectants is tested differently than that of antimicrobial agents. Microbiology laboratories that test disinfectants must know the special methods needed to accurately assess their activity. In fact, MICs are of little help because the goal of disinfection is to kill rather than inhibit the growth of microorganisms. In contrast to sterilization, but similar to antimicrobial agents, killing curves for disinfectants are not linear and the rate of log killing decreases as the inoculum concentrations decrease (i.e., as the number of CFU per milliliter decreases). Therefore, a 3-log-unit killing is more easily achieved with disinfectants if the inoculum is large, e.g., 10⁸ CFU, than if the inoculum is 10⁴ CFU. Most disinfectants must be inactivated before they are incubated in media or plated because bacteria do not grow in the presence of very low concentrations of a disinfectant (inhibitory effect). However, if the compound is inactivated, bacterial growth can be demonstrated. Like antimicrobial agents, some disinfectants display a postexposure effect on bacterial growth. The post-exposure effect has been quantified for a variety of disinfectants. Alcohols lack a postexposure effect, but chlorhexidine, octenidine, polyhexanide, and chloramine delay regrowth after exposure for several hours (23).

Low-level disinfectants destroy lipid-enveloped viruses, such as HIV, and most vegetative bacteria (Fig. 1) (23), but many disinfectants, including alcohol, are ineffective against non-lipid-enveloped or small viruses such as poliovirus. For example, isopropyl alcohol has little activity against poliovirus but >90% ethanol is very active (152). The FDA requires that the microbicidal efficacy of liquid chemical sterilants and high-level disinfectants be assessed in three different types of tests before they can be legally marketed in the United States.

1. Potency testing incorporates the EPA test requirements for registration of germicides, such as the Association of Official Analytical Chemists’ (AOAC) sporicidal test, tuberculocidal test, and use-dilution tests for *S. aureus* ATCC 6538, *Salmonella enterica* serovar Choleraesuis ATCC 10708, and *P. aeruginosa*; EPA virucidal tests for viruses, including poliovirus type 2 and herpes simplex virus; and FDA-recommended tests, such as total killing or endpoint analysis and comparing survivor and predicted curves. (Note: in Europe, disinfectants should have been tested by the methods defined by European Norms [EN] such as EN 1040 [bactericidal activity] and EN 1275 [fungicidal activity]).

2. Simulated-use testing involves testing the disinfectant under artificially created worst-case scenarios to determine how long instruments need to be in contact with the disinfectant if cleaning failed and the instruments are still contaminated with substantial organic matter and microbes. The instruments are contaminated with an organic load and appropriate test microorganisms (the organism depends on the level of disinfection being claimed), and the conditions of the artificially contaminated devices represent worst-case postcleaning conditions prior to exposure to the germicide.

3. “In-use” testing involves cleaning medical devices used for clinical purposes according to a facility’s operating procedures.

As noted above, the FDA includes a tuberculocidal test in its testing procedures. This test does not account for the effect of cleaning before devices are disinfected. Devices are treated with 2% horse serum (proteinaceous load) and with 10^5 to 10^6 CFU of *Mycobacterium terrae* or equivalent nontuberculous mycobacteria. Under these conditions, a device would need to be immersed in a disinfectant (e.g., 2.4% alkaline glutaraldehyde) for ≥45 min at ≥25°C for complete tuberculocidal killing. However, Rutala and Weber demonstrated that proper cleaning eradicates at least 4 log units of microorganisms (153), and Hanson et al. showed that cleaning bronchoscopes before disinfection removed all detectable contaminants, with up to an 8-log-unit reduction in the viral load (154). Therefore, Rutala and Weber recommended that the FDA accept a standardized cleaning protocol followed by a 20-min immersion at 20°C with an FDA-approved disinfectant as adequate to kill mycobacteria (153). An updated list of low-level and intermediate-level disinfectants registered by EPA or high-level disinfectants and sterilants approved by the FDA is provided on their websites: http://www.fda.gov/MedicalDevices/DeviceRegulationandGuidance/ReprocessingofSingle-UseDevices/ucm133514.htm and http://www.epa.gov/oppad001/chemregindex.htm.

**Overview of Commonly Used Disinfectants for Devices**

**Glutaraldehyde**

Among aldehydes that exhibit biocidal activity, including glyoxal, ortho-phthalaldehyde (OPA), succinaldehyde, and benzaldehydes, glutaraldehyde and formaldehyde are the most extensively studied aldehydes. In-depth reviews may be found elsewhere (20, 155, 156).

In commercially available products, glutaraldehyde is the predominant aldehyde. Because it has potent and broad-spectrum microbicidal activity and is compatible with many materials (including metal, rubber, and plastic), glutaraldehyde is often regarded as the high-level disinfectant and chemical sterilant of choice in many health care facilities. Glutaraldehyde-based formulations are most commonly used for high-level disinfection of medical equipment such as endoscopes, transducers, dialysis systems, and anesthesia and respiratory therapy equipment (156). The mechanism of action is complex and is related to alkylation of sulfhydryl, hydroxyl, carboxy, and amino groups in the cell wall, cell
membrane, nucleic acids, enzymes, and other proteins of microorganisms. The biocidal activities of glutaraldehyde solutions are dependent on a variety of variables, such as pH, temperature, concentration at the time of use, the presence of inorganic ions, and the age of the solution (155). Aqueous solutions of glutaraldehyde are usually acidic and are not sporicidal in this form. Therefore, they need to be activated by adding an alkalizing agent. These activated solutions, however, rapidly lose their activity because glutaraldehyde molecules polymerize at an alkaline pH. Therefore, the shelf life of such solutions is limited to 14 days unless the manufacturer recommends otherwise. To overcome this problem, some manufacturers have developed novel formulations with longer shelf lives (e.g., activated dialdehyde solutions containing 2.4 to 3.5% glutaraldehyde with a maximum reuse life of 28 days).

The activities of disinfectants increase as the temperature rises. Among eight disinfectants tested, glutaraldehyde was found to be the chemical most strongly affected by temperature (157). Some stable acid glutaraldehydes may be used at temperatures of 35 to 55°C at concentrations below 2%. Glutaraldehyde retains its activity in the presence of organic matter. A standard 2% aqueous solution of glutaraldehyde buffered to pH 7.5 to 8.5 is bactericidal, tuberculocidal, sporidical, fungicidal, and virucidal. It rapidly kills both Gram-negative and Gram-positive vegetative bacteria. Longer exposure times are required to inactivate spores and mycobacteria. Spores of Bacillus and most Clostridium spp. are generally destroyed by 2% glutaraldehyde in 3 h, whereas spores of Clostridium difficile are eliminated more rapidly (158). In contrast, Cryptosporidium parvum oocysts remained viable and infectious after 10 h in a 2.5% glutaraldehyde solution (159). Several investigators have questioned glutaraldehyde’s ability to inactivate mycobacteria. For example, Rubbo et al. (160) demonstrated that glutaraldehyde more slowly inactivated M. tuberculosis than did alcohols, formaldehyde, iodine, and phenol. Ascenzi (155) showed in the quantitative suspension test that 2% glutaraldehyde killed only 2 to 3 log units of M. tuberculosis in 20 min at 20°C. Similarly, Collins (161) reported that glutaraldehyde could not completely inactivate a standardized suspension of M. tuberculosis within 10 min. Nontuberculous mycobacteria such as Mycobacterium avium, Mycobacterium intracellulare, and Mycobacterium gordonae are more resistant to inactivation than M. tuberculosis (162). These and other data suggest that 20 min (at 20°C) is the minimum exposure time needed to reliably inactivate tuberculous and nontuberculous mycobacteria by 2% glutaraldehyde, provided that the contaminated item has been thoroughly cleaned before disinfection (20, 163). Glutaraldehyde-resistant mycobacteria have been isolated from endoscope washer-disinfectors (164, 165; see “Endoscopes” below). The virucidal activity of glutaraldehyde extends to the nonenveloped (hydrophilic) viruses, which are generally more resistant to disinfectants than are the enveloped (lipophilic) viruses. Numerous viruses were documented to be inactivated, including HIV, HAV, HBV, poliovirus type 1, coxsackievirus type B, yellow fever virus, and rotavirus (21, 155). The disadvantages of glutaraldehyde include the fact that it coagulates blood and can fix proteins and tissue to surfaces (20, 166). In addition, glutaraldehyde has a pungent and irritating odor, and its vapor at the level of 0.2 ppm irritates the eyes, throat, and nose. HCEWs exposed to glutaraldehyde can develop allergic contact dermatitis, asthma, rhinitis, and epistaxis. Measures that may minimize employee exposure include covering immersion baths with tight-fitting lids, improved ventilation, ducted exhaust hoods or ductless fume hoods with vapor absorbents, personal protective equipment, and appropriate automated machines for endoscope disinfection (20, 167). Due to dilution, glutaraldehyde concentrations in Europe, Asia, and Latin America. Compared with glutaraldehyde, OPA has several advantages: (i) it does not require activation; (ii) it is compatible with many materials (i.e., similar to glutaraldehyde); (iii) it is more stable during storage and reuse as well as at a wide pH range of 3 to 9; (iv) it has low vapor properties; (v) its odor is barely perceptible; (vi) it is more rapidly mycobactericidal than glutaraldehyde in vitro and has good activity against glutaraldehyde-resistant strains at longer exposure times (171). However, 0.5% OPA is slowly sporidical and does not inactivate all spores within 270 min of exposure (172). In addition, OPA stains proteins, skin, clothing, and instruments. OPA vapors may irritate the respiratory tract and eyes. At present, the effects of long-term exposure and safe exposure levels are not well defined. Therefore, OPA must be handled with appropriate safety precautions (i.e., gloves, fluid-resistant gowns, and eye protection), and it must be stored in containers with tight-fitting lids. If additional studies corroborate OPA’s advantages, this compound may replace glutaraldehyde for many uses, especially endoscope disinfection. The new agent appears to be particularly useful in washer-disinfectors, where glutaraldehyde-resistant mycobacteria have emerged (165, 172).

Formaldehyde
Formaldehyde and its condensates are reviewed in depth elsewhere (173). Formaldehyde in aqueous solutions or as a gas has been used as a disinfectant and sterilant for many decades. Its use in the health care setting, however, has sharply decreased for several reasons. The irritating vapors and pungent odor produced by formaldehyde are apparent at very low levels (<1 ppm). Moreover, allergy to formaldehyde is fairly common. In addition, the Occupational Safety and Health Administration limits the 8-h time-weighted average exposure in the workplace to a concentration of 0.75 ppm. Elevated levels of occupational exposures have been found among workers in dialysis units and gross anatomy laboratories (174). Consequently, formaldehyde and formaldehyde-releasing agents are used infrequently in health care institutions, despite this agent’s broad-spectrum microbici-
Chlorine and Chlorine-Releasing Compounds

Due to its hazardous nature, chlorine gas is rarely used as a disinfectant. Among the large number of chlorine compounds commercially available, hypochlorites are the most widely used disinfectants. Hypochlorite has been used for more than a century and remains an important disinfectant. Rutala and Weber published an extensive review of uses for inorganic hypochlorite in health care facilities (175), and Karol reviewed the potential hazards and significant benefits of chlorine use (176). Aqueous solutions of sodium hypochlorite are usually called household bleach. Bleach commonly contains 5.25% sodium hypochlorite or 52,500 ppm available chlorine; a 1:10 dilution of bleach provides about 300 to 600 mg of free chlorine per liter. Alternative chlorine-releasing compounds frequently used in health care facilities include chloramine-T, sodium dichlorosocyanurate tablets, and chlorine dioxide. Demand-release chlorine dioxide is an extremely reactive compound and must be prepared at the point of use. It is used primarily to chlorinate potable water, swimming pools, and wastewater. In Europe, commercial chlorine dioxide preparations are available to disinfect instruments. In aqueous solution, all chlorine compounds release hypochlorous acid, the most likely active compound. The mechanism of microbicidal action of hypochlorous acid has not been fully elucidated, but it inhibits key enzymatic reactions within cells and denaturates proteins. Lowering the pH or raising the temperature or concentration increases its antimicrobial efficacy. Chlorine compounds have broad antimicrobial spectra including, at higher concentrations, bacterial spores and M. tuberculosis. Therefore, hypochlorite can be used as a high-level disinfectant for semicritical items. Concentrations of 100 ppm of available chlorine inactivate vegetative bacteria and viruses in 10 min. Suspension tests document that both enveloped and nonenveloped viruses, including HIV, HAV, HBV, herpes simplex virus types 1 and 2, poliovirus, coxsackievirus, and rotavirus are inactivated (175). In one study, a concentration of 100 ppm chlorine eliminated 99.9% of Bacillus subtilis endospores in 5 min (177). However, endospore-forming bacteria, mycobacteria, fungi, and protozoa usually are less susceptible to chlorine than other microorganisms, and high concentrations of chlorine (1,000 ppm) are required to completely destroy them. Despite this limitation, sodium hypochlorite solutions (500 ppm and 1,600 ppm) have been reported to decrease C. difficile environmental contamination and terminate outbreaks of infections caused by this organism (178). Cryptosporidium oocysts are particularly resistant to chlorine. These oocysts remain infective for several days in swimming pool water containing recommended chlorine concentrations, and because of their small size, they may not be removed efficiently by conventional pool filters. Outbreaks of Cryptosporidium infections have been associated with drinking water and swimming pools (179). Of note, chloramine-T and sodium dichlorosocyanurate seem to have less sporicidal action than does sodium hypochlorite. Hypochlorite is fast acting, nonstaining, nonflammable, and inexpensive. However, its use is limited because it is corrosive, inactivated by organic matter, and relatively unstable. Sodium hypochlorite can injure tissue; however, this occurs rarely in health care facilities (175). Inhalation of chlorine gas may irritate the respiratory tract, resulting in cough, dyspnea, and pulmonary edema or chemical pneumonitis. The potential carcinogens trihalomethanes have been detected in chlorine-treated water, and high levels of trihalomethanes can be detected when hospitals hyperchlorinate their water systems (180).

Chlorine compounds have other important disadvantages. Blood or other organic matter substantially inactivates hypochlorites and other chlorine compounds. Consequently, items used for patient care and environmental surfaces must be cleaned before hypochlorite is used. In addition, biofilm (e.g., in the pipes of a water distribution system) also reduces the efficacy of chlorines significantly. Moreover, the free available chlorine levels in solutions can decay to 40 to 50% of the original concentration after the container has been opened for 1 month. Therefore, concentrations higher than those established in laboratory experiments should be used in practice. Loss of free chlorine can be minimized if the solutions are kept and used at room temperature, in dilution, in an alkaline pH range, and stored in closed opaque containers.

Depending on the concentrations employed, sodium hypochlorite is used in hospitals as a high-level disinfectant for selected semicritical devices (e.g., dental equipment and mannequins used for cardiopulmonary resuscitation training), as an intermediate-level disinfectant (e.g., hemodialysis equipment), and as a low-level disinfectant for environmental surfaces and hydrotherapy tanks. For example, the CDC recommends that HCsWs use a 1:100 dilution (5,000 ppm) of hypochlorite to decontaminate spills of blood and certain other body fluids (181). Because chlorine can be inactivated by blood and other organic material, a full-strength solution or a 1:10 dilution will be safer unless the surface is cleaned before it is disinfected (182–184). Household bleach also can be used to disinfect tabletops, incubators, and spills in laboratories or to disinfect syringes used by drug addicts if sterile disposable syringes are not available (185). At low concentrations, chlorines (usually about 0.5 ppm free chlorine) are used to chlorinate the drinking water. Hyperchlorination of institutional water systems has controlled epidemics caused by Legionella pneumophila (180) but also corrodes the water distribution system (180). Stabilized solutions of chlorine dioxide appear to be less toxic and more efficacious than chlorine for controlling growth of legionellae (186). A growing number of municipal water treatment plants in the United States are using monochloramine as a residual disinfectant. Chloramination of drinking water has several advantages compared to the use of free chlorine, including decreasing the risk of Legionnaires’ disease at the municipal level or in individual hospitals (187). However, outbreaks of Cryptosporidium infections have occurred in cities that use chloramines in their drinking water.

Hydrogen Peroxide

Hydrogen peroxide, a strong oxidizer, is used for high-level disinfection and sterilization. It produces destructive hydroxyl free radicals that attack membrane lipids, DNA, and other essential cell components. Although the catalase produced by anaerobic and some aerobic bacteria may protect cells from hydrogen peroxide, this defense is overwhelmed by the concentrations used for disinfection (188). Generally, a 3% hydrogen peroxide solution is rapidly bactericidal, but it kills organisms with high cellular catalase activity (e.g., S. aureus and S. marcescens) less rapidly. Surprisingly, 3% hydrogen peroxide was ineffective against vancomycin-resistant enterococci (19, 189). Spores are more resistant than vegetative bacteria to hydrogen peroxide. For example, a
3% solution of hydrogen peroxide destroyed 10⁶ spores in six of seven exposure trials that were 150 min long; a 10% solution was always successful in 60 min (190). Higher concentrations of hydrogen peroxide (17.7 and 35.4%) killed Bacillus subtilis spores in 9.4 and 2.3 min, respectively (191). It has been found that 10% hydrogen peroxide was the most active of the seven chemical disinfectants tested against B. subtilis spores (192). However, other investigators found that the sporicidal activity of hydrogen peroxide was lower than those of peracetic acid and chlorine (193). Hydrogen peroxide’s sporicidal activity can be enhanced by increasing the concentration or temperature or by using it in conjunction with ultrasonic energy, UV radiation, and some chemical agents such as peracetic acid (25, 152, 194). A 0.3% solution of hydrogen peroxide is able to inactivate HIV in 10 min (25), and a 3% concentration inactivates rhinovirus in 6 to 8 min at 37°C (194). However, a 6% solution was ineffective against poliovirus at 1 min (152). Hydrogen peroxide does not coagulate blood and does not fix tissues to surfaces. In fact, it may enhance removal of organic material from equipment. Hydrogen peroxide has a sweet odor, which depends on oxidation, and, therefore, it is environmentally safe. It is neither carcinogenic nor mutagenic. Concentrated solutions may irritate the eyes, skin, and mucous membranes. Hydrogen peroxide can be destroyed easily by heat or enzymes (catalase and peroxidases). Stabilized solutions can be used for high-level disinfection of semicritical items, considering the corrosive effects of hydrogen peroxide on copper, zinc, and brass (20). The FDA has approved commercial products containing either 7.5% hydrogen peroxide alone or combinations with peracetic acid as liquid sterilants and high-level disinfectants for processing reusable medical and dental devices (www.fda.gov) (195). Concentrations of 3 to 6% are used to disinfect ventilators, soft contact lenses (3% for 2 to 4 h) (196), and tonometer bipsims (20, 188, 197). Vaporized hydrogen peroxide is also used for plasma sterilization (see below). Despite its limited toxicity, hydrogen peroxide can damage human tissues. Patients exposed to endoscopes contaminated by residual hydrogen peroxide have developed pseudomembrane-like enterocolitis (pseudolipomatosis) (195). In addition, patients who were exposed to tonometer tips disinfected with hydrogen peroxide and rinsed improperly suffered corneal damage (197). Use of hydrogen peroxide to clean wounds and in dental regimens remains controversial (188).

Peracetic Acid

Peracetic acid (or peroxyacetic acid) is a more potent germicidal agent than hydrogen peroxide and was the most active agent in several in vitro studies (198, 199). Concentrations of ≤1% are sporicidal even at low temperatures. The mechanism of action of peracetic acid has not been fully elucidated, but its mechanism of action is likely to be similar to that of hydrogen peroxide and other oxidizing agents. Peracetic acid remains effective in the presence of organic matter. At low concentrations, it is considerably less stable than hydrogen peroxide; preparations with appropriate stability have been developed and are commercially available. Peracetic acid corrodes steel, galvanized iron, copper, brass, and bronze, and it attacks natural and synthetic rubbers. In addition, concentrated solutions can seriously damage eyes and skin. Furthermore, some investigators have raised concerns about the potential toxicity of the combination of peracetic and acetic acids (200). Feldman et al. reported that mortality rates in freestanding dialysis facilities that reproccessed dialyzers with peracetic and acetic acid were higher than in facilities that discarded dialysis filters or used formaldehyde for reproducing (201). To date, investigators have not determined whether the higher death rate was caused by the disinfectants or associated with other practices at the facilities or with patient risk factors. Nevertheless, because peracetic acid has powerful germicidal activity and does not produce toxic residues, peracetic acid is very attractive for use in health care settings, most frequently in combination with hydrogen peroxide to disinfect hemodialyzers. The FDA lists several commercial products containing a combination of peracetic acid and hydrogen peroxide as high-level disinfectants and chemical sterilants. The use of peracetic acid for chemical sterilization of instruments and endoscopes (Steris System 1) is discussed below.

Alcohols

Alcohols are also excellent products for intermediate-level and low-level disinfection of small, clean surfaces, equipment, and the environment (e.g., rubber stoppers of medication vials, stethoscopes, and medication preparation areas). However, alcohols may damage rubber, certain plastic items, and the shellac mountings of lensed instruments after prolonged and repeated use (200). Moreover, alcohols are flammable (one should consider the flash point) and thus must not be used on large surfaces, particularly in closed, poorly ventilated areas. Alcohols cannot penetrate protein-rich materials. Therefore, a spray or a wipe with alcohol may not disinfect a surface contaminated with blood or other body fluids that has not been cleaned first. For mechanisms of action and antimicrobial activity see discussion under “Antisepsics.”

Phenolics

Since Lister’s pioneering use of phenol (carbolic acid) as an antiseptic, a large number of phenol derivatives (or phenolics) have been developed and marketed. Phenol derivatives originate when one of the hydrogen atoms on an aromatic ring is replaced by a functional group (e.g., alkyl, benzyl, phenyl, amyl, or chloro). The three phenolics most commonly used as constituents of disinfectants are o-phenylenol, o-benzyl-p-chlorophenol, and p-tert-amylphenol. The addition of detergents to the basic formulation results in products that clean, dissolve proteins, and disinfect in one step. Phenolics at higher concentrations act as gross protoplasmic poisons, penetrating and disrupting the bacterial cell wall and precipitating the cell proteins (202). Lower concentrations of these compounds inactivate cellular enzyme systems and cause essential metabolites to leak from the cell. Phenol compounds at concentrations of 2 to 5% are generally considered bactericidal, tuberculocidal, fungicidal, and virucidal against lipophilic viruses (202). However, the manufacturers’ efficacy claims have generally not been verified by independent laboratories or the EPA (20). A collaborative study by Rutala and Cole documented the fact that randomly selected EPA-registered phenolic detergents and quaternary ammonium compounds do not consistently meet the manufacturers’ bactericidal label claims (203). Phenolics tested by the AOAC use-dilution method at the recommended use dilution failed to kill P. aeruginosa in 33 to 78% of laboratories. However, extreme variability of test results has been observed among laboratories testing identical products (203). Phenolics at in-use dilutions are not lethal to bacterial spores. Terleckyj and Axler found that a 2% phenolic killed a wide spectrum of clinically important fungi but did not kill Aspergillus fumigatus (204). Although 5% phenol inactivated both lipophilic and hydrophilic viruses, Klein and DeForest found that 12% o-phenylenol...
was effective only against lipophilic viruses (21). Similarly, other investigators demonstrated little or no virucidal effect of a phenolic against coxsackievirus type B4, echovirus type 11, or poliovirus type 1 (205). Martin et al. showed that a 0.5% commercial phenolic formulation (2.8% α-phenylphenol and 2.7% α-benzyl-p-chlorophenol) inactivated HIV (25), but another commercial product containing phenolics at a final concentration of 1% did not completely inactivate cell-associated HIV suspended in blood (206). A phenol-based preparation (14.7% phenol diluted 1:256 in tap water) and a bleach dilution (800 ppm of available chlorine) reduced rotavirus numbers similarly and interrupted transfer of virus from disks to fingerpads (207). Phenolic compounds are relatively tolerant of anionic and organic matter. They are absorbed by rubber and plastics and leave a residual film, which may irritate skin and tissues. p-tert-Butylphenol and p-tert-amylphenol have been reported to depigment skin. Although differences between the various compounds exist, phenolics are degraded in wastewater at a lower rate than other germicides, which limits their use in Europe. Phenolic germicidal detergent solutions may be used for intermediate-level and low-level disinfection of surgical instruments and noncritical patient care items. These compounds are also appropriate for decontaminating the hospital environment, including laboratory surfaces. They should not be used to disinfect bassinets and incubators because they can cause hyperbilirubinemia in infants (20).

Quaternary Ammonium Compounds

A wide variety of quaternary ammonium compounds (quats) with antimicrobial activity have been introduced in the past decade. Some of the compounds used in health care settings are benzalkonium chloride, alkyldimethylbenzyl ammonium chloride, and didecyldimethyl ammonium chloride. Quats are cationic surface-active detergents, which appear to kill microorganisms by disrupting cell membranes, inactivating enzymes, and denaturing cell proteins (208). However, they have a limited antimicrobial spectrum. Products sold as hospital disinfectants are not sporidical and are generally not tuberculocidal or virucidal against hydrophilic viruses. Scientific investigations using the AOAC use-dilution method have not reproduced the bactericidal and tuberculocidal claims made by the manufacturers (209). Consequently, HCWs should be suspicious of the claims on labels and of results from in-house evaluations that have not been verified by an independent laboratory. The overestimation of the germicidal activity may be related to incomplete inactivation of the compounds tested. In this case, the bacteriostatic (inhibitory) activity rather than the bactericidal activity is measured (208). The antimicrobial spectrum of quats may be improved by combining them with amines and biguanides or by using them at higher temperatures in washing machines.

Several outbreaks of infections have been associated with quat solutions contaminated in use by Gram-negative bacteria such as Pseudomonas spp. or S. marcescens or by Mycobacterium abscessus (210–212). The contaminated solutions were used as antiseptics on skin and tissue and to disinfect patient care supplies or equipment (i.e., cardiac catheters and cystoscopes). In fact, microbiology laboratories use the quat cetrimide in selective media to isolate P. aeruginosa.

In addition, it has been demonstrated that vaginal ultrasound probes can be contaminated with human and human papilloma virus DNA, despite disinfection with quats and use of a probe cover (213).

Quats have other disadvantages. Genes conferring resistance to quats have been detected in 6 to 42% of S. aureus isolates collected in Japan and Europe (40). Organic matter, anionic detergents (soaps), and materials such as cotton and gauze pads can reduce the microbicidal activities of quats. Despite these limitations, quats are nonstaining, odorless, noncorrosive, and relatively nontoxic. They are excellent cleaning agents, but sticky residue may build up on surfaces. On the basis of their limited antimicrobial spectra, they should be used in hospitals only for environmental sanitation of noncritical surfaces such as floors, furniture, and walls (20).

Other Germicides of Interest

Glucoprotamine, the conversion product of l-glutamic acid and cocopropylene-1,3-diamine, possesses a broad antimicrobial spectrum that includes vegetative bacteria, mycobacteria, fungi, and enveloped viruses (214, 215). A clinical study examining used specula from a gynecologic clinic demonstrated that the product killed >6 log units of vegetative bacteria, excluding spores (216). The manufacturer's data sheets indicate good compatibility of the compound with humans, the environment, and various materials. A commercial product, available in Europe, can be used to disinfect instruments and endoscopes.

Peroxygen compounds have proven efficacy against bacteria, bacterial spores, fungi, and a broad spectrum of viruses. A 1% concentration of a new commercial formulation containing peroxygen achieved a 10⁵-fold killing of B. subtilis in 2 to 3 h in the absence of blood, but killing was poor in the presence of blood (217). Moreover, several investigators have found that peroxygen has poor mycobactericidal activity (164, 218). Besides other applications, these compounds may be suitable for disinfecting laboratory equipment and workbenches. Superoxidized water is prepared at the point of use by the electrolysis of NaCl solution, which generates hypochlorous acid and a mixture of radicals with strong oxidizing properties (219). Freshly generated solutions rapidly destroy bacteria, including spores and mycobacteria, fungi, and viruses in the absence of organic loading (220). A commercial adaptation of this process (i.e., Sterilox) has been marketed in Europe since 1999 and recently was approved by the FDA (see “Endoscopes” below) (219). Because Sterilox solutions are unstable, they should be used only once for high-level disinfection. Some investigators have claimed that superoxidized water is compatible with instruments and that it does not damage the environment, irritate the respiratory tract and skin, or corrode metal. However, others have reported that superoxidized water damages flexible endoscopes. Further studies are needed to explore the use of this new disinfectant in clinical settings.

Metals such as copper and silver ions inactivate a wide variety of microorganisms (221). Although further work is required to explore their use in health care, they currently are used to disinfect water and to prevent infections associated with medical devices (e.g., intravascular catheters impregnated with silver sulfadiazine). For example, copper-silver ionization systems are successfully used to minimize legionella colonization in water systems (222). Surfacine is a new silver-based surface germicide that may be applied to inanimate or animate surfaces. Surfacine immediately eliminates microorganisms from surfaces and also has long-term residual activity (223, 224).

Emergence of Resistance to Biocides

Microorganisms rarely become resistant to disinfectants. However, frequent use of sublethal concentrations of
disinfectants can select for resistant strains (225–227). Mechanisms of resistance include acquisition of resistance plasmids, changes in the cell membrane (e.g., chlorhexidine in *Pseudomonas stutzeri*), capsule formation (*Klebsiella spp.*), and activation of the norA efflux pump (*S. aureus*). A large proportion of household soaps now contain antibacterial agents (up to 45% in one study), which may increase the probability that resistant bacteria will emerge (228). Multiple outbreaks have been associated with soaps containing antibacterial agents such as chlorhexidine, heptetidination, solution, or chloroxylben (225–227). However, the concentrations of biocides used in the health care setting are much higher than the minimum biocidal concentrations in *vivo*. Therefore, resistance has not become a major problem in the clinical setting to date. However, a recent study demonstrated high-level resistance to gluteraldehyde (229).

Readers desiring more information about disinfectants and antiseptics (6, 230) and resistance to these agents should read several excellent articles (6, 230–232).

**Inactivation of Emerging Pathogens and Antibiotic-Resistant Bacteria**

New and emerging pathogens such as the causative agent of *CJD*, noroviruses, SARS and Middle East respiratory syndrome coronaviruses, avian and swine influenza viruses, hypervirulent *C. difficile*, *Panton-Valentine leukocidin-producing S. aureus*, *Enterobacteriaceae* producing extended-spectrum beta-lactamases and/or carbapenemases, and drug-resistant nonfermenting Gram-negative bacilli threaten the public health. Only limited data exist regarding the susceptibility of emerging pathogens to commonly used disinfectants or sterilants. Surrogate microbes have been studied for some pathogens. Examples include feline calcivirus for noroviruses, vaccinia virus for variola virus, and *Bacillus atrophaeus* (formerly *B. subtilis*) for *Bacillus anthracis* (233). Other infectious agents that cannot be evaluated by standard testing procedures (e.g., hepatitis C virus [HCV]) have been tested by alternative methods, such as PCR. With the exception of prions, there is no evidence that emerging pathogens are less susceptible to approved standard disinfection and sterilization procedures than are comparable classical pathogens. Standard disinfection and sterilization procedures for patient care equipment as recommended in guidelines and in this chapter are adequate to disinfect or sterilize instruments or devices contaminated with blood and other body fluids (234). Hospital disinfectants registered by the EPA, other than one peroxycyan compound, do not have specific claims for activity against noroviruses. Because noroviruses are nonenveloped, most quats do not have significant activity against them. Phenolic-based preparations have been found to be active *in vitro* against a surrogate virus of this group. However, concentrations two- to fourfold higher than those recommended for routine use by manufacturers may be required. In the event of a norovirus outbreak, the CDC recommends using a hypochlorite solution (minimum chlorine concentration of 1,000 ppm) to decontaminate hard, nonporous, environmental surfaces (http://www.cdc.gov/norovirus/index.html). SARS coronavirus and avian influenza virus are inactivated by sodium hypochlorite and a commercially available peroxycyan compound (235); phenolic compounds and quats are less effective. A sporicidal germicide is required to efficiently eliminate *C. difficile* spores. In a recent study, glutaraldehyde (2%), peracetyl ions (1.6%, equivalent to 0.26% peracetic acid), and acidified nitrite demonstrated biocidal activity against *C. difficile* spores (236). Hypochlorite-based disinfectants have been used to disinfect environmental surfaces in areas with ongoing transmission of *C. difficile*. Daily disinfection with bleach wipes with 0.55% active chlorine reduced hospital-acquired *C. difficile* infections on units with high endemic incidence by 85% (237). Recent outbreaks with virulent strains may require more focus on environmental cleaning and disinfection (238, 239). There is some evidence that sporulation of *C. difficile* can be enhanced by contact with non-chlorine-based cleaning agents in subinhibitory concentrations (240). There are no data demonstrating that disinfectants used at recommended contact conditions and concentrations are less effective against antimicrobial-resistant bacteria than against antimicrobial-susceptible bacteria (234). Inactivation of prions, including those causing *CJD*, is discussed below.

**Mode of Application of Chemical Disinfectants**

Cleaning and Disinfecting Surfaces and Floors

In general, the environment is not a primary reservoir for nosocomial pathogens. However, in some cases, environmental contamination may be important. Recent examples include respiratory syncytial virus (241) and the SARS coronavirus (242). The CDC’s recent guidelines for environmental infection control in health care facilities recommend using an EPA-registered hospital detergent/disinfectant designed for general housekeeping purposes in patient care areas, especially in intensive care units, operating theaters, and emergency rooms, where blood, body fluids, or multidrug-resistant organisms may have contaminated surfaces (148). A one-step process is adequate in most areas, but a rinse step is necessary in nurseries and neonatal intensive care units, especially if a phenolic agent was used (243). Products with quats allow cleaning and disinfecting in one step, but residual quats on the surface may result in sticky, smerey surfaces. Other products may require a two-step approach (a cleaning step and a disinfection step), doubling the workload. “High-touch” surfaces (e.g., doorknobs, bed rails, and light switches) should be disinfected more frequently than “minimal-touch” surfaces. A simple detergent is adequate for cleaning surfaces for other patient care areas and in non-patient-care areas. Cleaning with a detergent is much more important than adding a disinfectant to the solution. In fact, several studies found that adding a disinfectant did not prolong the reduction in bacterial load on surfaces (146). Routine disinfection of environmental surfaces is necessary for all areas with patients in contact isolation (e.g., patients infected with MRSA). Twice-daily disinfection may be necessary to control an outbreak with vancomycin-intermediate *S. aureus* (239, 244).

In rare situations, routine disinfection of surfaces and floors is crucial: when cases of norovirus or clusters with *C. difficile* or MRSA are detected, an immediate switch from cleaning floors and surfaces to using a highly active disinfectant is warranted. Several studies demonstrate a correlation between contaminated surfaces and clinical cases (245–247). When patients with suspected norovirus infection vomit, immediate disinfection of the vomitus with highly concentrated bleach or an oxygen-release compound is crucial. Norovirus is highly contagious; in fact, 100 virions are sufficient to induce infection, whereas >10^9 virions are shed by infected patients.

The conventional disinfection methods may be limited by reliance on the operator to ensure appropriate selection, formulation, distribution, and contact time of the agent. “No-touch” automated room disinfection (NTD) systems have been introduced with the goal to reduce these problems. Available NTD systems include hydrogen peroxide (H_2O_2) vapor systems, aerosolized hydrogen peroxide, and
ultraviolet radiation. The more frequently described H₂O₂ vapor systems and the aerosolized hydrogen peroxide require isolation of air vents and doors of the room to be decontaminated. Peroxide will be either aerosolized or vaporized. There is some evidence that the use of H₂O₂ vapor systems reduces transmission of pathogens that are associated with the environment in the endemic as well as epidemic setting (248–252). However, the cost-effectiveness of NTD systems will be affected by the degree to which they reduce transmission and requires further evaluation. There are few studies disclosing the cost, but further information can be found in a review by Otter et al. (253).

**Disinfection of Medical Devices**

### Classification of Devices for Reprocessing

The principal goal of disinfection and sterilization of medical devices is to reduce the numbers of microorganisms on a device to a level that will prevent transmission of infectious organisms, with a considerable safety margin. The most conservative approach would be to reprocess all items and devices with overkill sterilization. Obviously, not all items must undergo the most vigorous process to eliminate any microorganisms. For example, items such as blood pressure cuffs that are used at nonsterile body sites do not need to be sterilized between patients. In contrast, only sterilization will eliminate any risk of infection for devices used in a normally sterile body site. In some cases, the best choice may be to use disposable items instead of reusable devices because reprocessing may be more expensive or does not provide the desired level of safety. The latter may apply to items in contact with neural tissue of a patient suffering from any form of CJD or with tonsils and other lymphatic tissues of persons with spongiform encephalopathy (bovine spongiform encephalopathy [BSE] or vCJD) (254–256). Therefore, devices must be classified to allow staff to define the appropriate method for disinfection and/or sterilization for each item. A classification system should balance the potential risks for transmission of infection (e.g., the infectious dose) and the resources available to achieve the necessary or desired level of antimicrobial killing. The most commonly used classification was proposed by Earle H. Spaulding in 1968 (257). He proposed three categories that are based on the devices’ potential for transmitting infectious agents: critical, semicritical, and noncritical (Table 4). The CDC cites this classification in its “Guidelines for Environmental Infection Control in Health-Care Facilities” (http://www.cdc.gov/hicpac/pdf/guidelines/eic_in_hcf_03.pdf), as does the FDA for approval of sterilants and high-level disinfectants (see http://www.fda.gov/MedicalDevices/DeviceRegulationandGuidance/ReprocessingofSingle-UseDevices/ucm133514.htm). Most infection control professionals worldwide use this classification as well. However, this simple classification does not work perfectly for all devices. Even the definition of sterilization as the absence of any viable microorganisms must be revised to address the prions responsible for CJD and vCJD (258).

### Critical items.

Items that enter normally sterile parts of the human body, such as surgical instruments, implants, or invasive monitoring devices (Table 4), are classified as “critical items.” Because items classified as critical carry the highest risk for the patient, sterilization is the preferred method for reprocessing these items. Autoclaving is the method of choice if the device is not heat labile. Alternative sterilization processes that use ethylene oxide or plasma require prolonged times, and the FDA has not approved them for use with instruments that have small dead-end lumens, which are difficult to sterilize. Liquid sterilization with a glutaraldehyde-based formulation or peracetic acid is acceptable if sterilization by one of the methods mentioned above is not feasible and the formulation and/or automated device has been cleared by the FDA.

### Semicritical items.

Semicritical objects come into contact with mucous membranes or nonintact skin and should be free of microorganisms except spores. Intact mucous membranes generally resist bacterial spores but are susceptible to other microorganisms such as vegetative bacteria (e.g., *M. tuberculosis*) or viruses (e.g., HIV and cytomegalovirus). Examples of semicritical equipment include anesthesia equipment, respiratory equipment, and endoscopes. These items should be processed with a high-level disinfectant such as glutaraldehyde, stabilized hydrogen peroxide, peracetic acid, or a chlorine compound. Chlorine compounds corrode items and, therefore, are rarely used to disinfect medical devices.

Noncritical items. Noncritical items (bedside tables, crutches, stethoscopes, furniture, and floors) come into contact with intact skin only. Intact skin is a very effective barrier against microorganisms, and therefore, these items and devices do not need to be sterilized. Such items pose a low risk for direct transmission of pathogens and can usually be cleaned at the bedside or at their point of use with a low-level disinfectant. For example, HCWs can disinfect their stethoscopes by wiping the surfaces with alcohol. However, noncritical devices can contribute to the transmission of pathogens by the indirect route. For instance, to 60% of cultures of the environment near patients colonized or infected with vancomycin-resistant enterococci are positive for this organism (259). HCWs can contaminate their hands when they touch these surfaces. If they do not practice hand hygiene, they can spread these pathogens to devices or directly to other patients. Therefore, noncritical items must be decontaminated if they are likely to be contaminated with pathogenic organisms. The FDA also developed a classification based on safety considerations and the regulations manufacturers must meet before marketing a device. Medical products are listed as class I to III products (Table 5). Simple products (e.g., a tongue depressor) are classified as medical product class I, which must meet very simple requirements before being marketed legally. Class II products (e.g., autoclaves) require a premarket notification [510(k)] demonstrating that the device is at least as safe and effective as a legally marketed device. Class III devices are those that support or sustain human life and are of substantial importance in preventing impairment of human health (e.g., a pacemaker).

Due to the level of risk associated with class III devices, the FDA requires companies (section 515 of the Federal Food, Drug, and Cosmetic Act) to file a premarket approval application to obtain marketing clearance. The premarket approval application must contain sufficient valid scientific evidence documenting that the device is safe and effective for its intended use (258).

Endoscopes
Reprocessing endoscopes is probably the most challenging reprocessing task in health care. Multiple reports of outbreaks associated with insufficient reprocessing techniques or defects of the endoscope have been published (Table 6). However, ample data indicate that a sufficient level of safety can be achieved even with manual disinfection of endoscopes if the guidelines are strictly followed (260). Flexible endoscopes have intricate, sophisticated small parts that are difficult to clean but must be cleaned before they can be disinfected because organic material such as blood, feces, and respiratory secretions interfere with disinfection (261). Several studies have demonstrated the importance of cleaning in experimental studies with duck HBV, HIV, and Helicobacter pylori (262, 263). A large study in several centers in the United States found that 25.3% of the cultures of specimens from the internal channels of 71 gastrointestinal reprocessed endoscopes grew ≥10^6 CFU of bacteria and that 78% of the facilities did not sterilize all biopsy forceps (264). Other studies have documented that up to 40% of the institutions do not follow published guidelines for endoscope disinfection (167, 265, 266), and reuse of disposable endoscopic accessories is common in the United States. These items frequently are not sterilized, and reprocessing protocols are not standardized. Therefore, reused disposable items might be a source of cross-transmission (261, 267). Currently, most high-level disinfectants approved by the FDA for reprocessing endoscopes contain >2% aldehyde with or without peracetic acid (http://www.fda.gov/MedicalDevices/DeviceRegulationandGuidance/ReprocessingofSingle-UseDevices/ucm133514.htm). However, aldehydes should only be used after completing the cleaning cycle because they may stain prions to the instruments. Endoscopes, which are semicritical items, must be immersed in ≥2% glutaraldehyde for ≥20 min to achieve the necessary level of disinfection. These parameters are sufficient to kill ≥3 log units of mycobacteria, the most-resistant vegetative bacteria. Glutaraldehyde-resistant mycobacteria have been identified (164). Several authors raised concerns that C. difficile may not be fully inactivated by standard reprocessing procedures. However, transmission of C. difficile by contaminated endoscopes has not been reported to date. Moreover, cryptosporidia withstand several hours of exposure to glutaraldehyde (159) but do not survive on dry surfaces (268). Therefore, drying before storing reprocessed items is part of the process and should not be cut to save time, e.g., in endoscopy units. The glutaraldehyde concentration in commercial cleaner-disinfectors can decrease by more than 50% after 2 weeks, which may promote the emergence of resistant bacteria (165). Higher concentrations of glutaraldehyde (3.2% instead of 2%) appear to be safe for endoscopes and achieve the required ≥3-log-unit killing with a higher margin of safety than achieved with the standard concentration (269). OPA and peracetic acid plus hydrogen peroxide can be

used to disinfect endoscopes. Because the latter might corrode some endoscopes, reprocessing staff should ensure that the manufacturer of the endoscope approves this disinfectant for reprocessing. Automated washer-disinfectors specifically for endoscopes were developed, in part, to reduce the work needed to reprocess endoscopes and to decrease the risk of human errors during manual reprocessing. These machines rinse the endoscopes, clean them in several steps, and run a full-cycle disinfection process. The time endoscopes are exposed to disinfectants is set by the machine and cannot be shortened, as it can be by busy staff manually reprocessing endoscopes. However, endoscope washers can become contaminated with pathogenic bacteria. For example, one study found Gram-negative bacteria and/or mycobacteria in 27% of cultures of specimens obtained before the final alcohol rinse and in 10% of cultures of specimens obtained thereafter. In the same study, 37 and 27% of the manually disinfected endoscopes remained contaminated at the same time points (270). In 1992, Olympus recalled (recall no. Z-039/040-2 by the FDA) its 835 model endoscope washers because the design allowed the internal tanks and tubing to become colonized by waterborne organisms such as *Pseudomonas* spp. In 1999, CDC reported three outbreaks related to the Steris System 1 (271). This device is supposed to sterilize the endoscopes, but they must first be cleaned manually (272). See Table 6 for a summary of outbreaks related to endoscopes,
including those related to contaminated washer-disinfectors. Newer washer-disinfectors should continuously monitor the pressure in all channels to detect debris blocking the channels, provide adapters for all types of endoscopes, use an appropriate disinfection process with an FDA-approved disinfectant, use filtered water or sterile water for rinsing, and have a built-in automatic disinfection process. These washer-disinfectors can help staff trace problems by monitoring and documenting the disinfecting process in a manner similar to that used by autoclaves. To avoid problems, knowledgeable staff should review currently marketed machines before purchasing a washer-disinfector to ensure that the one they choose is appropriate for their needs (273). To facilitate this process, the FDA recommends that the manufacturer provide a list of all brands and models of endoscopes that are compatible with the washer-disinfector and highlight limitations associated with processing of certain brands and models of endoscopes and accessories. Preferably, the manufacturer should identify endoscopes and accessories that cannot be reliably reprocessed in the device (negative list). In addition, HCWs should be trained to use the equipment and monitored subsequently to ensure that they follow the protocol exactly. Although this is not yet mandatory, it is prudent to regularly culture the rinse water of washer-disinfectors for pathogens such as *Pseudomonas* spp. and *Mycobacterium* spp. to identify problems before clinical cases occur. In Europe, validation of the whole procedure is necessary to ensure that it complies with the requirements of the European Standard EN ISO 15883 parts 1, 4, and 5 for automated endoscope reprocessing (274). However, outbreaks may occur despite negative routine culture results (159, 268).

If washer-disinfectors recycle water, residual glutaraldehyde may remain on the endoscopes. Manual reprocessing is more prone to leave residual glutaraldehyde on endoscopes than are automated washer-disinfectors (275). Thus, endoscopes that are manually disinfected should be thoroughly rinsed to remove any residual disinfectant, specifically glutaraldehyde. Patients exposed to residual glutaraldehyde can develop colitis (168, 169). Reprocessed endoscopes should be stored vertically (to facilitate drying) in a cabinet (to protect them from dust and secondary contamination). Drying cabinets with a heat fan, which keep the endoscope dry in a clean-air environment, are available. Reprocessed endoscopes that are stored for days or weeks before use probably should be reprocessed again, or alternatively, the channels should be rinsed with spore-filtered alcohol (70% g%) if this agent is compatible with the instrument. In France, reprocessing is mandatory if the reprocessed endoscope has not been used within certain time limits. However, the necessity of these precautions has not been established. Guidelines for infection prevention and control in flexible endoscopes have been updated (167) and should be consulted before choosing a method and/or disinfectant for reprocessing. A checklist adapted from the FDA recommendations may help staff re-processing endoscopes avoid errors (http://www.fda.gov/MedicalDevices/Safety/AlertsandNotices/PublicHealthNotifications/ucm062282.htm) (Table 7).

An updated list of sterilants and high-level disinfectants approved by the FDA in a 510(k) with general claims for processing reusable medical and dental devices can be found on the FDA website (http://www.fda.gov/MedicalDevices/DeviceRegulationandGuidance/ReprocessingofSingle-UseDevices/ucm133514.htm). Of note, more than 20% of all damage to endoscopes is associated with disinfecting agents. Therefore, staff members who reprocess these items must ensure that the instruments and the disinfectant are compatible (267). More detailed information is available in the

### TABLE 7 Checklist to avoid reprocessing errors of endoscopes

1. All staff must comply with the manufacturer’s instructions for cleaning endoscopes
2. Determine whether your endoscope is suitable for reprocessing in an automatic washer-disinfector, which is the preferred method
3. Compare the reprocessing instructions provided by the endoscope and washer-disinfector manufacturer and resolve any conflicting recommendations
4. Follow the instructions provided by the manufacturers of the endoscopes and the chemical germicides
5. Consider drying endoscopes with alcohol
6. Monitor adherence to the protocols for reprocessing endoscopes
7. Provide comprehensive, intensive training for all staff reprocessing endoscopes; keep records of persons attending training
8. Endoscopes sent for repairs should be labeled as “contaminated equipment for repair”
9. Implement a comprehensive quality control program

Newer CDC guideline (www.cdc.gov/hicpac/Disinfection_Sterilization/acknowledg.html).

**Dental Equipment**

Critical and semicritical dental instruments should be sterilized; if they will not be used immediately, they should be packaged before they are sterilized. All high-speed dental handpiece pieces should be sterilized routinely between patients. Handheld pieces that cannot be heat sterilized should be retrofit to attain heat tolerance; if this is not feasible, they should not be used. The adequacy of sterilization cycles should be verified by periodically (e.g., at least weekly) including a biological indicator with the load. This recommendation is rarely followed in Europe (276). In fact, 33% of British dental practices do not have a policy on general disinfection and sterilization procedures and only 3% own a vacuum autoclave (277), and 52.9% of the Irish dentists who responded to a survey did not autoclave their dental handpieces and only 44.7% disinfected impressions before sending them to the laboratory (278). Environmental contamination can be a problem in dental offices (279). For example, *Legionella* spp. can contaminate the air-water syringes and high-speed outlets. Water used on patients infected with bloodborne pathogens can contaminate surfaces and equipment. In fact, Piazza et al. found that more than 6% of samples from workbenches, air turbine handpiece pieces, holders, suction units, forceps, and dental mirrors were positive by PCR for HCV (280). Therefore, infection control issues, particularly in regard to HCV and HBV, may be more important in dentistry than has been appreciated previously. The CDC and the American Dental Association (ADA) have published guidelines for infection control in dental settings (281, 282). The ADA recommends that...
metal and porcelain equipment be immersed in glutaraldehyde or exposed to this disinfectant, that removable dentures and acrylic or porcelain be disinfected with iodophors or chlorine compounds, and that wax rims or bite plates be disinfected with a spray containing iodophors. Additional information can be found on the website of the ADA (http://catalog.ada.org/ProductCatalog/601/OSHA-Infection-Control/The-ADA-Practical-Guide-to-Effective-Infection-Control/P692).

Guidelines for Choosing a Disinfectant
Rutala and Weber have published guidelines for the selection and use of disinfectants and recommendations on the preferred method for disinfection and sterilization of patient care items (20, 283). The CDC issued guidelines for environmental infection control in health care facilities, including recommendations for cleaning and disinfection (148) and updated its recommendation in 2008 (www.cdc.gov/hicpac/Disinfection_Sterilization/acknowledg.html) (142).

When choosing a disinfectant, individuals responsible for infection control should review its effectiveness against the expected spectrum of pathogens (Tables 3 and 8) to ensure that it is adequate for the intended purpose. In addition, staff must ensure that the disinfectant is compatible with the devices it is intended to disinfect and that devices that are immersed longer than recommended will not be damaged. The latter is important because staff might forget to remove instruments, for example, during weekends or night shifts. Prolonged exposure to a disinfectant may damage the instrument. Staff should also consider the toxicity, odor, compatibility with other compounds, and residual activity of disinfectants before choosing them (Table 8). Advice from health care professionals of different institutions is very helpful to learn about their experience and to uncover problems such as interactions with detergents, unexpected coloring, odors, and, last but not least, emotions elicited. A new disinfectant used for environmental surfaces may interact with those used in the past and temporarily release unpleasant odors. Written infection control standards for environmental surfaces help to avoid incompatibilities. It is prudent to contact colleagues already using a disinfectant before introducing it in a health care facility. Once staff have identified a product that meets a facility’s needs, only strong evidence from good studies should lead to a change to a new product (e.g., the product has improved activity or works faster).

Disinfection by Heat versus Immersion in Germicides
Disinfection by heat has become much more common than in the past and has replaced disinfection with germicides.

*Data from references 6, 20, 149, 226, and 129. Abbreviations: CS, chemical sterilant; +, yes; –, no; ±, variable results. Efficacy of the disinfectants is based on an exposure time of less than 30 min at room temperature. Spores require prolonged exposure times (up to 10 h) unless used with a machine at higher temperatures.
for many applications in European health care facilities (284). The advantages of these devices are obvious: (i) the processes are automated and are monitored and documented in a manner similar to that for sterilization; (ii) microorganisms have not developed resistance to these processes; (iii) the cost per load is probably less than the cost of germicides. In addition, studies by Guerevich et al. (285) indicate that pasteurization with a germicide is more effective than pasteurization without a germicide. However, washers include a cleaning process with an average reduction of 4 log units, coupled with heat disinfection (5-log-unit killing; washer-disinfectors such as the AMSCO Reliance 430 achieve an inactivation factor of >5 log units) (2, 51), resulting in a total reduction of 8 to 9 log units. This surpasses any international requirements for high-level disinfection.

Thermal disinfection has several disadvantages. First, the cost to purchase and install the equipment is much higher than for systems using a germicide. Second, considerable power is needed to heat the water. Third, some non-spore-forming microorganisms such as enterococci resist temperatures of up to 71°C for 10 min. Thus, recommendations such as those in the United Kingdom (the Department of Health requires 65°C for 10 min, 71°C for 3 min, or 80°C for 1 min) may not be adequate for these organisms (286). Medical washer-disinfectors that are intended to clean, disinfect at a low or intermediate level, and dry surgical instruments, anesthesia equipment, hollowware, and other medical devices are exempt from the premarket notification procedures in subpart E of part 807 of the chapter subject to §880.9 (287). The ISO provided standards for these processes in ISO norm 15883, which defines the standards for washer-disinfectors by heat with and without the addition of disinfectants. This organization has not defined a temperature at which these devices must work but rather allows manufacturers to choose a temperature in a given range at which their devices should operate. In the United States, hot-water pasteurization is generally performed at 77°C for 30 min (288), but few scientific data support use of a particular temperature. ISO 15883 introduces the \( A_0 \) concept, which is based on the fact that a defined temperature will generate a predictable lethality effect against microorganisms. Corresponding exposure temperatures and time periods that achieve high-level disinfection can be calculated assuming the presence of particularly heat-resistant microorganisms in numbers in excess of those likely to be encountered on the medical devices to be processed. ISO 15883 introduces the term \( A_0 \) for moist heat disinfection (thermal disinfection). The \( A_0 \) value of a moist heat disinfection process denotes the lethality effects expressed in terms of the equivalent time in seconds at a temperature of 80°C delivered by the process to the medical device with reference to microorganisms possessing a \( z \) value of 10. Given a predefined \( A_0 \) equivalent killing of microorganisms is achieved if the following formula is followed: \( A_0 = \frac{T \log(10^{-80})}{t} \), where \( T \) is the temperature in degrees Celsius, and \( t \) is time in seconds. An \( A_0 \) value of 600, which can be achieved at 80°C over 10 min, 90°C over 1 min, or 70°C over 100 min, is the minimum requirement for noncritical medical devices (287, 288). An \( A_0 \) value of at least 3,000, which can be achieved by exposure to hot water, e.g., at 90°C (the medical device must tolerate this temperature for >5 min), must be employed for medical devices contaminated with heat-resistant viruses such as rotavirus and HBV. An \( A_0 \) value of at least 3,000 is also appropriate for high-level disinfection of all semicritical devices. The test procedure based on the \( A_0 \) concept has been highly reproducible and found to be suitable to test washer-disinfectors (289, 290).

STERILIZATION
Principles, Definitions, and Terms
As outlined in Table 2, sterilization is not a relative term but defines the complete absence of any viable microorganisms, including spores. However, this absence cannot be proven by current microbiological techniques (291). Therefore, sterilization can be defined as a closely monitored, validated process used to render a product free of all forms of viable microorganisms, including all bacterial endospores. To test the ability of sterilization systems to meet the latter definition of sterilization, manufacturers developed a worst-case scenario that allows the process (log killing) to be quantified and estimates the probability of process failure. Large safety margins were included in this test, which is based on the assumption that items are heavily contaminated with spores, soil, and proteins. It is important to note that, while these conditions are used for testing, in clinical practice, items that are heavily soiled should not be sterilized and such a scenario would represent a critical failure of the reprocessing cycle. Any device undergoing sterilization first must undergo an appropriate cleaning process. A manufacturer must demonstrate that a sterilizer is effective against a wide range of clinically important microorganisms before being approved by the FDA. In addition, proof of efficacy must be performed with organisms (usually bacterial spores) that have been shown to be the most resistant to the new technology. A validated and reliable biological indicator must be developed, and studies must establish that sterility will be consistently achieved when critical process parameters operate within a defined range. This assures the operator that as long as there is no operational error or equipment failure, sterility is achieved. Several guidelines are essential documents for staff needing to understand reprocessing and sterilization of medical devices. ISO 14937 provides general criteria for characterizing a sterilizing agent and for the development, validation, and routine control of a sterilization process for medical devices. ISO 11134 (moist heat) and ISO 11135 (ethylene oxide) documents describe the standards for use of these methods of sterilization in the industrial setting in the United States. The American National Standard Institute/Association for the Advancement of Medical Instrumentation (ANSI/AAMI) published adaptations of these standards for health care facilities: standard 46 (moist heat) and standard 41 (ethylene oxide) (Table 2). In Europe, EN 550, EN 554, and EN 285 define the standards for steam and ethylene oxide sterilization. ISO 14161 provides guidance that staff can use when selecting and using biological indicators and when interpreting the results of these tests. ISO 17664 specifies which information medical device manufacturers must provide so that the medical device can be processed safely and continue to function properly. Readers are referred to other publications for additional information about sterilization (6, 291, 292). Hot-air sterilization does not belong to the state-of-the-art technologies, but it is still used in many countries. However, the distribution of dry heat to the instruments requires long exposure times. Temperatures of >185°C resinsify paraffin, destroying the lubricating function of instruments, and higher temperatures are corrosive, resulting in loss of hardness. Therefore, hot-air sterilization has largely been replaced by better, safer, and faster technologies.
Monitoring

Any sterilization process must be monitored by mechanical, physical, chemical, and facultatively biological methods. Before routine use, the performance of the machine should be validated with the most difficult load used at the institution to ensure safety of the process. In routine use, a printout of the physical parameters (e.g., temperature and pressure) during sterilization should be kept for documentation purposes. In addition, chemical indicators placed on the tested items change color if they are exposed to adequate temperatures and exposure times. They are inexpensive and easy to use and provide a visual indication that the item has been exposed to the sterilization process. Good clinical indicators are able to identify a sterilizer failure. However, some are too sensitive, giving false-positive results (293, 294), which may cause unnecessary recalls of adequately sterilized items. Less-sensitive chemical indicators do not detect small deviations in the process. In 1963, Bowie and Dick determined that if residual air remained in a sterilizer after the vacuum phase and there was only one package in the chamber, the air would concentrate in that package (295). They developed the Bowie-Dick test to determine whether steam penetration and air removal occurred successfully. This test does not provide information about the sterilization process.

Biological indicators are the best monitors of the sterilization process. If the spores in commercially available standard biological indicators do not grow during an appropriate incubation period, the results indicate that the process was able to kill $\geq 10^6$ CFU. For flash sterilization, the Attest Rapid Readout biological indicator detects the presence of a spore-associated enzyme, α-D-glucosidase, and permits staff to assess the efficacy of sterilization within 60 min (296). Staff should investigate positive biologicals because they can provide the only indication that something is wrong with the sterilization process (297).

An important question is whether a load can be distributed before the final results of the biological indicator are available (i.e., parametric release). The Joint Commission on Accreditation of Healthcare Organizations standard allows the use of appropriate chemical indicators without routine use of a biological indicator. A common approach is to use the sterilized items if the physical and chemical parameters of adequate sterilization were met without awaiting the culture results from the biological indicators. In Europe, routine use of biological indicators is not required if the sterilizer has undergone testing by a validation procedure used for industrial steam sterilization (EN 285, EN 550, EN 554, or EN 556). Most sterilizers in European hospitals probably do not meet these very strict requirements (298), and consequently, biological indicators are used regularly to ensure that they are working properly. These industrial standards for validation of steam sterilization will be implemented in health care organizations, but this change is controversial because of the associated expenses. The future is likely to involve parametric release with regular validation and/or commissions of the equipment. Legal aspects will probably determine the outcome of this discussion, and lawyers are likely to accept nothing but a zero risk. However, the goal of a zero risk for contamination in central sterilization services will probably contribute to excessive health care costs. Therefore, standards for sterilization should exclude a risk for contamination after the reprocessing cycle but should avoid steps that are performed only for legal reasons.

Packaging, Loading, and Storage

Items that are clean and dry should be inspected and then wrapped and packaged (or put in containers) before sterilization. Wrappers should allow steam or gas to penetrate into the package but should protect the items from recontamination. For steam sterilization, muslin as the only wrapper has limitations and handling of items made of muslin leads to contamination (299). Items should be labeled with information such as expiration date, type of sterilization, and identification code for traceability.

Steam Sterilization

The most reliable method of sterilization is one that uses saturated steam under pressure. It is inexpensive, nontoxic, and very reliable.

Steam penetrates fabrics, and its inherent safety margin is much higher than that of any other sterilization technique. Therefore, it should be used whenever possible. Obviously, other techniques must be used for heat-sensitive items. Steam irreversibly coagulates and causes denaturation of microbial enzymes and proteins. Three parameters are critical to ensure that steam sterilization is effective: the amount of time the items are exposed to steam, the temperature of the process, and moisture. Unlike time and temperature, the moisture condition in the autoclave cannot be directly determined. The D-value determines the time required to kill $10^6$ CFU of the spores most resistant to the sterilization process under study. Devices or instruments must reach the desired temperature, which is not necessarily identical to the temperature displayed on the autoclave’s gauge. A drop of only 1.7°C (3°F) increases the time required to sterilize an item by 48%. Without moisture, a temperature of 160°C is required for dry-heat sterilization. Dry air does not provide steam for condensation, and the heat transfer to objects is slower than when moisture is present. Pressurized steam quickly transfers energy to the sterilizer load and causes more rapid denaturation and coagulation of microbial proteins. In addition, pressurizing the steam allows one to achieve dry 100% saturated steam. Thus, there is no mist that could cause the packaging and/or the items to become wet.

Residual air in the autoclave interferes with the sterilization process. The amount of air within the sterilizer can be estimated by comparing the chamber pressure with the saturated steam pressure calculated from the average chamber temperature. A measured pressure greater than the calculated saturated pressure indicates the presence of residual air in the chamber. Such monitoring devices are common in the United Kingdom.

Several types of autoclaves are available: gravity displacement steam sterilization, prevacuum steam sterilization, and steam flash-pressure pulsing steam sterilization autoclaves. The sterilization process is less consistent in gravity displacement steam sterilizers than in the other sterilizers (300). For example, gravity displacement autoclaves are more likely than the other systems to leave residual air in the chamber before the steam is introduced. Prevacuum sterilizers resolved part of this problem and cut the cycle time in half. However, the effectiveness of sterilization still can be compromised by small leaks (1 to 10 mm Hg/min) in the sterilizer (291). The most current technology is the steam flash-pressure pulsing steam sterilization technique. Because air leaks do not decrease the effectiveness of the process, it nearly eliminates the problem of air in the chamber and it reduces the thermal lag upon heating of the load to the desired exposure temperature (300).

The process of sterilization has several cycles: conditioning, exposure, and drying. Common cycles for steam sterilization in prevacuum or flash-pressure pulsing steam sterilizers are 121°C for 15 min (121°C for 30 min in a gravity displacement sterilizer) or 132°C for 4 min. EN 554 requires
steam sterilizers to provide this temperature throughout the entire chamber within a narrow margin (0 to +3°C).

Flash sterilization is an emergency process used, for example, after a surgical instrument is dropped but needs to be immediately available during a procedure (301). Unwrapped devices are exposed to pressurized steam for 3 min, usually in the operating suite, sometimes without a biological indicator. The autoclaves employed are gravity displacement sterilizers that have the problems mentioned above. If HCWs are in a hurry, they may not clean the item properly, which will prevent proper sterilization. In addition, because the items are not wrapped, they can be contaminated easily when they are transported to the operating room. Even properly wrapped sterile items can become contaminated if they are transported several times (299). Moreover, some patients have been injured by items that were flash sterilized (302). Therefore, flash sterilization is controversial and several investigators have suggested that it should be used only in emergency situations when no other device is available.

Flash sterilization should not replace standard sterilization protocols (303) and should not be used to save time instead of sterilizing items by the standard methods or because the health care facility does not want to purchase an extra instrument set (103). If flash sterilization of an implantable device is unavoidable, records must be kept (i.e., load identification, patient’s name/hospital identifier, and biological indicator result) to facilitate epidemiological tracking.

Ethylene Oxide Gas

Temperature- and/or pressure-sensitive items have been sterilized traditionally with ethylene oxide in a standard gas. Ethylene oxide inactivates all microorganisms, including spores, probably by an alkylation process. B. subtilis bacterial spores are among the most resistant, and therefore, these are used as a biological monitor for this process. A new rapid-readout ethylene oxide biological indicator indicates an ethylene oxide sterilization process failure by producing fluorescence, which is detected in an autoreader within 4 h of incubation at 37°C, and a color change related to a change in pH of the growth media within 96 h of continued incubation (224).

The process of sterilizing items with ethylene oxide begins by adding nitrogen gas to remove air or by evacuating the chamber. Items are then exposed to ethylene oxide at 55°C (130°F). Six variable but interdependent parameters—gas concentration, vacuum, pressure, temperature, relative humidity, and time of exposure—must be controlled when ethylene oxide is used. The gas concentration cannot be measured online, limiting the extent of monitoring. Therefore, the concentration should be validated as outlined in ISO 11135.

Ethylene oxide sterilization has several disadvantages. It is useful only as a surface sterilizer because it does not reach blocked-off surfaces. In addition, ethylene oxide is flammable, explosive, and carcinogenic to laboratory animals, and it requires special safety precautions. Moreover, items sterilized by ethylene oxide must be aerated for approximately 12 h to remove any traces of the gas. Thus, the entire process takes >16 h, but modern sterilizers can run at shorter cycles. Furthermore, toxic residues can be trapped in the wrapper or the items. Polyvinyl chloride and polyurethane absorb ethylene oxide readily and require long periods to dissipate the oxide. The wrapper should be a barrier against recontamination after sterilization, but it also can prevent ethylene oxide from reaching the item. Therefore, only materials with documented ethylene oxide penetration and dissipation properties should be used as wrappers.

The future of ethylene oxide in sterilization is limited, mainly due to its toxicity. However, no currently available technology, including plasma sterilization (see below), can replace sterilization with ethylene oxide entirely. In addition, sterilization with ethylene oxide does not fail as frequently as sterilization with plasma when residual proteins and/or salts are present on the items (146).

Plasma Sterilization

The low-temperature plasma is produced in a closed chamber with deep vacuum, an electromagnetic field, and a chemical precursor (hydrogen peroxide or a mixture of hydrogen peroxide and peracetic acid). The resulting free radicals, the chemical precursors, and the UV radiation are thought to be the products that rapidly destroy vegetative microorganisms including spores.

The Sterrad 100 sterilizer was the first plasma sterilizer for use in health care facilities and has been on the market in Europe since 1990 and in the United States since 1993. In August 1997, the Sterrad 100 system was approved to sterilize certain surgical instruments with long lumens, such as those used in urologic, laparoscopic, and arthroscopic procedures, including instruments with single stainless steel lumens of 3 and <400 mm in length. The Sterrad 100S has since replaced the Sterrad 100. The Sterrad 100S adds one sterilization cycle and thereby fulfills the requirement to kill 10⁶ spores halfway through the cycle. A smaller device, the Sterrad 50, has been independently tested for efficacy (304). Other systems, e.g., the large Sterrad 200, approved by the FDA in 2003, can sterilize small lumens (single stainless steel lumens with an inside diameter of 1 mm or larger or Teflon/polyethylene lumens with an inside diameter of 6 mm or larger). The new Sterrad NX system, approved by the FDA in April 2005, is the fastest low-temperature hydrogen peroxide gas plasma sterilizer yet. This system employs a new vaporization system that removes most of the water from the hydrogen peroxide, improving diffusion of peroxide into lumens. Consequently, a broad range of instruments, including single-channel flexible endoscopes, can be processed within 38 min. In 2001, the FDA cleared biological indicators suitable for plasma sterilization. Regardless of the model, the basic steps are the same.

Medical instruments are placed in the sterilization chamber, a strong vacuum is created in the chamber, and a solution of 59% hydrogen peroxide and water is automatically injected from a cassette into the sterilization chamber. The solution vaporizes and diffuses throughout the chamber, surrounding the items to be sterilized. Radiofrequency energy is applied to create an electric field, which in turn generates the low-temperature plasma, inducing free radicals. The combination of the diffusion pretreatment and plasma phases sterilizes the item while eliminating harmful residuals. At the end of the cycle, the radiofrequency energy is turned off, the vacuum is released, and the chamber is filled with filtered air, returning it to normal atmospheric pressure.

Plasma sterilizers have several disadvantages. First, materials that absorb too much hydrogen peroxide (e.g., cellulosics and some nylons such as those from connectors, cables, and insulators), materials that catalytically decompose hydrogen peroxide (e.g., copper and nickel alloys from electrical wire, solder, and surgical instruments), and materials that react with hydrogen peroxide (such as organic dyes [colored anodized aluminum] and organic sulfides of solid lubricant in endoscopic devices) cannot be sterilized in a Sterrad. Second, the cassettes required to run the device and the special nonmuslin wrapper are relatively expensive.
Low-Temperature Sterilization by Ozone

The 125L Ozone Sterilizer (TSO3, Quebec, Canada) uses medical-grade oxygen, water, and electricity to generate ozone within the sterilizer to provide an efficient sterilant without producing toxic oxygen chemicals or using high temperatures (it runs at 25 to 35°C). Ozone forms when oxygen is submitted to an intense electrical field that separates oxygen molecules into atomic oxygen (O), which in turn combines with other oxygen molecules (O₂) to form triatomic oxygen (O₃), or ozone, providing a sterility assurance level of 10⁻⁶ in approximately 4 h. At the end of the cycle, the oxygen and water vapor safely vent directly into the room. The sterilization chamber has a capacity of 125 liters. Processed medical instruments require no aeration at the end of the sterilization cycle. Medical devices are packaged in a TSO3 sterilization pouch or in anodized aluminum sterilization containers. The TSO3 OZO-TEST self-contained biological and chemical indicators should be used to evaluate the machine’s performance. An ozone sterilizer can be installed as a free-standing unit or recessed behind a wall. These devices are used primarily in Canada. These sterilizers are approved by the FDA, but few health care facilities in the United States use them.

Liquid Sterilization

The FDA approved the Steris System 1 in 1988, but it is not considered a sterilizer in Europe (305). The machine is designed to sterilize immersible devices, including flexible endoscopes, with 35% liquid peracetic acid (an FDA-approved sterilant that is sporicidal) (306, 307), supplemented with buffering, anticorrosion, wetting, and surface-active agents. Peracetic acid is automatically diluted with sterile filtered water, and the items are exposed for 12 min. The entire sterilization process takes approximately 30 min at ca. 50°C. Items can be used immediately after the process is completed and do not need to be aerated.

Clinical studies of the Steris System 1 have been performed with bronchoscopes, hysteroscopes, colonoscopes, and rigid endoscopes (272, 308). Independent efficacy tests demonstrated some failures (272). Exposure time and temperature are monitored electronically, and conductivity is used as a surrogate marker for peracetic acid concentration. However, the machine can complete its cycle normally and print a report stating that the concentration of peracetic acid was in the normal range when it was run intentionally without peracetic acid (309). Commercially available spores can be used for monitoring sterilization (310), but false-positive test strips can occur as a result of improper use of the clip used to attach the test strips (311). Other disadvantages of this system include the high cost of purchasing and using the equipment, which is considerably greater than the cost of purchasing and using systems for high-level disinfection with glutaraldehyde (312). In addition, the device does not clean the items. Thus, the cleaning step adds to the overall time of reprocessing the items. The Steris System 1, like all other nonsteam sterilizers, cannot meet the requirement for sterilization if residual debris and/or proteins are present on the items. The system has been considerably improved over the last decade, but the changes have not yet been approved by the FDA, which has issued a letter of concern (http://www.fda.gov/ICECI/EnforcementActions/WarningLetters/2008/ucm1048303.htm).

REUSE OF SINGLE-USE DEVICES

Current FDA policy states that the responsibility for the safety and performance of reprocessed single-use devices lies with the reprocessor, not the original manufacturer. The FDA considers the hospital to be the manufacturer of a single-use device if it has been resterilized. Therefore, the reprocessor must ensure that the reprocessed items are sterile and not contaminated with toxic substances such as endotoxins or residual ethylene oxide and that the product’s integrity, composition, and function are essentially identical to those of a new product. Most hospitals cannot afford to generate appropriate data on the quality and performance of reprocessed single-use items. In addition, if a manufacturer changes the product, the reprocessor would need to redo the analyses before the device could legally be marketed after reprocessing (management of change).

The FDA published a final guidance on this topic (see website for details: http://www.fda.gov/MedicalDevices/DeviceRegulationandGuidance/ReprocessingofSingle-UseDevices/default.htm). Some institutions resterilize items that have not been used on patients but that, for instance, were dropped and/or whose package was damaged. Even this approach can be problematic. For example, the FDA published an alert documenting that the sterilant of an implant that was originally sterilized with ethylene oxide and resterilized with steam was impaired by the reprocessing method. In addition, the quality, product integrity, and performance of many plastic or rubber products after reprocessing are unknown. Moreover, the FDA does not allow health care facilities that send equipment and supplies to a reprocessing company to transfer full responsibility to that company (see the full text at http://www.fda.gov/MedicalDevices/DeviceRegulationandGuidance/ReprocessingofSingle-UseDevices/default.htm). Furthermore, if a hospital reprocessee a single-use device, the hospital is responsible for ensuring that the device complies with all applicable FDA labeling requirements, even if the device is exempt from the premarket requirements. If the hospital does not ensure that the device complies with FDA labeling requirements, the device is misbranded, and the hospital may be considered in violation of section 301(k) of the Act. As of 14 August 2001 and of 14 February 2002, FDA enforced premarket filing requirements for reprocessed class II devices (i.e., moderate-risk devices such as a cardiac mapping catheter used to map electrical activity of the heart).

In many countries throughout the world, health care facilities reprocess single-use items (sometimes illegally) because resources are limited and this may be the only way to provide patients with access to state-of-the-art health care. We believe that new reprocessing technologies using washer-disinfectors coupled with highly effective low-temperature sterilizers can kill all microorganisms, even in narrow lumens such as cardiac catheters. In fact, a commercial reprocessor in Germany legally has reprocessed >4 million single-use items without any published serious side effects, saving between 30 and 50% of the cost for a new item. With the expertise of an infection control professional, the health care facilities may provide the desired level of microbiological and toxicological safety. However, they probably cannot ensure that the design and function of the device are still adequate. Thus, in the United States and countries with similar regulations on quality assurance programs, reuse of single-use devices may not be cost-effective. In addition, organizations that sell used single-use devices to patients and/or insurance companies as new devices will encounter legal and ethical issues. Continuous improvements of new devices also impede reprocessing of single-use devices on a large scale. However, financial restriction
may change the current beliefs; the reader should consult the FDA website and experts in the field before considering reprocessing single-use devices.

BSE AND vCJD

CJD has been identified on all continents and is thought to occur worldwide. The incidence of CJD is estimated to be about 1 case per 10⁶ persons per year. Most cases of CJD are sporadic; <10% of CJD cases may be related to a genetic autosomal dominant predisposition, and few nosocomial cases are related to use of contaminated tissue or contaminated human growth hormone. The emergence of vCJD has brought about a major medical and economic crisis in Europe (313–315). As of 2014, no curative therapy is available for CJD or vCJD; however, several approaches have been investigated with limited success (316). It is generally accepted that eating BSE agent-contaminated meat is the cause of vCJD (314, 317).

The agent causing vCJD is not a classic microorganism but an altered prion protein (258, 318–320). Its origin remains obscure, but the BSE agent from cattle is most probably responsible for vCJD in humans. vCJD has a different clinical presentation and occurs at a much younger age (321). The mean age at death from vCJD is 28 years; only 6 of 90 patients died at the age of 50 years or older (322).

Among several hypotheses that may explain why this age group is most affected is that the incubation period is shorter in the young than in the elderly or they are more susceptible to infection. In the United Kingdom, the number of people exposed to potentially infective doses through food may be extremely high. All patients genotyped so far are homozygous for methionine on codon 129 of the prion protein gene. It is postulated that heterozygous individuals may have much longer incubation times before vCJD becomes evident. Therefore, asymptomatic carriers may pose a risk for transmission if they undergo routine surgery and instruments are not reprocessed by a prion-safe program. A recent study of appendix samples by the United Kingdom Health Protection Agency estimates 1 in 2,000 silent prion infections in the United Kingdom population (323).

Patients suffering from vCJD harbor large numbers of prions in their tonsils and spleen before they have signs, symptoms, and pathological findings of the disease. In contrast, patients with sporadic CJD suffer from spongiform encephalopathy long before the prion spreads into muscles and lymphoid tissue (324). Consequently, the United Kingdom has developed very strict precautions; for example, it was required that all tonsillectomies be performed with disposable instruments. In 2002, this practice was discontinued because serious complications arose when disposable instruments were used. However, none of the samples, including 276 samples initially reactive in one enzyme immunoassay, that were investigated by immunohistochemistry or immunoblotting was positive for the presence of CJD.

The fact that the vCJD prion agent is found in lymphoid tissue and tonsils indicates that prions are not restricted to neural tissue (316). Lymphatic organs typically show early accumulation of prions, and B cells and follicular dendritic cells are required for efficient neuroinvasion. The actual entry into the central nervous system probably occurs via peripheral nerves, and the prions accumulate in neural tissue once inflammation of the lymphoid tissue is in progress (325).

Experimental evidence from animal models indicates that blood can contain prion infectivity, which suggests a potential risk for BSE transmission via proteins isolated from human plasma (326). Three cases of probable transmission by blood transfusion raise more concern about the safety of the blood supply (327).

Previously, problems with reprocessing instruments used on patients with CJD were limited to invasive instruments that came into contact with neural tissue, predominantly instruments used in neurosurgery. However, as noted above, vCJD is highly lytropic, so that any instruments used on lymphoid tissues may be contaminated with prions (325). As outlined above, appropriate reprocessing of surgical items includes cleaning, disinfection, and sterilization. Aldehydes enhance the resistance of prions and abolish the inactivating effect of autoclaving (170). Therefore, aldehydes are no longer recommended for disinfecting surgical instruments in Europe before they have undergone a thorough cleaning process. In France, aldehydes are no longer used for endoscope reprocessing, despite evidence that peracetic acid may stain prions as well (328). Small resistant subpopulations of infective prions may survive autoclaving at 132 to 138°C. These resistant subpopulations are not inactivated by simply reautoclaving, and they have biological characteristics that differentiate them from the main population (329). The worst-case scenario is that the agent for vCJD might become self-replicating when it contaminates surgical instruments. Therefore, prions challenge reprocessing techniques like never before.

The minimum requirements for decontamination procedures and precautions for materials potentially contaminated with the agent that causes CJD or, still more, vCJD, remain unknown. However, it is clear that dry heat (160°C for 24 h), formaldehyde sterilization, and standard steam sterilization do not sterilize prion-contaminated items (330). The scientific uncertainties and lack of data do not allow agencies such as national health departments, the WHO, or the CDC to formulate guidelines that are completely evidence based, and this explains why various countries have taken different approaches to addressing issues of reprocessing instruments. In January 2001, the British government spent the equivalent of $500 million to improve reprocessing techniques in Central Sterilization Services and required the use of disposable instruments for tonsillectomies. The French Public Health Office published its recommendations on 14 March 2001. They require all surgical instruments with potential exposure to lymphatic tissue, the central nervous system, or the eyes to be soaked in sodium hypochlorite for 1 h or NaOH for 1 h and sterilized at 134°C for 18 min. If instruments do not tolerate this aggressive approach, they must be cleaned twice; treated with various chemicals such as peracetic acid, iodophors, 3% sodium dodecyl sulfate, or 6 M urea; and autoclaved at 121°C for 30 min. In Germany, it is recommended to decontaminate instruments with NaOH, NaOCl, or guanidine thiocyanate or to use medical washer-disinfectors with a superalkaline cleaner (pH >10) followed by sterilization at 134°C for 5 min. Since 2002, Switzerland requires all surgical instruments to be sterilized at 134°C for 18 min. The background of the Swiss recommendation is that the usual rendering process for carcasses, which was discontinued, resulted in only a 1-log-unit reduction of the infectious particles (331). Therefore, a reduction in the number of infectious particles may suffice to stop transmission.

CDC recommends that instruments exposed to potentially prion-contaminated items be autoclaved for 1 to 1.5 h at 132 to 134°C, immersed in 1 N sodium hydroxide for 1 h at room temperature, or immersed in sodium hypochlorite 0.5% (at least 2% free chlorine) for 2 h at room temperature.
See the CDC website for further information (http://www.cdc.gov/ncidod/dvd/vcjd/index.htm).

In the United States, one patient who was a former resident of the United Kingdom has been diagnosed with vCJD, and the first case of BSE in cattle was identified in 2003. However, more cases may occur because 37 tons of “meals of meat or offal” that were “unfit for human consumption” was sent from the United Kingdom to the United States in 1997, well after the government banned imports of such risky meat (332).

High-risk patients are patients with suspected CJD and their family members, patients treated with pituitary extracts, and patients who received corneal transplants. In addition, items should be considered contaminated with prions if a brain biopsy for the diagnosis of CJD is requested. Instruments used in such procedures should be discarded or placed under quarantine until the histopathological diagnosis is known. The incidence of vCJD in the United Kingdom is decreasing rapidly, indicating that current reprocessing techniques suffice. However, knowledge about this topic is increasing rapidly over time and our current understanding may be shown to be false in the future (254). In May 2005, British officials published an excellent assessment of the risk for contaminating surgical instruments with prions (https://www.gov.uk/government/publications/guidance-from-the-acdp-tse-risk-management-subgroup-formerly-tse-working-group). The key observation in this report is that, on average, 0.2 mg of protein remains on surgical instruments despite “standard cleaning and disinfection,” which was sufficient to cause an experimental case of CJD. Therefore, more research and new methods of cleaning and disinfection are needed for surgical instruments.

In laboratories, all samples should be handled using gloves and the processing of suspected specimens should be performed while wearing protective covering, e.g., gloves and disposable gowns or aprons (333). Masks and eyewear may be appropriate if splashing or aerosols are anticipated. Contaminations or spills should be decontaminated immediately with NaOH. To minimize environmental contamination, disposable cover sheets could be used on work surfaces (12).

The reader is referred to the websites of the CDC, the FDA, and the WHO to obtain the most recent updates on this topic. In addition, the Society for Healthcare Epidemiology of America published detailed guidelines on this topic (12). More information about prions can be found in chapter 109 of this Manual.

In conclusion, monitoring the processes of antiseptics, cleaning, disinfection, and sterilization is an essential part of infection control programs. The wide variety of applied techniques, germicidal agents, and procedures not only requires a broad understanding of the material, but it also needs well-trained personal to avoid incidents that result in damage to patients or equipment.

Biothreat Agents

SUSAN E. SHARP AND MICHAEL Loeffelholz

The ideal qualities for a successful biothreat agent are a high rate of illness in exposed persons/animals, a high case fatality rate, a short incubation period, and a paucity of immunity in the targeted population. In addition, success is also influenced by the availability of treatment, the ability of the agent to transmit from person to person, the ease with which the agent can be produced and disseminated, and a disease that is difficult, at least initially, to recognize clinically or to diagnose.

General clues that one may be dealing with an unrecognized biothreat event include a large outbreak of illness with a high death rate, a recognized case(s) of an uncommon disease, illness in a geographic region where the disease is not endemic, disease out of its usual seasonality, simultaneous outbreaks of the same disease in various parts of the country/world, and the presence of sick and dying animals. The Centers for Disease Control and Prevention (CDC) have classified potential biothreat agents into categories depending on the basis of their threat to national security, with those organisms belonging to category A being the most serious threats, due to their unique features in causing diseases capable of mass destruction (Table 1). These and other agents are discussed in this chapter.

The LRN

The Laboratory Response Network (LRN) was established through the work of the Department of Health and Human Services (HHS) and the CDC, in accordance with Presidential Decision Directive 39. This directive, signed by President Bill Clinton on 22 May 1998, made the fight against terrorism a top national security priority and defined policies regarding the federal response to threats or acts of terrorism involving nuclear, biological, and/or chemical material and/or weapons of mass destruction. Specifically, this directive outlined the United States’ efforts to “deter, defeat and respond vigorously to all terrorist attacks on our territory and against our citizens, or facilities, whether they occur domestically, in international waters or airspace or on foreign territory. The United States regards all such terrorism as a potential threat to national security as well as a criminal act and will apply all appropriate means to combat it. In doing so, the U.S. shall pursue vigorously efforts to deter and preempt, apprehend and prosecute, or assist other governments to prosecute, individuals who perpetrate or plan to perpetrate such attacks” (http://www.fas.org/irp/offdocs/pdd39.htm).

Through a collaborative effort involving the Federal Bureau of Investigation and the Association of Public Health Laboratories (APHL), the LRN was established in August 1999. Its objective was to improve and ensure an effective laboratory response to bioterrorism. The LRN worked toward this goal by improving the public health infrastructure, increasing laboratory capacity and staffing, and training laboratory personnel in advanced diagnostic technologies. The LRN forms an integrated network of more than 150 local and state public health, federal, and military laboratories (representing all 50 states, Australia, Canada, the United Kingdom, Mexico, and South Korea) that can respond to bioterrorism, chemical terrorism, and other public health emergencies.

The LRN states its mission as follows: “The LRN and its partners will develop, maintain and strengthen an integrated national and international network of laboratories that can respond quickly to needs for rapid testing, timely notification and secure messaging of results associated with acts of biological or chemical terrorism and other high priority public health emergencies” (http://www.bt.cdc.gov/lrn/).

There are an estimated 25,000 private and commercial laboratories (including clinical, food testing, veterinary diagnostic, and environmental testing laboratories) in the United States, some of which serve as critical sentinel laboratories. While most of these laboratories do not perform confirmatory testing, they represent the first contact with patients and are in a position to alert public health officials of possible biothreat agents. These laboratories conduct tests to rule out other diseases and send possible biothreat samples/organisms to the appropriate LRN reference laboratories for confirmatory testing. The LRN structure is shown in Fig. 1.

LRN sentinel laboratories are certified to perform high-complexity testing under the Clinical Laboratory Improvement Amendments of 1988 (CLIA) by the Centers for Medicare and Medicaid Services (CMS) for the applicable microbiology specialty. Laboratory in-house testing includes Gram stains and at least one of the following: lower respiratory tract, wound, or blood culture. LRN reference laboratories are responsible for investigation and/or referral of specimens to LRN national laboratories. LRN reference laboratories consist of over 100 state and local public health, military, federal, and international laboratories (veterinary, agriculture, food, and water testing laboratories) in and outside the United States. LRN national laboratories, including

\textsuperscript{a}Note that the CDC divides bioterrorism agents into three categories (A, B, and C) depending on how easily they can be spread and the severity of illness or rate of death they cause. Category A agents are considered the highest risk, as they can easily be disseminated or transmitted from person to person, result in high mortality rates, have the potential for major public health impacts, might cause public panic and social disruption, and require special action for public health preparedness. Category B agents are the second-highest-priority agents and include those that are moderately easy to disseminate, result in moderate morbidity rates and low mortality rates, and require specific enhancements of the CDC’s diagnostic capacity and enhanced disease surveillance. Category C agents are the third-highest-priority agents and include emerging pathogens that could be engineered for mass dissemination in the future because of availability, ease of production and dissemination, and potential for high morbidity and mortality rates and major health impacts.

The American Society for Microbiology (ASM), along with the APHL and the CDC, has been instrumental in the development of sentinel-level laboratory testing protocols for the detection of bioterror agents. These protocols were developed to allow LRN sentinel laboratories to rapidly rule out or refer suspected bioterror agents to the appropriate LRN reference laboratory. Along with the CDC and APHL, ASM serves as a resource for training and education for microbiologists in hospital and commercial laboratories regarding their roles and responsibilities as LRN sentinel laboratories. These protocols and other useful information regarding bioterror agents...
can be found at the following ASM website page: http://www.asm.org/index.php/guidelines/sentinel-guidelines.

The College of American Pathologists (CAP), together with the CDC, also serves an important role in promoting the diagnostic capability and capacity of clinical and public health laboratories by developing the Laboratory Preparedness Exercise (LPX) proficiency test. There are additional sources of proficiency testing for laboratory bioterrorism preparedness, such as the Wisconsin State Laboratory of Hygiene (http://www.slh.wisc.edu/proficiency/). These proficiency programs help to ensure the capability of participating sentinel laboratories to rule out and/or refer biological threat agents to the appropriate LRN reference laboratory.

A directory of LRN public health reference laboratories is available at http://www.cdc.gov/mmwr/international/refres.html.

Federal Select Agent Program

The Federal Select Agent Program was established due to a heightened concern about the ease with which disease-causing agents could be obtained. Section 511 of the Anti-terrorism and Effective Death Penalty Act of 1996 (Public Law 104-132) directed the HHS to establish a list of biologically dangerous agents that possess, use, or transfer select agents, and ensuring that all individuals who work with these agents undergo a security risk assessment performed by the Federal Bureau of Investigation/Criminal Justice Information Service. The list of agents that the Federal Select Agent Program regulates is shown in Table 1. The list is reviewed by the HHS and APHIS at least every 2 years to determine if agents need to be added to or deleted from the list. Most recently (2012), Coccioidoides species were deleted from the select agent list. Refer to the ASM website for flowcharts and additional information on bioterror agents and preparedness: http://www.asm.org/index.php/issues/sentinel-laboratory-guidelines.

CDC Bioterrorism Agents and Diseases: Categories and Definitions

The CDC divides bioterrorism agents into three categories (A, B, and C) depending on how easily they can be spread and the severity of illness or rate of death they cause (Table 1) (http://www.bt.cdc.gov/agent/disease-categories/). Category A agents are considered the highest risk, as they can easily be disseminated or transmitted from person to person, result in high mortality rates, have the potential for major public health impacts, might cause public panic and social disruption, and require special action for public health preparedness. Agents included in this category are Bacillus anthracis, Clostridium botulinum toxin, Yersinia pestis, variola virus (the agent of smallpox), Francisella tularensis, and hemorrhagic fever viruses (HFVs), such as filoviruses (e.g., Ebola virus and Marburg virus) and arenaviruses (e.g., Lassa virus and Machupo virus). Characteristics of several of these agents are listed in Table 2.

Category B agents are the second-highest-priority agents and include those that are moderately easy to disseminate, result in moderate morbidity rates and low mortality rates, and require specific enhancements of the CDC's diagnostic capacity and enhanced disease surveillance. Category B agents include Brucella species (Brucella abortus, Brucella melitensis, and Brucella suis), epsilon toxin of Clostridium perfringens, food-safety threats (e.g., Salmonella species, Escherichia coli O157:H7, and Shigella species), Burkholderia mallei, Burkholderia pseudomallei, Chlamydia psittaci, Coxiella burnetii, ricin toxin from Ricinus communis (castor beans), staphylococcal enterotoxin B (SEB), Rickettsia prowazekii, viral encephalitis viruses (such as alphaviruses, e.g., Venezuelan equine encephalitis [VEE] virus, Eastern equine encephalitis [EEE] virus, and Western equine encephalitis [WEE] virus), and water-safety threats (e.g., Vibrio cholerae and Cryptosporidium parvum).

Category C agents are the third-highest-priority agents and include emerging pathogens that could be engineered for mass dissemination in the future because of availability, ease of production and dissemination, and potential for high morbidity and mortality rates and major health impacts. These emerging pathogens are covered in their individual organism chapters.

BIOTHREAT AGENTS AND INFECTIONS

Category A Agents

Anthrax (Bacillus anthracis)

Significance
The biothreat associated with the inhalation of spores from B. anthracis has been known for decades, and in the past the organism was developed as a potential military weapon by many countries, including the United States (1, 2). In 2001, envelopes containing confirmed anthrax spores were mailed to southern Florida, New York City, and Washington, D.C., resulting in 22 cases of anthrax (11 inhalational cases, with 5 deaths, and 11 cases of cutaneous anthrax) (2).

Transmission and Disease
B. anthracis is a large, aerobic or facultative anaerobic, spore-forming, Gram-positive bacillus that naturally inhabits the soil. Four forms of the disease can occur: cutaneous (>95% of all human anthrax cases), inhalational, gastrointestinal, and meningitis forms. The inhalational form (acquired through inhalation of organism spores) is primarily associated with bioterror attacks and causes pulmonary anthrax. In addition, anthrax meningitis can occur as a result of a bioterror event. Any case of inhalational or meningeval anthrax should prompt suspicion of possible bioterrorism. Human-to-human transmission of anthrax has not been reported. See ASM’s sentinel-level clinical microbiology laboratory guidelines for anthrax (http://www.asm.org/index.php/guidelines/sentinel-guidelines). Additional information regarding B. anthracis can be found in chapter 26.

Botulism (Clostridium botulinum)

Significance
Clostridial toxins are among the most powerful neurotoxins known. Botulinum toxin acts at the neuromuscular junction and at the peripheral autonomic synapses, resulting in neuromuscular weakness and autonomic dysfunction (3). A bioterror attack using botulinum toxin could occur through ingestion or inhalation of the toxin, such as contamination of a food or air supply. Many countries, including Japan, the United States, the former Soviet Union, and Iraq, have, at some point, developed botulinum toxin for biological warfare (3).

Transmission and Disease
C. botulinum is an anaerobic, spore-forming, Gram-positive bacillus that is found naturally in the environment (soil and water). The organisms primarily associated with human disease produce toxin types A, B, and E. Botulism is naturally acquired from contaminated food products processed by methods that do not destroy spores. This allows bacteria contained in the food to become vegetative and toxins to be produced. The clinical presentation associated with a bioterror attack with botulinum would include gastrointestinal symptomology (nausea, vomiting, and diarrhea) followed by neurological signs of dry mouth and blurred and/or double vision. In cases of severe disease, symptoms include difficulty swallowing, voice impairment, and peripheral muscle weakness. If the muscles of the respiratory tract are involved, respiratory failure and death may result. See ASM’s sentinel-level clinical microbiology laboratory guidelines for botulism (http://www.asm.org/index.php/guidelines/sentinel-guidelines). Additional information regarding C. botulinum can be found in chapter 53.

Plague (Yersinia pestis)

Significance
The first reported use of Y. pestis as a bioweapon was in the 1300s, as the Tartars, invading the city of Kaffa (now Feodosiya, Ukraine), catapulted bodies of plague victims over the city walls, resulting in an epidemic (4). Many countries have developed this agent as a bioweapon, including the former Soviet Union and Japan (5). An incident involving a white supremacist who fraudulently obtained cultures of Y. pestis from the American Type Culture Collection prompted the U.S. Congress to pass a 1996 regulation governing the acquisition, transfer, and use of agents that could be used for bioterrorism purposes (6).

Transmission and Disease
Y. pestis is a slow-growing (optimal growth is at 28°C; up to 5 days of incubation is recommended), plump, Gram-negative cocccobacillus/bacillus and is part of the Enterobacteriaceae family. Plague is a worldwide zoonotic disease that is transmitted between animals via infected fleas. There are three forms of plague: bubonic, septicemic, and pneumatic. The pneumonic form would be the most likely disease manifestation seen in the event of a bioterror attack. See ASM’s sentinel-level clinical microbiology laboratory guidelines for plague (http://www.asm.org/index.php/guidelines/sentinel-guidelines). Additional information regarding Y. pestis can be found in chapter 39.

Smallpox (Variola Major)

Significance
An excellent overview of smallpox and its historical use as a biowarfare weapon is given by Rotz et al. (7). Briefly, one of the first possibilities of smallpox being used as a bioweapon dates back to the 1600s, when the Spanish supplied the natives of South America with smallpox-contaminated clothing in an effort to gain control of their lands. Then, in the 1760s, the North American British forces gave smallpox-contaminated blankets to the native Indians in an effort to reduce their populations and gain control of land. In more recent times, the Russians associated with Bioperparat worked with many potential biothreat agents, including smallpox, for use in intercontinental missiles (8). Today, concern still exists regarding illegitimate stores of the agent and their potential use in bioterrorism, especially because routine vaccination has not been in place for decades, leading to a susceptible populace.

Transmission and Disease
Variola virus belongs to the genus Orthopoxvirus in the family Poxviridae. Variola virus is a large, brick-shaped virus measuring approximately 302 to 350 nm by 244 to 270 nm and is comprised of a single linear double-stranded DNA genome. As there is no known disease associated with smallpox in the world, even one case would prompt the suspicion of a bioterror incident. Human transmission occurs primarily by inhalation of airborne particles containing the virus, but transmission may occur via fomites (contaminated bedding or clothing) as well. Disease consists of symptoms such as malaise, fever, chills, vomiting, headache, and backache, with the eventual formation of a papular rash on the face, hands, and arms, later spreading to the legs and, lastly, the trunk. The mortality due to smallpox in the unvaccinated population is approximately 30% (9). See ASM’s sentinel-level clinical microbiology laboratory guidelines for unknown viruses (http://
Tularemia (Francisella tularensis)

Significance
The highly infectious nature of *F. tularensis*, due to low inhalation inocula and a very susceptible human population, as well as its substantial morbidity and mortality in untreated patients, makes this bacterium a potential agent of bioterrorism. The Japanese began experiments on human prisoners for use of this agent as a military weapon in the early 1930s, and in 1955 the United States used volunteers and military personnel to test the effects of inhaled organisms (10). In the 1990s, Russia developed antibiotic- and vaccine-resistant strains of *F. tularensis* (http://www.pbs.org/wgbh/nova/bioterror/agen_tularemia.html).

Transmission and Disease
*F. tularensis* is an extremely small, fastidious, pleomorphic, Gram-negative coccobacillus. Aerosolized particles containing the organism account for the acquisition of pneumonic tularemia, the primary disease that would be associated with a bioterror attack; however, patients inhaling aerosolized organisms may present with other forms of tularemia (ulceroglandular, glandular, ocuologlandular, pharyngeal, and typhoidal). Respiratory failure or shock causes most fatalities from pneumonic disease (http://www.pbs.org/wgbh/nova/bioterror/agen_tularemia.html). Two subspecies of *F. tularensis*, *F. tularensis* subsp. *tularensis* (type A) and *F. tularensis* subsp. *holarctica* (type B), are of clinical importance in causing tularemia. See ASM's sentinel-level clinical microbiology laboratory guidelines for *F. tularensis* (http://www.asm.org/index.php/guidelines/sentinel-guidelines). Additional information regarding *F. tularensis* can be found in chapter 46.

Diseases Caused by HFVs

Significance
Hemorrhagic fever viruses (HFVs) were developed as biological weapons by both the United States and the former Soviet Union. The United States stopped this program and destroyed all weapons in the late 1960s.

Transmission and Disease
The HFVs comprise four families: the Arenaviridae, Bunyaviridae, Filoviridae, and Flaviviridae. The clinical course following exposure varies with the virus causing the infection, but typically patients have symptoms of fever, myalgia, and malaise followed by exacerbation of symptoms and development of prostration and hemorrhage, with central nervous system (CNS) depression. Patients who develop shock with extensive hemorrhage and CNS damage generally have poor outcomes (11).

See ASM’s sentinel-level clinical microbiology laboratory guidelines for unknown viruses (http://www.asm.org/index.php/guidelines/sentinel-guidelines). Additional information regarding HFVs can be found in section IV of this Manual.

Category B Agents

Brucellosis (Bacillus Species)

Significance
*B. suis* was the first biological agent to be utilized in the biological warfare program in the United States during the mid-1950s. Brucella species are considered among the agents less likely to be utilized in a bioterrorism attack, in part because brucellosis results in a high morbidity but low mortality. However, it remains a threat because the disease process is long and can be incapacitating. *Brucella* species listed as category B agents are *B. abortus*, *B. melitensis*, and *B. suis*.

Transmission and Disease
Brucellosis is a zoonotic infection, with four species being recognized as causing infection in humans: *B. abortus* (cattle), *B. melitensis* (goats, sheep, and camels), *B. suis* (pigs), and *Brucella canis* (dogs). In addition, it is a common laboratory-acquired infection. *Brucella* organisms are small, aerobic, Gram-negative coccobacilli that grow slowly (2 to 3 days for initial isolation). *Brucella* can cause both acute and chronic infections. Brucellosis is a disease of nonspecific symptoms, consisting of fever, sweats, headache, anorexia, back pain, and weight loss, which can last for months and relapse after discontinuation of therapy (12). The chronic form of the disease can mimic miliary tuberculosis, with extensive lesions in the liver, spleen, and bone. Brucellosis has a mortality of 5% in untreated individuals. See ASM's sentinel-level clinical microbiology laboratory guidelines for *Brucella* (http://www.asm.org/index.php/guidelines/sentinel-guidelines). Additional information regarding *Brucella* species can be found in chapter 47.

Glanders and Melioidosis (Burkholderia mallei and B. pseudomallei)

Significance
It is believed that *B. mallei* was used to infect large numbers of Russian horses and mules on the Eastern Front during World War I and that the Japanese infected horses, civilians, and prisoners of war during World War II. The United States studied this agent as a possible bioterror agent in 1943 and 1944 but did not weaponize it. The former Soviet Union is also believed to have been interested in *B. mallei* as a potential bioterror agent (13).

Transmission and Disease
Glanders and melioidosis are related diseases produced by bacteria of the *Burkholderia* species, which are nonsporulating, obligately aerobic, Gram-negative bacilli. They produce similar diseases which consist of several forms: localized infections, pulmonary infections (pneumonia, pulmonary abscesses, and pleural effusions), septicemia, and a chronic form (multiple abscesses in internal organs). Both *B. mallei* and *B. pseudomallei* are considered potential bioterror agents in the aerosolized/pulmonary form in that they are highly infectious by inhalation and because of their resistance to many routine antibiotics (http://emedicine.medscape.com/article/830235-overview). See ASM’s sentinel-level clinical microbiology laboratory guidelines for *Burkholderia* species (http://www.asm.org/index.php/guidelines/sentinel-guidelines). Additional information regarding *Burkholderia* species can be found in chapter 43.

Q Fever (Coxiella burnetii)

Significance
*C. burnetii* has a very low infective dose and is resistant to the effects of drying and heat. Humans are very susceptible to infection with this organism, and a single organism is capable of causing disease in a susceptible person. In the
1960s, the U.S. military considered Coxiella an excellent “incapacitating” agent, as the disease is debilitating but rarely lethal, and envisioned using this agent to cripple enemy forces. Russia, and possibly also Iraq, has also developed and tested the Q fever agent as a biothreat agent, and the cult Aum Shinrikyo obtained C. burnetii but was unsuccessful in weaponizing it.

**Transmission and Disease**

C. burnetii is a pleomorphic, Gram-negative, intracellular coccobacillus that cannot be cultured on routine bacteriologic media. Q fever is a zoonotic disease seen primarily in parturient goats, sheep, and cattle. Aerosolized contaminated dust particles are the source of human infection, and the infectious dose is very low. There are three clinical presentations of this infection: atypical pneumonia, progressive pneumonia (of a rapid nature), and as an incidental finding in a patient with fever and pneumonia. The last description is the most common form of the disease (14). Q fever may present as a chronic infection. See ASM’s sentinel-level clinical microbiology laboratory guidelines for Q fever ([http://www.asm.org/index.php/guidelines/sentinel-guidelines](http://www.asm.org/index.php/guidelines/sentinel-guidelines)). Additional information regarding Q fever can be found in chapter 66.

**Staphylococcal Enterotoxins**

**Significance**

Staphylococcal enterotoxin B (SEB) was part of the United States’ bioweapons program until the early 1970s. SEB was thought to be useful as a weapon due to its ease of aerosolization, stability, and ability to produce multisystem organ failure in humans and animals. SEB is also a potent superantigen, which is a ubiquitous, nonmotile, Gram-positive bacterium that cannot be cultured on routine bacteriologic media. Q fever is caused by Coxiella burnetii, which is an obligately intracellular bacterium that survives for long periods in dry environments, is spread naturally through the aerosol route, and has the potential to cause severe disease in humans. For these reasons, it is listed as a potential bioterrorism agent.

**Transmission and Disease**

SEB is one of several enterotoxins produced by Staphylococcus aureus, which is a ubiquitous, nonmotile, Gram-positive coccus found on the skin and mucous membranes of humans and animals. SEB is also a potent superantigen capable of massive overstimulation of the immune system, resulting in an overwhelming inflammatory response and an endotoxin-like shock which can result in multisystem organ failure and death (15). See ASM’s sentinel-level clinical microbiology laboratory guidelines for staphylococcal enterotoxin B ([http://www.asm.org/index.php/guidelines/sentinel-guidelines](http://www.asm.org/index.php/guidelines/sentinel-guidelines)). Additional information regarding SEB can be found in chapter 21.

**Epsilon Toxin (Clostridium perfringens)**

**Significance**

Because of its potency—nearly equal to that of botulinum neurotoxin (16)—epsilon toxin of C. perfringens is considered a potential bioterrorism agent.

**Transmission and Disease**

C. perfringens is a spore-forming, Gram-positive bacillus that naturally inhabits the soil. C. perfringens produces several toxins, including epsilon toxin, which is synthesized by toxinoctyes B and D. C. perfringens toxinoctyes B and D are animal pathogens. Epsilon toxin forms pores in the plasma membranes of eukaryotic cells, but its mode of action is not fully elucidated. In animals, high levels of epsilon toxin are produced in the intestine. The toxin then spreads via the circulatory system to various organs, where it causes edema and hemorrhage. It is fast acting, causing death within hours or minutes of exposure (17). Documented human cases of enterotoxemia due to epsilon toxin are very rare, with only two reported cases, both reported in 1955 (16). Because of its rarity, any case of enterotoxemia due to epsilon toxin should prompt suspicion of possible bioterrorism. As a biothreat agent, epsilon toxin would likely be delivered as an aerosol or through water- or foodborne routes. Additional information regarding C. perfringens and epsilon toxin can be found in chapter 53.

**Psittacosis (Chlamydia psittaci)**

**Significance**

C. psittaci survives for long periods in dry environments, is spread naturally through the aerosol route, and has the potential to cause severe disease in humans. For these reasons, it is listed as a potential bioterrorism agent.

**Transmission and Disease**

C. psittaci is an obligately intracellular bacterium that causes respiratory disease in birds. Human infections (psittacosis) are usually associated with exposure to bird secretions. Gardening and lawn mowing have been linked with psittacosis, and person-to-person transmission may occur (18). C. psittaci infection in humans usually presents as a mild to severe respiratory infection, with a wide range of symptoms. Signs and symptoms include fever, headache, muscular aches, nonproductive cough, and difficulty breathing. Extrapulmonary complications may also occur. As a bioterror agent, C. psittaci would likely be spread through the aerosol route. Additional information regarding C. psittaci can be found in chapter 63.

**Epidemic Typhus (Rickettsia prowazekii)**

**Significance**

Among the characteristics that make R. prowazekii a potential bioterrorism agent are its aerosol transmission, high infectivity, stable extracellular forms, and high virulence. R. prowazekii was developed as a biological weapon by several countries during the 1930s and 1940s (19).

**Transmission and Disease**

R. prowazekii is an obligately intracellular bacterium that relies on an arthropod host (human body louse) as its principal vector. The classic epidemiologic cycle of epidemic typhus requires the feeding of an infected louse on a susceptible human host. Symptoms include high fever, myalgia, and arthralgia. Because of the nonspecific symptoms, infections may go undiagnosed or be treated with ineffective antibiotics. Among untreated patients, the mortality rate can reach 20% (20). Human-to-human transmission of R. prowazekii has not been reported. As a bioterror agent, R. prowazekii would likely be spread through the aerosol route or through infected lice. Additional information regarding R. prowazekii can be found in chapter 64.

**Viral Encephalitis (Alphaviruses)**

**Significance**

Among the alphaviruses, Eastern equine encephalitis (EEE) virus, Venezuelan equine encephalitis (VEE) virus, and Western equine encephalitis (WEE) virus share several characteristics related to their joint classification as potential bioterrorism agents: route of transmission, morbidity in humans and equines, and cell culture infectivity.
Transmission and Disease

The genus *Alphavirus* is a member of the family *Togaviridae*. There are 29 species in the genus *Alphavirus*, including EEE, VEE, and WEE viruses (21). Alphaviruses infecting humans are arthropod borne and cause encephalitis in humans. Diseases can range from mild fever and myalgias to fatal encephalitis. Survivors of encephalitis often suffer from permanent neurologic sequelae. As bioterror agents, alphaviruses would likely be spread through the aerosol route or through infected mosquitoes.

Additional information regarding alphaviruses can be found in section IV of this Manual.

Food- and Water-Safety Threats (Bacteria, Viruses, and Protozoa)

Significance

Contamination of food and water supplies is a real as well as potential route for the dispersal of bioterrorism agents because of the ability to infect a large number of individuals. Food- and waterborne agents considered to be potential bioterrorism agents include *Salmonella*, *Shigella*, toxigenic strains of *Escherichia coli*, *Campylobacter*, *Vibrio cholerae*, and *Vibrio parahaemolyticus*, *Listeria monocytogenes*, *Yersinia enterocolitica*, noroviruses, hepatitis A virus, *Cryptosporidium*, *Vibrio cholerae*, *E. coli* serotype O157:H7). Some associated with additional syndromes, such as septicemia and *Salmonella* (24).

Transmission and Disease

The food- and waterborne agents listed above share some features, such as the fecal-oral route of transmission (especially secondary cases), yet they also have unique characteristics. Characteristics that are compatible with bioterror use include a low infectious dose (*Shigella*, norovirus, hepatitis A virus, and *C. parvum*) and environmental stability (norovirus, hepatitis A virus, and *C. parvum*), including in aerosols (norovirus). While most of these agents cause an acute or protracted gastroenteritis, some are associated with additional syndromes, such as septicemia (*Salmonella enterica* serotype Typhi and *L. monocytogenes*), Guillain-Barré syndrome (*Campylobacter jejuni*), and hemolytic-uremic syndrome (*E. coli* serotype O157:H7). Some cause significant morbidity and mortality in immunocompromised persons, including those with AIDS (*L. monocytogenes*, microsporidia, *T. gondii*, and *C. parvum*). A challenge with the prompt identification of bioterrorism events involving food- and waterborne agents is the tendency of these agents to produce large outbreaks of disease naturally. Epidemiological evidence may be necessary to indicate suspicion of bioterrorism.

In summary, there is a very real possibility that the laboratory will be the first to recognize an act of bioterrorism. In a suspected or confirmed bioterrorism event, immediate and effective communication with all appropriate institutional and medical personnel and public health officials is imperative. The laboratory may be called upon to assist in the diagnosis and management of patients who have been exposed overtly or covertly to a bioterrorism agent. The laboratory needs to promptly assist clinicians by providing them with accurate information on the selection, collection, and transport of specimens. In addition, the laboratory must handle these specimens in a manner that will result in the greatest probability of success in establishing a diagnosis and minimizing the exposure of hospital personnel and patients to infectious agents.

REFERENCES

The total number of bacteria in the human body is estimated to be at least 10 times greater than the number of human cells (1, 2), and recent studies, particularly the efforts of the NIH Human Microbiome Project (HMP) Consortium, have led to a greater understanding of the identity and distribution of microorganisms that constitute these microbial populations. In particular, implementation of next-generation sequencing (NGS) has helped to illuminate how these bacteria contribute to and are affected by human health and disease. Significant progress in cataloging and characterizing these microorganisms and genes has been made in recent years, thanks to NGS approaches, and microbiome studies have expanded beyond the gut to other body sites. NGS DNA sequencing platforms have made it possible to sequence the DNA of the collective genome (or metagenome) of entire microbial communities (Fig. 1) from different body sites in health and disease and in different life stages, effectively enabling the characterization of the "human microbiome" (see Table 1 for basic definitions).

INTRODUCTION TO THE HUMAN MICROBIOME PROJECT

In 2007, an NIH Roadmap for Medical Research project called the Human Microbiome Project (HMP) was initiated (http://nihroadmap.nih.gov/hmp/). The overarching goal of the HMP is to develop tools and resources for characterization of the human microbiota and to relate this microbiota to human health and disease. The HMP is leveraging the constantly advancing sequencing and bioinformatic technologies to address the following broad goals:

- Determining whether individuals share a core human microbiome
- Understanding whether changes in the human microbiome can be correlated with changes in human health and disease
- Developing the new technological and bioinformatic tools needed to support these goals
- Addressing the ethical, legal, and social implications raised by human microbiome research

A comprehensive clinical protocol outlined standardized sampling (3) and nucleic acid extraction procedures for the two clinical sampling centers (one at Baylor College of Medicine [BCM] and one at Washington University, St. Louis, MO). Further efforts were made to standardize how samples were processed, sequenced, and analyzed (4). The progress within the HMP culminated in the publication of two flagship manuscripts (5, 6) and more than 30 companion papers (e.g., see http://www.ploscollections.org/hmp), beginning in June 2012, that describe the initial observations associated with the HMP healthy cohort and numerous derivative studies that examine specific facets of these more deeply characterized communities (Fig. 1).

Among initial microbiome comparisons, analyses of samples across 18 body sites confirmed high interindividual variation (7) and determined that even rare organisms in these communities are important reservoirs of genetic diversity (8). Additionally, data from the large HMP cohort suggest that the composition of the gut microbiome is most often characterized by smooth abundance gradients of key organisms (6) and does not necessarily cluster subjects into discrete types. However, microbial communities found in other niches, such as the vagina, can exhibit such clustering (4). While the microbial communities varied among subjects, the metabolic pathways encoded by these organisms and necessary for human-commensal viability were consistently present, forming a functional "core" to the microbiome at all body sites (6, 9, 10). Although the pathways and processes of this core were consistent, the specific genes associated with these pathways varied. Microbial sugar utilization, for example, was enriched for metabolism of simple sugars in the oral cavity, complex carbohydrates in the gut, and glycogen/peptidoglycan degradation in the vaginal microbiome (10).

TECHNIQUES FOR THE STUDY OF THE HUMAN MICROBIOME

Early studies of the human microbiome relied on culture-dependent methods; however, it is now known that the majority of microorganisms from the human body cannot be cultured in vitro. Most current techniques for characterization of a metagenomic sample are PCR based and target the highly conserved bacterial small-subunit 16S rRNA gene. Portions of the gene can be amplified and fingerprinted by using electrophoretic techniques, such as terminal restriction fragment length polymorphism (TRFLP) analysis and denaturing gradient gel electrophoresis. Full-length 16S rRNA genes or segments of these genes can be amplified prior to microarray analyses or DNA sequencing studies on
FIGURE 1 Model for microbiome data generation and analyses. (A) Various components (green) and processes (lavender) involved in microbiome projects. (B) Processes of sequencing data generation/editing and data analyses (bioinformatic strategies). Adapted from reference 128 with permission from the Public Library of Science. doi:10.1128/9781555817381.ch15.f1

NGS platforms (e.g., the 454 platform and, more recently, the Illumina MiSeq and Life Technologies Ion Torrent platforms). 16S rRNA gene sequences that are ≥97% identical are considered to be within the same species, while those that are ≥95% identical are within the same genus.

Culture-dependent and culture-independent surveys have shown that the human body hosts four predominant phyla (Table 2). The four phyla, *Actinobacteria*, *Bacteroidetes*, *Firmicutes*, and *Proteobacteria*, are the most highly represented phyla across all body sites (Fig. 2). In a recent study, these four phyla comprised 92.3% of bacterial DNA sequences analyzed from multiple human sources, including hair, oral cavity, skin, and gastrointestinal (GI) tract (11). The predominant phyla vary by anatomical site, and presumably the host milieu has a crucial role in shaping the composition of microbial communities at each site. Recent efforts have been aimed at expanding the DNA sequence representation within each phylum so that more comprehensive phylogenetic assessments can be performed in the future (12).

### TABLE 1 Basic terminology of the human microbiome

aPhyla are listed in order of predominance at each body site, based on the cited reference(s).

$^*$Rothia, Catcnoctophaga, Selenomomas, Treponema, and TM7. Additionally, Methanobrevibacter taxa from the Archaea domain are present in the human oral cavity. Different sites within the oral cavity have various degrees of biological diversity, with plaque and saliva specimens containing the greatest relative diversity (8).

New concepts have emerged because of these pioneering studies, including relative differences in biological diversity between body habitats. Relative to human skin, several sites in the human oral cavity demonstrated relatively greater richness in terms of microbial ecology within individuals but lower beta diversity or a greater similarity of microbial communities between individuals (5, 6). Health-associated microbial communities may protect against infection, but the oral cavity also harbors organisms that are implicated in both local and systemic diseases, including periodontal diseases (14), endocarditis (15), and aspiration pneumonia (16). The relative preponderance of health- or disease-associated mi-

---

228  ■  DIAGNOSTIC STRATEGIES AND GENERAL TOPICS

FIGURE 2  Differences in microbial composition by body habitat. The figure shows the relative abundances of six different bacterial phyla at eight different body sites. The relative abundances were obtained by next-generation DNA sequencing of 16S rRNA genes. Adapted from reference 129 with permission from the Nature Publishing Group. doi:10.1128/9781555817381.ch15.f2
Microbes combined with human genetic susceptibility may ultimately account for different disease phenotypes.

Periodontitis is an infectious and inflammatory disease condition that is associated with disturbances in microbial ecology among human adult tooth-borne microbes. Socransky et al. proposed that periodontitis is the result of complexes or consortia of pathogens (17). The so-called red complex, containing Porphyromonas gingivalis, Tannerella forsythia, and Treponema denticola, is the pathogenic group most strongly associated with this disease process (17, 18). Periodontitis is an independent predictor and comorbidity factor contributing to different disease conditions, including preterm birth, cardiovascular disease, pulmonary disorders, diabetes, and obesity (19). Progressive periodontitis in pregnant women has been reported to increase the risk of severely adverse pregnancy outcomes (20, 21). These associations underscore the significance of the oral microbiome to the systemic health status and predisposition to specific diseases.

Microbial community profiling by 16S rRNA gene sequencing and other methods has been used to evaluate the oral microbiome. These methods include denaturing gradient gel electrophoresis (22–24), TRFLP analysis (25–28), and checkerboard DNA-DNA hybridization, where 45 DNA samples can be queried against 30 to 40 DNA probes (29). Socransky and coworkers applied checkerboard DNA-DNA hybridization to examine microbial communities in supragingival (30) and subgingival (17) plaque and microbiota succession patterns (shifts) during dental biofilm development in health and periodontitis (31, 32). In both studies, distinct complexes were identified by principal component and correspondence analyses and were assigned to color groups. The communities in supragingival plaque samples from 187 subjects (4,475 samples in total) clustered into six groups, including the aforementioned pathogen-associated red complex. One bacterial pathogen, Aggregatibacter actinomycetemcomitans, has been linked to a highly aggressive periodontitis (localized aggressive periodontitis) in Africans (19). The uncultured bacterial taxon TM7 has been associated with periodontitis based on whole-genome shotgun (WGS) sequencing studies, but this disease association has yet to be evaluated fully in a population-based cohort.

As in the HMP, other studies have examined microbial colonization and succession at different sites in the oral cavity. Aas et al. (33) examined nine oral sites: tongue dorsum, tongue lateral sides, buccal epithelium, hard palate, soft palate, supragingival plaque, subgingival plaque, maxillary anterior vestibule, and tonsils. A total of 2,589 16S rRNA gene clones from five subjects were evaluated; this sequencing effort resulted in 141 predominant species and 13 new phylotypes. All sites contained the Gemella, Granulicatella, Streptococcus, and Veillonella genera. The tonsils were found to have the greatest microbial diversity and varied significantly among subjects. Organisms implicated in bacterial endocarditis, such as Streptococcus suis, Streptococcus oralis (34), and Granulicatella adiacens (35), were found in each healthy subject, which supports the concept that such oral microbes may potentially translocate into the bloodstream secondary to dental procedures. A central concept that emerged from the HMP was that opportunistic pathogens were much more prevalent than canonical pathogens and were present across multiple body sites in a given individual (6). Individuals with breaches in mucosal integrity or immunocompromised status may be vulnerable to opportunistic pathogens present in the human microbiome.

A human oral microbe identification microarray (http://mim.forsyth.org) that contains 16S rRNA gene oligonucleotide probes representing approximately 300 oral bacterial species was described previously (36). While the presence of more periodontal pathogens was observed in the diseased subjects, the main conclusion from the study was that increased microbial diversity was associated with diseased subgingivae. The salivary microbiome has also been studied (37, 38). Samples from 120 healthy subjects from 12 geographic locations were analyzed by Sanger sequencing of the V4 to V6 regions of the 16S rRNA gene. A total of 101 genera were identified, and the numbers of bacterial genera per subject ranged from 6 to 30. The most prevalent genus was Streptococcus (23.7%), consistent with the predominance of Streptococcus in the esophagus and stomach of healthy individuals.

The Gastrointestinal Microbiome

The human GI tract encompasses numerous different anatomical sites, including the esophagus, stomach, small intestine, colon, rectum, and anus. Each of these sites is colonized by different numbers and populations of microbes.

Esophageal Microbiome

The esophagus is colonized by bacteria that are introduced from the oropharynx by swallowing or from the stomach by reflux. Early studies focused on surveys of cultured bacteria (39–43). Limited numbers of bacteria were examined, and in nondiseased subjects, aerobic and anaerobic Gram-positive organisms predominated. Only three metagenomic surveys of the esophageal microbiota have been reported. A study by Pei et al. (44) showed that the distal esophageal microbiomes of four adults had compositions similar to that of the oropharynx, with the exception that no sputchotes were found in the esophagus. As in the oral cavity, Streptococcus was the dominant genus in the healthy esophageal microbiome. Bacterial DNA sequences were categorized into the following six phyla or groups: Firmicutes (70%), Bacteroidetes (20%), Actinobacteria (4%), Proteobacteria (2%), Fusobacteria (2%), and TM7 (1%). This distribution highlights the preponderance of Firmicutes and Bacteroidetes in the GI tract. Thirty-six new species were discovered, and Chao 1 (45) analysis estimated that the esophageal community contains about 140 species-level operational taxonomic units (OTUs) (44). The same group examined differences in the esophageal microbial communities in patients with esophagitis or Barrett’s esophagus (intestinal metaplasia) (46, 47). Two distinct microbiomes were seen in healthy and diseased subjects. Healthy individuals had esophageal microbiomes that were composed predominantly of streptococci, while the diseased patients’ microbiomes had larger numbers of Gram-negative anaerobes and increased bacterial diversity (47). A similar shift in terms of bacterial composition was reported in an earlier study of esophageal carcinoma (41).

Gastric Microbiome

The low pH and rapid peristalsis in the stomach suppress persistent colonization by many bacteria. The stomach and small intestine each are thought to contain about 100 microorganisms/ml, but the organismal counts can increase to 10^9 per ml following a meal (48). The best-studied and most dominant member of the stomach microbiota is Helicobacter pylori (49). Culture-dependent methods have revealed other genera, such as Lactobacillus, Streptococcus, and Staphylococcus, as well as members of the Enterobacteriaceae, in the stomach (50), although a metagenomic analysis of gastric
biopsy specimens revealed far greater diversity (128 phylogenotypes) than had been appreciated previously by culture-based approaches (51). The most prevalent genera in the gastric microbiome, besides H. pylori, include several genera found commonly in the oral cavity and esophagus. Bacterial genera found in the human stomach include Prevotella, Streptococcus, Veillonella, and Rothia. The genus Streptococcus is a predominant genus in the stomach when H. pylori is absent (52).

Small Intestinal Microbiome
Like the stomach, the proximal small intestine (duodenum and jejunum) is colonized by relatively limited numbers of bacterial species. Acidic pH and bile in the proximal to mid-small intestine inhibit bacterial colonization. Bacterial communities in the small intestine typically consist of lactobacilli, enterococci, Gram-positive aerobes, and facultative anaerobes, and the genus Streptococcus seems to be the dominant genus in the duodenum and jejunum (2, 50, 53). This portion of the GI tract has been assessed mainly by culture-dependent methods, with a relative paucity of molecular data. A recent quantitative-PCR-based study described differences in microbial composition between ileostomy specimens and small intestinal tissue (54). In the jejunum, the microbial composition becomes complex and approaches that of the colon in terms of species richness and the nature of predominant bacterial genera.

Colonic Microbiome
The human colon contains a rich collection of microbial communities, with numerical estimates ranging from $10^{11}$ to $10^{12}$ bacteria/g, and likely exceeding 1,000 bacterial species (6, 8) per individual, the majority of which belong to the phyla Bacteroidetes and Firmicutes (6, 55, 56). Other phyla with sufficient representation in the intestine include Actinobacteria, Proteobacteria, and Verrucomicrobia. In patients with different GI diseases, bacterial population shifts occur such that Proteobacteria become relatively more abundant (57). Comprehensive evaluation of self-collected stool specimens from healthy adults documented high degrees of species richness and microbial diversity in the human intestine (5, 6) relative to other body habitats. The intestine is characterized by a long "tail" of rare, unknown bacterial taxa that accounts for the majority of species or OTUs in the gastrointestinal tract (8). In contrast, in the absence of nucleic acid amplification, the healthy intestinal microbiome contains 70 to 100 known bacterial taxa, on average, based on whole-genome shotgun sequencing (6, 58). In terms of known gut bacteria, the dominant genus by relative abundance in stool is Bacteroides. A relatively abundant signature species is another organism from the phylum Bacteroidetes, known as Prevotella copri (6), and these signature organisms vary between different body habitats. The spatial distribution of gut microbes also depends on the mucosal versus luminal locations of these communities (56). The mucosa-associated microbiomes differ in composition from those found in stool specimens.

Bacteria from the distal gut are critical to host nutrition and may play key roles in health and disease. Microbe-derived carbohydrate fermentation by-products, such as short-chain fatty acids (SCFAs) (e.g., butyrate, acetate, and propionate), provide 10% or more of the body’s metabolic requirements (59). Butyrate, produced by clostridial clusters IV and XIVa, is the primary energy source of the colonic epithelium, and this SCFA has been reported to possess anticancer features (60–62). SCFAs may play a role in preventing infection by pathogens such as Salmonella enterica.
Clostridiales members were diminished in relative abundance, including many bacterial taxa in clostridial cluster XIVa, which contains butyrate-producing organisms. Subsequent studies revealed deficiencies of Faecalibacterium prausnitzii in patients with IBD (75–78). Beyond studies of microbial composition, differences in the relative abundances of metabolic pathways were found in patients with IBD (79). Oxidative stress pathways were relatively enriched in the IBD microbiome, whereas several microbial metabolic pathways associated with carbohydrate metabolism and amino acid biosynthesis were enriched in healthy subjects. IBD genotype (e.g., NOD2 status) and phenotype have been associated with specific compositional changes in the intestinal microbiome (80). Differences in gut microbial composition have been described for type 2 diabetes, a chronic disorder with autoimmune and metabolic components. Metagenome-wide association studies (MGWAS) have identified genetic signatures in the metagenome which are associated with type 2 diabetes (81). These studies strongly suggest that the microbiota in the gut may contribute to activation of signaling pathways required for the development of human diseases such as diabetes.

The Vaginal Microbiome

The vaginal microbiota plays an important role in preventing genital and urinary tract infections. The composition of the vaginal microbiota varies with age, pH, and hormonal levels (82). The vaginal microbiome is dynamic and changes during the menstrual cycle (83) and during pregnancy (84). Interestingly, the placent al microbiome that develops during pregnancy has also been described (85), and the microbial composition of the placental microbiome is distinct from that of the vaginal microbiome. The placent al microbiome is more similar in metagenomic composition to the oral microbiome. In the vagina, lactobacilli are considered the most prevalent organisms in healthy premenopausal women (86, 87), and these are considered protective for the host based on their proposed role in suppression of pathogen colonization. Such effects may result from mucous adherence by lactobacilli, production of organic acids and reduction of vaginal pH, and production of antimicrobial compounds which prevent pathogen proliferation (88). In addition to the lactobacilli, the predominant cultured vaginal microbes in the clinical microbiology laboratory are Mobiluncus spp., Gardnerella vaginalis, Bacteroides spp., Prevotella spp., and Mycoplasma hominis (89).

Microbial community profiling studies have demonstrated that the vaginal microbiota is highly variable and fluctuations in composition presumably depend on differences in sexual and hygienic practices, in addition to host genetics. In the HMP, three sites in the vagina were studied, and differences were documented among these sites (6). The vagina is relatively limited in terms of microbial diversity within and between individuals. Lactobacillus is the predominant member of the vaginal community in most individuals, but in some cases, vaginal lactobacilli may be undetectable. The microbiota of eight healthy women with three different “grades” of vaginosis was examined by sequencing the V1 to V3 regions of the 16S RNA gene by the Sanger method (90). The vaginal bacterial composition associated with each of these grades was quite distinct: grade 1 individuals (healthy) were almost exclusively colonized by Lactobacillus crispatus, Lactobacillus gasseri, and Lactobacillus jensenii; grade 2 subjects had Lactobacillus iners, Atopobium vaginae, Prevotella bivia, and Sneathia sanguinogens; and grade 3 subjects were predominantly colonized with A. vaginae or Peptostreptococcus anaerobius. Several studies have associated an altered vaginal microbiota with an increased risk of viral coinfection (91–93).

Previous studies showed that the microbial composition of the vaginal microbiota varies among healthy Caucasian women (94). The number and distribution of phylotypes differed among the five subjects. Two females had exclusively or nearly exclusively L. crispatus, one had L. iners as the predominant species, and one was predominantly colonized by A. vaginae. The fifth subject had seven phylotypes, predominantly L. iners, but also significant amounts of A. vaginae, Megaplasma, and Leptotrichia. Like lactobacilli, Leptotrichia and Atopobium are lactic acid producers. Different microbial communities may manifest shared functions. A relatively large study included 396 asymptomatic North American women and documented the presence of five groups based on vaginal microbiome composition (87). Four of the five groups were dominated by different Lactobacillus species, whereas the fifth group contained larger proportions of strict anaerobes. The proportions of each microbiome group varied among four ethnic groups included in this study and highlighted the interrelationships between the host genotype/phenotype and vaginal microbiome composition (87). Such differences in microbial communities may contribute to differences in disease susceptibility.

The Microbiome of the Respiratory Tract

The healthy nares and nasopharynx contain streptococci, staphylococci, corynebacteria, Moraxella spp., Neisseria spp. (including Neisseria meningitidis), and Haemophilus (95). The HMP documented the relative predominance of the genera Corynebacterium, Moraxella, Propionibacterium, and Staphylococcus in the anterior nares (6). Potential pathogens often colonize the nares and nasopharynx. Microorganisms associated with inner ear infections of children (e.g., Streptococcus pneumoniae, Haemophilus influenzae, and Moraxella catarrhalis) have been found in the nasopharynx (96). The carriage rate for Staphylococcus aureus has been estimated to be approximately 30%, with methicillin-resistant S. aureus representing 1.5% of the strains isolated (97). Studies of the human microbiome reported that Staphylococcus aureus was a prominent species in the anterior nares (6), and this species represents a possible pathogen in its human host. Changes in airway microbiome composition have been associated with different disease states involving the respiratory tract. Microbial diversity was greater in patients with tuberculosis than in healthy controls (98), and a core cystic fibrosis-associated microbiome including seven bacterial genera has been proposed (99). The respiratory tract is relatively understudied in terms of its microbiome, but it is becoming clear that significant shifts in composition can be associated with different disease phenotypes.

The Skin Microbiome

The skin microbiome is the first line of defense against infection and plays a role in modulating the inflammatory response. Minutes after birth, colonization of the initially sterile skin habitat begins to occur, as newborns are first colonized with similar, low-diversity microbiomes at multiple body sites (100, 101). Members of the environmental microbiota then begin to colonize different regions of the skin as they acquire distinct moisture, temperature, and glandular characteristics, giving rise to habitats with increasingly diverse microbiotas (102). These skin-associated microbial communities continue to change in puberty, depending on age, gender, and environmental exposures (103–107). Metagenomic studies using 16S RNA gene sequencing in adults showed that the vast majority of skin (as well as
gut) commensals are grouped into four dominant phyla: Actinobacteria, Firmicutes, Bacteroidetes, and Proteobacteria. These phyla contain thousands of distinct species (103, 108, 109). For instance, the palm microbiome comprised 4,742 distinct species in 51 healthy subjects, with an average of 158 species colonizing a single palm (103). Surveys of more than 20 different skin sites showed that similar habitats, such as the axillae and the popliteal fossae, share similar microbial compositions (Fig. 3) (110). For instance, in all individuals, Propionibacterium species dominate sebaceous areas, such as the back, forehead, and retroauricular crease (6), whereas Staphylococcus and Corynebacterium species dominate moist areas, such as the axillae (Fig. 3). Unexpectedly, Proteobacteria, typically thought to appear on skin only as gastrointestinal contaminants, were found in dry skin habitats, such as the forearm and leg. Diversity and variance fluctuate in a body-site-dependent manner. For example, the antecubital fossa is characterized by fewer distinct species than those at other skin sites. This relatively low alpha diversity is contrasted with a higher beta diversity in comparing the antecubital fossa communities between individuals (6, 111, 112). The skin microbiota generally protects individuals against colonization by pathogens, but skin microbes may be pathogenic if these organisms penetrate the skin in a susceptible host. For example, Staphylococcus epidermidis is a common skin colonizer. However, this species may cause infections in immunocompromised patients or those with indwelling devices. Conversely, Pseudomonas fluorescens is thought to be a protective skin organism, because it produces the polyketide antibiotic mupirocin (113), which is active against Gram-positive bacteria, including methicillin-resistant S. aureus (108–110, 114). The skin microbiome varies substantially between individuals, and colonizing microbes may produce antimicrobial compounds that shape microbial communities.

REFERENCE STRAIN GENOMES
A critical component of the HMP has been the generation of genome sequences of microbes and viruses that inhabit the human body to create a catalog of reference genomes (115). This catalog serves as a reference data set for metagenomic analyses. Bacterial genome sequences (draft or higher quality) from nearly 5,000 nonpathogenic strains that inhabit the human body have been deposited in the NCBI database, and nearly 2,000 were contributed by the HMP Consortium. The HMP goal is to contribute 3,000 reference genomes (bacterial, fungal, and viral) to the catalog. Community input was sought to nominate strains and isolates for sequencing, and an effort was made to distribute isolates across the five major body sites, although strains from the gastrointestinal tract and oral cavity are overrepresented. These genomes have been added to the comprehensive human microbiome catalog (http://www.hmpdacc.org/catalog/).
The Roche 454 long-tag, paired-end sequencing strategy, originally used by the HMP Consortium for reference genome sequencing, has been replaced by high-coverage (ca. 100× to 400×), short-read sequencing on the Illumina HiSeq platform. Reads are assembled using various assemblers, such as Velvet, ALLPATHs, or the Celera Assembler. Nearly all genome sequences that are currently being deposited are draft WGS sequences that consist of one to dozens of unordered scaffolds. To address the draft nature of these sequences, a set of nomenclature, criteria, and standards for different levels of genome finishing was established (115, 116). The five levels are as follows: (i) standard draft, (ii) high-quality draft, (iii) improved high-quality draft, (iv) annotation-directed improvement, and (v) finished sequence. The levels range from basic assembled contigs (standard draft) to a gold standard complete genome that is assembled into one contiguous piece (finished sequence), has less than 1 error per 100,000 bp, and has all repetitive sequences (including rRNA operons) correctly ordered and placed. Most HMP reference genomes (ca. 70%) are high-quality drafts, defined as having >90% of the genome contained in contigs longer than 500 bp, >90% of the genome covered >5-fold, an average contig length of >5 kb, a contig N50 of >5 kb, and a scaffold N50 of >20 kb.

The HMP Consortium evaluated methods for gene finding using algorithms such as Glimmer (117) and GeneMark (118). Gene calling was established based on evidence from BLAST searches against the NCBI's bacterial nonredundant nucleotide and protein databases and alignments to proteins in the Pfam database (http://pfam.sanger.ac.uk/). An automated annotation pipeline was established using tools such as tRNAscan-SE to identify tRNA genes (119) and Rfam (120) and Pfam (121) to predict noncoding RNA genes. Gene product annotation is based on evidence from programs such as InterProScan (122), PSORTb (123), and KEGG (http://www.genome.jp/kegg/). Uniform protein naming follows Enzyme Commission nomenclature and descriptors suggested by the JCVI Prokaryotic Annotation Pipeline (124).

The utility of the HMP Reference Genomes Catalog was demonstrated by the Human Microbiome Consortium in a read-mapping exercise. A total of 3.5 Tb of Illumina WGS data were generated from 681 microbiome samples from the HMP cohort (5). Following trimming and filtering of human DNA contamination, these reads were aligned to a carefully curated nonredundant reference genome set that contained 2,265 complete and draft genomes plus plasmid sequences that included the sequences of 800 HMP reference genomes (http://hmpdacc.org/HMREFG). In this case, 57.6% of the 35 billion reads were aligned to a reference genome in the HMREFG data set. Furthermore, 26% of these reads could be aligned to one of 223 select HMP reference genomes (5). This result is encouraging, but the coverage is far less than 100%, indicating the importance of continuing reference genome sequencing.

SUMMARY AND CONCLUSIONS

The human microbiome includes a diverse collection of human-associated microbes that represent a small fraction of the total microbial "universe" in other animals, life forms, and the environment. This human microbiome can be defined due to the rapid development of advanced DNA sequencing technologies coupled with bioinformatic strategies. Bioinformatic tools include augmented phylogenetic sequence databases, annotation and genome assembly tools, and refined functional approaches to aggregate sequence data. Metagenomic strategies are being applied to provide glimpses into the variation in microbial composition and function at different body locations and among different individuals.

Future approaches in medical microbiology will be shaped in part by developments in the fields of metagenomics and human microbiome research. The identification of single agents of infection will be supplemented by techniques exploring the relative compositions of microorganisms in the context of different infections and other disease states. Differences in microbial composition that are associated with noninfectious immune-mediated disorders may extend the "reach" of the medical microbiology laboratory into other areas of human medicine in the future. Finally, pathogen discovery efforts (see chapter 16) will be enhanced by new metagenomic strategies, and these studies may uncover single etiologic agents of infections as well as changes in microbial communities at specific body sites that may contribute to infectious diseases.

This work was supported in part by research support from the National Institutes of Health (NIH) (grants R01 AT004326, R01 DK065075, U01 CA 170930, UH3 DK083990, and U54HG004973). We also acknowledge the support of the NIH (grant P30 DK56338) to the Texas Medical Center Digestive Diseases Center.

REFERENCES

In recent years, our understanding of microbial diversity has grown tremendously as many previously unidentified bacterial, archaeal, and viral species have been discovered and sequenced. In the era of the human microbiome and metagenomics (chapter 15), large-scale DNA sequencing projects and advances in bioinformatics have yielded abundant data regarding human-associated microbes. As human microbiology rapidly expands beyond its past framework of cultured pathogens in the medical microbiology laboratory, opportunities for detection and identification of novel human pathogens associated with infectious diseases abound. In this chapter, we focus on specific or defined sets of pathogens associated with human infections, in contrast to microbial components of disease and microbial ecology (topics covered in chapter 15). We begin with an overview of historical methodologies, followed by a brief description of the evolution of nucleic acid sequencing technologies. Finally, we describe how microarrays, nucleic acid sequencing technologies, and mass spectrometry are profoundly reshaping strategies aimed at pathogen discovery and identification. A timeline of these scientific advances is depicted in Fig. 1.

Our ability to visualize human microbes first arose in the 17th century when Anton van Leeuwenhoek created the microscope and observed human-associated bacteria in the human oral cavity, which provided the first physical evidence of the diversity and ubiquity of microbes in the world. Another giant leap occurred in the 19th century when Robert Koch first demonstrated that bacteria could be grown in pure culture, beginning with the analysis of blood from cows infected with the anthrax agent. He subsequently became most widely known for the postulates regarding microbial disease causation that bear his name. For decades following, microbiologic culture and microscopy were the only tools available to directly examine human microbes. In the last 2 decades of the 20th century, however, DNA amplification of consensus rRNA gene sequences and other genetic targets revealed a vast diversity of bacteria, viruses, and other microbes that had eluded cultivation in the laboratory. Today, DNA and RNA sequencing technologies have evolved to the point that it is feasible to comprehensively define the collection of microbes present in humans (i.e., the human "microbiome") or any other ecological niche in a fashion that is independent of microbiologic culture or microscopy.

**A BRIEF HISTORY OF PATHOGEN DISCOVERY**

**Classical Methods**

Classical methods of microbial discovery relied on the ability to culture microorganisms in the laboratory and to directly visualize microbial morphology by microscopy. Body fluid or tissue specimens associated with specific disease phenotypes and considered to be of infectious origin are still used today to inoculate microbiologic growth media and cultivate the microbe(s) present in the sample. In the case of suspected bacterial agents, selective or nonselective growth media can be utilized, and biochemical or serological tests can facilitate identification of cultured isolates. Primary or immortalized human and mammalian cell lines are inoculated for suspected viruses, and viruses have been identified by cytopathic effects (light microscopy), immunological methods (serological reactions based on different antisera), and viral particle morphology (electron microscopy). For pathogen discovery and biomedical research purposes, clinical specimens have been used for decades to infect animal models and prove Koch’s postulates. These classical methods have been very useful and resulted in the discovery of many currently accepted human pathogens; examples include *Bacillus anthracis*, *Mycobacterium tuberculosis*, *Yellow fever virus*, and *Poliovirus*. However, there are two fundamental limitations with conventional approaches: (i) these methods depend on the ability of microbes to grow on media substrates in the laboratory; and (ii) even if the microbe can be cultivated, unknown candidate agents may not be unambiguously identified.

**Molecular Strategies: Pathogen Discovery**

In the 1980s, scientists began to apply DNA amplification technologies to detect microbes present in human specimens if existing knowledge about DNA sequences in microbial genomes could be targeted. The recognition that selecting PCR primers designed to highly conserved regions in a set of sequences (e.g., multiple bacteria or several viruses from a common taxonomic group) could enable the detection of previously unidentified microbes provided a novel approach for the identification of microbes. One of the broadest applications of this technique has been the design of primers to

doi:10.1128/9781555817381.ch16
the conserved 16S rRNA gene, which enables the detection of most members of the bacterial domain depending on the selection of specific primer pairs. Alternatively, more specific primers can be selected that are conserved within a given taxon (family, genus, or species) to identify a targeted set of microbes. The ability to design highly conserved primers depends on the existence of sufficient amounts of DNA sequencing data, and recent advances in the Human Microbiome Project have contributed greatly to a refinement of primer selection and amplification strategies for bacterial genera and species. Different microbes have been discovered by using PCR in conjunction with the classical methods of microbial detection. With the advent of Sanger sequencing, entire 16S rRNA genes could be sequenced, including the Escherichia coli 16S rRNA gene in 1978 (1).

Relman and coworkers described the first examples of using consensus PCR primers to identify the causative agents of specific human diseases. Bacillary angiomatosis was commonly considered to be infectious in origin. A putative agent could be visualized in tissue sections following staining,
but efforts to culture the organism had failed. Amplicon sequencing using 16S rRNA gene consensus primers demonstrated that a previously uncharacterized rickettsia-like bacterium was present in tissue samples of patients with bacillary angiomatosis (2). The bacterium was identified as a member of the genus *Bartonella*. A similar approach was subsequently applied to address the etiology of Whipple’s disease. Whipple’s disease was first described in 1907 as a rare systemic disorder that primarily caused malabsorption but could affect any part of the body. Consensus PCR using primers targeting bacterial 16S ribosomal genes resulted in the identification of an uncharacterized actinomycete, which was classified as *Tropheryma whippelii* (3). These two cases demonstrated the power of molecular pathogen discovery methods.

Conserved PCR primers and nucleic acid probes have been applied to virus discovery. However, since no universally conserved sequence akin to 16S rRNA sequences in bacteria is present in all viruses, different consensus nucleic acid sequences must be identified for different classes of viruses and consensus primers designed for each viral taxon of interest. A seminal example of using consensus PCR to identify a viral pathogen occurred during the emergence of hantavirus pulmonary syndrome in 1993 (4). In the course of investigating an unusual outbreak of a lethal pulmonary disease in otherwise healthy young adults in the southwestern United States, extensive testing by classical microbiological methods ruled out the most likely candidates known to cause severe respiratory disease. Serological tests revealed that patient sera were cross-reactive with known hantaviruses. PCR primers were designed to conserved regions of known hantavirus sequences, which were then used to amplify nucleic acids extracted from tissue samples isolated from dying patients. Sequencing of the amplicon generated by the primers resulted in the identification of a novel member of this family, which was ultimately named *Sin Nombre virus*.

Since these seminal applications of consensus PCR for the identification of bacterial and viral pathogens, many applications of nucleic acid amplification for pathogen discovery have been published. Consensus PCR, either alone or in conjunction with microbiologic culture, microscopy, and antigen detection methods, has been used to detect novel microbes, as illustrated by the recent discoveries of new groups of rhinoviruses (5–9), parechoviruses (10–15), *Chapare virus* (arenavirus) (16), *Bundibugyo ebolavirus* (arenavirus) (17), the Middle East respiratory syndrome coronavirus (18), and an entirely new bacterium associated with cord colitis syndrome (19). However, broad-range PCR strategies often failed to identify a specific infectious agent. In these examples, the authors had robust hypotheses regarding the nature of the microbes of interest (i.e., bacterium versus virus) or which specific candidate viral taxon might be present. Often, leading candidates or phylogenetic groups of interest may not be apparent, limiting the application of specific molecular strategies. Outside of the bacterial kingdom, the relative paucity of consensus probes or primers for archaea, eukaryotic microbes, and viruses emphasizes the limits of targeted molecular strategies. For these reasons, more comprehensive genomics-based strategies have been applied to pathogen discovery and in-depth characterization.

**Early Applications of Microbial Genomics: Pathogen Discovery**

The discoveries of *Hepatitis C virus* (HCV) and *Human herpesvirus 8*, also named Kaposi’s sarcoma-associated herpesvirus, represented two breakthroughs in the application of genomics-based molecular methods for pathogen discovery. In 1989, the identification of HCV in patients with non-A, non-B (NANB) hepatitis relied on a DNA library-based immunoscreening strategy (20). A randomly primed cDNA library was made from material from infected animals and screened using patient serum from NANB hepatitis patients with the goal of identifying cDNA clones that generated peptide sequences recognized by the patient sera. More than 1 million clones were screened, and a single clone reacted specifically with NANB hepatitis patient sera. From this initial cDNA clone fragment, the entire HCV genome was eventually sequenced. HCV is now recognized as being responsible for the vast majority of cases of NANB hepatitis. In 1994, human herpesvirus 8 was discovered in the lesions of AIDS-associated Kaposi’s sarcoma (21). The identification of Kaposi’s sarcoma-associated herpesvirus relied on representational difference analysis, a subtractive hybridization-based method, to enrich for and identify unique sequences present in Kaposi’s sarcoma lesions but not in healthy tissue controls. While these two examples demonstrated the potential utility of early genomics-based strategies, subsequent success stories were rare, most likely due to the technical challenges associated with first-generation genomics-based strategies.

By the end of the 20th century, classical microbiologic culture-based methods for microbial discovery had been augmented by early molecular and genomics-based strategies, such as consensus PCR, library immunoscreening, and representational difference analysis. In parallel, reference genome sequencing of specific microbes was becoming feasible, setting the stage for the convergence of pathogen discovery and microbial genomic sequencing efforts. Further developments in genomics-based strategies were needed to advance pathogen discovery in the 21st century.

**RECENT HISTORY OF MICROBIAL GENOMICS**

Microbe sequencing in the 20th century relied exclusively on Sanger dideoxy sequencing, the dominant sequencing strategy since its invention in 1977. From its initial incarnation using slab-gel electrophoresis, incremental advances in sequencing capacity evolved as sequencing transitioned to capillary electrophoresis.

Formally, the era of microbial genomics began with the complete sequencing of the *Haemophilus influenzae* genome in 1995. However, it was recognized almost 2 decades earlier that an organism’s genomic sequence could serve to classify and define the relatedness of both prokaryotic and eukaryotic organisms (22). When the *H. influenzae* genome was sequenced, this bacterium became the first free-living organism to have its genome sequenced in its entirety (23). This was a landmark achievement, notable also because of the use of a “shotgun” strategy to assemble the complete genome. “Shotgun” refers to the random fragmentation and cloning of DNA fragments followed by computational assembly of the overlapping regions to generate a complete genome sequence. Based on this proof of principle, genomes of larger microbes and eukaryotic organisms were subsequently sequenced. The following year, *Saccharomyces cerevisiae* was the first eukaryotic organism to be fully sequenced (24), and then in 1998, the first multicellular eukaryotic genome to be sequenced, that of *Caenorhabditis elegans*, was published (25). Since then, the complete genomes of many human and animal pathogens have been sequenced, including notable pathogens such as *M. tuberculosis* (26), *Yersinia pestis* (27), and *Plasmodium falciparum* (28). In 2004, the complete 1.2-
microbial genera, the largest known virus, was published (29).

Next-generation DNA sequencing modalities have revolutionized the depth and throughput of sequencing applications in medical microbiology. Three major platforms in current use are 454 (454 Life Sciences, a Roche Company, Branford, CT), HiSeq and MiSeq (Illumina, San Diego, CA), and Ion Torrent/PGM (Life Technologies, Carlsbad, CA). Key characteristics of these platforms include the fact that all of them have exponentially increased the raw sequence generation capacity and dramatically decreased the cost per base relative to Sanger sequencing. For a more detailed description of each of these platforms and capabilities, see reference 30. With these increases in sequencing capacity, the sequencing of microbial genomes has become routine. Next-generation DNA sequencing platforms have enabled scientists to comprehensively explore the microbial diversity of the human microbiome and the viral diversity, the "virome," present in humans (see chapter 15). These efforts have vastly expanded the world of sequenced microbes, and sequences have been deposited in various databases (e.g., http://www.ncbi.nlm.nih.gov/genome/ and http://hmpdacc.org).

THE MERGING OF PATHOGEN DISCOVERY AND MICROBIAL GENOMICS

The fields of pathogen discovery and microbial genomics have converged in the past 2 decades so that more pathogens can be detected and identified (Fig. 1). Two basic molecular approaches for massively parallel analysis have recently emerged that are capable of defining the spectrum of microbes present in clinical specimens: microarrays and sequencing-based detection. Both strategies benefited greatly from the increased focus on human and microbial sequencing. Multiple databases of nucleic acid sequences provide the substrate from which consensus PCR primers for sequencing applications and probes for microarrays have been designed. DNA sequencing-based approaches have evolved rapidly in the past decade and have resulted in next-generation DNA sequencing pipelines for pathogen discovery and detection. As sequencing technologies are rapidly supplanting microarray-based hybridization strategies, microarrays continue to represent a useful option for bacterial and viral detection. Data analysis or bioinformatics tools and pipelines are also being refined to meet the challenge of genomics and "big data" in the clinical laboratory, whether the data are generated by microarray or sequencing platforms.

Microarray-Based Approaches

Microarrays were initially developed in the early 1990s to analyze gene expression patterns of a single organism in a highly parallel fashion. For example, early studies analyzed every gene present in the yeast S. cerevisiae (31). Regardless of the technical format, the fundamental principle driving all microarrays is that of nucleic acid hybridization. If a given sample contains sequences that are complementary to those represented on the array, hybridization should occur. Thus, the target sequences to be detected by a given microarray are limited only by the availability of DNA sequences from which probes can be designed. As DNA microarray technology evolved in the late 1990s, it became clear that microarrays might make excellent microbial diagnostic tools. The inherently highly parallel nature of microarrays, coupled with the expanding amount of microbial sequencing data, made it possible to design microarrays with the capacity to simultaneously detect a wide range of microbes.

The first significant effort to develop a microarray for broad-range pathogen identification focused on detecting all known respiratory viruses (32). This microarray contained 600 oligonucleotide probes representing ~140 virus families from all virus families with members known to cause respiratory disease. A more comprehensive array, the ViroChip, was designed using 70-mer oligonucleotides derived from every fully sequenced viral genome in GenBank at the time (33). The oligonucleotide probes selected were highly conserved 70-mers from each viral taxon, allowing the detection of known and unknown family members through cross-hybridization. Following the random amplification of extracted nucleic acids, samples are labeled with fluorescent dyes (typically Cy3 or Cy5). The resulting hybridization patterns on the microarray can be interpreted to infer the presence or absence of known or novel viruses. A variety of approaches for microarray data analysis, including visual inspection, hierarchical clustering (34), and several customized bioinformatics programs, such as GreenelAMP (35), E-Predict (36), DetectiV (37), PhyloDetect (38), and VIPR (39) and VIPR HMM (40), have been developed.

The ViroChip was successfully utilized to identify a novel coronavirus as the causative agent for the severe acute respiratory syndrome outbreak in 2003 (33, 41, 42). Other broad-range DNA microarrays, in addition to the ViroChip, have been described. GreenelChip, a pan-microbial microarray that contains probes for viruses, bacteria, and parasites (35), has been successfully used in a variety of diagnostic scenarios to detect known or unexpected viruses (43–47). Lawrence Livermore Microbial Detection Array is a high-density microarray that contains target probes against every bacterium and virus whose full genome sequence was available at the time of development (48, 49). This array, in combination with multiple displacement amplification-based whole-genome amplification via isothermal amplification by the φ29 polymerase, was successfully used to detect the presence of many DNA and RNA viruses in various types of clinical specimens (50). PathChip is another pathogen microarray option that utilizes random-tagged PCR prior to hybridization, and has been used to identify viral pathogens in nasal wash specimens collected from pediatric patients with respiratory tract infections (51). DNA microarrays can also be used for subtyping of viruses such as influenza A (52).

On the bacterial front, microarrays with probes targeting detection of 16S rRNA gene sequences have been developed to define the bacterial diversity present in a given sample. The PhyloChip, a high-density 16S rRNA gene microarray containing ~300,000 probes, was used to examine microbial diversity in three environmental samples, including urban aerosol, subsurface soil, and subsurface water (53). This study demonstrated that this DNA microarray could reveal a broad range of microbial diversity. A second microarray containing 10,500 probes, including 9,000 taxonomically specific probes targeting the 16S rRNA gene, was used to perform a systematic and quantitative study of bacterial colonization in the infant gastrointestinal tract (54). These microarray results compared favorably with data generated by sequencing-based techniques, demonstrating the utility of microarrays. Microarray-based assays have been successfully utilized to identify bacterial pathogens in several types of infections, such as bacteremia (55–57), genitourinary infections (58, 59), and infectious diarrhea (60).

Fungal identification strategies by microarrays have utilized targets such as the 28S rRNA gene and internal transcribed spacer regions within rRNA gene clusters. Microarray technology has been used to identify common fungal
pathogens in humans, including microbes in the genera Aspergillus, Candida, and Fusarium (61, 62).

DNA microarrays aimed at microbial diagnostics have benefited immensely from the genomics era, which has spawned a wealth of microbial sequences available in public DNA databases. As demonstrated by successful examples using the ViroChip, microarrays can be a robust platform for virus and pathogen discovery. However, a clear limitation of all hybridization-based strategies for pathogen discovery, including DNA microarrays, is that sequences must be known and well characterized. DNA sequencing strategies, by contrast, offer a relatively open-ended strategy for pathogen discovery that does not rely on the development of specific probes in advance. The data generated by DNA sequencing platforms can be used as virtual “probes” with DNA databases for identification of unexpected pathogens.

**Sequencing-Based Approaches**

Pathogen discovery and microbial sequencing techniques merged with the discovery of Human metapneumovirus (HMPV) in 2001, which combined classic viral culture with a molecular strategy, termed random arbitrarily primed PCR (63). Efforts to culture respiratory secretions from children suffering respiratory tract infections led to the identification of a putative unidentified virus that could be passaged in several mammalian cell lines. Arbitrary primers were used to generate PCR amplicons, and those amplicons that were uniquely present in infected cells were selectively sequenced by Sanger sequencing methods. Multiple fragments having limited sequence identity to avian pneumoviruses were detected, indicating that a novel virus, now known as HMPV, was present in the infected cells. Seroprevalence studies indicated that by the age of 5 to 10 years, most individuals were antibody positive, suggesting that this virus is a common infection acquired in childhood. HMPV can cause severe respiratory infections similar in presentation and case severity to respiratory syncytial virus, including pneumonia and bronchiolitis, and is responsible for 5 to 10% of hospitalizations of patients with respiratory tract infections (64).

In the same year, a candidate independent sequencing strategy for identification of novel viruses, termed DNase-SISPA, was described (65), and it was the methodological basis for discovering novel viruses for nearly a decade. The experimental strategy relied on sequence-independent single primer amplification (SISPA), wherein an adaptor containing a primer-binding sequence is ligated to both ends of a cDNA fragment and a single primer is then used for PCR. To enrich specifically for viral nucleic acids present in virions, the clinical specimen is first subjected to ultracentrifugation to collect the virions, which are subsequently treated with DNase to degrade any cellular nucleic acids that are not protected within the viral capsids. Following this enrichment, the sample is extracted for DNA or RNA and amplified using SISPA. The enrichment steps in this protocol are necessary to increase the chances of sequencing a virus-derived sequence, given the labor and costs of performing extensive Sanger sequencing on the unenriched sample. In this proof-of-concept study, two novel bovine paroviruses were identified (65). DNase-SISPA and variations of this method were successfully applied to discover many potentially pathogenic viruses with low sequence homology to known viruses during the next several years (Table 1). The identification of these novel viruses highlights the utility of DNA sequencing for viral detection.

Advances in virus discovery continued with the combination of DNase-SISPA-based methods and high-throughput Sanger sequencing. Human bocavirus (HBoV) was discovered in 2005 (66) from respiratory secretions pooled from multiple patients with an unexplained respiratory illness. Amplicons of 600 to 1,500 bp were cloned and sequenced using high-throughput Sanger sequencing with one 384-well plate. Phylogenetic analysis demonstrated that this novel genome is a previously uncharacterized species of the genus Bocavirus, HBoV. Subsequent studies of this virus have demonstrated that HBoV is frequently detected in children with respiratory tract infections, children with asthma exacerbations, and children with acute gastroenteritis. Seroprevalence studies have confirmed infection in a Japanese cohort, with 71.1% overall prevalence with exposure by age 6 (67), while a second study in Sweden reported a lower rate, 33%, in a cohort of children with acute wheezing (68). The application of the same method with multiple specimen types resulted in the discovery of several novel viruses that have yet to be confirmed as pathogens (see Table 1). These discoveries demonstrate that sequence-independent amplification followed by limited Sanger capillary sequencing (typically ≤384 clones) is a robust method for identification of novel viruses present in clinical specimens.

The advent of next-generation sequencing (NGS) technology increased the sequencing depth of specimens, allowing for detection of microbes present at lower titers as well as facilitating the generation of complete genomes of novel microbes. The 2008 discovery of Merkel cell polyomavirus (MCPyV) was the first study describing the identification of a novel virus using NGS on the Roche 454 FLX platform (69). In this instance, cDNA libraries made from Merkel cell carcinoma tumors were sequenced, and from the ~382,000 high-quality sequence reads generated, one fragment had detectable sequence similarity to a known polyomavirus. Further analysis demonstrated that a highly divergent polyomavirus genome, that of MCPyV, was present in the majority of the Merkel cell carcinoma tumors examined. Subsequent studies have corroborated this finding, and subsequent mapping of integration sites demonstrated that the virus was clonally integrated in the respective tumors. Given the very low abundance of MCPyV mRNA sequences in these samples, the detection of viral transcripts would not have been possible without the use of the next-generation platform, which enabled deep sequencing of the specimens in a cost-effective manner. For other novel tumor-associated viruses that have been identified using NGS technology, see Table 2.

NGS by 454 FLX has played a pivotal role in defining the etiology of several unexplained infectious illnesses. The first was a mysterious case cluster of five patients with undiagnosed hemorrhagic fever (70). RNAs from two postmortem liver biopsy samples and one serum sample were randomly amplified and sequenced, and the analysis of ~300,000 sequences yielded nine fragments with limited sequence similarity to viruses in the genus Arenavirus. Phylogenetic analysis of the novel Lujo virus demonstrated that it branched from the Old World arenavirus complex and had the greatest similarity to Mobala virus, Lassa fever virus, and Tamiami virus, with 67 to 74% amino acid identity in the nucleoprotein. Further examination of the receptor-binding domain of G1 demonstrated that Lujo virus is equally distant from the Old World and New World arenaviruses. Other elusive etiologic viral agents of unexplained gastroenteritis have recently been identified using 454 FLX, and they are summarized in Table 2.
Sequencing-based discovery of novel bacterial pathogens can be performed by sequencing specific gene targets or using a combination of whole-genome shotgun sequencing (WGS) and a range of data analysis tools. These tools may be applied to the assembly and analysis of bacterial genomes from either pure culture or patient specimens. A workflow for implementing bacterial WGS-based molecular diagnostics is depicted in Fig. 2. In 2013, a novel species of *Bartonella* was identified from a patient with chronic bartonellosis by combining culture methods, PCR amplification, and Sanger sequencing of three gene fragments important for speciation. Blazes et al. targeted the *rrs*, *gltA*, and *rpoB* genes, and based on sequence analysis using BLAST, ClustalW, and MEGA5 software, they showed that the sequence similarities to other known *Bartonella* spp. were below the standard similarity ranges for *Bartonella*, and identified this novel isolate as “*Candidatus Bartonella ancashi*” (71). In the same year, Bhatt et al. (19) applied WGS to DNA isolated from formalin-fixed, paraffin-embedded biopsy specimens from patients with cord colitis in an effort to identify a novel etiologic agent for the disease. Previous theories for the etiology of cord colitis assumed it was a manifestation of graft-versus-host disease as opposed to a distinct clinical syndrome. Their efforts resulted in the identification of a novel bacterial draft genome, *Bradyrhizobium enterica*, which was absent from control specimens and associated with all cord colitis specimens they analyzed (Fig. 3). NGS has also been applied to areas of molecular epidemiology and pathogen emergence. In 2011, Wright et al. (72) used NGS to quickly complete the whole-genome characterization of an anthrax-like agent within days of its recovery from antemortem cultures. The etiologic agent was determined to be *Bacillus cereus*, not *B. anthracis*. Rapid genome sequencing and analysis of the causative agent of this fatal,

anthrax-like pneumonia effectively determined the etiology of the infection. WGS was first applied as a genome-based molecular epidemiological tool in 2013. Roetzer et al. (73) assessed WGS-based genotyping as a means to track the spread of M. tuberculosis in a metropolitan area and follow its decade-long clonal expansion to determine the short-term evolution of the M. tuberculosis genome. The results showed that genotyping of an M. tuberculosis outbreak using WGS methods was more robust than conventional methods like IS6110 restriction fragment length polymorphism, spoligotyping, and mycobacterial interspersed repetitive-unit–variable-number tandem repeat typing, which examine <1% of the genome. Through these efforts, Roetzer and colleagues were able to identify a large outbreak and trace the transmission and evolution of an M. tuberculosis clone of the Haarlem lineage. Additionally, WGS has been used to investigate the emergence of hypervirulent and invasive group A Streptococcus (GAS) strains in a single human host. Flores et al. (74) analyzed genome sequences generated on the MiSeq platform (Illumina) of paired noninvasive and invasive GAS isolates from a patient with a skin/soft tissue infection. Whole-genome comparisons of these paired isolates showed that emergence of an invasive GAS phenotype originated from mutations that countered the established paradigm and enhanced the importance of understanding the molecular evolution of pathogenicity. Having the ability to apply NGS to molecular epidemiology and pathogen evolution could significantly enhance our ability to effectively manage and control public health threats.

Studying historical pathogens can provide scientists with important information to counteract potentially disastrous outbreaks. To sequence the 1918 influenza virus, cDNA libraries were made from highly degraded RNA isolated from nearly century-old, formalin-fixed and paraffin-embedded lung tissue. The whole genome of the 1918 pandemic influenza A virus was sequenced at 3,000-fold coverage in a single run using the Illumina Genome Analyzer IIx platform (75). This strategy represented a significant advance over the first sequencing attempt, which took ~9 years using Sanger methods (76). Both 454 and SOLiD NGS methods have been used to identify a previously unknown family of mobile genetic elements, the transpovirons (77). The transpovirons are linear mobile genetic elements that infect large viruses, contain genetic elements similar to virophages, and contribute to the evolution of large DNA viruses and interviral gene transfer. Additionally, high-throughput sequencing methods have been used to identify bacterial defense mechanisms, or toxin-antitoxin gene pairs, against bacteriophages. WGS of 1.5 million genes on a Sanger platform aided in the identification of hundreds of toxin-
antitoxin pairs important for neutralizing the effects of bacteriophage toxins (78). Phage display is extremely useful in identifying protein-protein interactions between unknown factors, but has historically been very labor-intensive. The application of NGS to phage display has enabled the analysis of phage libraries to increase from hundreds of clones to thousands or more. The HiSeq/MiSeq (79–82) and 454 (83–85) platforms have been successfully applied to phage display. Additionally, NGS methods have been combined with other methods like proteomics and metabolic modeling to study clinically relevant pathogens like Listeria monocytogenes (86), Helicobacter pylori (87), and Francisella tularensis (88). The application of NGS techniques to these areas of interest can provide timely and valuable information with regard to emerging and reemerging pathogens.

NGS platforms have created the burden of analyzing extremely large data sets ("big data"), which has resulted in the demand for innovation in bioinformatics and data analysis tools. A major impetus for bioinformatics tool development resulted from the generation of massive quantities of sequencing data by the Human Microbiome Project (89). Bioinformatics tools were developed using an open-source software pipeline, QIIME (Quantitative Insights Into Microbial Ecology) (90). The QIIME workflow can process millions of sequences, conduct sequence alignments and phylogenetic comparisons, and provide graphical displays that can be used on platforms ranging from laptops to high-performance computing clusters. In an effort to control or predict outbreaks of emerging or reemerging pathogens, scientists have developed data analysis tools that act as surveillance mechanisms for predicting potential species crossovers and dominant influenza strains. Two automated data analysis platforms have been developed for identifying novel pathogens from long-read NGS platform data, VirusHunter (91) and PathogenFinder (92). VirusHunter enables the automated mining of Roche 454 and other long-read NGS platform data to identify novel viruses, while PathogenFinder works to predict bacterial pathogenicity from NGS data. Batch-Learning Self-Organizing Map (BLSOM) (93) is an analysis tool that has been applied to track sequence changes in influenza virus genomes after viruses invaded human hosts from other mammalian or avian hosts. This analysis tool is capable of surveying millions of genomic sequences to identify potentially novel influenza A and B strains. In addition to these newly developed pipelines, there are preexisting well-known alignment algorithms (BLAST, BLAT, BWA, BWA-SW, BWA-MEM, BFAST, Bowtie2, Novoalign, GSNAP, SHReMP2, and STAR) that can be used to characterize DNA or RNA sequences from NGS data, and these tools have recently been evaluated for their accuracy at identifying divergent viral sequences (94). Researchers have surveyed viral metagenomic sequence data from bat specimens, an important reservoir for emerging pathogenic viruses, using BLAST analysis tools and have discovered several novel viruses (Table 2) that could potentially pose a zoonotic health threat (95–97). When considering the ability to sequence century-old genomes and to perform comprehensive molecular surveillance with DNA sequencing data, NGS provides opportunities for advancing diagnostic microbiology in the era of genomics and metagenomics.

**ASSESSING THE ROLE OF PATHOGENICITY**

A broad range of microbial diversity is being uncovered, and many more microbes remain to be discovered. The pace at which new microbes (and viruses in particular) in clinical specimens are being discovered is growing exponentially.

The challenge that faces the scientific community is defining the relevance of the growing list of new microbes to human infections. In 1890, Robert Koch published a set of postulates in an attempt to standardize the evidence needed to demonstrate a causal role for a microbe in a disease (98). Koch’s postulates are well known to this day and, despite being more than 100 years old, still serve as guidelines for proof of causality. They are as follows.

1. The parasite occurs in every case of the disease in question and under circumstances which can account for the pathological chances and clinical course of the disease.
2. The parasite occurs in no other disease as a fortuitous and nonpathogenic parasite.
3. After being fully isolated from the body and repeatedly grown in pure culture, the parasite can induce disease anew.

A major challenge in the fulfillment of Koch’s postulates, especially in a molecular era, is that many microbes cannot be grown in pure culture. Another limitation is that microbes that have either a carrier state or can cause subclinical infections, such as Neisseria meningitidis and M. tuberculosis, violate Koch’s postulates. Other scenarios that limit the applicability of Koch’s postulates include cases in which coinfection with more than one microbe causes disease or situations in which the host genetic background contributes to the disease state.

Koch’s postulates have been reconsidered in various publications. Bradford Hill (99) and Alfred Evans (100) proposed broader criteria for causation, including epidemiological and immunological data. Most recently, a guide for disease causality that accounts for molecular methods of microbial detection has been proposed by Fredericks and Relman (101). These revisions of Koch’s postulates have remained focused on the traditional concept that disease arises from the presence of a foreign microbe (and the biological consequences of its presence). However, in the genomics era, the concept of a “pathogen” and how it causes disease must be reimagined in the 21st century. With the advent of the Human Microbiome Project (89), we have learned about the intricate relationships between human hosts and the complex microbial communities that reside within them. The human intestinal microbiome contains sets of genes encoding core microbial functions and stable microbial communities contributing to the function and integrity of the gastrointestinal tract. Perturbations of the composition of microbial communities, known as dysbiosis, may result in increased susceptibility to infectious diseases (102). With this observation, it is possible that some “diseased” states may result from disruptions in the microbiome. The pathogenesis of a particular disease may involve more than just the presence of a pathogenic microbial species, and may include intrakindom interactions between microbes and interkingdom interactions between microbes and host. Scientists have begun to elucidate the complex role of microbial communities in several disease states such as obesity (103), inflammatory bowel disease (104), autoimmunity (105), and atopy (106) by comparative analysis of the microbiomes of healthy and diseased populations.

With the advancement of NGS technologies and the large amounts of data generated by each sequencing run, careful consideration must be taken before reporting a microorganism as the cause of infection in a particular case. When analyzing data from WGS or metagenomic studies, the presence of genetic elements associated with virulence does not identify a microorganism as an etiologic agent in an infection. To determine the pathogenicity of an organism or virulence factors identified by metagenomic analyses,
several important factors such as site of specimen collection, host status, and clinical presentation must be carefully examined (107, 108).

CONCLUSIONS
Since the era of the microbe hunters in the late 19th and early 20th centuries, mankind has been interested in the discovery and eradication of human pathogens. Traditional microbiologic techniques that relied substantially on laboratory cultivation have been supplanted in part by molecular methods including nucleic acid amplification and sequencing. Advances in microarrays and nucleic acid sequencing culminated in many discoveries of previously uncultured pathogens. Microbial genomic sequencing has yielded a refined understanding of molecular epidemiology of various pathogens, and has assisted with the refined stratification of viral and bacterial pathogens. NGS strategies have been applied to diagnosis of infections in real time in the clinical laboratory (72, 109), and such applications are expected to grow, especially in reference and public health laboratory settings (110). The ability to rapidly scan complex collections of microbial and viral genetic information for compositional and functional information will continue to profoundly impact our understanding of pathogenesis and the development of new diagnostic tests in this era of metagenomic medicine.

A hitherto undetected similarity exists between Lewis Carroll’s Alice and taxonomists, and bacterial taxonomists in particular. Alice lived (or dreamed) in a world of fantasy in which the eating or drinking of various delicacies gave her the ability to magnify or minimize characters, and she not only upset preconceived ideas of relationships but also disturbed the significance or importance attached to hereditary factors (such as monarchy) and the normal (as distinct from the decapitate) state of the whole organism. Taxonomists also seem to do these things, though they do not need to bite mushrooms or drink magical concoctions in the laboratory. Like the people of Wonderland they tend to be argumentative, and one taxonomist seldom sees a problem through the same spectacles (whether rose tinted or not) as his colleagues. Again like Alice, the taxonomist makes an individual approach to the world around him, and while each is extremely conservative in his views about bacteria, he is by inclination a radical if not an anarchist, and an opportunist if not a dreamer.

With these words, S. T. Cowan introduced a sparkling essay on bacterial taxonomy in 1970 (1). His contributions to the practice of bacterial taxonomy, written in the 1960s and 1970s (1–3), should be read by everyone interested in this field, also now that genomics has moved the species concept from obscurity into the spotlight of microbiology’s highest-impact journals (4–7). “Taxonomy” is generally considered a synonym of “systematic” and is traditionally divided into classification (the orderly arrangement of organisms into taxonomic groups on the basis of similarity), nomenclature (the labeling of the units), and identification (the process of determining whether an unknown belongs to one of the units defined). It is generally accepted that bacterial classification should reflect as much as possible the natural relationships among bacteria. For a long time, these were considered the phylogenetic relationships as encoded in highly conserved macromolecules such as 16S or 23S rRNA genes (8), but nowadays, whole-genome comparisons offer new and exciting opportunities for the study of these natural relationships. Boundaries are nevertheless made by humans, and every classification of bacteria is artificial. Classification serves very practical purposes, i.e., recognition of organisms that were encountered previously and categorization of new ones into a logical and tractable system. In this era of whole-genome sequence analysis, it is more than ever obvious that the genomes of microbes undergo change, sometimes considerably. Although the extent of lateral gene transfer (LGT) is controversial, it does not alter our need to identify organisms, particularly in the context of epidemiological studies and surveillance, as identification yields a tremendous amount of accompanying information. Science indeed has a way of making itself useful, and the useful application of classification is identification (2).

CLASSIFICATION OF BACTERIA

Early classification systems used mainly morphological and biochemical criteria to delineate the species of bacteria. This type of classification was monothetic, as it was based on a unique set of characteristics necessary and sufficient to delineate groups. These early classification systems were replaced by theories of so-called natural systems, which were the phenetic and phylogenetic classifications. In the former, relationships between bacteria were based on the overall similarity of both phenotypic and genotypic characteristics. Phenetic classifications demonstrate the relationships among organisms, as they exist without reference to ancestry or evolution. In phylogenetic classifications, relationships are described by ancestry, not according to their present properties.

Special-purpose and general-purpose classification systems are the main categories of classification systems. Special-purpose classification systems are objectively determined and do not fit a preconceived idea. For instance, the separation between the very closely related species Escherichia coli and Shigella dysenteriae or between Bordetella pertussis and Bordetella bronchiseptica does not conform to the general ideas of present-day species delineation but fits primarily a practical and historical purpose. Yet, nowadays, most taxonomists favor a general-purpose classification system that is stable, objective, and predictive and that can be applied to all bacteria. The classifications obtained with a general-purpose classification system do not fit a single purpose but attempt to reflect the natural diversity among bacteria. The best way to generate such general-purpose classifications is by combining the strengths of both phenetic and phylogenetic studies, a practice nowadays often referred to as polyphasic taxonomy (9).
Criteria for Species Delineation

The criteria used to delineate species have developed in parallel with technology. The early classifications were based on morphology and biochemical data. When evaluated by means of our present views, many of these early phenotype-based classifications generated extremely heterogeneous assemblages of bacteria. Individual species were characterized by a common set of phenotypic characters and differed from other species in one or a few characters that were considered important. The introduction of computer technology allowed comparison of large sets of characteristics for large numbers of strains, forming the basis for phenetic taxonomy. Such numerical analyses of phenotypic characters yielded superior classifications in terms of objectivity and stability. Yet the principles and practices of numerical taxonomy, whereby taxa are classified from comparisons of large strain sets using large numbers of equally weighted features, have largely been abandoned (10). Gradually, chemotaxonomic and genotypic methods were introduced into classification systems. Numerous different chemical compounds were extracted from bacterial cells, and their suitability for use in the classification of bacteria and the definition of species has been analyzed (11).

In 1987, the Ad Hoc Committee on Reconciliation of Approaches to Bacterial Systematics (12) stated that taxonomy should be determined phylogenetically and that the complete genome sequence should therefore be the standard for species delineation. Whole-genome DNA-DNA hybridization analysis was the best approach to the sequence standard for several decades and represented the best applicable procedure. A bacterial species was defined as a group of strains, including the type strain, that share 70% or greater DNA-DNA relatedness, with a \( T_m \) of 5°C or less (\( T_m \) is the melting temperature of the hybrid, determined by stepwise denaturation; \( \Delta T_m \) is the difference in \( T_m \) [in degrees Celsius] between the homologous hybrid and the heterologous hybrid formed under standard conditions) (12). This species definition was based on a large amount of empirical data, including both DNA-DNA hybridization data and other characteristics. The designated type strain of a species serves as the name bearer of the species and as the reference specimen. It was also recommended that phenotypic and chemotaxonomic features should agree with this definition. Preferentially, several simple and straightforward tests should endorse the species delineation based on DNA-DNA hybridization values. Groups of strains that were delineated by means of DNA-DNA hybridization studies as distinct species but that could not be distinguished by phenotypic characteristics should not be named.

The Polyphasic Species Concept

A wide variety of cellular components have been used to study relationships among bacteria and to design classifications (13). The information present at the DNA level has been analyzed by estimations of the DNA base composition and the genome size, whole-genome DNA-DNA hybridization, restriction enzyme analysis, and, increasingly more often, direct sequence analysis of various genes. rRNA fractions have been studied intensively, particularly because they serve as phylogenetic markers. Various chemical compounds, including fatty acids, mycolic acids, polar lipids, polysaccharides, sugars, polyamines, and respiratory quinones, as well as, again, a tremendous number of expressed features (data derived from, e.g., morphologic, serologic, and enzymologic studies), were all used to characterize bacteria (11, 14). Several of these approaches have been applied to taxonomic analyses of virtually all bacteria. Others were performed with a limited number of organisms because they are laborious, time-consuming, or technically demanding or because they were relevant only for a particular group.

The term "polyphasic taxonomy" was coined by Colwell (15) in 1970 and described the integration of all available genotypic, phenotypic, and phylogenetic information into a consensus type of general-purpose classification. It departs from the assumption that the overall biological diversity cannot be encoded in a single molecule and that the variability of characters is group dependent; it integrates several generally accepted ideas for the classification and reclassification of bacteria. Polyphasic taxonomy is phylogeny based and uses sequence analysis and signature features of rRNA for the deduction of a phylogenetic framework for the classification of bacteria (5, 9). The next step in the process of classification is the delineation of individual species—and other taxa—within these phylogenetic branches. Despite its drawbacks, DNA-DNA hybridization still forms the cornerstone of species delineation. However, the threshold value for species delineation should be allowed variation. This polyphasic approach is pragmatic; for instance, B. pertussis, Bordetella parapertussis, and B. bronchiseptica, which share DNA-DNA hybridization levels of >80%, are considered three distinct species because they differ in many phenotypic and chemotaxonomic aspects (16). It is essential that the boundaries of species demarcation be flexible in order to achieve a classification scheme that facilitates identification.

The application of numerous other types of analyses of genotypic, chemotaxonomic, and phenotypic characteristics of bacteria to the delineation of bacteria at various hierarchical levels represents the third component of polyphasic taxonomy (9). The goal is to collect as much information as possible and to evaluate all results in relation to each other in order to draw useful conclusions. An additional advantage is that once the taxonomic resolution of these approaches has been established for a particular group of bacteria through the analysis of taxonomically well-characterized strains, they may be used as alternative tools to identify new isolates at different taxonomic levels. It should be noted that the resolution of these alternative methods is often group dependent. For instance, cellular fatty acid analysis is useful for the accurate identification of strains of many bacterial species to the species level. In certain bacterial groups, however, the cellular fatty acid profile may be indicative of the genus or a group of phylogenetically related genera but not of a particular species within one of these genera.

The contours of a polyphasic bacterial species are obviously less clear than the ones defined by Wayne et al. (12), and this lack of a rigid definition has been contested, as it allows too many interpretations (10, 17, 18). Polyphasic classification is empirical and contains elements from both phenetic and phylogenetic classifications. There are no strict rules or guidelines, and the approach integrates any significant information on the organisms, resulting in a consensus type of classification. In this respect, its main weakness is indeed that it relies on common sense to draw its conclusions. The bacterial species appears as a group of isolates in which a steady generation of genetic diversity resulted in clones characterized by a certain degree of phenotypic consistency, by a significant degree of DNA-DNA hybridization, and by a high level of 16S rRNA sequence similarity.
The species is the most important and, at the same time, the central element of bacterial taxonomy. There are at present no rules for the delineation of higher hierarchical ranks such as genus, family, and order. Although there is an expectation that at the generic level taxa should be supported by phenotypic descriptions (5, 10, 13), in practice, higher ranks are mostly delineated on the basis of 16S rRNA sequence comparison and stability analyses of the clusters that are obtained (19, 20). The latter has weakened the emphasis on phenotypic descriptions of taxa. Nevertheless, analyses of conserved signature indels and conserved signature proteins demonstrate that groups of prokaryotes ranging from phylum to genus levels can be recognized and support a tree-like vertical inheritance of the genes containing these molecular signatures that is consistent with phylogenetic trees (21).

**Multilocus Sequence Analysis: A Short-Lived Alternative to DNA-DNA Hybridization Experiments?**

In 2002, a new ad hoc committee for the reevaluation of the species definition in bacteriology made various recommendations in light of developments in methodologies available to systematists (22). One of the particularly interesting developments was multilocus sequence analysis (MLSA). In contrast with multilocus sequence typing (MLST), a specific tool designed for molecular epidemiology and for defining strains within named species, whereby similarities and differences are usually measured as differences in allelic profiles, MLSA employs phylogenetic procedures based on the nucleotide sequences of the alleles instead to reveal similarities between strains representing different species and genera (6, 23). Many examples of such studies have been published, and in general the clusters delineated correlated well with species demarcated by DNA-DNA hybridization experiments (6). It is, for instance, noteworthy that the DNA-DNA hybridization results that demonstrated that *Yersinia pestis* and *Yersinia pseudotuberculosis* represented a single species were mirrored in the MLSA tree, where *Y. pestis* clusters among *Y. pseudotuberculosis* strains; the same observation was made for *Burkholderia mallei* and *Burkholderia pseudomallei* (24, 25). There is no universal MLSA cutoff or descriptor of clusters that characterizes species, nor are ecological features consistently available to distinguish natural clusters that could be used to define species. Therefore, MLSA thresholds for species delineation must be validated through the analysis of taxonomically well-characterized reference strains (13) before this method can replace DNA-DNA hybridization experiments in the frame of polyphasic taxonomic studies (see, e.g., reference 26). Especially for depicting relationships within and between closely related species, this approach has a resolution superior to the traditional 16S rRNA gene sequence analysis. The deduced phylogenetic trees not only provide a phylogenetic backbone but also reveal intraspecies relationships at a level where comparative 16S rRNA sequence analysis is no longer discriminatory.

The number and lengths of gene fragments to be used in MLSA studies have not been systematically studied, although typically six to eight genes are analyzed (27). Housekeeping genes are preferentially used because they evolve relatively slowly and most of the variation that accumulates in these genes is considered selectively neutral. Sequence diversity, however, often precludes the development of primer sets that can be used for studying multiple genera or even species. Although very appealing for its resolution, portability, and throughput capacity, MLSA thus suffers from the difficulty of developing widely applicable schemes. As the costs of whole-genome sequencing continue to decline, it is conceivable that extracting MLSA sequences (or MLST alleles) from draft genome sequences will become more straightforward and affordable than performing traditional MLST or MLSA analyses (28).

**Toward a Genomic Threshold for Species Definition**

For several decades, bacterial taxonomists have considered whole-genome information the standard for determining taxonomy. The number of whole-genome sequences is increasing rapidly and allows assessment of genome-level variation within and between species. It has become clear that in addition to nucleotide substitutions, other genetic forces such as gene loss, gene duplication, chromosomal rearrangements, but also LGT shape the genome and that considerable fractions of the genome of any particular strain may be unique to that strain (29). One of the more significant recent discoveries in bacterial genomics is that bacterial species appear to comprise a set of core and accessory genes, with only the former present in all isolates of that species and with the sum of the two components forming the species pan-genome (30). The origin, composition, and size of bacterial pan-genomes and whether they are finite or infinite have been the source of debate (31).

In particular, the extent to which LGT occurs and its consequences for bacterial evolution, a biological species concept of bacteria, and eventually a bacterial species definition have been debated vigorously. Although recognized decades ago, LGT was long viewed as a minor phenomenon that did not jeopardize the general idea of vertical evolution as depicted in phylogenetic trees based on rRNA or other conserved genes. An overwhelming disruptive influence of LGT also did not correspond with daily diagnostic practices during which numerous bacterial isolates can be recognized as belonging to long-established species. However, MLSA and especially phylogenomics studies have shown that numerous genes have different evolutionary histories, and the ribosomal tree of life has been referred to as “the tree of one percent” (of all genes in microbial genomes) (32, 33). Microbial evolution seemed better modeled in the form of a dynamic network of evolution in which the nodes were bacterial and archaean genomes and the edges were the fluxes of genetic information between the genomes (33). Yet there is now compelling evidence that a considerable set of genes share a highly significant phylogenetic signal that can be used to reconstruct bacterial phylogeny (34). The traditional tree of life can be replaced with a common and coherent phylogenetic trend of many genes, called the phylogenetic forest or the statistical tree of life (33, 34). Several studies of complete genomes have suggested universal sets of protein-coding genes that may be useful for a phylogenomic species delineation in microbial taxonomy, and genes that encode components of the translation system in particular show substantial congruency between each other and with the standard rRNA tree (35–39). It also became apparent that not only does the frequency of LGT vary dramatically among bacteria (an observation that was apparent more than a decade ago through numerous DNA fingerprinting studies) but that LGT should be considered a cohesive force in evolution rather than a disruptive force leading to a genetic melting pot (18, 40, 41), as the requirement for physical proximity, the homology dependence for
successful recombination, and the fitness reduction in the recipient organism all favor recombination between closely related bacteria (40). Finally, the differential existence of an accessory genome is clearly compatible with LGT-driven environmental adaptation. In a study of the evolutionary origin of the genomic repertoires in Gammaproteobacteria, Lerat et al. (42) concluded that gene acquisition was very common based on the large number of genome- or clade-restricted gene families. However, beyond their initial acquisitions, few gene histories conflicted with the organismal tree. The picture emerged that bacterial lineages are constantly subjected to the input of new genes from a large available pool, which may be of bacteriophage origin, and that resident genes are continually lost. The diversity of gene families unique to single genomes indicates that the pool of available genes is very large, allowing the rate of gene acquisition to be both high for a genome and very low for a particular gene. A taxonomically particularly interesting study was published by Lefebvre et al. (43), who analyzed 96 genome sequences derived from two closely related sympatric sister species of pathogenic bacteria Campylobacter coli and Campylobacter jejuni. The results showed that both species had finite pan-genomes and that there are unique and cohesive features to each of their genomes defining their genomic identity. The two species have a similar pan-genome size; however, C. coli has acquired a larger core genome and each species has evolved a number of species-specific core genes, possibly reflecting different adaptive strategies, in spite of their occurrence in the same niche (the gastointestinal tract of several hosts). Genome-wide assessment of the level of LGT within and between the two sister species, as well as within the core and noncore genes, demonstrated a resistance to interspecies recombination in the core genome of the two species and therefore provided persuasive support for the core genome hypothesis for bacterial species.

How can all of this information be used in a new species definition? Studies by Konstantinidis and Tiedje (29) and Gorris et al. (44) revealed the average nucleotide identity (ANI) of the shared genes between two strains to be a robust means to compare genetic relatedness. ANI values of ~95% corresponded to the traditional 70% DNA-DNA hybridization standard of the current species definition, and several recently published descriptions of novel bacterial species have incorporated the ANI analysis of draft whole-genome sequences (a minimum of 20% of the randomly sequenced complete genome must be available) to replace DNA-DNA hybridization experiments (5, 45). At the 95% ANI cutoff, current species include only moderately homogeneous strains, apparently as a result of the strains having evolved in different ecological settings. A large fraction of the differences in gene content within species was associated with bacteriophage and transposase elements, revealing an important role of these elements during bacterial speciation. These findings were consistent with a definition for species that would include a more homogeneous set of strains than that provided by the current definition and one that considers the ecology of the strains in addition to their evolutionary distance (46). Gorris et al. (44) also demonstrated that the 70% DNA-DNA reassociation threshold corresponded with 69%-conserved DNA, or, when the analysis was restricted to the protein-coding portion of the genome, 85%-conserved genes.

ANI values detect the DNA conservation of the core genome, whereas conserved DNA calculates the proportion of DNA shared by two genomes. Both estimates of intraspec-
The largest phylum by far is the Proteobacteria, which contains five main clusters (classes) of genera that are referred to with the Greek letters alpha, beta, gamma, delta, and epsilon. More recently, two additional classes within the Proteobacteria have been reported, the “Zetaproteobacteria” (a name that has not been validly published and therefore is formally written between quotation marks) and the Acidothiothiobacillia (50, 51). The Proteobacteria comprise the majority of the known Gram-negative bacteria of medical, industrial, and agricultural significance. This phylum includes Brucella, Ehrlichia, and Rickettsia (Alphaproteobacteria); Burkholderia, Bordetella, and Neisseria (Betaproteobacteria); Aeromonas, Legionella, Vibrio, and the family Enterobacteriaceae (Gammaproteobacteria); and Campylobacter and Helicobacter (Epsilonproteobacteria). The Deltaproteobacteria, “Zeta- proteobacteria,” and Acidothiothiobacillia comprise a variety of mainly environmental bacteria that have little clinical relevance.

Uncultured Bacteria

The classification and nomenclature of uncultured bacteria that are only minimally characterized by morphological characteristics or by differences in molecular sequence are outstanding challenges in bacterial classification (52). A category that formally classifies incompletely described prokaryotes has been recognized (53). “Candidatus” is considered a taxonomic status for uncultured candidate species for which relatedness has been determined (for instance, for which phylogenetic relatedness has been determined by amplification and sequence analysis of prokaryotic RNA genes by use of universal prokaryotic primers) and whose authenticity has been verified by in situ probing or a similar technique for cell identification. In addition, it is also mandatory that information concerning phenotypic, metabolic, or physiological features be made available. The latter data may serve as a starting point for further investigation and eventual description and naming. With the advent of genomics, these original concerns may appear trivial now that we have the technical means to study large genomic fragments of uncultured microbes by shotgun cloning and sequencing of bulk DNA extracted from mixed communities (54,55) or by DNA amplification from single cells (56), enabling sequencing from uncultured microorganisms from the environment (57). In particular, the metagenomics field has opened a fascinating new window for studying the uncultured microbial diversity in a range of ecosystems, including those of the human body (see chapter 15). Exploring the diversity of such ecosystems by comparative RNA sequence analysis is based on identification of phylotypes, which are defined as groups of 16S rRNA gene sequences with a certain level of similarity. The cutoff values of rRNA sequence similarity that are used for phylotype definition are not consistent. In studies of the diversity of microbes in the human gastrointestinal tract, these values vary between 97 and 99% (58). The higher the cutoff value, the higher is the number of distinct phylotypes and thus estimated species richness. Regardless of the cutoff value used, the resulting diversity estimates should be considered rough indicators of the microbial diversity present, as bacteria with rRNA sequences that are 99% similar may still encompass multiple species and considerable ecological and genomic heterogeneity (6).

IDENTIFICATION

Identification is part of taxonomy. It is the process whereby an organism is recognized as belonging to a known taxon (species, genus, or higher taxonomic rank) and designated accordingly. It relies on a comparison of the characters of an unknown with those of established units in order to name it appropriately. This implies that identification depends on adequate characterization.

As part of identification strategies, dichotomous keys based on morphological and biochemical characteristics have only partly been replaced by other methods. Taxonomic studies provide an impressive array of alternative techniques derived from analytical biochemistry and molecular biology for examination of numerous cellular compounds (11, 13). Various identification approaches are discussed in chapters 4 through 6 of this Manual. Each of these techniques is useful for characterization and hence identification of bacteria. Databases of many types of biological data, including rRNA and other gene sequences, whole-cell fatty acid components, and matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectra, or miniaturized series of phenotypic characteristics may allow identification of many isolates. Yet the success of these databases also depends on the completeness of the databases, the exactness of the methods, and how carefully the individual entries have been delineated.

CLASSIFICATION AND IDENTIFICATION METHODS

In principle, all genotypic, phenotypic, and phylogenetic information can be used to classify bacteria. Genotypic information is derived from the nucleic acids present in the cell, whereas phenotypic information is derived from proteins and their functions, different chemotaxonomic markers, and a wide range of other expressed features. In the present polyphasic-species definition, a minimal taxonomic study consists of sequence analysis to determine the phylogenetic position of the unknown species (the 16S rRNA gene is most commonly used), DNA-DNA hybridizations to determine its precise level of relatedness toward its nearest phylogenetic neighbor, and biochemical characterization to distinguish the new taxon from the established ones.

Typical for the process of polyphasic taxonomy is that information from other approaches is used to classify bacteria at different taxonomic levels. When working one’s way through lists of methods, it is of primary interest to understand at which level these methods carry information and to realize their technical complexity, i.e., the amount of time and work required to analyze a certain number of isolates. The validation of a new classification or identification tool involves a determination of its taxonomic resolution by means of well-characterized reference strains. As a proof of concept, such validation studies mostly start with the analysis of type strains only, but because of the genotypic variability of bacterial species (both in gene content and in gene sequences), the true value of new classification or identification tools can appropriately be assessed only through the analysis of multiple well-characterized reference strains and subsequent validation using new isolates. The list of methods given below is not meant to be complete or to describe all of their aspects. It comprises the major categories of taxonomic techniques required to classify and identify bacteria and focuses on novel developments.

DNA-DNA Hybridization Studies

Although contested for its technical difficulties and for the inability to build cumulative databases, at present, DNA-DNA hybridization is still acknowledged as the reference method to establish relationships within and
between species. Different DNA-DNA hybridization procedures have been described, both traditional and miniaturized versions (9, 59–61). In DNA-DNA hybridization studies, it is commonly unclear if hybridizations were performed under optimal, stringent, or suboptimal conditions. The stringency of the reaction is determined by the salt and formamide concentrations, by the temperature, and by the molar percentages of G+C of the DNAs used. DNA-DNA hybridizations performed under standard conditions are not necessarily optimal or stringent for all bacterial DNAs. As a standard, optimal conditions for hybridizations should be preferred because the optimal temperature curve for hybridization is rather broad (∼5°C) (9).

Whole-Genome Sequence-Based Methods

The percentage of conserved DNA (pcDNA) method introduced by Goris et al. (44) and the MUM index of Deloger et al. (62) can be regarded as in silico imitations of DNA-DNA hybridization. Both similarity measures are based on finding subsequences that are conserved in the genomes under comparison. However, pcDNA traces inexact matches using a BLAST approach (63), whereas the MUM index uses the MUMmer software (62) to find all maximal unique exact matches (MUMs) shared by the genomes. MUMmer applies suffix trees as an index structure to speed up the search process. As a result, computing the MUM index is ~100 times faster than the pcDNA method (64).

Both methods require complete or nearly complete genome sequences, as they are highly sensitive to small sequence stretches missing in draft genomes.

The ANI method (5, 44, 65) and core gene identity (CGI) method (66) are both natural extensions to MLSA in case complete or draft genome sequences are available. Whereas MLSA computes similarity values as the average similarity among a limited set of orthologous protein-coding genes shared among all organisms studied, ANI and CGI maximize the information content by taking all orthologous protein-coding genes of the genomes into consideration. The main difference between the approaches is that ANI computes a pairwise genome similarity based on all orthologous genes shared by the genomes while CGI restricts the computation of pairwise genome similarity to orthologous genes shared by all genomes under study.

The present state of the art demonstrates that both pcDNA and MUM index parameters are equivalent (because they have the same taxonomic resolution) but superior (because they are sequence based and thus cumulative) approaches to the traditional DNA-DNA hybridizations for the species-level classification of bacteria. Similarly, the ANI and CGI parameters are equivalent but superior tools for studying their phylogeny. The latter approaches are superior compared with traditional 16S rRNA-based approaches because they are based on a much larger part of the genome and because they have a better resolution for discriminating closely related bacteria. Each of these methods is starting to be used in taxonomic studies of different bacteria (45, 64, 66, 67), and it can be anticipated that the practice of DNA-DNA hybridization experiments as the cornerstone for species delineation in taxonomic studies of bacteria will be abandoned fairly soon.

rRNA Studies

rRNA is the best single target for studying phylogenetic relationships because it is present in all bacteria, it is functionally constant, and it is composed of highly conserved as well as more variable domains (8). The components of the ribosome (rRNA and ribosomal proteins) have been the subjects of phylogenetic studies for several decades, and direct sequencing of partial or nearly entire 16S or 23S rRNA molecules has become common practice. The larger the conserved elements examined, the more information they bear and the more reliable the conclusions become. International databases comprising published and unpublished partial or complete sequences have been constructed (68) but have also accumulated poor-quality sequences and sequences that are not accurately or even not correctly labeled. For these and other reasons, several initiatives for providing the scientific community with curated 16S rRNA databases have been undertaken (e.g., see references 69–71). The “All-Species Living Tree” project (69; http://www.arb-silva.de/projects/living-tree/) aims to reconstruct a single 16S rRNA tree harboring all sequenced type strains of the hitherto classified species of Archaea and Bacteria. Sequences are selected manually due to a high error rate in the names and information fields provided for the publicly deposited entries. A most useful tool to track the identity of strains for which sequence are deposited is the StrainInfo bioportal (72; http://www.straininfo.net/), which brings together the biological material kept at multiple biological resource centers into a single portal interface, with direct pointers to the relevant information at the culture collections’ websites. This information is automatically linked to related sequences in the public domain and refers to all known scientific publications that deal with the organism. To support the taxonomic depth of the information provided by the StrainInfo bioportal, all taxonomic names appearing in the bioportal are fully integrated with and linked out to key taxonomic information sources.

rRNA sequence analysis not only is used to determine relationships among genera, families, and other higher ranks but often replaces DNA-DNA hybridization studies for the delineation of species in taxonomic practice. Such application of rRNA similarity data may not be appropriate, as some genera, for instance, Bacillus, Burkholderia, Corynebacterium, Mycobacterium, and many others, comprise clusters of closely related species that exhibit nearly identical 16S rRNA gene sequences. Stackebrandt and Goebel (73) reported that organisms sharing >98.5% rRNA similarity may or may not belong to a single species and that the resolution of 16S rRNA sequence analysis for determination of the degree of relatedness between closely related organisms is generally low. There is no single threshold value of 16S rRNA similarity for species recognition (73). However, organisms with <97% 16S rRNA sequence similarity do not give a DNA-DNA reassociation level of >60%, no matter which DNA-DNA hybridization method is used. Subsequent studies revealed that for the majority of organisms, the 97% cutoff value could be raised to 98.7 to 99% (74). Nevertheless, other studies extended the observations on intraspecies 16S rRNA divergence considerably, as differences in 16S rRNA gene sequence of up to 4.5% were reported among strains of several species belonging to the Epsilonproteobacteria (75, 76).

In spite of its limitations, rRNA sequence analysis is commonly used for the identification of bacteria (77, 78), and commercial identification systems based on analysis of rRNA gene sequences are available (e.g., MicroSeq 500 16S rDNA Bacterial Sequencing Kit; Perkin-Elmer Applied BiotecSystems, Foster City, CA). A fraction of the 5′-terminal region of the 16S rRNA gene (positions 60 to 110 of the E. coli numbering system) is one of the most informative or discriminating regions for closely related organisms (19).
Comparison of 16S rRNA gene sequences in many bacterial genera will lead to correct identification to the species level, but it is equally true that many taxonomic studies have revealed that comparative rRNA sequence analysis is often not sensitive enough to identify strains to the species level. There is a lack of knowledge not only of the strain-to-strain variation within a species but also of the interoperon variation within a single strain. Therefore, concluding that an unidentified isolate belongs to a particular species because it shares a high percentage of its 16S rRNA gene sequence with particular species or concluding that it represents a novel species because it occupies a unique position in the phylogenetic tree supported by a high bootstrap value or because it shares only 97% of its 16S rRNA sequence with its closest neighbor is premature in the absence of appropriate complementary data. This is even more true for partial sequence data, as partial rRNA gene sequences carry only limited information about the molecule and different parts of the gene may carry information about different taxonomic levels.

The interesting taxonomic properties of rRNA or rRNA gene molecules have been exploited in many ways. Although highly conserved, the rRNA genes also consist of variable domains that are particularly useful for diagnostic purposes and for mixed-community analyses (79–82). New technologies, exploiting the universal characteristics of the rRNA genes and their potential for species identification, emerge regularly. A growing number of studies report on the use of pyrosequencing (Biotage, Uppsala, Sweden), which provides rapid, short-read sequencing of 30 bases to classify, identify, and subtype bacteria, yeasts, and fungi (see, e.g., references 83 and 84). Turenne et al. (85) used single-stranded conformation polymorphism analysis of PCR amplicons to distinguish between organisms, and Yang et al. (86) used high-resolution melt analysis to characterize PCR products generated from three hypervariable regions of the 16S rRNA gene of clinically relevant bacterial pathogens and concluded that it allowed highly specific species identification. Still other approaches combine the diagnostic potential of 16S rRNA genes with the speed and discriminatory power of mass spectrometric analyses (see below).

Sequence Analysis of Protein-Encoding Genes

As an alternative to 16S rRNA gene sequence analysis, numerous other macromolecules have been examined for their potential as microbiological clocks and their applications as identification tools. Among others, various ribosomal proteins (37, 87, 88), chaperonin (88), RNA polymerases (89), RecA (90), and manganese-dependent superoxide dismutase (91) were shown to be valuable molecular chronometers. These alternative macromolecules should be widely or universally distributed among bacteria, they should not be transmitted horizontally, and their molecular evolution rate should be comparable to or somewhat higher than that of 16S rRNA, which would render them more suitable for differentiation of closely related organisms.

Potential pitfalls of overreliance on a single phylogenetic marker are illustrated in the taxonomic studies of species of the Streptococcus bovis group. Streptococcus infantarius subsp. coli was reclassified as the novel species Streptococcus luteiensis, and another group of streptococci was proposed as the novel species Streptococcus pasteuriannus, primarily on the basis of manganese-dependent superoxide dismutase gene sequences (92), while subsequent studies demonstrated that neither S. luteiensis nor S. pasteuriannus represented novel species (93). As mentioned above, studies of complete genome sequences have suggested universal sets of protein-encoding genes (35–39), and the analysis of multiple protein-encoding genes (not necessarily the most conserved ones) buffers the distorting effects of horizontal gene transfer or recombination events (65).

Other Genotypic Methods for Bacterial Classification

A range of different genotypic techniques has been used to characterize bacteria at various taxonomic levels. The molar percentage of guanine plus cytosine (the DNA base ratio or percent G+C value) is one of the classical genotypic characteristics and is part of the standard description of bacterial taxa. Generally, the range in G+C content observed among the strains of a species should not be >3%, and among the species of a genus it should not be >10%. In general, in the bacterial world the G+C content varies between 24 and 76%.

A tremendous number of molecular diagnostic methods, most of which are PCR based, have been developed. Most of these generate arrays of DNA fragments that are separated and detected in various ways, and appropriate software has been developed for pattern recognition and analysis and for database construction. One of these DNA fingerprinting methods, amplified fragment length polymorphism analysis (94), is useful for the classification of strains at the species and genus levels. The basic principle of amplified fragment length polymorphism analysis is restriction fragment length polymorphism analysis, modified by using PCR-mediated amplification to select particular DNA fragments from the pool of restriction fragments. This selective amplification process results in an array of about 30 to 40 DNA fragments, some of which are species (or even genus) specific, while others are strain specific (95). PCR-based typing methods that use random or repetitive elements as primers have been applied to strain characterization of a wide variety of bacteria (96–98). Although primarily applied for interspecies strain comparisons, these techniques are useful in classification as well.

Phenotypic Methods

Phenotypic methods comprise all those that are not directed toward DNA or RNA and therefore also include the chemical or chemotaxonomic techniques. The classical phenotypic tests traditionally constituted the basis for the formal description of bacterial species, subspecies, genera, and families. While genotypic data are used to allocate taxa to a phylogenetic tree and to draw the major boundaries in classification systems, phenotypic consistency is required to generate useful classification systems and may therefore influence the depth of a hierarchical line (12, 22). The paucity or variability of phenotypic characteristics for certain bacterial groups regularly causes problems in describing or differentiating taxa. For such bacteria, alternative chemotaxonomic or genotypic methods are required to reliably characterize strains.

The classical phenotypic characteristics of bacteria comprise morphological, physiological, and biochemical features. Individually, many of these characteristics are poor parameters for genetic relatedness, yet as a whole, they provide descriptive information for the recognition of taxa. The morphology of a bacterium comprises both cellular (shape; the presence of an endospore, flagella, and inclusion bodies; and Gram staining characteristics) and colonial (color, dimensions, and form) characteristics. The
physiological and biochemical features comprise data on growth at different temperatures; growth in the presence of different pH values, salt concentrations, or atmospheric conditions; growth in the presence of various substances, such as antimicrobial agents; and the presence or activities of various enzymes and utilization of compounds, etc. Very often, highly standardized procedures are required to obtain reproducible results within and between laboratories.

Phenotypic data were the first to be analyzed by means of computer-assisted numerical comparison. In the 1950s, numerical taxonomy arose in parallel with the development of computers (99) and allowed comparison of large numbers of phenotypic traits for large numbers of strains. Data matrices showing the degree of similarity between each pair of strains and cluster analyses resulting in dendrograms revealed a general picture of the phenotypic consistency of a particular group of strains. Because such large numbers of characteristics reflect a considerable amount of genotypic information, it soon became evident that numerical analysis of large numbers of phenotypic characteristics was indeed taxonomically relevant. In taxonomic practice, phenotypic characterization became compromised and sometimes more of a burden than a useful taxonomic activity. Frequently, phenotypic data are compared with literature data obtained using other conditions or methods. The need for continued phenotypic characterization at every taxonomic level not only to delineate taxa and appreciate their phenotypic coherence but also to evaluate their physiological and ecological functions cannot be denied. A minimal phenotypic description is not only the identity card of a taxon but also a key to its biology. Although accepted as necessary, differential phenotypic characters are often hard to find with a reasonable amount of effort and time.

**Chemical Methods**

The term "chemotaxonomy" refers to the application of analytical methods to the collection of information on various chemical constituents of the cell to classify bacteria. As with the other phenotypic and the genotypic techniques, some of the chemotaxonomic methods have been widely applied to vast numbers of bacteria, whereas others were so specific that their application was restricted to particular taxa. The markers studied include whole-cell protein profiles, isoprenoid quinones, cytochromes, peptidoglycans, polyamines, polar lipids, pigments, particular enzymes, steroids, and hopanoids (11). Very often, analytical difficulties have been the main restrictions to their wide-scale application.

**Cell Wall Composition**

The distinction between Gram-negative and Gram-positive types of bacteria is still one of the characteristics that are first analyzed in order to guide subsequent characterization and identification steps. The determination of the cell wall composition has traditionally been important for Gram-positive bacteria. The peptidoglycan type of cell wall of Gram-negative bacteria is rather uniform and provides little information. The cell walls of Gram-positive bacteria, in contrast, contain various peptidoglycan types that may be genus or species specific (100). The most valuable information is derived from the type and composition of the peptide cross-link between adjacent chains in the polymer network. A variable that received little attention is the degree of N and O acetylation of the amino sugars of the glycan chain. The analytical procedure is time-consuming, although a rapid screening method has been proposed. Membrane-bound teichoic acid is present in all Gram-positive species, but cell wall-bound teichoic acid is present in only some Gram-positive species. Teichoic acids can easily be extracted and purified and can be analyzed by gas-liquid chromatography (101).

**Cellular Fatty Acid Analysis**

More than 300 fatty acids and related compounds are present in bacterial cells. Polar lipids are the constituents of the lipid bilayer of bacterial membranes and have been frequently studied for classification and identification purposes. Other types of lipids, such as sphingophospholipids, occur in only a restricted number of taxa and were shown to have taxonomic value within these groups (11). Variations in chain lengths, double-bond positions, and substituent groups are very useful for the characterization of bacterial taxa (102). Mostly, the total cellular fatty acid fraction is extracted, but particular fractions, such as the polar lipids, have also been analyzed. The cellular fatty acid methyl ester composition is a stable parameter provided that highly standardized culture conditions are used. The methylated fatty acids are typically separated by gas-liquid chromatography, and both the occurrence and the relative amounts of methylated fatty acids characterize bacterial fatty acid profiles.

**MALDI-TOF and Other Mass Spectrometric Methods**

The first reports involving the use of MALDI-TOF mass spectrometry (MS) were published in the late 1980s, and its application has increased exponentially. By now, this methodology and its many applications have revolutionized the routine practices in clinical microbiology. In MALDI-TOF MS, the sample is mixed with a matrix that is chosen such that it specifically absorbs a laser beam. The resulting high-energy impact is followed by the formation of ions that are extracted through an electric field and that are subsequently focused and detected as an m/z (mass/charge) spectrum. Typically, high-abundance peptides, like those derived from ribosomal protein fractions, that are of low mass and ionize readily are observed in the spectra (103). The simplicity and speed of analysis represent part of its strength, and the whole process can be highly automatized. These features make the approach particularly attractive to research laboratories that routinely deal with the analysis and identification of large numbers of bacterial isolates. In microbiology, MALDI-TOF MS is primarily being used for species-level identification of various bacteria and fungi, but its potential for infraspecific typing of bacteria is being explored (103, 104). The technique is nowadays used for an increasing range of applications, including the analysis of mixed cultures, the differentiation between antimicrobial-resistant and -susceptible strains, direct identification of bacteria and yeasts in clinical specimens, and the rapid grouping of bacterial species in large collections of isolates (105).

The potential of MALDI-TOF MS for bacterial identification has also been used in a number of alternative ways. These include the fast and accurate differentiation of PCR products according to their lengths and rapid analysis of PCR products and restriction fragment length polymorphism patterns of microbial samples for size determination of double-stranded amplicons and restriction fragments (106, 107). Because of limitations of these approaches by length heterogeneities of specific marker genes that diminish their discriminatory power, von Wintzingerode et al. (108)
combined base-specific cleavage of amplified 16S rRNA genes with MALDI-TOF MS. In this process, 16S rRNA gene signature sequences are amplified in the presence of dUTP instead of dTTP, followed by strand separation and uracil-DNA-glycosylase-mediated cleavage at each T-specific site. Fragment pattern detection was performed by MALDI-TOF MS and proved useful for the identification of several bacteria, including Bordetella and Mycobacterium strains (108, 109).

Other studies report on the use of surface-enhanced laser desorption ionization-TOF MS for the identification of bacteria (110–112). Surface-enhanced laser desorption ionization is distinguished from MALDI in its use of an active sample probe—the ProteinChip array—that has an adsorptive surface that allows bacterial lysates to be subjected, without prior treatments, to on-chip sample preparation steps, such as selective washing and desalting. This procedure minimizes sample losses, while speeding up and simplifying sample preparation, compared to the standard methods normally employed prior to the use of MALDI. Furthermore, the active capture of the proteins by the protein chip array enables nondiscriminatory binding of target proteins, which in turn improves the reproducibility and allows both peak mass-to-charge ratios and intensity to be used in sample characterization.

Finally, the Ibis T5000 biosensor technology (Bruker Daltonics Inc., Billerica, MA) uses broad-range PCR primers that target conserved regions of bacterial genomes, such as ribosomal sequences and conserved elements from essential protein-coding genes (i.e., housekeeping genes), and is designed to rapidly detect and identify a variety of pathogens without prior knowledge of the pathogen’s nucleic acid sequence (113). The use of such broad-range priming targets across the widest possible grouping of organisms enables amplification of most species within a group. The T5000 biosensor uses electrospray ionization MS to analyze the products of broad-range PCR, which allows for the precise determination of the molecular mass of the PCR products. These high-precision mass measurements are then used to unambiguously derive base compositions of the PCR products, which are compared to a database for identifying the organism. This technology allows for a multilocus identification of bacteria in the samples with significantly less time and effort than sequencing and performs well with samples from a variety of clinical and environmental matrices, including blood, serum, various tissues, and even mosquito homogenates (114).

FTIR Spectroscopy

Fourier transform infrared (FTIR) spectroscopy is used for the identification of substances in chemical analyses. In general, the wave number, the reciprocal of the wavelength, is used as the physical unit. FTIR spectroscopy involves the observation of vibrations of molecules that are excited by an infrared beam. Molecules are able to absorb the energy of distinct light quanta and start a rocking or rotation movement. An infrared spectrum represents a fingerprint that is characteristic for any chemical substance. The composition of biological material and, thus, of its FTIR spectrum is exceedingly complex, representing a characteristic fingerprint. Naumann and coworkers suggested identifying microorganisms by FTIR spectroscopy (115). In principle, a reference spectrum library is assembled based on well-characterized strains and species. The FTIR spectrum of any unidentified isolate is then measured under the same conditions as those used for the reference spectra and is compared to spectra in the reference spectrum library. FTIR spectroscopy is now used for the identification and typing of a growing number of bacteria and yeasts (116–119).

Conclusions

The scientifically and economically ideal identification technique remains beyond reach. Cowan’s (2) intuitive approach (which is used when the identity of the unknown is anticipated) and the stepwise method (which involves the use of dichotomous keys) suffice for numerous isolates and require only simple, rapid, and inexpensive biochemical tests. Cowan’s views are easily adapted to modern methodology. If this first-line approach fails, alternative procedures are required and available. For several reasons, including the comprehensiveness of the public databases, complete 16S rRNA gene sequence analysis is the most straightforward and obvious choice for establishing a rough identity of an isolate, although it often fails to differentiate closely related species. Much of its superiority is based on its robust capacity to reveal the phylogenetic neighborhood of the organism studied, which is information not provided by any of the other current identification protocols. This information will direct the additional analyses required for final identification to the species level. Accurate species-level identification is thus very often a two-step process in which an unknown is first assigned to a particular group, after which it can be accurately identified at the species level. The former can be achieved through sequence analysis of 16S rRNA genes using near-universal primers, the latter through an appropriate selection of housekeeping genes and specific primers once the tentative identity of an unknown is established.

NOMENCLATURE

Nomenclature is the supreme generator of heat, bad temper and ill-will among taxonomists and every kind of microbiologist; the reason is that in matters of nomenclature we are all conservative. We hate change (3).

Valid Publication of Bacterial Names

The International Code of Nomenclature of Bacteria (120) includes rules on how to name bacteria at different taxonomic ranks. The aim of nomenclature is to ensure that an organism is tagged with a unique name that carries valuable information. Prior to 1980, a proposal of a new bacterial taxon could be validly published in any microbiological book or journal, and the authors of the relevant sections of the successive editions of Bergey’s Manual of Determinative Bacteriology had to attempt to give a complete list of the members of any particular genus or group of genera. The unavailability of type strains and the fact that microbiologists from different disciplines were not always familiar with one another’s work caused great difficulty. All too often a worker would discover several years later that “his” or “her” organism had in fact been described earlier under a different name.

To overcome such problems and others, 1 January 1980 was chosen as a new starting date for bacterial nomenclature. At that time, the Approved Lists of Bacterial Names were published on behalf of the Judicial Commission of the International Committee on Systematic Bacteriology (121). Only those names included on these lists had standing in bacterial nomenclature, and names of taxa were to be included only if they were adequately described and if a
type strain was available. From then onwards, all new names were validly published only in the International Journal of Systematic Bacteriology (165) and the International Journal of Systematic and Evolutionary Microbiology. Names can effectively be published in other journals and then validated subsequently by announcement in the Validation Lists in the International Journal of Systematic and Evolutionary Microbiology. Complete overviews of validly published names can easily be obtained through Internet sites such as http://www.bacterio.net/. One of the conditions for valid publication of names is that type strains of novel species must be deposited in two public culture collections in different countries. In case different names for the same organism are validly published, nomenclatural priority goes to the name that was validated first. As a result of this practice, all validly named species in any particular group can easily be traced and reference strains are available.

Why Do Names Change?

There have been more important causes for the modification of bacterial names than the occasional detection of synonymy. As described above, our present view on bacterial classification is phylogeny based. With the advent of DNA-DNA hybridization in the 1970s and subsequently of rRNA classification is phylogeny based. With the advent of rRNA hybridization experiments. A classification based on results obtained with a single strain cannot be stable. Indeed, already the detection of a second strain will inevitably necessitate revision of the original species description.

As a concluding remark, it should be mentioned that there is no “undo” function in bacterial nomenclature. A name that was validly published remains valid regardless of the number of modifications it undergoes thereafter. For instance, the changes of the name Pseudomonas maltophilia to Xanthomonas maltophilia and finally to Stenotrophomonas maltophilia (128) may be reasonable to some taxonomists, but the changes, particularly the most recent, have been refuted by many clinical microbiologists. As these three names were all proposed according to the rules of bacterial nomenclature, they were all validated, and the use of each of them is correct and valid.

CONCLUSIONS

There seems to be a clear and bright future for bacterial taxonomy in the genomics era. A much broader range of taxonomic studies of bacteria has gradually replaced the former reliance on morphological, physiological, and biochemical characterization. This polyphasic taxonomy takes into account all available phenotypic and genotypic information and integrates it in a consensus type of classification, framed in a general phylogeny derived from 16S rRNA gene sequence analysis. The bacterial species appears as a group of isolates that originated from a common ancestor population in which a steady generation of genetic diversity resulted in clones that had different degrees of recombination and that were characterized by a certain degree of phenotypic consistency, a significant degree of DNA-DNA hybridization, and a high degree of 16S rRNA gene sequence similarity (9). Whole-genome sequences will make the practice of polyphasic taxonomy even more complete, and several genomic parameters like pcdNA, MUM index, and ANI values are ready to replace DNA-DNA hybridization as the cornerstone of species description.

While the old DNA-DNA hybridization species threshold is being replaced by MLSA or ANI value-based thresholds (3, 13, 23, 44), a fair reappraisal of bacterial taxonomy and the species definition will require more than a mere methodological translation of threshold levels. Several considerations should be made. First, whole-genome sequence studies confirm that in the space of microbial diversity many cores can be distinguished (see, e.g., reference 43), and these cores very often correspond with established species that are phenotypically but not necessarily ecologically coherent. It would be wrong to let the discussion be steered by an attempt to hold on to species boundaries defined by DNA-DNA hybridization experiments. A new discussion on the bacterial species concept, directed by insights in genome
evolution and metagenomics but also by practical concerns (classification should remain practical and facilitate identification), is badly needed (18, 33, 129) and should yield whole-genome sequence-based thresholds, irrespective of their degree of correlation with DNA-DNA hybridization thresholds.

A second key point in the discussion of a modern bacterial species definition was raised by Sutcliffe et al. (10), who called for a significant reappraisal of the procedures used to describe novel prokaryotic taxa, including the introduction of new publication formats. They rightly pointed out that although progress in the description of new microbial taxa is being made at accelerating rates, there is an enormous backlog of work and conservative estimates suggest that the presently described bacterial species ($<$10,000) may represent significantly less than 0.1% of the existing microbial diversity (130). Thus, even if progress in describing new taxa can be accelerated considerably over current rates, the challenge of adequately describing prokaryotic diversity could take several centuries (10, 130)! Consequently, a key question for the systematics community is to consider how we should continue to describe new prokaryotic taxa if we want to uncover more than the tip of the iceberg in the next few decades. Conflicting with this need to dramatically change our throughput capacity to describe new prokaryotic taxa, comprehensive guidelines for the description of novel species have been published by leading scientists of the systematics community (13). In light of the vast unreported microbial diversity, this is counterproductive, and one must reassess how much characterization is enough (10).

Other practical considerations in this respect are that the number of bacterial taxonomists in Western countries is in sharp decline and that the extent of new species descriptions is primarily constrained by journal capacities rather than taxonomists’ activities (130). A revitalization of the practice of prokaryotic systematics is indeed badly needed (10, 130).

One of the key principles of good specimen collection is to avoid introduction of colonizing bacteria surrounding the site of infection or on the skin or mucous membranes near the infectious site. This is done by disinfecting the surface skin and aspirating material, by using sheathed collection devices, or by collecting samples during surgical procedures. For sites naturally colonized by more than one species, selective methods are used to detect specific pathogens and prevent contamination with nonpathogenic commensals. More detailed information about sample collection and handling can be found in the Infectious Diseases Society of America (IDSA) and American Society for Microbiology (ASM) guideline document (1).

Specimens for bacteriologic culture should be collected as soon as possible after the onset of disease and before the initiation of antimicrobial therapy or as soon after the start of therapy as possible. A second specimen may be necessary because of poor specimen quality or inadequate transport conditions that affected the first specimen, but is otherwise rarely required for diagnosis of an acute infectious disease. Exceptions include the collection of multiple blood specimens for culture and those obtained for additional studies other than those originally requested.

Microbiologists must help caregivers to choose, collect, and transport the specimen in a manner that optimizes the laboratory’s diagnostic testing activities. A common mechanism today is to provide a written or online laboratory specimen collection guide (2); for an example, see http://www.stanfordlab.com/pages/microbiology.htm.

GENERAL PRINCIPLES OF SPECIMEN COLLECTION AND TRANSPORT

The Specimen Must Represent the Infected Site

The choice of specimen to be collected for laboratory diagnosis is based on the site of the infection and the nature of the suspected bacteria. Table 1 lists anatomic sites with appropriate and inappropriate clinical specimens (3). General specimen selection and collection guidelines include proper labeling of the sample to include two patient identifiers, the source of the sample, and information on who collected the sample and at what time collection occurred.

Suspected Agent of Bioterrorism or Intentional Release of Biological Agent

Specimens from suspected acts of terrorism are important legally, and a chain of custody must be employed. See the ASM Laboratory Response Network Sentinel Level Laboratories website (http://www.asm.org/index.php/guidelines/sentinel-guidelines) and chapter 14 for more in-depth information.

Use of the Best Collection Method (Table 2)

Swabs

Swabs are appropriate when a large volume of sample is not necessary, such as from surface wounds (where the organism load is high) or oropharyngeal samples (where the presence of even one colony of \textit{Streptococcus pyogenes} is clinically relevant) and where there will be a limited number of media to inoculate. Swabs should be collected carefully to avoid touching noninvolved surfaces or mucosae, which harbor contaminating bacteria, and they should be rolled or rubbed vigorously over the infected surface to maximize adsorption of the infecting agent.

Swabs may be transported dry (with desiccant to enhance survival) for recovery of \textit{Corynebacterium diphtheriae} and \textit{S. pyogenes} only (9, 10). Swabs should not be used when multiple media must be inoculated, as the sample must be diluted to reach sufficient volume. Swabs are also not recommended for anaerobic cultures (Table 3), or for fungal cultures, because hyphal elements are not picked up. Swabs may be used to collect material from surface lesions for detection of mycobacteria, such as \textit{Mycobacterium marinum}, but if there is fluid or tissue, that material should be obtained for culture, not a swab of...
the fluid. In all cases, the actual specimen (tissue, aspirate, or biopsy) is preferred over a swab of the specimen (1).

Swabs from the surface of decubitus ulcers are not recommended for culture, as they are likely to yield colonizing bacteria that have superinfected the surface, making interpretation of results difficult (11, 12). Swabs collected through the nose for diagnosis of sinusitis are other specimens of dubious value. If the swabs have been endoscopically obtained, they may be free of nasal mucosal contamination and reveal infecting bacteria, but they will not recover fungi, which are the etiological agents of chronic sinusitis in ~25% of cases (13).

**Aspirates**

For abscess contents, body fluids, and other fluid collections below the skin, aspirates obtained through disinfected intact skin are preferred over swabs. The skin should be thoroughly cleaned with 70% alcohol, followed by disinfection with tincture of iodine or chlorhexidine, which must be completely dry before inserting the needle. An angel wing type of device can be used to safely inject the fluid in the syringe into a transport container. If anaerobes are being considered, the transport container must be free of air. Anaerobic transport vials with a nitrogen atmosphere above a gel containing oxygen-scavenging components are commercially available. Special small anaerobic transport vials containing specific anaerobic transport media for endodontal samples are also available. Only laboratories with expertise in diagnosis of dental infection should attempt to culture this type of specimen.

Normally sterile fluids (such as pleural, synovial, and pericardial fluids) are aspirated, but in addition to placing some of the fluid into a sterile tube or a citrated or EDTA tube (to prevent clot formation) for immediate Gram stain evaluation, a quantity (preferably 10 ml) should be injected into either an aerobic blood culture bottle or a Wampole Isolator (Alere Inc., Waltham, MA) tube directly at the patient’s bedside (14, 15).

Complications occur in the clinical setting of intestinal tract perforation when microorganisms other than the expected Enterobacteriaceae, anaerobes, and enterococci are involved. Consensus standards include recommendations for when and how cultures from intra-abdominal sites should be handled (16, 17). Standard empirical therapy may not adequately treat *Staphylococcus aureus*, *Pseudomonas aeruginosa*, *Candida* spp., or multidrug-resistant bacteria. Laboratory policies on the extent of identification of isolates based on an arbitrary number (such as 3 or fewer) should be modified with appropriate clinician justification and discussion.

**Tissues**

Biopsied tissue should be obtained by the surgeon using aseptic technique. Surface skin should be disinfected with chlorhexidine before the skin is cut. Once the first incision is made, which may inadvertently cut through a subsurface microcolony of bacteria (*Propionibacterium acnes* and *Staphylococcus epidermidis*), surgeons should switch to a fresh, sterile scalpel. Tissue should be placed into an anaerobic transport vial. If anaerobes are not considered, tissue may be placed into a sterile tube or cup with a tight lid. Tissue from draining sinus lesions should be obtained by curetting deep within the interior of the tract after thorough surface skin disinfection. Swabs from the drainage are likely to harbor surface bacteria that may not be associated with the underlying infection. Bone biopsy samples to diagnose osteomyelitis should be obtained directly from the bone itself after debridement of the overlying, usually superinfected tissue (12, 13).

</tbody>
</table>
Respiratory, upper
Oral
1. Remove oral secretions and debris from the surface of the lesion with a swab. Discard this swab.
2. Using a second swab, vigorously sample the lesion, avoiding any areas of normal tissue.

Swab transport
≤2 h, RT
≤24 h, RT
1/day
Discourage sampling of superficial tissue for bacterial evaluation. Tissue biopsy specimens or needle aspirates are the specimens of choice.

Nasal
1. Insert a swab, premoistened with sterile saline, approx. 1–2 cm into the nares.
2. Rotate the swab against the nasal mucosa.

Swab transport
≤2 h, RT
≤24 h, RT
1/day
Anterior nose cultures are reserved for detecting staphylococcal carriers or for nasal lesions.

Nasopharynx
1. Gently insert a small swab (e.g., calcium alginate or nasopharyngeal flocked swab) into the posterior nasopharynx via the nose.
2. Rotate swab slowly for 5 s to absorb secretions.

Direct media inoculation at bedside or examination table, swab transport
Plates: ≤15 min, RT
Swabs: ≤2 h, RT
≤24 h, RT
1/day
Throat swab cultures are contraindicated in patients with epiglottitis.
Swabs for N. gonorrhoeae should be placed in charcoal-containing or other specific transport medium and plated ≤12 h after collection (36). Bio-Bags and the GonoPak are better for transport at RT.

Throat or pharynx
1. Depress tongue with a tongue depressor.
2. Sample the posterior pharynx, tonsils, and inflamed areas with a sterile swab.

Swab transport (dry swab with or without silica gel is good for S. pyogenes and C. diphtheriae)
≤2 h, RT
≤24 h, RT
1/day

Tissue Collected during surgery or cutaneous biopsy procedure
Anaerobic transport system or sterile, screw-cap container. Add several drops of sterile saline to keep small pieces of tissue moist.
≤15 min, RT
≤24 h, RT
None
Always submit as much tissue as possible. If there is excess tissue, save a portion of surgical tissue at −70°C in case further studies are needed.
Never submit a swab that has been rubbed over the surface of a tissue.
For quantitative study, a sample of 1 cm³ is appropriate.

Urine
Male and female, first void (for Chlamydia and N. gonorrhoeae NAAT)
Sterile tube or transport medium specified by NAAT manufacturer
Unpreserved: ≤2 h, RT; ≤24 h, 4°C
As specified by NAAT manufacturer
1/infectious episode
Do not collect >30 ml for NAAT.

TABLE 2  Collection, transport, and storage guidelines for microbiological laboratory diagnostic studies* (Continued)

<table>
<thead>
<tr>
<th>Specimen type</th>
<th>Collection guideline(s)</th>
<th>Transport device and/or minimum vol</th>
<th>Transport time</th>
<th>Storage time and temp</th>
<th>Replica limits</th>
<th>Comment(s)</th>
</tr>
</thead>
</table>
| Female, midstream (for bacterial culture) | 1. While holding the labia apart, begin voiding.  
2. After several milliliters has passed, collect a midstream portion without stopping the flow of urine.  
3. The midstream portion is used for bacterial culture. | Sterile, wide-mouthed container, ≥1 ml, or urine transport tube with boric acid preservative | ≤2 h, RT       | ≤24 h, 4°C             | 1/day          | Urine is toxic to cell lines and is therefore not the specimen of choice for chlamydial culture. Cleansing before voiding does not improve urine specimen quality; i.e., midstream urine samples are equivalent to clean-catch midstream urine samples (272). |
| Straight catheter             | 1. Thoroughly cleanse the urethral opening with soap and water.  
2. Rinse area with wet gauze pads.  
3. Aseptically, insert catheter into the bladder.  
4. After allowing ~15 ml to pass, collect urine to be submitted in a sterile container. | Sterile, leak-proof container or urine transport tube with boric acid preservative | ≤24 h, 4°C      | 1/day                 | Catheterization may introduce urethral biota into the bladder and increase the risk of iatrogenic infection.                                               |
| Indwelling catheter           | 1. Disinfect the catheter collection port with 70% alcohol. Clamp catheter below port and allow urine to collect in tubing for 10–20 min.  
2. Use needle and syringe to aseptically collect 5–10 ml of urine.  
3. Transfer to a sterile tube or container. | Sterile, leak-proof container or urine transport tube with boric acid preservative | ≤24 h, 4°C      | 1/day                 | Patients with indwelling catheters always have bacteria in their bladders. Do not collect urine from these patients unless they are symptomatic.                               |

18). Infected bone is soft enough to easily be removed by curetting or sometimes by aspiration with a large-bore needle.

Sputum
Expectorated sputum is the best noninvasive sample for diagnosis of pneumonia, a disease of the distal lung alveolar spaces. Endotracheal aspirates are more likely to contain upper respiratory microbes and saliva from the upper tract and may not represent the bacteria causing the pneumonia (19). For these reasons, respiratory tract secretions from patients other than those with cystic fibrosis should be evaluated microscopically for the presence of squamous epithelial cells (SECs) and bacteria (20, 21). Sufficiently hydrated patients with pneumonia should be able to produce a good sputum specimen if properly coached by the collecting staff. The patient should be sitting up, should rinse out his mouth with water, and should be encouraged to bring up a deep cough from the lungs. Sometimes mild percussion on the chest can help dislodge deep phlegm. If a patient cannot produce an acceptable sputum sample the first time, it is very unlikely that a repeat collection will yield a good specimen, and it is probably better to call respiratory therapy to try to obtain a specimen. For some respiratory diseases, such as pneumococcal pneumonia and Legionnaires' disease, the inability to obtain reliable sputum has spurred the development of urinary antigen tests with relatively good sensitivity (depending on the assay) and variable specificity (22–25).

Urine
Urine can be collected by midstream collection, catheterization (straight/in-out or indwelling), cystoscopic collection, or suprapubic aspiration. Foley catheter tips should not be submitted or accepted for culture, since they are always contaminated with members of the urethral microbiota and quantitation is not possible. A first-voided morning urine is optimal, since in most cases bacteria have been multiplying in the bladder for a number of hours. Cleansing of the periurethral areas has not been shown to improve the quality of urine culture, but midstream collection is still recommended (26).

Feces (Stool)
Stool is always superior to a rectal swab for bacterial testing, but if a swab is the only sample available, the swab should be inserted deep enough into the rectum to encounter some stool (appear brown). Swabs should always be submitted in transport media to preserve viability of pathogens. Some pathogens, especially Shigella, are labile in stool, so stool not submitted in appropriate transport medium (e.g., Cary-Blair medium) should be inoculated to media without delay. Testing more than one stool for bacterial pathogens is usually not productive. Fresh stool should be examined visually, and the areas showing blood, pus, or mucus should be sampled preferentially. Diarrheal stool is loose and takes the shape of the container. Although formed stool may be tested for some pathogens, it is less productive, and for *Clostridium difficile* in particular, testing formed stool (other than in cases of physician-documented ileus) can lead to recovery of organisms that are colonizers and not causing disease.

Prosthetic Devices
The device itself may be sent to the laboratory for microbiological studies. Sonication in a volume of liquid has been shown to facilitate detection of organisms forming a biofilm on prostheses (27, 28). Other studies have shown that sonication at 22°C for 7 min yields the best results (29). When the prosthesis is not removed and the infection is suspected in the site of a prosthetic joint, isolation of the same species from at least three of five separate tissue biopsies from the infected site can help differentiate contamination from true infection (30, 31). Rapid molecular methods have been used with some success to determine appropriate therapy before culture results are available (32).

Volume of Sample
In general, the more material available for testing, the better. This is true especially when more than one type of culture is requested. However, receiving more than the volume necessary to accommodate all requests could be problematic, particularly if less-trained staff choose the section to use for microbiological studies. Caregivers should be encouraged not to send large bags of fluids, except for peritoneal dialysate (from which the laboratory staff should remove 50 ml to concentrate by centrifugation), or very large pieces of tissue, as that requires more manipulation in the laboratory than necessary and could introduce contaminants or result in a less productive part of the sample being tested. Since a drop of material (~0.05 ml) is the minimum amount necessary to inoculate an agar plate or an enrichment broth, at least...
1 drop per medium used should be received in the laboratory. As a general rule, at least 0.5 ml or 0.5 g of material should be received for routine bacterial culture, and more is necessary for additional studies. If the volume received is not sufficient to perform all requests or to inoculate all the usual media, the physician should contact the laboratory to prioritize the requests. This not only helps the microbiologist to perform the appropriate tests but also alerts the physician that the sample was problematic and could serve as a motivator for more adequate specimens in the future. Problems with volume occur often when fine-needle biopsy samples from interventional radiology are sent for microbiological studies, as further discussed below.

**Specimen Maintenance during Transport**

The type of test to be performed determines the nature of the transport system. The performance of various swab types and transport media should be verified prior to implementation. Manufacturers are required to do this, and laboratories often perform limited verifications. Selected criteria are important for the laboratory and should be monitored. For example, some nonviable bacteria in transport media (allowed per U.S. Food and Drug Administration [FDA] specifications) may be seen in initial Gram stains, so microbiologists may wish to sample several lots of the product to ascertain a low burden of dead but stainable organisms. The Clinical and Laboratory Standards Institute has developed standards for evaluating transport devices (33). Table 2 summarizes transport recommendations for routine bacteriology.

1. Transport specimens to the laboratory as soon as possible after collection. If transport will require more than 2 h (some organisms require a shorter time period), either a specific transport medium or refrigeration is required (Table 2)(1). For samples to be tested by molecular methods only, refrigeration or even freezing (the lower the temperature, the better; −80°C is best) is acceptable. Be sure to use the manufacturer’s recommended or companion transport materials for commercial molecular assays. Any deviation from the product insert in sample collection and handling for any in vitro diagnostic test requires the laboratory to perform a relatively extensive verification of the performance of the assay.

2. Inoculate bacterial culture media within 24 h even if appropriate holding medium or refrigeration is maintained.

3. Small volumes of fluid (<1 ml) or tissue (<1 cm³) should be submitted within 15 to 30 min to avoid evaporation, drying, and exposure to ambient conditions. A few drops of nonbacteriostatic saline may be added for hydration. Larger volumes and those specimens in holding medium may be stored for as long as 24 h.

4. Bacteria that are especially sensitive to ambient conditions include *Bordetella pertussis*, *Shigella* spp., *Neisseria gonorrhoeae*, *Neisseria meningitidis*, *Haemophilus influenzae*, *Streptococcus pneumoniae*, and anaerobes. Reliable detection of these species requires immediate processing. Delays of up to 6 h result in some loss of CFU when transport media are used (34). Longer delays, even with the use of transport media, result in significant loss of organisms. For delays beyond 6 h, refrigeration improves recovery; however, specimens containing anaerobes should be stored at ambient temperatures (35, 36).

5. Moving clinical specimens and infectious substances from one laboratory to another, regardless of the distance and vehicle used, requires adherence to specimen packaging and labeling instructions mandated by the federal government. Materials for transport must be labeled properly, packaged so as to be able to absorb and contain any liquid released during a break or spill, and protected during transport. See the Centers for Disease Control and Prevention (CDC) website (http://www.cdc.gov/od/eaipp/shipping/) and the International Air Transport Association (http://www.iata.org/publications/dgr/Pages/other-dgr-products.aspx) for more information.

6. Some fastidious microbes or special testing protocols have more unusual transport requirements (Table 4). The laboratory test guide or manual should include clear instructions for special transport methods (37). If specimens are to be shipped to a distant reference laboratory, the reference laboratory’s conditions and requests must be met, and in many instances the laboratory provides transport devices to users. Continuous dialogue with physicians and other caregivers ensures that the appropriate information on collection and transport is accessed before specimen collection begins.

**LABORATORY SAFETY ISSUES REGARDING BACTERIAL PATHOGENS**

Workers should always maintain a level of suspicion that any specimen could harbor an infectious agent. Physicians may fail to alert the laboratory when they suspect the possibility of any dangerous pathogen, including *Coccidioides immitis*, *P. pseudotuberculosis*, *Brucella*, etc. Some bacteria, such as *Mycobacterium tuberculosis*, and potential bioweapons on the list of select agents, such as *Francisella tularensis*, pose a threat to health care workers (38). Some precautions can be taken even before laboratory activities occur. These include obtaining proper vaccines, such as those for *N. meningitidis* and more unusual agents if the laboratory is expected to encounter them. It is prudent to obtain baseline sera from each worker and store it in an ultralow-temperature freezer to have a basis for comparison in the event of a future exposure. Workers with conditions that place them at higher risk for some infections (immuno-compromised persons and those in certain ethnic groups) may wish to avoid those tasks or laboratory assignments that could place them at risk. Any laboratorians who handle specimens or who might have to enter an environment where aerosols are possible must be fit tested for an N95 mask or similar protective face shield respirator. These masks should be worn in any situation where aerosols are possible. The Occupational Safety and Health Administration mandates the Respiratory Protection Standard specifically for potential tuberculosis or severe acute respiratory syndrome coronavirus exposures, but other regulatory agencies and most employers have extended these rules to other respiratory hazards (https://www.osha.gov/SLTC/respiratoryprotection/standards.html). The CDC’s most recent biosafety manual, found at http://www.cdc.gov/biosafety/publications/bmbl5/bmbl.pdf, has guidelines for research laboratories. A CDC-produced *Morbidity and Mortality Weekly Report* relates more specifically to clinical laboratories (http://www.cdc.gov/mmwr/preview/mmwrhtml/su6101a1.htm). Chapter 12 of this Manual contains a more in-depth discussion of biosafety in the laboratory.

**Engineering Controls**

Laboratory environments should be designed to protect workers from biohazards inherent in the nature of the work. Ready access to properly maintained and certified biosafety level 2 (BSL2) laminar-flow biological cabinets and good training in the proper use of such equipment
are important and should be encouraged, even in resource-poor laboratory settings. The laboratory environment should have good lighting over work surfaces and sufficient air exchanges to decrease exposure for workers (12 exchanges per hour has been recommended). When BSL2 cabinets are not available, all manipulations that may result in aerosol formation, and those involving samples containing blood or body fluids (such as blood culture bottles), should be performed behind a Plexiglas or other clear shield. As many devices as possible to prevent contamination or acquisition of pathogens should be employed, including showers, eyewashes, and hands-free faucets at all hand-washing sinks. Specimen containers should be carried within the laboratory in trays with backstops, and in BSL2 or -3 rooms, the ceiling and walls should be smooth and waterproof and the floor should be smooth with coved edges. See chapter 12 for more information.

### Personal Protective Equipment

Workers should be allowed to wear gloves on the bench if they wish, and gloves should be changed often. Gloves should always be worn when handling original patient samples. Whether gloved or not, workers must wash their hands with alcohol gel or soap and water before leaving the laboratory, after removing gloves, and often at other times during normal work tasks. If splattering or aerosol is possible, face shields or goggles should be freely provided by the employer.

### Education and a Culture of Safety

Supervisors, managers, and directors should create an atmosphere where workers maintain an environment of safe working habits and are constantly reminded of their responsibilities in this area. Everyone should know what to do in the event of a spill or accidental release in the laboratory, and drills should be conducted periodically to reinforce proper responses (38).

### HANDLING OF SPECIMENS IN THE LABORATORY

#### Documentation of Arrival, Condition, and Appropriate Sample for Test Ordered

Upon arrival of specimens in the laboratory, the time and date of receipt should be recorded. Subsequently, the time of plating, which may differ substantially from the time of receipt, should be recorded. At the time of receipt, all specimens and requisitions should be carefully inspected. Specimens must be labeled and accompanied by a requisition reflecting the physician's order. The requisition must include the following information: patient name, age, sex,
identifying number (such as social security number or unique registration/billing number), and location (hospital room, physician’s office address, etc.); ordering physician’s name; specimen source (detailed); date and time of collection; and test ordered. If an electronic system is being used, such as a barcode data entry system, all of the relevant information mentioned in this section must be captured. One good quality assurance activity is to document that correct and complete information is captured during the accessioning process. If the information is incomplete, laboratory personnel must call the collecting location and request the missing information. If a specimen is mislabeled or no patient name is provided, another specimen should be collected. Relabeling of a specimen is allowed only if another specimen cannot be collected, such as for tissue collected during a surgical procedure. Laboratory procedures must clearly state the exceptions that are allowed, the steps needed to verify and document exceptions, and the individuals responsible for relabeling. When relabeling has occurred, the course of events must be outlined in the laboratory report so the physician interpreting the results is aware of potential errors. Speedy initial inspection of incoming samples can allow re-collection or notification of problems in an actionable time frame.

Laws governing specimen labeling can be reviewed at the Clinical Laboratory Improvement Amendments website (http://www.cms.gov/Regulations-and-Guidance/Legislation/CLIA/Downloads/apcsubk1.pdf). Specimens from outpatient facilities require additional information for Medicare and Medicaid billing. Patient diagnosis, in the form of an International Classification of Diseases, 9th revision or newer 10th revision code, is needed to confirm the justification for a particular test. If a test is not deemed necessary for a specific diagnosis, the patient must sign an advanced beneficiary notice documenting that the test is not considered necessary and that if it is performed, the patient will be required to pay the test charge. Medicare and Medicaid compliance rules also can be reviewed at the Centers for Medicare and Medicaid Services website (http://www.cms.hhs.gov).

### Specimen Rejection

In spite of acceptable labeling, some specimen collection sites, transport containers, or transport conditions render the specimen unacceptable for processing (39). Table 2 lists acceptable criteria for specimen management based on collection or transport conditions and times. When specimens fall outside these limits (too long in transit, incorrect temperature, not in proper transport medium, wrong site for requested test, etc.), new specimens should be collected whenever possible. To protect the safety of laboratory workers, specimens that leaked or those that are grossly contaminated on the outside of the container should also be rejected. In addition, specimens may be rejected because of poor quality of specimen material collected or because it is the wrong specimen type for the test requested, rather than the conditions of transport (Tables 3 and 5). Specimen quality is evaluated by examining the quantity and cellular composition. Although the quantity of many specimens is limited by the collection method or physical size of the infected area, some specimens, such as urine, stool, and sputum, are available in abundance. If another specimen can be collected easily with a larger volume, it is appropriate and necessary to request new or additional material. If the specimen volume is less than needed for essential tests, small volumes of liquid specimens can be extended by adding 0.5 to 1 ml of sterile saline or a nutrient broth. It is important to add just enough liquid to provide specimen for all tests requested. A comment such as “Specimen has been diluted to allow performance of requested tests” should be added to the results documenting this action. In some cases, too much sample should also be considered for rejection. For example, if >30 ml of urine is received for Chlamydia trachomatis and N. gonorrhoeae molecular testing, the dilution of rare infectious particles may yield false-negative results. When blood culture bottles are overfilled, the excess blood volume may overwhelm the ability of sodium polyanethol sulfonate (SPS) to adequately anticoagulate the blood or remove inhibitors.

Mixed fecal morphologies on Gram stain may indicate fistula into bladder from gastrointestinal tract</td>
</tr>
</tbody>
</table>

*Modified from reference 3 with permission.*
Specimens determined to have gross bacterial contamination from members of the normal microbiota, indicated by an abundance of SEGs visualized on the initial Gram stain, should be rejected. Specimens are rejected by contacting the patient’s caregiver, explaining the reason for rejection, and requesting a replacement specimen of acceptable quality. Timely notification and collection of replacement are necessary, especially in instances where antimicrobial therapy has been initiated. Regardless of the reason for rejection, it may be more politically palatable to state that the specimen cannot be accepted due to inability to correctly interpret the results, rather than to use the word “rejected” (N. Cornish, personal communication). Specimen rejection criteria should be reviewed by appropriate laboratory and medical staff representatives before becoming policy. Examples of acceptable and unacceptable specimens based on screening criteria are listed in Table 5.

Handling Samples That Are To Be Processed at a Remote Site

Transport and processing time limits suitable for laboratories near the specimen collection site are not appropriate for remote laboratories. Specimens must be handled in the same manner as if they are to be transported via public or private mail service. See the CDC Office of Health and Safety site and the Pipeline and Hazardous Materials Safety Administration site (http://www.phmsa.dot.gov/hazmat/standards-rulemaking/bmic) for the latest guidelines. The IDSA, recognizing the problem, has suggested guidelines for providing the best patient care under less-than-ideal circumstances (40). Managing movement of specimens using temperature-controlled boxes, reliable courier service, and good tracking systems is a challenge facing many providers today.

Prioritization

For busy laboratories that receive many samples over a short period, it is helpful to use a priority list to assist accessioning staff to determine in which order samples should be processed. Specimens ordered for STAT tests, such as Gram stains on specimens from patients still in the operating rooms, should receive the highest priority. A sample priority list is shown in Table 6.

Initial Sample Handling

1. Swabs that will be inoculated onto only one or two plates can be rolled directly onto the agar surface, inoculating the least inhibitory medium first. If a Gram stain is requested or if numerous media must be inoculated, the swab can be vortexed in 0.8 to 1.0 ml of sterile saline or Trypticase soy broth and drops of the suspension can be used to prepare the slide and inoculate media. Swabs should also be used to dip into stool, but usually not for sputum unless the sample is uniformly viscous without visible saliva. Sputum is best picked up from the container with wooden sticks which do not absorb the fluid sections but stick to the more purulent portions, where the pathogens are likely to be.

2. Clear fluids other than urine should be concentrated on a slide using a cytocentrifuge. If a cytocentrifuge is not available, samples of >1 ml should be centrifuged (1,500 to 2,500 x g) and the supernatant removed with a pipette down to 1.0 ml. This sediment is mixed thoroughly (vortex or pipette) and used for testing. Only if the material is thick, bloody, or frank pus can it be placed onto the slide without concentration, and it should be smeared thinly, similar to making a thin blood film.

3. Tissue and bone should be minced (using two sterile scalpels), and if fungus cultures are requested, a small piece of intact tissue should be inoculated into the surface of each agar medium (see chapter 114) in addition to the standard inoculum. Tissue and bone for bacteriology cultures should also be ground up in a mortar and pestle, or tissue may be dispersed in an automated stomacher (Seward Limited, Worthing, West Sussex, United Kingdom) or grinder. A drop of this suspension should be streaked to obtain isolated colonies.

4. A Gram stain should be examined for all fluids and tissues and some swabs, such as those received for diagnosis of bacterial vaginosis (BV). Gram stains can deliver rapid, actionable results to clinicians; can determine if a specimen is acceptable for culture based on cellularity; and should be used to aid the microbiologist in interpretation of the culture (42). Table 7 suggests specimen types appropriate for Gram stain. Infection gives rise to purulence (abundant polymorphonuclear cells), blood, necrosis, and mucus (mucous membrane specimens). In general, gross examination of the specimen should identify yellow to tan purulence, red to rust-colored blood, clear and tenacious mucus, and brown to black discoloration of necrotic tissue. Portions for smear and culture should be taken from these areas. It may be beneficial to ask the assistance of a surgical pathologist when choosing the best portion of excised tissue for examination (43). Two smears of thick material such as sputum or tissue can be prepared by placing sufficient material between two glass slides and pressing the slides together while sliding them back and forth lengthwise to spread the material evenly one cell layer thick and to break up mucous strands. Ideally, microscopic examination of smears, using a 10x microscope objective, should demonstrate many polymorphonuclear cells and few or no SEGs that would suggest cutaneous or mucocutaneous contamination with members of the normal bacterial microbiota. Specimens in which tissue necrosis is present also may show elastin fibers (Fig. 1) in stained smears.

### Table 6  Suggested priority list for accessioning samples received for bacteriology studies

| 1. STAT requests (in order: operating room, pediatric intensive care units, emergency department) |
| 2. CSF for routine culture and Gram stain |
| 3. Rapid antigen detection tests (group A Streptococcus, Campylobacter, others) |
| 4. Endotracheal aspirates in Lukens trap (patients on transplant and neonatal and pediatric intensive care units only) |
| 5. Acid-fast specimens (if arrive near the processing cutoff time) |
| 6. Bronchoalveolar lavage samples |
| 7. Tissues from operating room |
| 8. Body fluids (not CSF) |
| 9. Blood cultures |
| 10. Tissues and aspirates (not from operating room) |
| 11. Fresh stools not in transport media (place into transport medium) |
| 12. Sputa, other tracheal aspirates |
| 13. Swabs in transport tubes |
| 14. Urine samples |
| 15. Stools in transport medium, including Cary-Blair, viral transport medium, and sodium acetate-acetic acid formalin |

*Virology, mycology, and molecular test specimens may also need to be included in the list depending on the laboratory’s policies and sample-handling personnel distribution.*

(Continued on next page)
Lower respiratory tract specimens are likely to show alveolar macrophages and Curschmann’s spirals (Fig. 2), indicating that secretions have originated from the distal airways. Curschmann’s spirals are casts of bronchioles found in patients with chronic lung disease caused most commonly by asthma and cigarette smoking. Although elastin fibers are present in noninfected surgical wounds and specimens from areas of tissue damage, they are also found in infected tissue where necrosis has occurred.

5. Based on the site of the sample and the physician’s requests, each specimen should be inoculated to an appropriate medium chosen to recover suspected pathogens (Table 7). In this era of diminishing resources, two relatively recent innovations improve this process: chromogenic agars and automated plate inoculators. Chromogenic agars produce colonies that can be identified to genus or sometimes even species level directly from the appearance of the colonies without any further testing. Not only are they available for urinary tract pathogens (44) and some stool pathogens (45, 46), but also they are used widely for screening samples for resistant bacteria, such as methicillin-resistant S. aureus (MRSA), vancomycin-resistant enterococci (VRE), and multidrug-resistant Gram-negative rods (47, 48). These special media are discussed further in chapters covering organisms for which chromogenic media are available. In most cases, they are cost-effective by reducing both time and reagents used to identify the organisms in the conventional manner (44).

At least four automated media inoculators are available, and all have been reported to perform at least as well as manual plating and to reduce workload for short-staffed laboratories (49). Some require that the sample be inoculated onto the plate, e.g., Isolater (Vista Technology, Edmonton, Alberta, Canada); others handle the container containing any liquid specimen, e.g., MicroStreak (LabTech Systems, Adelaide, South Australia, Australia) and InocuLAB (Dynacon, Mississauga, Ontario, Canada). Streaking patterns vary from spiral to quadrant. Some recent instruments even manage to handle Eswabs (swabs submitted in liquid transport media), e.g., WASP, or Walk-Away Specimen Processor (Copan Inc., Murrieta, CA), and other liquid sample devices, e.g., InoquLA (BD Kiestra, Franklin Lakes, NJ) and PREVI Isola (bioMérieux, Durham, NC) (50). The calculated estimated return on investment for one of the instruments was approximately 4 years (http://www.vista.isolation.com). These instruments are seeing increasing adoption as laboratory staffing becomes leaner.

The use of enrichment broth is controversial, but it should be conservative. Table 7 presents our recommendations. For many samples, such as swabs, broth cultures are more likely to yield contaminating members of the skin microbiota than pathogens (51). When fastidious species or organisms that may be present in small numbers are clinically important, enrichment broths make sense. When simultaneously inoculated plates yield growth, it is rarely useful or efficient to continue with work with the broth. When initial plates do not show growth in the face of a sample with polymorphonuclear leukocytes (PMNs) or other suggestions of an infectious process, the broth should be held for at least 5 days, and sometimes up to 14 days (looking for Actinomyces in eye samples or P. acnes in prosthetic joint infection fluids, for example). Broths inoculated with cerebrospinal fluid (CSF) samples obtained from patients with indwelling shunts, joint fluids (should be injected directly into blood culture bottles), pericardial effusions, and other important fluids should be held for 14 days. Growth of skin organisms, such as coagulase-negative Staphylococcus and Propionibacterium species, must be evaluated in concert with clinical criteria to avoid overtreatment (52). In fact, for clean orthopedic surgeries, culture is not indicated (53).

Once inoculated to the appropriate media based on the laboratory’s protocols (Table 7), plates and broths are incubated in the appropriate atmosphere before they are examined for growth. Chocolate plates are always incubated in 5% CO₂, blood may be incubated in either air or CO₂ (depending on the requirements of the organisms to be recovered), and selective agar plates are best incubated in air, although MacConkey agar colonies appear virtually the same whether incubated in CO₂ or air. Special incubation atmospheres are mentioned in the chapters covering those species and in this chapter. Lighting a candle in an enclosed jar or metal box and allowing it to burn out naturally creates an excellent CO₂ atmosphere for good recovery of microaerophilic, capnophilic (requiring higher CO₂ concentration than air) bacteria. Unless otherwise noted, ideal temperatures for bacterial growth are 35 to 37°C.

Specimens for anaerobic culture should be processed as soon as possible after arrival in the laboratory. Usual media include an anaerobic blood agar plate (CDC blood agar or brucella blood agar), a medium that inhibits Gram-positive and facultative Gram-negative bacilli such as KV blood agar (kanamycin-vancymycin), a differential or selective medium such as Bacteroides bile esculin, a Gram-positive

selective medium (colistin-nalidixic acid blood agar or phe- 
nylethyl alcohol blood agar), and an enrichment broth such as 
chopped meat carbohydrate or thioglycolate (Table 7).

Media should be incubated in an anaerobic environment 
immEDIATELY AFTER INOCULATION. Incubation in anaerobic con- 
tainers, such as GasPak jars (Becton Dickinson Microbiol- 
ogy Systems, Cockeysville, MD), AnaeroPack (Mitsubishi 
Gas Chemical America, Inc., New York, NY), or Bio-Bag 
Anaerobic Culture Set (Becton Dickinson Microbiology 
Systems) or in an anaerobic chamber is acceptable (54).
A commercial product (Anoxomat; Mart Microbiology, 
Drachten, The Netherlands) can rapidly evacuate air and 
replace it with an anaerobic atmosphere in special jars for 
efficient anaerobic incubation. Anaerobes grow more slowly 
than aerobic or facultative bacteria. Jars or boxes should 
not be opened in air until after 48 h so that organisms in 
growth phase are not killed by exposure to oxygen (55).
Anaerobic cultures should be held for at least 5 days before 
being reported as negative. Longer incubation (at least 7 
days) of the broth is necessary for isolation of Actinomyces, 
Propionibacterium species from prosthetic joint infections, 
and some other fastidious anaerobes (56). See chapter 50 
for further discussion.

6. For many reasons, it is best to retain specimens, 
even empty containers if the entire specimen was used. 
Sometimes additional tests are requested later after other 
results, such as histopathology, become available. Somet- 
times there is an error during laboratory processing and the 
original aliquot must be resampled. Other reasons include 
checking the label on the specimen, preparing a second 
smear if there is a question on interpretation of the first 
one, or examining the gross appearance of the sample. If 
possible, specimens should be stored in a refrigerator or 
ultracold freezer. A minimum of 5 days is recommended.

Culture Examination and Interpretation

Once colonies have grown on agar culture plates, microbiol- 
ogists must differentiate potential pathogens requiring iden- 
tification and antimicrobial testing from contaminants that 
represent members of the normal microbiota. Aids to inter- 
pretation are the relative quantities of each isolate, correlat- 
ing culture results with Gram-stained smear results, and 
recognizing usual contaminants and pathogens from respec- 
tive specimen sites. In general, when examining cultures of 
specimens from sites adjacent to normally colonized muco- 
sae (e.g., sputum, urine, or superficial wounds), potential 
pathogens should outnumber indigenous members of the 
microbiota and should be seen in the direct Gram stain (3).

When examining cultures of specimens from presumably 
sterile sites (e.g., CSF, joint fluids, other body fluids, and 
deep tissue), potential pathogens occur in any quantity and 
may or may not be seen in the direct Gram-stained smear.
Specific criteria for identifying potentially significant iso- 
lates and contaminating members of the normal microbiota 
are addressed in the following sections of this chapter. It is 
a useful policy to save culture plates with significant growth 
for 1 week, allowing caregivers the opportunity to call to 
request further identification or additional antimicrobial 
testing when clinically indicated.

Specimens Received for Molecular Detection of 
Bacteria

Although blood has not yet been used widely for direct 
detection of bacteria using nucleic acid amplification tests 
(NAATs) or hybridization, such tests are being evaluated. 
Whole blood can be collected in EDTA tubes, in specially 
formulated acid-citrate vacuum tubes, or in other specialized 
tubes developed for NAATs. In cases in which plasma is 
the specimen for testing, removal of the liquid component 
from the red blood cells or using a plasma preparation tube 
as quickly as possible will provide the most accurate test 
results.

Tissue should be collected aseptically and submitted in 
a sterile container. Tissue is usually treated in some way to 
dissolve the matrix and release the nucleic acid contents of 
the microbe being sought; often this is done on an automated 
extraction instrument, or after initial grinding of the tissue, 
if necessary. If >24 h will pass before the test can be per- 
formed, tissue should be frozen at −70°C and transported 
 to the laboratory on dry ice to prevent thawing. For culture, 
nasopharyngeal swabs and aspirates for B. pertussis or oro- 
pharyngeal swabs for Mycoplasma pneumoniae should be 
transported on ice, but room temperature transport is suffi- 
cient for molecular detection. Special swabs with propriety 
transport media or first-void urine (<30 ml) are often sent 
for molecular detection of N. gonorrhoeae and C. trachomatis.

The transport system should be specific for the type of test. 
Recommended procedures and transport systems vary widely, 
so it is important to consult the laboratory and discuss the 
test system employed. A recent guideline addresses these 
issues (1).

18. Specimen Collection, Transport, and Processing: Bacteriology

No growth- and normal microbiota-type reports can be 
safely entered into a laboratory information system for rou- 
tine reporting to be seen by the caregiver whenever the 
caregiver chooses to look. But reports that are important 
and require telephone or personal or telephone discussion 
may no longer be actively following the case, it is especially 
important to telephone those results. Critical values, those 
that are immediately life-threatening, require the recipient 
of the call to write the result down and read it back to the 
caller. Each institution must develop its own critical-call 
procedure. Examples of critical values in bacteriology might 
include a positive CSF Gram stain, results suggestive of gas 
gangrene, a bioterrorism-related isolate, or a positive blood 
culture. Many microbiology results, including detection 
of a sexually transmitted infectious agent, detection of M. 
tuberculosis, or detection of a multidrug-resistant bacterium, 
should also be called to infection control personnel and/or 
local public health officials.

SPECIAL CONSIDERATIONS BASED ON 
SPECIFIC SPECIMEN TYPES (ALSO SEE 
TABLE 8)

Tissue Biopsy Samples

Tissue from a sterile site is usually obtained during a surgical 
procedure. Because this is among the most difficult and 
important specimens to get, it should be handled with ut- 
most care and the surgeon should prefer to send the specimen 
early or to preserve it carefully. Specimens may be delivered 
in the original biopsy container. Special swabs with propriety 
transport media or first-void urine (<30 ml) are often sent 
for molecular detection of N. gonorrhoeae and C. trachomatis. 

A recent guideline addresses these issues (1).

- 18. Specimen Collection, Transport, and Processing: Bacteriology
Necrotizing Fasciitis

Necrotizing fasciitis and gas gangrene (myonecrosis) are medical emergencies requiring immediate diagnosis and therapy that may include antimicrobials, surgical debridement, and the use of immunoglobulin and immunomodulators to combat the fatal complications of severe septic shock (64, 65). Necrotizing fasciitis and gas gangrene are caused most commonly by toxin-producing S. pyogenes, other beta-hemolytic streptococci, S. aureus, Clostridium sp., and mixed aerobic and anaerobic bacteria (64, 66). Gram-stained smears generally show protease-negative fluid, necrotic cell debris, rare or few PMNs (because of cell lysis), and the bacterial etiology. Culture should confirm the etiology and provide antimicrobial testing results where appropriate.

Cellulitis

Several studies have shown that aspirates from the leading edge of areas of cellulitis are not particularly fruitful. Injection of nonbacteriostatic saline and subsequent aspiration may be necessary to obtain enough material to culture (67, 68). Under the best of conditions, these specimens are unlikely to be positive (69). Blood cultures from patients with cellulitis are also unlikely to be positive (70). Tissue biopsy may be required if microbiological testing is deemed crucial for a rapidly progressing lesion.

Uncultivable Bacteria in Tissues

Some bacterial infections in tissue cannot be cultivated in vitro using standard microbiological media. These include tissue stages of syphilis caused by Treponema pallidum, donovoniosis caused by Klebsiella (formerly Calymmatobacterium) granulomatis, rat-bite fever caused by Spirillum minus, and others. The organisms may be visualized by histopathologic stains. Newer molecular technologies are proving to be most reliable, especially for organisms causing genital ulcer disease and those found in biofilms (71, 72). The use of universal primer PCR to identify bacteria seen in tissue sections by histology, including Treponema whitlocki, Coxiella burnetii, and Bartonella henselae, is gaining widespread favor (73, 74).

Additional discussion can be found in chapter 48.

Placenta for Agents of BV

Placentas are sent to microbiology to determine the etiology of a preterm birth or if the obstetrician suspects an infection. A piece of tissue from the chorionic layer below the amnion should be obtained in an anaerobic transport vial. If the intact placenta is received in the laboratory, the top layer (amnion) of the placenta is cut using sterile scissors, and sterile forceps are used to pull it away from the underlying chorionic layer. Sterile scalpels or another sterile scissors is used to cut a small piece of the freshly exposed chorionic tissue for aerobic and anaerobic culture, and occasionally a piece can be placed into 2SP or SP4 transport medium for Mycoplasma or Ureaplasma culture. Molecular methods have not been productive (75). Chapter 62 has more information on detection of mycoplasmas.

Quantitative Culture

Tissue from traumatic wound or burn injury may be submitted for quantitative culture, with results of ≥10^5 CFU/g being used to predict the likelihood of the development of wound-related sepsis (76). Limitations include the lack of reproducible results and the low predictive value compared to histologic examination of tissue. Swab cultures have been shown to correlate poorly with the biopsy culture results. Full-thickness punch biopsy samples should be collected for this process. To perform a quantitative culture, a portion of the specimen is weighed and homogenized in saline. The saline suspension is used to prepare serial dilutions for culture. Detailed procedures for quantitative tissue culture are given elsewhere (77).

Blood Cultures

Detection of bacteria and fungi circulating in the bloodstream is a major function of the microbiology laboratory (78–80). Key factors in obtaining optimal samples are thorough disinfection of the skin surface or the catheter port through which the blood will be obtained, an adequate volume of blood removed, and the appropriate timing of when to draw the blood, ideally before antibiotics have been administered. Blood obtained through an indwelling intravenous line is twice as likely to contain a surface organism contaminant, leading to a false-positive culture result, as is blood obtained through a peripheral skin site (81). It is important to recognize potential contaminants that grow, since treating contaminants as significant isolates is associated with unnecessary expense and danger of antimicrobial misuse (82, 83). Common contaminants include coagulase-negative staphylococci, coagulase-negative enterococci, Bacillus spp., and propionibacteria. In general, single cultures positive for these bacteria represent contamination. Multiple, separate cultures growing the same strain of these organisms are more likely to indicate a clinically significant bacteremia (78). Careful site preparation using 70% ethanol and chlorhexidine is critical to avoiding drawing up those contaminants, primarily coagulase-negative staphylococci (84). For patients for whom chlorhexidine is contraindicated, either tincture of iodine or povidone-iodine can be used after alcohol disinfection. All skin disinfectants are activated as they go from wet to dry on the skin surface, so a waiting period of 30 s (chlorhexidine) to 1 min (povidone-iodine) is necessary after application before the needle is inserted. Contamination rates of less than 2 to 3% are desired (85). Higher rates should be investigated and corrected by educational efforts (83, 85).

Another factor that aids the laboratory in interpreting blood culture results is to obtain two separate blood culture sets from two separate sites (78). Especially if one set has been obtained via a central or peripheral intravenous line, the second set should be drawn through well-prepared intact skin. Skin organisms involved in true sepsis should be recovered from both sites. Some hospital laboratories have a standard policy that blood culture orders always involve obtaining blood from two separate sites and inoculating at least two separate bottles. Recovery of all organisms is enhanced if two types of media are used. Most often, laboratories choose one aerobic and one anaerobic broth and recover growth from both media. Application of the blood culture results in an additional opportunity to recover a greater range of bacteria. In addition, failure to detect an anaerobe can have serious consequences, as empirical therapy may not be adequate (87).
tive method in which the 5-cm distal portion of the catheter is rolled across a blood agar plate four times (88). The catheter tip is discarded. Growth of >15 colonies is considered to be significant, i.e., implicating the catheter tip as the likely source of a bacteremia caused by the same organism simultaneously isolated from blood cultures. Interpretation of clinical importance is not possible without an accompanying positive blood culture. Soft tissue infections around a catheter insertion site should be cultured as a wound specimen using freshly expressed purulence that can be aspirated.

Some laboratories have adopted a method for determining if the indwelling intravenous (usually central) line is the source of a bacteremia without removing the line. Because many intravenous lines are removed unnecessarily, this method can preserve those lines not considered colonized, as determined by a higher number of organisms recovered in the blood obtained through the line than that obtained peripherally. Determining CFU is too labor-intensive, so a surrogate marker, the time to positivity in an automated blood culture system, has been used to arrive at similar conclusions, with the assumption that a faster time to a positive signal in the instrument, more than 2 h before the peripheral blood culture flags positive, relates to a higher original number of organisms in the culture and thus a colonized line requiring removal (89). Both catheter-tip surface cultures and time-to-positivity methods appear to predict catheter-related bloodstream infection better when used together than does either one used alone (90). Neither seems to work well to predict catheter-related candidemia (91).

The Isolator system is additionally utilized to recover fastidious organisms or those that do not multiply well in standard blood culture broth formulations or atmospheres. If specialized broth/atmospheres available for recovery of fungi and mycobacteria are not used routinely, laboratories should stock a supply of Isolator tubes and the centrifuge and capping instruments required to use the Isolator tubes. Because the white blood cells are lysed, intracellular organisms are released and better able to grow in cultures. The sediment containing the organisms can be inoculated onto any number of specialized media to enhance recovery. Infectious agents best recovered by the Isolator system include filamentous or dimorphic fungi (Fusarium and Histoplasma capsulatum are examples), some yeasts (Cryptococcus and yeasts from patients on antifungal therapy), Bartonella species, some N. meningitidis strains, N. gonorrhoeae, and other fastidious organisms that fail to grow in routine blood culture media or that fail to produce sufficient metabolites to trigger the detection system of an automated blood culture instrument (92). Direct plating of blood onto selective agar or performing a blind subculture after 4 days of incubation has been shown to recover Legionella from blood cultures better than the Isolator system (93). The Isolator system does not perform as well as other systems when recovering S. pneumoniae, other streptococci, P. aeruginosa, and anaerobes (94). Advantages of the Isolator system are the ability to inoculate the pellet to specific agar media when attempting to detect unusual etiologies of bacteremia, such as those caused by F. tularensis and Bartonella spp., and to provide colony counts, reported as CFU per milliliter of blood. Disadvantages of the system are the labor involved with initial processing and the potential for increased contamination that accompanies manipulation during processing (95).

Total volume of blood cultured is the major factor for identifying true-positive patients. For an adult, the most sensitive recovery requires at least 40 ml of blood (86). This is a small percentage of total blood volume. Yields from 20 ml and 30 ml of blood were 29.8 and 47.2% greater, respectively, than those from 10 ml of blood; yields from 40 ml were 7.2% greater than from 30 ml (86). In fact, more blood can and should be obtained from all patients than is currently practiced. Table 9 shows recommended blood culture volumes based on the weight of the patient and the corresponding percentage of the patient’s total blood volume (96). Blood should be collected as quickly as possible after the culture is ordered and before antibiotics are given, if possible, and all the blood can be obtained at the same time (from different sites) (97, 98).

For automated blood culture systems, the standard 5-day protocol is sufficient to recover all the usual pathogens and some unusual ones, such as Legionella spp., and holding bottles for additional incubation time only increases the numbers of contaminants recovered (93, 99, 100). For patients with suspected bloodstream infections that fail to yield a pathogen with standard blood culture protocols, either the Isolator tube should be employed for culture or serological or molecular methods (which may not be available) must be attempted (78). However, blind subculture may be needed for Legionella recovery or if the patient is receiving antimicrobials at the time of blood collection, particularly for recovery of yeast species (99).

In most cases, timing of the blood culture with respect to the maximum temperature recorded for the patient during a febrile episode is less important than total volume cultured. This has been reinforced by results of a multicenter study (98). Although there was a slight benefit for patients <30 years old for blood cultures to be obtained >1 h after the maximum temperature, this was not seen with other age groups, and in general, only 10% of positive blood cultures were actually drawn at the time of the patient’s peak temperature.

Semiautomated blood culture systems are present in nearly every clinical laboratory. Refer to chapter 4 for a complete discussion of manual and automated blood culture.

*Data from reference 96.

*Blood volume calculated by assuming 85 ml/kg in newborns and 73 ml/kg in other patients. Two 20-ml blood specimens collected from an 80-kg adult (40 ml total) represent ~0.7% of the patient’s total blood volume.
systems. The anticoagulant used in all blood culture systems is SPS and is known to be inhibitory to meningococci, gonococci, Peptostreptococcus anaerobius, S. moniliformis, and G. vaginalis (61), for which other methods of detection should be employed.

Positive blood culture bottles are evaluated initially by examining a Gram-stained smear of the broth (101). The report should include a description of the bacterial morphology and the Gram reaction. If a presumptive identification of the microorganism can be made, it may be added to the report. For example, a blood culture Gram stain report might state “Gram-positive cocci in clusters suggesting staphylococci.” Specimens in positive blood culture bottles should be subcultured to media based on the organism seen in the Gram-stained smear. In addition, since 5 to 10% of all bacteremias are polymicrobial (contain more than one bacterial type), additional media are recommended. Anaerobic media and culture conditions should be used if the morphology of the organism seen in the Gram-stained smear is suggestive of an anaerobic bacterium or if the organism is recovered from an anaerobic culture bottle only. If a positively flagged bottle shows no organisms on Gram stain, a second smear should be prepared and stained using acridine orange, a DNA stain (102). If organisms are present, even if they have damaged or no cell walls, they will stain bright orange, a DNA stain (102).

Rapid sample preparation and improvements in matrix-assisted laser desorption ionization–time-of-flight mass spectrometry databases have made identification of organisms from positive blood cultures by mass spectrometry more feasible for clinical laboratories (103). Other molecular methods, performed directly from positive blood cultures and available from several manufacturers, are helping to shorten the time to result reporting. A PCR method for detection of a number of pathogens from blood obtained directly from the patient is available in Europe (Roche Molecular Diagnostics, Basel, Switzerland). See chapter 4 for more details on matrix-assisted laser desorption ionization–time-of-flight mass spectrometry and related technologies.

Gram staining a smear of peripheral blood or buffy coat layer may detect bacterial cells in the blood of patients with meningococcemia, S. pneumoniae infection, or overwhelming infection caused by other bacterial organisms. If organisms are present in blood cultures by Gram stain, the likelihood of results affecting patient management does not warrant use as a routine laboratory procedure.

Diagnosis of leptospirosis may prompt a special blood culture request (see below). A recommended method is to use 0.1 ml of heparinized whole blood or 0.2 ml from high-speed-centrifuged plasma sediment inoculated into Ellinghausen-McCullough-Johnson-Harris medium and incubated from a minimum of 1 month up to 3 months (104). PCR and a commercially available probe amplification technology have been reported to be sensitive and specific for the detection of M. tuberculosis in CSF (110–112). Anaerobes are rarely found in CSF, even in cases of mixed anaerobic abscess of brain tissue. However, anaerobic incubation of CSF is necessary to recover microaerophilic streptococci that cause infection after trigeminal nerve injection. Broth enrichment should not be used routinely (31). P. acnes may be the cause of infection in patients with indwelling CSF shunts, hence the recommendation to inoculate an anaerobic broth such as thioglycolate or chopped meat carbohydrate with an aliquot of shunt fluid (113).

Smears should be Gram stained and results reported to the physician immediately. Results should include a description and semiquantitative enumeration of polymorphonuclear inflammatory cells and bacterial morphology. If the results are suggestive of a bacterial group, this too can be communicated. Because of low sensitivity and lack of effect on the care and management of patients (in the developed world), and because the cost of antigen testing is much higher than the cost of the Gram stain, direct antigen tests should be considered only in circumstances when direct communication with the clinical service documents a specific need, such as prior antimicrobial therapy (114). However, in locations where empiric antibiotics are not standard of care and laboratory skill levels are low, bacterial antigen tests may be useful adjunctive tests (115). Note that cryptococcal antigen tests are still valuable. Direct nucleic acid amplification of panmicrobial RNA and DNA from CSF will likely completely replace the residual antigen tests in laboratories that can justify the expense; one company has already received funding for development of such a panel. Leptospires can be detected in CSF during the first 10 days of acute illness. CSF should be collected before initiation of antimicrobial therapy and while the patient is febrile. Direct detection of leptospires by dark-field examination of CSF is not recommended. CSF should be inoculated into Ellinghausen-McCullough-Johnson-Harris medium and inoculated with a 0.5 ml inoculum. CSF should be cultured and evaluated at room temperature for up to 13 weeks (37).
diagnosis of conjunctivitis, corneal scrapings collected with a sterile spatula for the diagnosis of keratitis, vitreous fluid collected by aspiration for the diagnosis of endophthalmitis, and fluid material collected by aspiration or tissue biopsy for the diagnosis of periorbital cellulitis (116). Pathogenic bacteria potentially present in these anatomic sites are listed in Table 7 (118). Because the volume of specimen collected from corneal scrapings and vitreous fluid aspiration is very small, direct inoculation of agar culture plates and preparation of smears in the clinic or at the bedside is recommended (116). A close working association is needed between the laboratory and ophthalmologist to ensure a supply of appropriate culture media, correct technique for inoculation of media, and rapid transport of plates and smears to the laboratory. Media should be inoculated by rubbing the specimen onto a small area of the agar plates (swab) or wiping the material from the scraping off the spatula gently onto the agar surface, sometimes in the shapes of little C’s. Plates are placed directly into the incubator without cross-streaking by laboratory personnel. This allows the plate reader to detect more easily airborne contaminants that settle on the plate during inoculation procedures that occur outside controlled laboratory conditions.

Media needed for the detection of usual pathogens should include chocolate agar for fastidious bacteria and most fungi (Table 7) (118). Media for other microorganisms (some fungi, viruses, mycobacteria, etc.) should be inoculated if deemed appropriate by the ophthalmologist and microbiologist and specifically ordered. Incubation at 35 to 37°C in 3 to 5% CO₂ is necessary.

C. trachomatis in Eyes
Detection of chlamydial nucleic acid (nucleic acid amplification [NAA]) in conjunctival scrapings is the test of choice in the diagnosis of inclusion conjunctivitis or trachoma, despite the lack of FDA-cleared tests in the United States (119, 120). Examination of conjunctival smears using direct fluorescent-antibody (DFA) staining with fluorescein-conjugated monoclonal antibodies is possible for those laboratories with the skilled staff, appropriate reagents, and UV microscope available. A less sensitive but readily available method is examination of Giemsa-stained conjunctival smears for intracytoplasmic, perinuclear inclusions within epithelial cells (121). Cell culture for the isolation of C. trachomatis is more time-consuming and technically demanding than DFA or NAA and less sensitive than molecular methods (122). Conjunctival scrapings and secretions for culture should be transported in 2SP medium (sucrose phosphate or sucrose phosphate glutamate) with bovine serum and antimicrobials (usually gentamicin, vancomycin, and nystatin or amphotericin B). Swabs with wooden shafts should be avoided, since constituents of the wood are toxic to chlamydiae. Specimens for culture should be refrigerated during short delays or stored at −70°C for delays longer than 48 h.

Ears
Nasopharyngeal cultures have poor predictability for detection of middle ear pathogens and should not be used for that purpose (123). Two types of ear specimens are received most commonly by the laboratory: swab specimens for the diagnosis of otitis externa and middle ear fluid specimens for the diagnosis of otitis media (Table 8). Potential pathogens at these two sites differ (124). Since anaerobic bacteria may be involved in middle ear infections (albeit rarely), anaerobic culture, if ordered, should be performed on properly collected aspirates that are transported in anaerobic transport vials. Middle ear fluid is less likely to be contaminated than external ear specimens. All isolates from middle ear aspirates should be reported and, if requested, antimicrobial testing performed on strains with unpredictable susceptibility to antimicrobials. Direct examination of Gram-stained smears of middle ear fluid is helpful and is recommended with all culture requests. Due to poor yield of bacterial cultures, physicians usually treat empirically.

External ear specimens may be contaminated with normal members of the microbiota of the skin or ear canal. Isolates of coagulase-negative staphylococci, diphtheroids, and viridans group streptococci may be listed as presumptive identifications without including results of antimicrobial testing. Even S. aureus is often recovered from patients without infection, so the presence of inflammation should be used to help guide the extent of workup (125). It is a useful policy to save the culture plates for 1 week, allowing physicians the opportunity to call to request further identification or antimicrobial testing when clinically indicated.

Genital Discharge, Exudates, and Lesions
Bacterial infections of genital tract sites produce various clinical syndromes, including vulvovaginitis, BV, genital ulcers, urethritis, cervicitis, endometritis, salpingitis, and ovarian abscess in females and urethritis, epididymitis, prostatitis, and genital ulcers in males. These diseases and their etiologies are listed in Table 8.

Many specimens are contaminated with members of the normal microbiota of the skin or mucous membranes. Pathogens such as Haemophilus ducreyi, N. gonorrhoeae, Trichomonas vaginalis, T. pallidum, and C. trachomatis are always significant. Other organisms such as S. aureus, beta-hemolytic streptococci, Enterobacteriaceae, and anaerobes are pathogenic only in certain clinical situations. The specimen source, relative quantity of potential pathogen compared to members of the normal microbiota, and Gram stain interpretation help the technologist determine which isolates require identification and antimicrobial testing. At a minimum, isolates from presumably sterile specimens and pure or predominant potential pathogens from specimens likely to be contaminated with members of the normal microbiota and containing PMNs should be identified and reported. Mixtures of anaerobes do not require individual identification and listing in most cases. Laboratories should avoid isolating, identifying, and performing antimicrobial testing on every bacterial isolate from all specimens (126). In addition to the excessive cost of this approach, unnecessary reporting of bacterial species contributes to excessive treatment of patients. Exact protocols for workup and reporting may require discussion and mutual agreement with knowledgeable clinicians in each practice environment.

Detection of N. gonorrhoeae and C. trachomatis
NAA methods are the state of the art for detection of N. gonorrhoeae and C. trachomatis in endocervical, vaginal, urethral, and urine specimens. Users must pay close attention to the types of specimens approved for use with each kit. Specimens should be collected using the procedures and devices recommended by the manufacturer. In addition, false-positive and false-negative reactions have been reported with some kits, particularly when nonvalidated sample types are tested, necessitating confirmation of results from some commercial assays (127–130).

Although eye, rectal, oropharyngeal, and abscess specimens are not FDA cleared for testing in the commercial amplification systems, molecular amplification is still the best method (131, 132). In fact, self-collected swabs by both
men and women perform at least as well as those collected by health care personnel for molecular tests for C. trachomatis and N. gonorrhoeae (133). At this time, culture is still the only acceptable diagnostic procedure in some jurisdictions for medical-legal cases, but that should be changing soon (1).

Culture for N. gonorrhoeae is optimal when the specimen is directly inoculated to a selective medium, such as modified Thayer-Martin medium, and incubated immediately (35). Swab specimens (cotton swabs should be avoided because they may be toxic) should be placed in a transport system containing Stuart’s or Amies medium and delivered to the laboratory as quickly as possible. A new document from the Association of Public Health Laboratories contains much useful information (http://www.aphl.org/About/APHL/publications/Documents/ID_2014Mar_Transportation-of-Specimens-for-Neisseria-gonorrhoeae-Culture.pdf). Some newer products have shown good ability to retain the viability of N. gonorrhoeae (34). Specimens for N. gonorrhoeae culture should be held at refrigeration temperature during transport (35, 36). As transport time increases, recovery by culture decreases. Specimens requiring more than 24 h for transport are unacceptable. Recent publications have shown that for specimens from ocular, pharyngeal, or anal sites, molecular methods are far superior to culture (132, 134, 135). In fact, one system outperformed other methods. Molecular tests are replacing culture even for genital samples, although the need for isolates to perform antimicrobial susceptibility testing and for patients refractory to empiric treatment is still important (136). Follow guidelines from the test manufacturer for specimen collection and transport.

Although not a bacterium, T. vaginalis should now be routinely sought in genital infections due to the availability of commercial NAA Ts. Trichomoniasis is now known to be more common than either chlamydia or gonorrhea, primarily among women (137). See chapter 140 for more information.

BV and Vaginitis

BV occurs when conditions result in overgrowth of usual vaginal microbiota with various anaerobic genera, including Mobiluncus and Bacteroides (138). Although not characterized by a polymorphonuclear response, BV results in an increase in vaginal secretions that are relatively alkaline (pH > 4.5) compared to normal, the usual predominant microbiota of lactobacilli being replaced by anaerobes, and the presence of aromatic amines, which are detected by adding 10% potassium hydroxide and noting a pungent, fishy odor. In addition, excessive growth of the facultative bacterium G. vaginalis generally coincides with BV. Although G. vaginalis commonly is a member of the normal vaginal microbiota, the presence of increased concentrations that adhere to vaginal SECs, called clue cells, is characteristic of BV. Clue cells are SECs peppered with G. vaginalis bacteria, frequently showing heavier adherence toward the periphery of the cell and appearing like a doughnut (Fig. 3). New studies are showing that the bulk of bacteria actually associated with BV are identified only by molecular analysis, which at this time is beyond the scope of routine diagnostic laboratories (139). BV is still diagnosed best without culture (140, 141). Gram-stained smears should be examined and interpreted according to Table 10. In summary, until molecular amplification tests are available, BV should be diagnosed by performing a bedside pH and KOH “whiff test” and a laboratory Gram stain (142).

A combination probe assay (Affirm VPIII identification test; Becton Dickinson, Sparks, MD) is commercially available for the simultaneous detection of Candida spp., G. vaginalis (as a surrogate indicator for BV), and T. vaginalis in vaginal secretions, which in some studies outperforms more classical methods (143).

Screening for Group B Streptococcus

Pregnant women colonized vaginally or rectally with group B streptococci prior to delivery are at increased risk of infecting their newborn during delivery. Such women need intrapartum prophylaxis; currently 25% of all women receive antibiotics during labor in the United States, although the incidence of neonatal disease is only 0.3% (144). Current recommendations are for collecting vaginal and rectal swabs at 35 to 37 weeks of gestation for culture in a single enrichment broth such as LIM broth (145). This broth is incubated at 35°C for 18 to 24 h and subcultured to a blood agar plate the following day. Recent studies have shown that this approach misses ~10% of women who become colonized after their screening test, and a substantial number of women convert to negative and would not require prophylaxis (146–148). Real-time PCR performed on the enrichment broth culture has been used to improve sensitivity, but this approach still requires at least an 18-h turnaround time, not enough to allow timely use of intrapartum chemoprophylaxis for prevention of disease (149, 150). Newer PCR tests allow high sensitivity and specificity and rapid turnaround time, and some products can be performed by non-laboratory personnel at the time of delivery (151, 152). New recommendations are likely to include use of such tests for women who have not been screened previously or those with negative screening culture results (144, 145).

Dark-Field Examination for T. pallidum

Dark-field examination of tissues, tissue exudates, and material collected from chancre can be used to confirm the diagnosis of syphilis. For dark-field microscopy, the specimen should be examined within 20 min of collection to ensure motility of treponemes and should not be exposed to temperature extremes during transport to a dark-field microscope. The test requires a microscope equipped with a dark-field condenser and experienced personnel who are

able to recognize *T. pallidum* spirochetes based on the tightness and regularity of the spirals and on its characteristic slow, graceful, corkscrew movement (153). Only a few laboratories perform this test anymore. A DFA stain can be used and is performed on air-dried smears. The stability of the smear during transport and the easily identified, fluorescent treponemes make the DFA an attractive alternative to dark-field microscopy (154). Unfortunately, reagents for the DFA test are not commercially or widely available; it may be performed at some public health laboratories.

**H. ducreyi**

If infection with *H. ducreyi* is suspected, material from the base of the ulcer is collected and held at room temperature until it can be processed (155). One swab is used to prepare a smear for Gram staining. The presence of many small, pleomorphic Gram-negative bacilli and cocciococcal bacteria arranged in chains and groups (“school of fish”) suggests *H. ducreyi* but is rarely seen (see chapter 36). Recovery of the organisms by culturing on an enriched medium such as GC agar containing 3 µg of vancomycin/ml, 1% hemoglobin, 5% fetal bovine serum, and 1% IsoVitaleX or Mueller-Hinton agar with 5% horse blood, 1% IsoVitaleX, and 3 µg of vancomycin/ml is necessary to confirm the diagnosis; culturing at 33°C yields better recovery than does culturing at 35°C (see chapter 36). Genital ulcer disease is much better diagnosed with molecular methods (71).

**Actinomyces spp.**

Certain organisms classically referred to as *Actinomyces* spp., such as *A. israelii*, may cause pelvic inflammatory disease in women who use intrauterine contraceptive devices (IUDs) (156) (also see chapter 52). An IUD submitted for culture should be placed in a sterile liquid medium (preferably reduced, such as thioglycolate) and vortexed, and the liquid medium should be used to inoculate aerobic and anaerobic culture media. Inflammatory debris and tissue attached to the IUD should be removed and cultured aerobically and anaerobically. Mixed infections with Aggregatibacter actinomycetemcomitans and *Actinomyces*, sometimes mistaken for malignancy, involve bone or other tissue sites (157). *Actinomyces* spp. produce small knots of intertwined bacterial filaments called grains or granules, which may be 1 mm or more in diameter. These grains should be crushed on a slide for staining (Gram stain is acceptable), and transferred to medium for culture. See chapter 52 for more information. The presence of branching Gram-positive filaments suggests *Actinomyces* in this clinical setting; culture confirms the diagnosis. Molecular methods have been found to be more sensitive in at least one study (158).

**Lower Respiratory Tract**

Specimens from the lower respiratory tract are submitted to determine the etiology of airway disease (tracheitis and bronchitis), pneumonia, lung abscess, and empyema (159–161). Table 8 gives a list of lower respiratory tract diseases and their common etiologies. Usual specimens submitted consist of expectorated sputum; induced sputum; endotracheal tube aspirations (intubated patients); bronchial washings, washes, or alveolar lavages collected during bronchoscopy; and pleural fluid (162). Specimens should be delivered to the laboratory promptly and processed without delay (within 1 h of collection). If delays are unavoidable, the specimen should be refrigerated. *S. pneumoniae*, the most common etiology of bacterial pneumonia, is very susceptible to conditions outside the body and may be missed by culture when the sample is not plated immediately. A urinary antigen test for *S. pneumoniae* may be more sensitive in such cases (23, 163, 164). Given the difficulty of performing cultures for *Legionella pneumophila*, urinary antigen testing is recommended as an alternative method for diagnosis of legionellosis (165).

Lower respiratory tract secretions containing pathogens usually contain acute inflammatory cells (PMNs). Frequently, pathogenic bacteria are present within the PMNs. With the exception of aspiration pneumonia, characterized by mixed morphologies of bacteria including anaerobic species, pneumonia is caused by one or two organisms, and they should be predominant on Gram stain and culture. Endotracheal aspirates and sputum with numerous SECs are contaminated with upper respiratory tract organisms, and routine cultures cannot be used to determine the agent of the pneumonia. Quantitative cultures may enhance utility of endotracheal aspirates (166). Most bacterial lower respiratory tract disease is caused by inapparent aspiration of oropharyngeal contents. It follows that oropharyngeal microbiotas include the bacteria that cause lower respiratory tract disease. Detection of a potential pathogen in a grossly contaminated specimen may represent contamination with an oropharyngeal microbiota. The lack of usefulness of data from contaminated specimens has resulted in policies for screening and rejecting grossly contaminated respiratory tract specimens. There are many ways to assess the quality of respiratory tract specimens. A simple screening method involves assessment of SECs only (19, 167). SECs are found in the oropharynx but not in the lower respiratory tract. Increased numbers (defined as >10 per 10× objective microscopic field) indicate gross contamination with oropharyngeal contents, which includes usual members of the oral bacterial microbiota (Fig. 4). Acceptable sputum samples usually show numerous PMNs and rare SECs and often have mucous strands (Fig. 5). Table 5 lists respiratory tract specimens for the detection of *M. pneumoniae* and *Legionella* spp. should not be screened, as stated above, for adequacy. All specimens representing the lower respiratory tract are considered acceptable for the detection of these microorganisms (168). Different methods have been used to determine adequacy of samples for detection of *M. tuberculosis* (see chapter 30).

Bacteria should be reported when detected in Gram-stained smears if they are potential pathogens. Bacteria not in sufficient quantity or not representative of morphotypes resembling potential pathogens should be lumped together and reported as members of the normal respiratory microbiota. It is important to differentiate contaminating members of the respiratory microbiota from members of the respiratory microbiota causing aspiration pneumonia. Aspiration of relatively large amounts of oropharyngeal contents following loss of consciousness, paralysis of muscles involved with swallowing and breathing, or medical procedures such as intubation can result in infection of the airways with mixed members of the respiratory microbiota, leading to lung abscess and empyema (169). Gram stain of sputum from patients with aspiration pneumonia can be highly suggestive of the diagnosis. Stained smears show many PMNs and many mixed respiratory microbiota morphotypes, especially those suggesting streptococci and anaerobes. Much of the microbiota is intracellular. Aspiration pneumonia can be detected in hospitalized patients and those admitted directly from the community (170, 171).

Cultures of respiratory tract material should include a selective Gram-negative medium, such as MacConkey agar,
sheep blood agar, and chocolate agar for the detection of Haemophilus spp. (Table 7). Culture plates should be incubated at 35°C in 3 to 5% CO2 for 48 h before being reported as negative. Cultures are interpreted by examining the relative numbers and types of bacteria that grow and correlating these results to the Gram stain. Table 11 summarizes interpretative criteria used with respiratory tract specimens.

Special Considerations for Lower Respiratory Tract Specimens

Specimens Collected during Bronchoscopy

Bronchoalveolar lavage fluid and bronchial brush specimens from patients with suspected pneumonia should be cultured quantitatively to evaluate the significance of potential pathogens recovered (172, 175). Bronchial brush specimens, which contain approximately 0.01 to 0.001 ml of secretions, should be placed in 1 ml of sterile nonbacteriostatic saline or lactated Ringer’s solution, which is less inhibitory to Legionella species. If anaerobes are to be cultured, the broth must be chopped meat or freshly boiled thioglycolate. The specimen should be delivered to the laboratory immediately. In the laboratory, the specimen is agitated on a vortex mixer, a smear is prepared by cytocentrifugation for staining with the Gram stain, and 0.01 ml of specimen is inoculated to appropriate medium by using a pipette or calibrated loop. Any growth of >10 colonies per plate of potential pathogens (corresponding to 10^5 CFU/ml of original specimen) appears to correlate with disease. Bronchoalveolar lavage results in the collection of 50 ml or more of saline from a larger lung volume. In the laboratory, a smear is prepared by cytocentrifugation and Gram stained (174). The Gram stain report should include a comment about the presence of SECs and intracellular bacteria. Grossly contaminated fluid (>1% of all cells are SECs) may have falsely elevated counts of potential pathogens. Intracellular bacteria are more likely to be potential pathogens. A 0.01- or 0.001-ml aliquot of bronchoalveolar lavage fluid should be inoculated to agar media (Table 7). The recovery of <10,000 bacteria/ml suggests contamination. The recovery of >100,000 bacteria/ml suggests contamination. The detection of 10,000 to 100,000 bacteria per ml represents a “gray” zone (175). Counts of pathogens may be reduced by prior antimicrobial therapy or variations in transport medium storage conditions. Special media are needed to detect potential pathogens recovered (172,173). Bronchial brush specimens are also acceptable. The specimen should be placed immediately into a transport medium containing protein, such as albumin, and penicillin to reduce the growth of contaminating bacteria. Specimens may be stored in the transport medium for up to 48 h at 4°C or frozen for longer periods at −70°C. PCR methods have been used success-

Legionella spp.

Legionella spp., especially L. pneumophila, are important causes of community- and hospital-acquired pneumonia (176) (also see chapter 49). Legionellosis can be diagnosed by culture, DFA staining of smears of respiratory secretions, detection of antigens in urine, or serological testing. Although culture has been preferred historically because, unlike other methods, it is not limited to detection of certain species or serotypes, many laboratories now offer urinary antigen testing instead. The urinary antigen tests for L. pneumophila serotype 1 are relatively sensitive (24, 177, 178). The immunochromatographic product used most commonly (BinaxNOW Legionella; Inverness Medical, Waltham, MA) was 95% sensitive with frozen urine samples (product insert) and 100% sensitive in a recent outbreak investigation in Germany (179). Antigen tests for other serotypes are not widely available. Before culture, respiratory samples should be diluted 10-fold in a bacteriologic broth, such as tryptic soy, or sterile water to dilute inhibitory substances that may be present in the specimen. Because legionellae grow slowly, optimal isolation from highly contaminated specimens, such as sputum, is achieved by decontaminating the specimens with acid before plating and special media are employed (180, 181). The specimen is diluted 1:10 in KCl-HCl buffer (pH 2.2) and incubated for 4 min at room temperature. It is important not to incubate the specimen for longer than 4 min because legionellae may themselves be killed by acid exposure. Specimens are inoculated onto buffered charcoal-yeast extract (BCYE) agar with and without antimicrobial agents (e.g., vancomycin, polymyxin B, and anisomycin) and often other agars (181). The cultures are incubated in humidified air at 35°C for a minimum of 5 days. Using a dissecting microscope, small colonies with a ground-glass appearance, typical of Legionella spp., can be detected after 3 days of incubation. NAA for Legionella is sensitive and specific, although no commercial product is available yet (182).

M. pneumoniae

M. pneumoniae is a common cause of pneumonia, referred to as primary atypical pneumonia. Because M. pneumoniae is fastidious and grows very slowly, a definitive diagnosis is often based on the results of serological or molecular detection tests. When culture is required, the specimen of choice is a throat swab; however, sputum or other respiratory specimens are also acceptable. The specimen should be placed immediately into a transport medium containing protein, such as albumin, and penicillin to reduce the growth of contaminating bacteria. Specimens may be stored in the transport medium for up to 48 h at 4°C or frozen for longer periods at −70°C. PCR methods have been used success-
fully to detect M. pneumoniae directly in respiratory tract specimens, including as a component of a new respiratory panel assay (183), the FilmArray Respiratory Panel (BioFire Diagnostics, Inc., Salt Lake City, UT) (http://www.biofiredx.com/pdf/media/1/Press%20Release%20-%20BioFireRP17%20FDA%20Clearance-2014.pdf). Molecular detection by PCR or a related technique is the most sensitive method for the detection of M. pneumoniae (1).

Specimens from Patients with Cystic Fibrosis (Also See Chapters 42 and 43)

Respiratory samples (sputum, aspirates, or "gag spu[t] [deep throat swabs found to reliably recover important pathogens in these patients]) from cystic fibrosis patients require additional media and a tremendous extra effort to detect the important pathogens found in these patients (184). Burkholderia cepacia complex, particularly some genomospecies, is especially important (185, 186). This organism grows well on routine media; however, selective media such as B. cepacia selective agar, Pseudomonas cepacia agar, and oxidative-fementotive-polymyxin B-bacitracin-lactose agar are useful for optimal recovery from respiratory secretions (187). Comparative studies show B. cepacia selective agar to be superior (also see chapter 43) (187). H. influenzae, S. aureus (often difficult-to recognize small-colony variants), and mucoid P. aeruginosa are also important to identify. Many laboratories now use selective agar or chromogenic agar for S. aureus detection in cystic fibrosis patient samples (188). Molecular methods are proving useful for detecting important organisms in cystic fibrosis patients (185).

Chlamydia and Chlamydophila spp.

Chlamydiae are important causes of respiratory illnesses in children and adults (189, 190). C. trachomatis can cause serious respiratory disease in newborn infants. Chlamydia (also called Chlamydophilum) pneumoniae causes illness in all age groups, but most disease occurs in adolescents and young adults (also see chapter 63). Chlamydophila psittaci is primarily an animal pathogen but occasionally causes disease in humans exposed to sick animals. Lower respiratory tract secretions, in addition to nasopharyngeal washes, for the detection of chlamydiae are collected and transported to the laboratory in a medium containing antimicrobial agents (e.g., gentamicin and nystatin). If delays in transport or processing occur, the specimen should be stored at 4°C for up to 48 h. Longer storage should be at ~70°C or colder. Chlamydiae can be detected by rapid cell culture techniques (shell vial) using McCoy cells for C. trachomatis and C. psittaci and HEp-2 cells for C. pneumoniae. Most laboratories do not perform these types of cultures. As with M. pneumoniae, PCR is the most sensitive method for the detection of respiratory chlamydiae (191), and NAA detection of C. pneumoniae is commercially available as part of a multiplex PCR assay (183).

Nocardia spp.

Respiratory specimens for the detection of Nocardia spp. should be transported to the laboratory as soon as they are collected. Direct examination of a Gram-stained smear containing a Nocardia species shows thin, beaded Gram-positive branching filaments. The filaments are also partially acid fast when stained by the modified Kinyoun method (chapters 2, 19, and 29). Although Nocardia spp. grow readily on many common media such as sheep blood and chocolate agar plates, Sabouraud agar for fungi, and Lowenstein-Jensen medium for mycobacteria, better recovery may be seen on BCYE agar for Legionella and modified Thayer-Martin medium. Mycobacterial decontamination procedures reduce the recovery of Nocardia. Selective BCYE agar is optimal for culture from contaminated specimens (192). Although Nocardia spp. are detected commonly following 1 week of incubation, cultures are incubated for a total of 2 to 3 weeks at 35°C.

Upper Respiratory Tract

Upper respiratory tract specimens include the external nares, nasopharynx, throat, oral ulcerations, and inflammatory material from the nasal sinuses. Although few serious diseases involve these areas, many pathogens colonize or persist in these sites while causing symptomatic infection in deeper, less accessible sites (193).

Throat specimens are collected to diagnose pharyngitis. The most common etiological agent is S. pyogenes; however, other beta-hemolytic streptococci, Arcanobacterium haemolyticum, N. gonorrhoeae, C. diptheriae, mycoplasmas, chlamydophiles, and Fusobacterium necrophorum may also occasionally cause pharyngitis. Special requests are required for most of these agents, although routine throat cultures do not detect the beta-hemolytic streptococci and A. haemolyticum. New data on F. necrophorum suggest that it should be sought (by anaerobic culture) for patients with chronic sore throat and that the standard swab is sufficient for recovery (194–196). Swab specimens should be placed in a standard transport carrier containing Amies or modified Stuart’s medium. A selective agar for F. necrophorum can enhance detection (197). If only group A streptococci are to be detected, the swab can be sent dry with desiccant. Refrigeration is preferred if transport requires more than a few hours. Many rapid direct tests for group A streptococci are commercially available, including enzyme immunoassay (EIA), immunochromatographic assays, and nucleic acid-based probe assays (198). Rapid tests still lack sufficient sensitivity to be used without culture backup for negative results in the pediatric population (199). When a rapid test is requested, two throat swabs should be collected. If only one swab is received, the culture plate should be inoculated first. Material remaining on the swab is used for the direct test. If the rapid test is positive, the second swab can be discarded, but if the rapid test is negative, the second swab must be used for culture to confirm the negative direct test. The nucleic acid-based probe test is considered sensitive and specific enough by many to eliminate the need for confirmatory culture (200). A position paper by representatives of the American Academy of Family Physicians, the American College of Physicians-American Society of Internal Medicine, and the CDC and IDSA guidelines state that rapid tests do not require confirmatory culture when used with adult patients (199, 201). NAATs will likely become the test of choice in the future; commercial products available today have excellent sensitivity and specificity (202).

To culture group A streptococci, either horse or sheep blood agar or selective blood agar may be used. Selective agar makes the organism easier to visualize by inhibiting accompanying members of the microbiota but may delay the appearance of colonies of S. pyogenes. Cultures should be incubated for 48 h at 35°C in an environment of reduced oxygen achieved by incubating anaerobically, in 5% CO₂, or in air with multiple "stabs" through the agar surface. Stabbing the agar surface with the inoculating loop pushes inoculum containing streptococci below the surface, where the oxygen concentration is reduced compared to the ambient (203). These culture conditions allow the recovery of
groups C and G streptococci, organisms that may cause pharyngitis but do not cause the serious sequelae associated with group A streptococci (204). Reports from such cultures may state “beta-hemolytic streptococci, not group A, isolated.” Although relative numbers of colonies are usually reported (1+, 2+, etc.), this number may only reflect the quality of the sample and should not contribute to therapy decisions.

Throat specimens are also used to identify patients infected with N. gonorrhoeae. For best results, the specimen should be inoculated immediately to a selective medium, such as modified Thayer-Martin agar. Cultures are incubated at 35°C in the presence of 5% CO₂ for 72 h. Although no tests are yet cleared by the FDA and thus laboratories need to verify their use, NAATs are also the test of choice for detection of N. gonorrhoeae in the throat, due to their enhanced sensitivity (134). One recent assay uses two DNA targets to achieve better specificity (129). A. haemolyticum is usually recognized on the second day, when its characteristic hemolysis manifests (see chapter 28).

The external nares can be cultured to identify carriers of S. aureus by using a single swab inserted only as far as the tip to collect secretions from both the left and right nares. The nose should be gently pressed inward during collection to maximize contact of the swab. The usual carrier systems used for swab transport containing Amies or Stuart’s medium are acceptable. In the laboratory, the specimen can be inoculated to a sheep blood agar plate; however, use of selective media such as colistin-nalidixic acid agar or a selective and differential chromogenic medium (see chapter 19) is helpful in differentiating S. aureus or MRSA from other members of the microbiota and useful when interpreting large numbers of specimens (205, 206). Mannitol salt agar is not as sensitive as the chromogenic media (44).

Specimens for the recovery of B. pertussis and Bordetella parapertussis should be collected with a small-tipped Dacron swab. Cotton may be toxic to the organism. Swabs should be transported to the laboratory in special media. For delays of up to 24 h, Amies medium with charcoal can be used. If the transport time will exceed 24 h, Regan-Lowe transport medium should be used (210). Culture, DFA staining, and PCR have been used for detection, but PCR is the most sensitive for detecting B. pertussis and B. parapertussis (Dacron swabs are preferred for PCR tests) (211–213). Culture, primarily for epidemiological studies, is performed using Regan-Lowe charcoal agar containing 10% horse blood and cephalixin. Because a few strains of B. pertussis do not grow in the presence of cephalixin, the use of Regan-Lowe medium with and without cephalixin is recommended for optimal recovery (214). Cultures are incubated at 35°C for 5 to 7 days in a humid atmosphere. The DFA test can yield rapid results for Bordetella but should probably be discontinued in favor of PCR methods (215).

Nasopharyngeal swab specimens are used to identify carriers of N. meningitidis. Transport in a swab container with Amies or Stuart’s medium is acceptable. Specimens should be inoculated as quickly as possible to sheep blood or chocolate agar; however, selective agars for pathogenic Neisseria spp., such as modified Thayer-Martin, are necessary if interference by normal members of the microbiota is expected. Culture plates are incubated for 72 h in a humidified atmosphere at 35°C in the presence of 5% CO₂.

Vincent’s angina is an oral infection characterized by pharyngitis, membranous exudate, fetid breath, and oral ulcerations. Sometimes referred to as fusospirochetal disease or necrotizing ulcerative gingivitis, it is caused by Fusobacterium spp., Borrelia spp., and other anaerobes. Diagnosis is made by direct examination of a smear of a swab specimen collected from the ulcerated lesions and stained with the Gram stain (193). The presence of many spirochetes, fusiform bacilli, and PMNs is presumptive evidence of this disease. Culture or NAAT for F. necrophorum may also be attempted (195, 216). It should be noted that canker sores do not have a known microbial etiology and should not be cultured.

Inflammatory material from the nasal sinuses should be cultured to detect the etiologies of sinusitis. Nearly all cases of bacterial sinusitis follow a primary, upper respiratory tract viral infection. Bacteria are trapped in the sinus as a result of damage to the epithelial lining cells of the sinus, and inflammation and swelling narrow or close the nasal ostium, preventing normal drainage (217, 218). Specimens collected during endoscopic procedures by physicians specializing in otorhinolaryngology are optimal since they are sampled directly from the infected sinus, avoiding contamination by normal members of the microbiota in the nasal passages. Aspirates, washes, scrapings/debridements, and biopsy material should be kept moist and sent in a sterile container to the laboratory. Examination of Gram-stained smears can provide a rapid, presumptive identification of likely pathogens. Aerobic culture is needed in all cases; anaerobic transport and culture may be needed in cases of chronic sinusitis. Ventilator-associated sinusitis occurs in <10% of patients with nosotracheal intubation. Members of the nosocomial microbiota are implicated. Endoscopic inspection is needed to obtain acceptable specimens for culture (219). Although swabs obtained with endoscopic guidance correlate well with aspirates for recovery of bacteria, they do a poor job of recovering fungi, which have been implicated as etiological agents of chronic sinusitis (13). Recent evidence is casting doubt on fungi as a cause of this syndrome (220).

Special Considerations for Upper Respiratory Tract Specimens

A. haemolyticum

A. haemolyticum can cause pharyngitis and peritonsillar abscess (221). The organism can be recovered on media used to detect S. pyogenes. Colonies of A. haemolyticum are beta-hemolytic and easily confused with those of beta-hemolytic streptococci. Rapid differentiation can be accomplished with the Gram stain. A. haemolyticum is a diphtheroid-shaped Gram-positive rod (see chapter 28). Incubation of plates at 35°C for up to 72 h may be required for optimal detection.

C. diphtheriae

Culture of both throat and nasopharyngeal specimens is used in the diagnosis of diphtheria. When specimens are processed for culture without delay, no special transport medium or conditions are required. For transport to a reference laboratory, specimens should be sent dry in a container with desiccant (222). Alternatively, specimens collected on swabs may be placed in Stuart’s or Amies medium for transport to the laboratory. Smears of specimens for C. diphtheriae can be stained with the Gram stain and examined for pleomorphic (diphtheroid morphology) Gram-positive rods. In addition, smears can be stained with Loefler’s methylene blue stain and examined for pleomorphic, beaded rods with
swollen (club-shaped) ends and reddish purple metachromatic granules. Bacteria with thesecharacteristics are suggestive of but not specific for *C. diphtheriae*. Specimens should be inoculated to Loeffler’s serum and potassium tellurite media for the recovery of *C. diphtheriae*. Cultures are incubated for 2 days at 35°C in 5% CO₂ before being reported as negative. See chapter 28 for more information.

Epiglottitis

A throat swab specimen may be helpful in determining the etiology of epiglottitis, a rapidly progressing cellulitis of the epiglottis and adjacent structures with the potential for swollen tissues to cause airway obstruction. Epiglottitis in the United States was almost always caused by *H. influenzae* serotype b before widespread use of the *H. influenzae* type b vaccine, and now the disease is seen more often in adults. That species is still a cause of epiglottitis, even in vaccinated individuals, and certainly in areas of the world where the vaccine is not available. Other bacteria such as *S. pneumoniae*, *S. aureus*, *S. pyogenes*, and other beta-hemolytic streptococci are often involved (223, 224). The specimen should be collected by a physician only in a setting where emergency intubation can be performed immediately to secure a patent airway. Specimens should be inoculated onto enriched medium, such as chocolate agar, and incubated at 35°C in an atmosphere of 5% CO₂ for 72 h. Nearly 100% of patients with epiglottitis have a blood culture positive for the same bacterium, so blood cultures should be ordered as part of differential diagnostic testing.

Gastrointestinal Tract

Feces and in some cases rectal swab specimens are submitted to the microbiology laboratory to determine the etiological agent of infectious diarrhea or food poisoning. In fact, most diarrhea is caused not by bacteria but by viruses, parasites, immune-related disease, or other factors. Feces submitted for enteric pathogens should be collected in a clean container with a tight lid and should not be contaminated with urine, barium, or toilet paper. Because intestinal pathogens can be killed by the metabolism of other fecal bacteria rapidly acidifying the specimen, specimens should be transferred to Cary-Blair transport medium soon after collection. *Shigella* is the most labile, often becoming nondetectable within 30 min of collection. For *Vibrio cholerae*, other transport media such as alkaline peptone water are preferred (see chapter 41). Rectal swabs should be placed in a transport system containing an all-purpose medium such as Stuart’s. Recently, NAATs for a panel of stool pathogens (not limited to bacteria) have become commercially available, and they will likely be used broadly in the near future (225). Samples for molecular testing should be collected as described by the manufacturer.

It should be standard practice in all laboratories to evaluate the appropriateness of stool culture or NAAT requests. It is well established that hospitalized patients who did not enter the hospital with diarrhea are unlikely to develop bacterial enterocolitis caused by bacterial agents other than *C. difficile* (226, 227). For this reason, stool from patients who have been hospitalized for more than 3 days should not be processed for enteric pathogens without consultation with and justification by the patient’s physician or caregiver. A simple policy of rejecting stool for routine bacterial culture from patients hospitalized for more than 3 days and offering *C. difficile* testing for health care-acquired diarrhea is recommended. On the other hand, *C. difficile* infection is rapidly expanding as a community-acquired disease, sometimes following hospital discharge or the use of outpatient antimicrobial therapy, and sometimes in patients with no previous risk factors. Therefore, requests for *C. difficile* infection testing should not be rejected when ordered for outpatients (228, 229). After an initial negative NAAT for *C. difficile*, however, repeat testing is not routinely warranted, and use of NAATs for test of cure is inappropriate (230).

Fecal leukocyte examinations have been recommended for the differentiation of inflammatory diarrheas (fecal leukocyte positive) from secretory diarrheas (fecal leukocyte negative). Infectious, inflammatory diarrheas are caused by invasive bacteria, while secretory diarrheas result from toxin-producing bacteria, viruses, and protozoan pathogens (231). Unfortunately, fecal leukocytes degrade in feces, making accurate recognition and quantification difficult. A lactoferrin test can serve as a surrogate marker for fecal leukocytes (EZ Leuko Vue; TechLab, Blacksburg, VA) since lactoferrin is not degraded during normal transport and processing times. Lactoferrin-positive stool specimens are considered positive for fecal leukocytes. However, invasive pathogens may result in fecal leukocytes being intermittently present or unevenly distributed in stool specimens, and fecal leukocytes may not be present in severe *C. difficile* infection. Numerous studies have shown either fecal white blood cells or lactoferrin to be not useful for differentiating inflammatory from noninflammatory diarrhea (232, 233). For these reasons, use of any tests for fecal leukocytes should not be relied on to rule in or rule out acute, infectious diarrhea (231). The lactoferrin assay can be used in the evaluation of patients with inflammatory bowel disease (234).

Usual gastrointestinal pathogens are listed in Table 8 (227). Inclusion of less frequently encountered pathogens should be considered when epidemiological factors suggest an increased likelihood. This may require periodic surveys of one’s community to establish which pathogens are most common, especially when considering the addition of selective media or toxin assay for the routine detection of campylobacters other than *Campylobacter jejuni* or *Campylobacter coli*, *Vibrio spp.*, and *Yersinia enterocolitica*. Use of molecular multiplex panels could alleviate the need for selection.

Selective and differential media are used to detect *Salmonella* and *Shigella* spp. (Table 7). These should include one that is differential but not selective for these pathogens, such as MacConkey agar, and one that is a mildly selective medium, such as Hektoen enteric or xylose-lysine deoxycholate agar. In some settings, a highly selective medium such as salmonella-*shigella* agar is also included. In addition, enrichment broth, such as Gram-negative broth or Selenite F broth, may increase detection of Salmonella and is recommended for testing samples from sensitive populations such as food handlers. *Shigella* is generally not enriched. Subculture of Gram-negative and Selenite F broth to a mildly selective and differential medium after 6 to 8 h and 12 to 18 h of incubation, respectively, is necessary to prevent overgrowth of normal members of the microbiota and decreased usefulness of the broth (227). All agar plates should be incubated in air at 35 to 37°C for 2 days before being reported as negative. The decision whether to use a highly selective agar medium and an enrichment broth varies from one laboratory to another. Optimally, additional media are used for a trial period to determine their value, which is measured by the detection of strains not present on the two standard media. In settings where such a trial is not possible, the use of MacConkey agar, Hektoen enteric, or xylose-lysine deoxycholate agar and an enrichment broth is recommended.
C. jejuni and C. coli are detected in culture with a medium such as campylobacter agar with 10% sheep blood and selective antimicrobial agents (Table 7). Media are incubated at 42°C in a microaerophilic atmosphere of nitrogen (85%), carbon dioxide (10%), and oxygen (5%) for up to 3 days. Special enrichment broths do not increase the number of campylobacter-positive cultures significantly (235). Detection of other Campylobacter species may require media without antibiotics and 37°C incubation (236). EIA methods for detection of surface antigens of some Campylobacter species have been evaluated and shown to be relatively sensitive and specific (237). New molecular methods will probably replace culture for enteric pathogens, including Campylobacter, in the near future (238, 239). See chapter 56 for more information on methods of detection of fecal Campylobacter spp.

Special Considerations for Gastrointestinal Tract Specimens

Other Enteric Pathogens

A physician order for Vibrio spp., Y. enterocolitica, Aeromonas spp., and Pleisomonas shigelloides may be needed in some geographic locations or epidemiological situations, since incidence is so low in most parts of the United States that the routine use of selective media is not justified. Media used for these enteric pathogens include thiosulfate-citrate bile salts-sucrose agar for vibrios, cefsulodin-Ingasan-novobiocin agar for Y. enterocolitica, and blood agar or selective blood agar to demonstrate hemolysis and provide a medium for oxidase testing for Aeromonas spp. and P. shigelloides (both oxidase positive) (227). All of these enteric pathogens grow on usual media, but detection is enhanced and simplified using specific selective media.

STEC

The prevalence of Shiga toxin-producing E. coli (STEC) varies in different parts of the United States and the rest of the world. In addition to E. coli O157:H7, many other serotypes are implicated. In fact, in the United States, ~50% of STEC organisms, those capable of causing hemorrhagic colitis and hemolytic-uremic syndrome, are not serotype O157:H7 (240, 241). Shiga toxin EIAs and PCR assays detect all serotypes. Some Shiga toxin-producing strains may not harbor all the mechanisms needed to be fully pathogenic in humans. Routine culture of all stools on a selective medium and use of an EIA on an enriched broth (either Gram-negative broth or MacConkey broth) culture for detection of STEC have been recommended by the CDC (233). Recommendations from both the CDC and American Public Health Laboratory for universal STEC testing contain strategies for referral of non-O157 strains for further testing by public health laboratories (233, 242). A downloadable guide is available from the American Public Health Laboratory site (http://www.cdc.gov/AboutAPHL/publications/Documents/FY2012April_Guidance-for-PHL-Isolation-and-Characterization-of-Shiga-Toxin-Producing-Escherichia-coli-STEC-from-Clinical.pdf). Either sorbitol-MacConkey agar, cefoxime-tellurite-sorbitol-MacConkey agar, or a chromogenic agar can be used to detect O157 serotype strains. Note that non-O157 strains such as the recent European outbreak O104 strain may not be detected using conventional methods (243). New NAATs are available for specific toxin gene detection or detection of toxin-producing E. coli strains as part of a stool pathogen panel (239, 244).

C. difficile

C. difficile infection is diagnosed by detecting the organism or its toxins in stool, in conjunction with clinical criteria (228). The gold standard test for disease is the toxigenic culture, which requires direct plating on enrichment agar containing taurocholate, or alcohol or heat treatment to enrich for spores, followed by culture in broth and/or solid media (245, 246) (also see chapter 53). Colonies must then be tested by cell culture cytotoxin assay for toxin production (247). Because toxins are labile, molecular testing for the gene encoding toxin B, the major virulence factor, is becoming the standard test (248–250). Cell culture cytotoxicity assay for the detection of toxin B, EIA for the detection of toxins A and B, and latex agglutination or EIA for the detection of glutamate dehydrogenase (an antigen associated with C. difficile and occasionally other bacterial species) are all methods that have been used for diagnosis (249). EIAs are now known to have low sensitivity, depending on the prevalent strain types, and specificity (245, 251).

C. difficile-associated gastroenteritis is now appearing in patients without any risk factors, even in patients who had no antibiotic exposure (229, 252). Testing should not be performed on formed stool, with the major exception of patients with ileus or toxic megacolon, or as a follow-up to therapy to confirm cure. Repeat testing is only appropriate if symptoms persist or recur more than 7 days after an initial intervention (230). Since 2002, outbreaks of severe C. difficile disease in North America and Europe have been reported due to an epidemic strain, BI/NAP-1/027 (250, 253). This strain is also now widely acknowledged to cause more quickly progressing and serious disease, so aggressive diagnosis and treatment are important. Other strains are also associated with increased severity of disease, including those producing binary toxin (254, 255).

S. aureus, MRSA, and Bacillus cereus

Stool specimens or gastric contents collected from persons with short-incubation food poisoning (2 to 6 h) can be evaluated for S. aureus and B. cereus (also see chapters 21 and 26). In general, investigation is beneficial for general public health, rather than a sick individual who recovers quickly, and is best performed by public health laboratories rather than hospital clinical microbiology laboratories. Specimens should be examined by Gram stain, and because both of these organisms may be present normally in food, quantitative cultures must be performed. A series of dilutions (10⁻¹ to 10⁻⁵) of the specimen are prepared in buffered gelatin diluent, and 0.1-ml samples of the undiluted specimen and each of the dilutions are plated onto colistin-nalidixic acid or phenylethyl alcohol blood agar. The presence of 10⁵ CFU or more of S. aureus or B. cereus per g of specimen is of potential significance (256).

MRSA may be a cause of health care-associated antibiotic-associated diarrhea (257, 258). The overall incidence is unknown. Gram stain of smears of nonformed stool showing sheets of staphylococcal clusters in combination with appropriate clinical findings suggests the diagnosis. Diagnosis consists of the detection of heavy growth of MRSA in combination with the detection of staphylococcal enterotoxin in stool, available from some national reference laboratories and numerous public health laboratories (because Staphylococcus enterotoxin B is a category B bioterrorism agent). Greater recognition of this disease should confirm its significance and result in rapid diagnostic methods and appropriate treatment.
Clostridium botulinum

The clinical diagnosis of foodborne and infant botulism may be confirmed by detecting botulinum toxin, C. botulinum, or both in feces, although primary laboratories are now requested to submit samples to their appropriate public health laboratory for testing (also see chapter 53). In the United States when a case of botulism is suspected, investigators at the CDC should also be notified immediately. Optimally, 25 to 50 g of stool, 15 to 20 ml of serum, and a sample of suspect food should be collected (256). Botulinum toxin could be used as a biological weapon (see chapters 14 and 53). Unexpected numbers of cases or unusual presentations should be investigated. The ASM website has up-to-date guidelines on actions that should be taken in the event of a suspected case (http://www.asm.org/images/PSAB/Botulism_July2013.pdf).

Helicobacter pylori

H. pylori is an important cause of gastritis and peptic ulcer disease, and infection can lead to certain malignancies (259, 260). The organism can be observed in tissue sections by using hematoxylin and eosin, Giemsa, or Warthin-Starry silver staining. In addition, organisms can be visualized in touch preparations of dissected tissue stained with the Gram stain. As discussed above, the presence of H. pylori in stomach or small bowel lesions can be confirmed by culture, antigen detection, urease detection, or the detection of exhaled bacterial metabolite (H. pylori breath test) (261, 262). Tissue biopsy specimens collected during endoscopy are used for culture and urease detection. Specimens for culture should be placed in transport medium (a medium such as brucella broth containing 20% glycerol is best for transport and storage) and transported to the laboratory immediately, or refrigerated during delays (263). Lightly minced tissue is inoculated to freshly prepared blood agar and incubated in a humid, microaerophilic atmosphere (5 to 10% carbon dioxide, 80 to 90% nitrogen, and 5 to 10% oxygen) at 37°C for 7 days (Table 7). The addition of 5% hydrogen should improve the yield of H. pylori. Tissue for urease detection is placed as soon as possible into the detection system and processed as specified by the manufacturer. Stool for antigen detection should be collected and handled according to instructions from the manufacturer. Antigen tests are still useful; PCR methods have not yet become common practice (264). In some clinical situations, serological testing for H. pylori antibody may be necessary (see chapter 57). Serum should be collected and stored at refrigeration temperature for short periods (up to 1 week) or frozen at −70°C for longer periods, as for other antibody tests.

Screening for VRE or Beta-Hemolytic Streptococci

Identifying carriers of VRE for infection control purposes and group A streptococci during investigations of outbreaks of necrotizing fasciitis or streptococcal toxic shock requires collection of a rectal swab specimen. Carriers of VRE can be identified by culturing rectal swab or perirectal swabbed specimens. Carriers of VRE for infection control purposes should be investigated. The ASM website has up-to-date guidelines on actions that should be taken in the event of a suspected case (http://www.asm.org/images/PSAB/Botulism_July2013.pdf).

Small Bowel Bacterial Overgrowth Syndrome (268)

Occasional requests are received for quantitative culture to help with diagnosis of small bowel bacterial overgrowth syndrome, in which the numbers and types of organisms in the duodenum or jejunum increase to resemble the numbers in the colon (>10^9/ml) (269). At this time, it is unclear which method best aids in diagnosis of small bowel bacterial overgrowth syndrome (270). Laboratories receive duodenal or jejunal aspirate material in a sterile container. Because the test requested is to determine whether the number of CFU in the sample is above or below the threshold of 10^9 CFU/ml, a simple method such as thorough vortexing of the sample and inoculation of a blood agar plate using a 0.001-ml calibrated loop can be used. Counting colonies in the same manner as for urine cultures is sufficient.

Urinary Tract

Diseases of the urinary tract include prostatitis, urethral syndrome, cystitis, and pyelonephritis (271). Etiologies are summarized in Table 8. Urine, prostatic secretion, or urethral cell/secretion specimens are needed to diagnose these diseases. Urine can be collected by midstream (clean-catch) collection, catheterization (straight/in-out or indwelling), cystoscopic collection, or suprapubic aspiration. Foley catheter tips should not be submitted or accepted for culture since they are always contaminated with members of the urethral microbiota and quantitative is not possible. A first-voided morning urine is optimal, since in most cases bacteria have been multiplying in the bladder for a number of hours. Clean-catch urine, implying cleansing of periurethral areas, has not been shown to improve the quality of urine culture and is not recommended, although current guidelines still recommend clean-catch collection (271–273). Urine specimens should still be transported to the laboratory immediately and processed within 2 h of collection. If a delay occurs, specimens may be refrigerated for up to 24 h. Transport tubes containing boric acid are available to stabilize the bacterial population at room temperature for 24 h if refrigeration is not available (273). Boric acid–preserved urines are acceptable for dipstick leukocyte esterase testing (274). Urine culture is the most common test performed by most microbiology laboratories, and most urine cultures are negative; i.e., no specific potential pathogen is detected. Screening methods are available that attempt to rapidly separate those specimens containing significant counts of bacteria from negative specimens. In general, screening methods compare well with specimens containing bacteria at ≥10^8 CFU/ml but perform poorly when colony counts are lower. Screening urine specimens by staining with the Gram stain is rapid and economical with regard to reagents but is labor-intensive and requires a trained technologist. The presence of 1 or 2 bacteria of similar morphotype, or more, in each oil immersion field (100× objective lens) correlates with a count of 100,000 or greater by culture (275). Commercially available dipstick tests that detect leukocyte esterase (an enzyme produced by neutrophils) and surveillance of VRE, as positive PCR results will need to have the presence of a vanB-producing Enterococcus confirmed (266). Chromogenic agars for VRE are available and can enhance the speed and sensitivity of detection of these organisms (267). Carriers of group A streptococci can be identified by culturing rectal swab specimens on sheep blood agar or selective streptococcal agars used to identify patients with streptococcal pharyngitis.
nitrite (the result of bacterial nitrate reductase acting on nitrite in the urine) are rapid, inexpensive, and simple to perform, but their sensitivity is low in some patient populations. False-negative dipstick screening occurs because frequent voiding dilutes the concentrations of leukocyte esterase and nitrite in urine, enterococci and other less common urinary tract pathogens do not produce nitrate reductase, and many patients with asymptomatic bacteriuria do not have significant numbers of leukocytes in urine (276, 277). In spite of this, outpatient screening algorithms have been proposed that incorporate enzyme screening in a “reflexive” urine test: i.e., urinalysis is performed; if positive for leukocyte esterase or nitrate reductase, a culture is set up, and if negative, a culture is not done. Such screening works best for asymptomatic patients, diabetics, and women older than 60 years (277). Active research continues to find an accurate, cost-effective, sensitive, and specific automated urine screening system that eliminates the need to culture urine samples that are not indicative of urinary tract infection (UTI). After decades, this goal has not been reached.

The standard for quantitative bacterial culture of urine is the inoculation of 0.01 or 0.001 ml of specimen using a calibrated plastic or wire loop to appropriate medium, usually sheep blood and MacConkey agars or cystine–lactose–electrolyte-deficient agar. The loop is dipped vertically into the well-mixed urine, just far enough to cover the loop, and the loopful of urine is spread over the surface of the agar plate by streaking from top to bottom in a vertical line and again from top to bottom in a back-and-forth fashion. Prior to plate inoculation, it is necessary to ensure that a film of urine fills the loop with no bubbles to alter the calibrated volume. The inoculum of urine is spread over the entire agar surface to simplify counting of colonies after growth. Urine cultures are incubated at 35°C for 24 to 48 h. Although most urinary tract pathogens grow readily on usual agar media, slowly growing pathogens and those inhibited by the presence of antimicrobials in the patient specimen may not appear after overnight incubation (16 h). One approach uses the results of the leukocyte esterase and nitrite tests to determine which cultures get incubated for a full 48 h. Urine cultures that are negative after overnight incubation but had one or both positive enzyme tests are incubated for an additional day. Results that had negative enzyme tests are reported as “no growth” in a final report (271).

Contamination of urine, defined as growth of colonizing skin, vaginal, or fecal microbes in the absence of UTI, is detected in approximately 5 to 40% of cultures. Contamination is not reduced by the use of central processing areas, refrigeration, urine screening systems, specimen preservatives, or insulated specimen transport (278). Using a minicatheter to collect urine directly from the bladder can circumvent some of these contaminating bacteria, and collecting a suprapubic urine sample with a transcutaneous needle aspiration guarantees an even more representative urine sample. Urine collected by attaching a plastic bag to a baby’s perineal region (bagged urine) is never suitable for culture. Either catheter-obtained urine or a suprapubic aspirate of urine must be submitted to avoid a contaminated specimen from babies. Suprapubic aspirates should be handled in the same manner as sterile body fluids and may be cultured anaerobically.

Agar paddles are available for urine culture in settings where inoculation and incubation of conventional agar plates are not convenient or possible (279). A standard film of urine is distributed over the agar-covered paddle, usually by dipping the paddle into a jar of urine. The paddle is then reinserted into its plastic container for incubation. Following incubation, the density of growth is estimated by comparison to photographs or drawings. A preliminary identification of Gram positive or Gram negative can be determined by colony color and morphology, and when appropriate, the entire paddle can be forwarded to a reference laboratory for complete identification and antimicrobial testing of the isolate. Agar paddle culture of urine with approximate colony counts compares favorably with standard culture (279).

The urethra is colonized normally with many different bacteria from the vagina, skin, or feces. Because of this, voided urine often becomes contaminated during passage. Commensal bacteria are differentiated from potential pathogens by quantitative culture. Bacterial counts indicating “significant” bacteriuria (isolate is a likely pathogen) vary with the host and type of infection. Table 12 summarizes significant counts for common clinical situations (271). The urinary tract above the urethra had been thought to be sterile in healthy humans, but new genomic sequencing methods are revealing the predominance of nonculturable organisms in bladder urine in some patients (280). The implications of these findings are just being explored. For example, several studies have shown that Actinobaculum schaalii is an important cause of UTIs, especially in pediatric patients and patients >60 years old; efforts to recover this catalase-negative, pleomorphic Gram-positive cocccobacillus (requires anaerobic or CO₂ incubation) should be undertaken in such patients with pyuria (287).

Severe UTI generally involves the kidneys (pyelonephritis) and results in bacteremia. Rapid diagnosis and administration of appropriate antimicrobial therapy are necessary. In this clinical setting, blood cultures are needed and a STAT Gram stain of the urine can be useful. The Gram stain provides an immediate indication of the quality of the urine and a preliminary identification of the likely pathogen. Specimens containing high numbers of SECs are likely to be grossly contaminated with members of the periurethral or vaginal microbiota and should be re-collected immediately. For example, several studies have shown that Actinobaculum schaalii is an important cause of UTIs, especially in pediatric patients and patients >60 years old; efforts to recover this catalase-negative, pleomorphic Gram-positive cocccobacillus (requires anaerobic or CO₂ incubation) should be undertaken in such patients with pyuria (287).

Infectious prostatitis can be a difficult diagnosis. Prostatic secretions may be submitted for culture, but interpreting results when cultures yield low numbers of potential pathogens or mixed cultures is not clear-cut. Culture results should be correlated with Gram stain results. Organisms not recovered from routine cultures, such as mycoplasmas and chlamydiae, may be etiological agents in prostatitis. New molecular methods will likely provide assistance in the future (281).

Special Considerations for Urine Specimens

**Leptospires**

*Leptospira interrogans* can be recovered from blood and CSF during the acute stages of disease and from urine after the first week of illness and for several months thereafter. Urine should be processed as soon as possible after collection, because the acidity of urine harms the organisms. If a delay in processing is expected, urine should be neutralized with sodium bicarbonate, centrifuged (1,500 x g for 30 min), and resuspended in buffered saline before being used to inoculate media (see chapter 58). Alternatively, the urine may be diluted 1:10 in 1% bovine serum albumin and stored...

at 5 to 20°C. Undiluted urine and urine diluted 1:10, 1:100, and 1:1,000 in sterile buffered saline should be inoculated to Ellinghausen-McCullough-Johnson-Harris or equivalent medium, with and without neomycin (37). Cultures should be incubated at 30°C for at least 13 weeks (Table 7). Many clinicians also collect serum for serological tests for leptospirosis.

Bacterial Antigen Testing

Bacterial antigen testing kits, for the purpose of diagnosing bacterial meningitis, should not be used with urine specimens due to lack of strong correlation with meningitis. In particular, the FDA issued a product alert specifically cautioning against the use of the group B Streptococcus antigen kits with urine specimens because of the risk of both false-positive and false-negative results (282). As mentioned above in the sections on respiratory disease, urinary antigen testing is a recommended method for diagnosis of pneumococcal pneumonia and Legionella pneumonia.

Wounds

Superficial wound exudates and pus may be submitted on swabs, but this is inferior to biopsy samples or aspirates. Newer swab designs do allow better sample collection (7, 283). It is helpful to perform a Gram stain on all possible specimens to help determine how to interpret the culture, but with only one swab, this is difficult. The swab can be vortexed in <1.0 ml of sterile saline or broth and squeezed to express any moisture, and the suspension used to inoculate the plates and make a smear for Gram stain, but this is a labor-intensive activity. Therefore, two swabs or a flocked swab and transport medium system should be requested for samples collected on swabs (283). Examination of a Gram-stained smear reveals bacterial morphotypes, acute inflammatory cells (PMNs), intracellular bacteria, cell necrosis, and elastin fibers resulting from tissue necrosis (Fig. 8). The quality of a wound specimen can be evaluated by noting the relative number of polymorphonuclear cells and SECs (Table 5). Excess numbers of SECs suggest gross contamination with members of the cutaneous microbiota. It is acceptable to limit workup of bacterial isolates when the specimen shows gross contamination. An example of a limited workup would be to list by Gram stain morphology the isolates encountered, with a comment explaining that the physician must call if a replacement specimen cannot be collected and further identification and antimicrobial testing is clinically warranted. If swabs of ulcers or decubiti are received for culture, despite the laboratory’s attempts to discourage such samples, a limited workup of the organisms most likely to cause an underlying osteomyelitis should be performed (11, 12). The bacteria of importance include beta-hemolytic streptococci, S. aureus, P. aeruginosa, Proteus spp., E. coli, and Klebsiella spp.

Autopsy Samples

Microbiology testing as a component of the autopsy examination has been controversial (284). Postmortem and agonal invasion of sterile tissues confuses the significance of positive culture results, prompting some to argue against microbiology testing. Others found that the postmortem examination continues to uncover a significant number of infectious diagnoses, whether in the community or university hospital setting, that were missed by modern high-technology medicine (285). The value of autopsy microbiology is further enhanced by its use to identify emerging diseases, etiologies of biological warfare, community outbreaks, nosocomial infections, and antimicrobial resistance and uncover the cause of death in organ transplant patients and others with immunocompromising conditions. Safety precautions designed to protect the pathologist and dissection assistants during autopsy procedures have been thoroughly reviewed (286).
the body has been shown to decrease the incidence of false-positive postmortem cultures. Although it has been shown that cultures collected within 48 h of death from a refrigerated cadaver did not show an increase in false-positive results, tissue and fluid specimens, as a rule, should be taken from refrigerated bodies within 15 h of death (254). This serves to diminish the likelihood of postmortem overgrowth of contaminants and improve detection of true pathogens. Specimens should be obtained by sterilizing the surface of the organ with a hot spatula or iron surface until the surface is thoroughly dry. Body fluids, including blood, should be collected first. For blood collection, the wall of the heart and large vessel should be pierced with a sterile needle (18 to 20 gauge) inserted. A 20-ml volume, or as close to 20 ml as possible, should be collected and injected directly into aerobic and anaerobic blood culture bottles. Blood culture results obtained before opening the chest cavity by percutaneous subxyphoid aspiration have been shown to have greater interpretive value (less contamination but detection of relevant organisms). Most conclude that postmortem blood cultures rarely provide information that is not already known. Solid viscera should be sampled by immediately cutting blocks of tissue from the center of the seared area. Samples should be submitted to microbiology with a requisition providing a full explanation of the studies needed. Postmortem cultures can be very useful for detecting pathogens that are not considered members of the normal human microbiota, such as M. tuberculosis, Brucella spp., B. pertussis, some systemic fungi (H. capsulatum, C. immitis/posadasii, etc.), parasitic helminths, and agents of biologic warfare. Tissue samples should be transported to the microbiology laboratory immediately in sterile tubes. The use of transport media and laboratory processing methods should follow recommendations for premortem specimens. An efficient way to avoid unnecessary workup of contaminating microorganisms is to issue a preliminary report to the pathologist who performed the autopsy listing organisms detected by colony or Gram stain morphology, such as “lactose-fermenting Gram-negative rod” or “Gram-positive cocci in clusters.” This is accompanied with a notation that further identification and antimicrobial testing will not be performed unless there is consultation with the laboratory director or technologist conducting the culture investigation. Plates can be held for 1 week and discarded if no additional information is requested.

RONALD ATLAS AND JAMES SNYDER

REAGENTS
A number of classical and rapid tests are used for the identification of medically important bacteria. Below are brief descriptions of commonly performed tests and reagents used in clinical microbiology. See references 1–4 for more detailed descriptions of these tests and the reagents they use.

Biochemical Tests

■ Acetamide hydrolysis test (Nessler reagent)
Nessler reagent is used in the determination of acetamide hydrolysis. This test is useful in differentiating some Gram-negative bacteria. Acetamide agar or broth is inoculated. After incubation at 35 to 37°C until colonies or turbidity develops, 1 drop of Nessler reagent is added to 1 ml of broth or directly to the plate. A positive reaction is indicated by the formation of a red-brown sediment. Nessler reagent is prepared by dissolving 1 g of mercuric chloride in 6 ml of distilled water and then adding 2 or 3 drops of concentrated hydrochloric acid to dissolve the sediment. Separately, 2.5 g of potassium iodide is dissolved in 6 ml of distilled water and then added to the mercuric chloride solution. Then 6 g of potassium hydroxide is dissolved in 6 ml of distilled water and added to the mercuric chloride-iodide solution along with an additional 13 ml of distilled water. The solution is filtered using a sintered glass funnel (not a Nalgene filter). The Nessler reagent is stored in the dark and should be useful for several weeks. The solution should be checked for decomposition prior to use (any color change other than yellow indicates decomposition, and a fresh solution should be prepared). Nessler reagent is toxic if swallowed, inhaled, or absorbed through the skin. It presents a neurological hazard, may act as a carcinogen, and may be a reproductive hazard. It is corrosive and causes burns.

■ L-Alanine-7-amido-4-methylcoumarin (Gram-Sure)
L-Alanine-7-amido-4-methylcoumarin is a fluorogenic compound that is used as an adjunct to the Gram stain to distinguish between Gram-negative and Gram-positive aerobic rods or coccobacilli. It is available from Remel (Thermo Fisher Scientific, Lenexa, KS) as reagent-impregnated disks—Gram-Sure. This rapid disk test is used most commonly with Gram-positive organisms that may appear Gram variable or Gram negative, such as Bacillus or Lactobacillus. The mechanism of the test is dependent on the presence of aminopeptidase in the cell walls of Gram-negative organisms, which hydrolyzes the reagent L-alanine-7-amido-4-methylcoumarin in the disk from a nonfluorescent substrate to a blue fluorescent compound. A pure colony of overnight growth is inoculated into demineralized water and then inoculated onto the disk. The disk is incubated at room temperature for 5 to 10 min and then observed under long-wave UV light for blue fluorescence. Blue fluorescence is indicative of Gram-negative bacteria, and the absence of blue fluorescence is indicative of Gram-positive bacteria. Obligate anaerobes may fail to give expected results (5).

■ Alkaline phosphatase
Alkaline phosphatase is detected by the hydrolysis of a colorless phosphate-containing compound to a colored product, e.g., p-nitrophenol phosphate to p-nitrophenol, which is yellow; phenolphthalein phosphate to phenolphthalein, which is red under alkaline conditions; or indolyl phosphate to indigo, which is blue. This test is useful in the differentiation of Staphylococcus spp., and it is incorporated in several commercial identification systems.

■ Arginine arylamidase (L-arginine-4-methoxy-β-naphthalamide)
Arginine arylamidase is included as a diagnostic test in some commercial systems, e.g., the API test system of bioMérieux (Durham, NC). The substrate for this test is L-arginine-4-methoxy-β-naphthalamide. A negative test is colorless, and a positive test produces an orange color. This test is useful in differentiating staphylococcal species and various other bacteria.

■ Arginine dihydrolase
Arginine dihydrolase is detected by dense inoculation (McFarland standard of 4 to 5) of Moeller broth to which 1% arginine is added. After inoculation, the broth is overlaid with paraffin oil. Alkalinization, caused by the production of ammonia, is detected by the pH indicators. A positive

*This chapter contains some information presented by Kimberle C. Chapin and Tsi-Ling Lauderdale in chapter 21 of the ninth edition of this Manual. In particular, Table 1 and the section on medium additives have been taken directly from that chapter. Descriptions of a number of stains and reagents were also based on material in that chapter.
result is indicated by a purple color, which can be read after 4 h to up to 2 days.

**Benzidine test (benzidine hydrochloride)**

The benzidine test is useful for differentiating coagulase-negative *Staphylococcus* spp. This test is included in several commercial systems. It is based on the presence of ironporphyrin compounds. Addition of a solution of 1 g of benzidine hydrochloride dissolved in 20 ml of glacial acetic acid, 30 ml of water, and 50 ml of 95% ethanol followed by addition of a 5% solution of hydrogen peroxide (H₂O₂) results in the formation of a blue-green to deep blue color for positive organisms.

**Bile solubility test (deoxycholate)**

The bile solubility test is used in the presumptive identification of *Streptococcus pneumoniae*. The key reagent in this test is sodium deoxycholate, which is a surface-active bile salt. The test may be run in a tube or on agar plates. The test is performed on alpha-hemolytic streptococcal colonies. A few drops of a 10% solution of sodium deoxycholate can be applied directly to the surface of a colony. The plate is then incubated for 30 min at 35°C. Pneumococcal colonies are lysed, whereas viridans group streptococci are not lysed. Alternatively, a heavy suspension of cells can be added to physiological saline solution (pH 7.0) and divided into two tubes. The 10% sodium deoxycholate solution is added to one tube, and sterile physiological saline is added to the other. The tubes are incubated at 35°C and are visually compared. If the organism is bile soluble, the tube containing the deoxycholate will exhibit reduced turbidity within 15 min and show an increase in viscosity along with clearing of the solution.

**CAMP test (beta-lysin)**

The CAMP test is used to identify group B beta-hemolytic streptococci based on their formation of a substance (CAMP factor) that enlarges the area of hemolysis formed by streptococcal beta-hemolysin. Hardy Diagnostics’ (Santa Maria, CA) CAMP Spot Test Reagent is used as a rapid CAMP test method. The reagent, containing staphylococcal beta-lysin (also called beta-toxin, beta-hemolysin, or beta-staphylyosin), acts directly with the CAMP factor that is diffused into the medium around the suspect colony. The beta-lysin has a synergistic effect in the presence of CAMP factor, producing enhanced hemolysis of sheep erythrocytes. Enhanced hemolysis is visible within 30 min to 1 h of placing a drop of CAMP Spot Test Reagent next to an isolated beta-hemolytic *Streptococcus* colony.

**Catalase test (H₂O₂)**

H₂O₂ is used to detect bacterial production of catalase. A concentration of 15% is used for the differentiation of anaerobes, which do not produce catalase. A 30% peroxide concentration is used to test *Neisseria* spp. Cells from a colony are transferred to a clean glass slide, and a drop of hydrogen peroxide is added. Production of bubbles indicates a positive reaction. Blood must be avoided, as erythrocytes produce catalase and can cause a false-positive reaction. It is also possible to add a drop of hydrogen peroxide directly to a colony or slant as long as the medium does not contain blood. Immediate bubbling indicates a positive reaction.

**Coagulase test (rabbit plasma)**

Dehydrated rabbit plasma with EDTA is used to detect free or bound (clumping factor) coagulase produced by *Staphylococcus* spp. Human plasma is preferred for the detection of bound coagulase produced by *Staphylococcus lugdunensis* and *Staphylococcus schleiferi* but is not routinely used because it may contain antibodies against staphylococci. A heavy suspension of cells is added to a clean glass slide and mixed with a drop of distilled water. If agglutination does not occur spontaneously, the procedure can be performed by adding a drop of rabbit plasma to the suspension and mixing with a circular motion. The formation of visible white clumps indicates the presence of bound coagulase. Positive and negative controls should be run. The test can also be run in a test tube that detects both free and bound coagulase. For this test, 0.5 ml of rabbit plasma is added to a sterile tube. The tube is inoculated with a loopful of the test organism and incubated at 35°C for 4 h. Observations for clotting should be made within the first 4 h since some staphylococci produce fibrolisin, which can dissolve the clot. If no clotting is observed, however, the tube should be incubated overnight at room temperature and again observed for delayed clotting.

**Decarboxylase tests**

Bromcresol purple is used to detect the pH change due to decarboxylation of any of the amino acids lysine, ornithine, and arginine. Decarboxylase tests are useful for differentiating the *Enterobacteriaceae*. For the decarboxylase test, a broth at neutral or slightly acidic pH containing an individual amino acid being tested is inoculated for at least 24 h in most cases. The broth may contain the brom cresol purple or the test may be run after growth by adding a solution of brom cresol purple to a drop of the medium to determine if the pH is alkaline. A more rapid test has been described (6) that omits glucose from the medium and uses a starting pH of 5.5. In a positive result, the drop in pH is indicated by a change in color of brom cresol purple from yellow to purple.

**Esculin hydrolysis (ferric ammonium citrate)**

The hydrolysis of esculin to esculentin is detected using a 1% solution of ferric ammonium citrate. After incubation in esculin-containing medium for 1 to 2 days, a few drops of ferric ammonium citrate is added. The immediate formation of a brown-black color indicates a positive reaction. Esculin hydrolysis can also be determined using esculin agar, which is indicated by blackening after overnight incubation.

**β-Galactosidase (o-nitrophenyl-β-D-galactopyranoside [ONPG])**

ONPG at a concentration of 4 mg/ml is used to detect β-galactosidase activity. This enzyme facilitates growth on a carbon source like lactose by cleaving it into a molecule of glucose and a molecule of galactose, which the cells can catabolize and on which the cells can grow. The substrate ONPG is used in place of lactose. When the β-galactosidase cleaves ONPG, o-nitrophenol is released. This compound has a yellow color. This test is especially useful for identifica-
tion of members of the family Enterobacteriaceae. ONPG-impregnated tablets can be used for this test.

- **β-Glucuronidase (p-nitrophenyl-β-D-glucopyranoside, 4-methylumbelliferyl-β-D-glucuronide (MUG))**

Detection of β-glucuronidase activity can be accomplished using either a colorimetric substrate (p-nitrophenyl-β-D-glucopyranoside) or a fluorometric substrate (MUG). This test is useful for the rapid identification of *Escherichia coli*, members of the *Streptococcus anginosus* group, and other bacteria. For the colorimetric test, a solution of 0.1% (wt/vol) p-nitrophenyl-β-D-glucopyranoside (colorimetric substrate) in 0.067 M Sorensen phosphate buffer (pH 8.0) is prepared. Tubes containing 0.5 ml of the substrate solution are inoculated with a loopful of bacteria from an overnight culture. The tubes are incubated at 35°C and examined after 4 h for the appearance of a yellow color (liberated p-nitrophenol). In the fluorometric test, the substrate MUG yields the product 4-methylumbelliferyl, which fluoresces under long-wave UV light. The MUG test is normally used for the presumptive identification of *E. coli* and more recently for streptococcal strains. To prepare MUG for the fluorescent test, dissolve 50 mg of MUG in 10 ml of 0.05 M Sorensen phosphate buffer, pH 7.5. Dilute 1:16 of the stock MUG and add 1.25 ml to a vial containing 50 sterile paper disks. Allow the disks to be thoroughly saturated until no liquid remains in the vial. Spread the saturated disks out and allow to dry completely. The disks can be stored in a dark bottle at −20°C for 1 year or at 4°C for 1 month. Wet the disk with 1 drop of sterile water. Apply the organism to the disk using a wooden stick or loop and then incubate the disk for up to 2 h at 35°C. Shines a long-wave UV light on the disk. A positive reaction is indicated by blue fluorescence.

- **Hippurate hydrolysis (ninhydrin reagent) (ferric chloride)**

Hippurate hydrolysis to benzoic acid and glycine is useful in the identification of group B streptococci (GBS), some *Listeria* spp., *Gardnerella vaginalis*, *Campylobacter jejuni*, and *Legionella pneumophila*. Ninhydrin reagent can be used to detect the production of glycine. Ninhydrin reagent (3.5%) is prepared by adding 3.5 g of ninhydrin to 50.0 ml of acetone and 50.0 ml of 1-butanol. The ninhydrin reagent is stored in the dark at room temperature. A 1% (wt/vol) solution of sodium hippurate is prepared in 0.067 M Sorensen phosphate buffer (pH 6.4). Tubes containing 0.5 ml of this solution are inoculated and incubated at 35°C, for 2 h, after which 0.2 ml of the ninhydrin reagent is added. Development of a deep blue-purple color within 5 min indicates a positive reaction. For *L. pneumophila*, 0.5 ml of 1% sodium hippurate solution is inoculated with a loopful of organism and incubated at 35°C in ambient air for 18 to 20 h, after which 0.2 ml of ninhydrin reagent is added. The cells and ninhydrin are mixed and incubated for an additional 10 min at 35°C. The mixture is observed for 20 min for blue-purple color development, which is indicative of a positive reaction. Ferric chloride can also be used to detect hippurate hydrolysis. Ferric chloride reagent (12 g of FeCl₃·6H₂O in 100.0 ml of 2% HCl) is added to inoculated broth (e.g., heart infusion broth or Todd-Hewitt broth) supplemented with hippurate.

An insoluble brown ferric benzoate precipitate indicates a positive hydrolysis reaction.

- **Indole test (Ehrlich reagent, Kovács reagent, p-dimethylaminoncinmaldehyde (DMACA))**

The indole test is used for the determination of production of indole from deamination of tryptophan by tryptophanase. This reaction can be detected using Ehrlich reagent, Kovács reagent, or DMACA. To prepare Ehrlich reagent, add 1 g of *p*-dimethylaminoncinmaldehyde to 95 ml of 95% ethyl alcohol. Then slowly add 10 ml of concentrated hydrochloric acid. Using Ehrlich reagent, first extract the indole by adding 1 ml of xylene to a 48-h-old tryptone broth or other tryptophan-containing broth medium. Shake the tube vigorously for 20 s and let stand for 1 to 2 min to allow the xylene extract to come to the top of the broth. Gently add 0.5 ml of the Ehrlich reagent down the side of the tube. Do not shake the tube. A red ring at the interface of the medium and the reagent phase within 5 min represents a positive test. Ehrlich reagent is preferred for organisms that produce small amounts of indole, such as nonfermenters and anaerobes. To prepare Kovács indole reagent, add 10 g of *p*-dimethylaminoncinmaldehyde to 150 ml of either amyl or isomyl alcohol. Then add 50 ml of concentrated hydrochloric acid. Add 5 drops of Kovács reagent to either 48-h-old 2% tryptone broth or an 18- to 24-h-old tryptophan broth culture. Do not shake the tube after the addition of reagent. A red color at the surface of the medium indicates a positive test. For the spot indole test, add 2 ml of concentrated HCl to 18 ml of distilled water. Allow the mixture to cool. Then add 200 mg of DMACA. Moisten a piece of Whatman no. 3 paper with a couple drops of the reagent. Remove a well-isolated colony from an 18- to 24-h-old culture onto a blood agar plate with a sterile inoculating loop or a wooden stick and smear it onto the moistened filter paper. Observe for a blue to blue-green color within 2 min, which indicates a positive reaction. No color change or a pinkish tinge is considered negative. This test should be used only on colonies from media containing sufficient tryptophan and no glucose. Colonies from media containing dyes (e.g., MacConkey or eosin-methylene blue [EMB] agar) may cause misleading results and should not be used. Colonies from mixed cultures should not be used, as indole-positive colonies can cause indole-negative colonies to appear weakly positive.

- **LAP test (leucine naphthylamide)**

The LAP test detects the presence of leucine aminopeptidase (LAP). The substrate leucine naphthylamide is hydrolyzed by LAP to leucine and free naphthylamine. The LAP test is helpful in the presumptive characterization of catalase-negative, Gram-positive cocci (streptococci, enterococci, and streptococcus-like organisms). *S. pneumoniae*, *Streptococcus pyogenes*, *Pediococcus*, *Lactococcus*, and *Enterococcus* spp. are all LAP positive, while other beta-hemolytic streptococci are LAP negative. Disks are impregnated with leucine-β-naphthylamide or leucine-α-naphthylamide, which is hydrolyzed by the enzyme LAP produced by LAP-positive organisms. This enzymatic activity results in the release of β-naphthylamine, which couples with DMACA reagent (Dalynn RP95), when it is added, to form a highly visible red color. To perform this test, aseptically place an LAP disk in a sterile petri dish and allow the disk to warm to room temperature. Moisten with a small amount of water. Inculate with several colonies from an overnight culture.
plate. Incubate for 5 min at room temperature. Add 1 drop of DMACA and read within 1 min. Development of a red or pink color indicates a positive test.

- **Lysozyme test (lysozyme)**

The lysozyme test measures the ability of organisms, such as *Nocardia*, to grow in the presence of lysozyme. A solution of 50 mg of lysozyme in 50 ml of 0.01 N HCl is used for this test. The solution is filter sterilized and can be stored refrigerated for up to a week. For the lysozyme test, add 5 ml of lysozyme solution to 95 ml of basal glycerol broth (peptone, 1 g; beef extract, 0.6 g; glycerol, 14.0 ml; distilled water, 200 ml). Dispense in 5-ml aliquots and keep refrigerated. Growth of the test organism in the lysozyme-supplemented glycerol broth is compared with the growth in the unsupplemented glycerol broth.

- **Nitrate reduction test (N,N-dimethyl-naphthylamine and sulfanilic acid)**

The nitrate reduction test is used to determine the ability to reduce nitrate to nitrite or free nitrogen gas. This test involves the use of two reagents. Reagent B is prepared by adding 0.6 ml of N,N-dimethyl-naphthylamine to 100 ml of 5 N (30%) acetic acid. Reagent A is prepared by adding 0.8 g of sulfanilic acid to 100 ml of 5 N acetic acid. These reagents are stored in the dark under refrigeration. To perform the test, add 0.05 ml of reagent A to 10 drops of an overnight growth from the nitrate broth culture and incubate for 5 to 10 min. Then add 0.05 ml of reagent B and incubate for an additional 5 to 10 min. Incubation should be in the dark. (Note: reagents A and B may be mixed and added together as indicated in the ninth edition of this Manual, but this lowers the sensitivity of the test.) An organism may be reported as nitrate positive if a red or purple-magenta color develops in the medium within a few minutes after nitrate reagents A and B are added to the medium, indicating that the organism has reduced nitrate to nitrite. The absence of a red-purple color after the addition of both reagents does not automatically mean that the organism is unable to reduce nitrate. Strains may have reduced the nitrate to nitrite and then reduced the nitrite completely to nitrogenous gases that are not detected when nitrate reagents A and B are added to the medium. If the medium does not change color after the addition of sulfanilic acid and α-naphthylamine, a small amount (“knife point”) of zinc dust is added to the incubated medium. The zinc dust will catalyze the reduction of nitrate to nitrite chemically. Thus, if the nitrate has not been reduced by the organisms, i.e., they are nitrate negative, it will be reduced by the zinc dust and a red color will develop in the incubated medium within 15 min. If no color develops in the incubated medium after the addition of zinc dust, the organisms not only have reduced nitrate to nitrite but have reduced nitrite to nitrogenous gases; these organisms are also nitrate positive.

- **Oxidase test (TMPD/DMPD)**

The oxidase test is a test used in microbiology to determine if a bacterium produces certain cytochrome c oxidases (7). It uses disks impregnated with a reagent such as N,N,N′,N′-tetramethyl-p-phenylenediamine dihydrochloride (TMPD) or N,N-dimethyl-p-phenylenediamine dihydrochloride (DMPD), which is also a redox indicator. TMPD is more sensitive than DMPD and therefore generally the preferred reagent. The reagent is a dark blue to maroon color when oxidized and colorless when reduced. A modified oxidase test is used for the differentiation of *Micrococcus* and related organisms from most other aerobic Gram-positive cocci. Six percent TMPD (the same chemical used in Kovács oxidase reagent) dissolved in dimethyl sulfoxide is used as the reagent. Keep the reagent away from light. A loopful of colonies from blood agar plates is smeared onto filter paper, and the reagent is dropped onto the bacterial growth. Development of a blue to purple-blue color in 2 min indicates a positive reaction.

- **Phenylalanine deaminase test (ferric chloride)**

Ferric chloride is used to detect the action of phenylalanine deaminase. Twelve grams of FeCl₃·6H₂O is added to 100.0 ml of 2% hydrochloric acid. The hydrochloric acid is prepared by adding 5.4 ml of concentrated HCl (37%) to 94.6 ml of distilled water. To perform the phenylalanine deaminase test, 4 or 5 drops of ferric chloride reagent is added to a culture grown overnight on phenylalanine agar or broth. The development of a brown color in the medium indicates a positive reaction.

- **Pyrorolidonyl aminopeptidase activity (PYR test)**

Pyrorolidonyl aminopeptidase (pyrorolidonyl arylamidase) or PYR is a rapid colorimetric method for presumptive identification of certain groups of bacteria based on the activity of the enzyme pyrorolidonyl arylamidase. This test is used in the identification of Gram-positive cocci and nonfermentative Gram-negative bacteria. The reaction involves addition of DMACA, which can be suspended in a solution of 2.5 ml of sodium dodecyl sulfate, 2.5 ml of glacial acetic acid, 5.0 ml of 2-methoxyethanol, and 90 ml of distilled water (stored at 4°C in a dark container). There also is a commercial kit in which L-pyroglutamic acid β-naphthylamide is impregnated into the test disk and serves as the substrate for the detection of pyrorolidonyl arylamidase. Hydrolysis of the substrate yields β-naphthylamide, which combines with the PYR reagent (DMACA) to form a bright pink to cherry red color. A positive PYR tests allows for the presumptive identification of group A streptococci (*S. pyogenes*) and group D enterococci.

- **Urease test (phenol red)**

The urease test is used to determine the ability of an organism to split urea through the production of the enzyme urease. Ammonia is produced, which causes a rise in pH that is detected by a change in color of the indicator phenol red to pink under alkaline conditions (pH 8.4). Bacteria are cultured on a medium containing urea, e.g., Christensen urea agar. While many enteric bacteria can hydrolyze urea, only a few “rapid urease-positive” organisms, e.g., *Proteus* species, can degrade urea quickly (<4 h). Urea broth is formulated to test for rapid urease-positive organisms. The restrictive amount of nutrients coupled with the use of pH buffers prevents all but rapid urease-positive organisms, which combine enough ammonia to turn phenol red to pink. The rapid urease test also is used for the diagnosis of *Helicobacter pylori*. To detect *H. pylori*, this test is performed on stomach lining cells collected by biopsy. A basic broth for performing the urease test can be made by adding 10.4 ml of a 20% (wt/vol) aqueous solution of urea to a solution containing 0.1 g of K₂HPO₄, 0.1 g of K₃HPO₄,
and 0.5 ml of 1:500 phenol red, adjusted to pH 6.8 in 100 ml. To make 1:500 phenol red, dissolve 0.2 g of phenol red in NaOH and add distilled water to 100 ml. Red color developing within 4 h after inoculation indicates urease activity.

**Voges-Proskauer (VP) test (α-naphthol/KOH)**

The VP test is used to detect acetoin (acetyl-methylicarbinol), which is produced by certain bacteria during growth in a buffered peptone-glucose broth (methyl red-VP broth). The VP test is commonly used to aid in the differentiation between genera (such as E. coli from the Klebsiella and Enterobacter spp.) and among species of the Enterobacteriaceae family. The test can be used as a differential test for other organism groups (viridans group streptococci). The test uses 5% α-naphthol, which is prepared by dissolving 5 g of α-naphthol in 100 ml of absolute ethanol, and 40% KOH, which is prepared by dissolving 40 g of potassium hydroxide in 100 ml of distilled water. To perform the test, methyl red-VP broth is inoculated and incubated until good growth is obtained. Then 0.6 ml of the α-naphthol solution and 0.2 ml of the 40% KOH are added to 2.5 ml of culture broth. A positive reaction is indicated by the formation of a pink-red product within 5 min. However, allow 15 min for color development before considering the test negative.

**Buffers**

**Bovine albumin fraction V**

A 0.2% solution of bovine albumin fraction V is used to buffer mycobacterial specimens following decontamination with N-acetyl-L-cysteine-sodium hydroxide (NALC-NaOH). The solution is prepared by mixing 40.0 ml of 5% bovine albumin with 8.5 g of NaCl and 960.0 ml of distilled water. The pH is adjusted to 6.8 using 4% NaOH. The solution is filter sterilized and stored refrigerated. The preserved cells can then be examined microscopically or inoculated into a culture medium.

**Glycine-buffered saline**

Glycine-buffered saline (0.043 M glycine, 0.15 M NaCl [pH 9.0]) is used in some serological procedures and is also used as a transport medium for enteric organisms. It is prepared as 10× stock solutions. For 0.1 M NaHPO₄ (sodium phosphate, monobasic), dissolve 9.073 g of anhydrous NaHPO₄ in 1 liter of distilled water; and for 8.5% NaCl (sodium chloride), dissolve 85.0 g of NaCl in 1 liter of deionized water. Sterilize by autoclaving for 20 min or by filtration. For the working glycine-buffered saline, combine the appropriate amounts of the 10× stock solutions of the mono- and dibasic phosphate solutions with 100 ml of 8.5% NaCl and bring the volume to 1 liter with distilled or deionized water.

**Sorensen pH buffers**

Sorensen pH buffers are prepared by mixing appropriate amounts of 0.067 M dibasic sodium phosphate with 0.067 M monobasic potassium phosphate. To prepare 0.067 M dibasic sodium phosphate, dissolve 9.464 g of anhydrous Na₂HPO₄ in 1 liter of distilled water. To prepare 0.067 M monobasic potassium phosphate, dissolve 9.073 g of anhydrous KH₂PO₄ in 1 liter of distilled water.

**Decontamination Agents**

**Cetylpuridium chloride-sodium chloride (CPC-NaCl)**

CPC-NaCl is used for decontamination of transported sputum specimens for culturing mycobacteria. It is prepared by dissolving 1 g of CPC and 2 g of NaCl in 100 ml of distilled water. It can be stored in a sealed brown bottle at room temperature. If crystals form, the solution should be gently heated before use. An equal amount of sputum and CPC-NaCl is mixed until the specimen is liquefied, and then the specimen can be shipped to the testing site. Specimens treated with CPC-NaCl must be cultured on egg-based media or else residual CPC will inhibit mycobacterial growth.

**NALC-NaOH**

NALC-NaOH (mucolytic agent)-NaOH (decontamination agent) is used in the processing of mycobacterial specimens. The reagent consists of 50.0 ml of sterile 4% NaOH, 50.0 ml of 2.9% sodium citrate, and 0.5 g of NALC. The sodium citrate is included to stabilize the acetylcysteine. This reagent should be used within 24 h of preparation.

**Oxalic acid**

Oxalic acid is used as a decontamination agent for specimens that contain Pseudomonas spp. when culturing for mycobacteria. The reagent is especially helpful when processing respiratory specimens from cystic fibrosis patients. To prepare the solution, 50 g of oxalic acid is added to 1.0 liter of distilled water. The solution is autoclaved at 121°C for 15 min. It can be stored at room temperature for up to a year.

**Dyes and Indicators**

A variety of dyes and indicators are used to detect specific reactions such as pH and oxygen production. Commonly used dyes and pH indicators are shown in Table 1.

**Preservatives**

**Skim milk**

Skim milk is used to stabilize bacterial suspensions, particularly those containing anaerobes, for freezing. The skim milk is prepared by adding 20 g of skim milk powder to 100 ml of distilled water. After the skim milk is dissolved in the water, the solution is dispensed as 0.25- to 0.5-ml aliquots into 2-ml vials. The skim milk is autoclaved...

at 110°C for 10 min. The vials can be refrigerated for up to 6 months.

McFarland Standards

McFarland standards are used as a reference to adjust the turbidity of bacterial suspensions so that the number of bacteria will be within a given range. These standards can be prepared using BaCl₂. They also are available using latex beads. To prepare McFarland standards, mix the designated amounts of 1% anhydrous barium chloride (BaCl₂) and 1% (vol/vol) cold pure sulfuric acid (H₂SO₄) in screw-cap tubes. Tightly seal the tubes. When the barium sulfate is shaken up well, the density in each tube corresponds approximately to the bacterial suspension. Store the prepared standard tubes in the dark at room temperature. The absorbance of the 0.5 McFarland standard should be 0.08 to 0.10 at 625 nm using a spectrophotometer with a 1-cm light path. Standards are checked regularly using a densitometer. No policy exists regarding the frequency of monitoring. However, when placed in the densitometer and it fails to read in the defined optical range, it should be considered unusable. Companies that produce automated identification/antibiotic susceptibility testing systems provide guidelines with the instrument. The manufacturer is responsible for the accuracy and reliability of the McFarland standards and should supply a quality control record with each production lot.

STAINS

Microscopic examination is useful in the identification of clinically important specimens. Smears can be made from relevant tissues and body fluids. If there are sufficient quantities of cells, the smear may be prepared by direct contact with a tissue sample or by applying a drop of body fluid, e.g., sputum, to a clean glass slide. Cytocentrifugation may be used to concentrate cells (8–10). Samples are fixed to the slides with either heat or methanol. Methanol fixation is preferred since heating may produce artifacts, may create aerosols, and may not adhere the specimen adequately to the slide. A variety of stains can then be used to help visualize and differentiate bacteria from the specimen. The following are some of the commonly used staining procedures.

Acid-fast stain

Acid-fast staining is useful for the identification of Mycobacterium, Nocardia, Rhodococcus, Tsukamurella, Gordonia, and Legionella micdadei. These bacteria have long-chain fatty acids (mycolic acids) that make them difficult to stain with crystal violet and other basic dyes.

Mycobacteria often appear as slender, slightly curved rods and may show darker granules that give the impression of beading. Mycobacterium tuberculosis can appear as beaded rods arranged in parallel strands or “cords”; Mycobacterium kansasii may form long, often broad and banded cells; and Mycobacterium avium complex cells appear as short, uniformly staining cocccobacilli. Nocardia spp. often branch and almost always show a speckled appearance. A number of staining procedures have been developed for acid-fast staining.

In the Ziehl-Neelsen (Z-N) procedure, the slide is heat fixed for 2 h at 70°C. The slide is then flooded with carbol fuchsin (0.3 g of basic fuchsin is dissolved in 10 ml of 95% ethanol, 5 ml of phenol, and 95 ml of water; the solution is filtered before use). The slide is slowly heated to steaming and maintained for 3 to 5 min at 60°C. After cooling, the slide is washed with water and decolorized with acid-alcohol (97 ml of 95% ethanol in 3 ml of HCl). The slide is counterstained for 20 to 30 s with methylene blue (0.3 g of dye in 100 ml of water). An acid-fast organism will stain red, and the background of cellular elements and other bacteria will be blue, the color of the counterstain.

In the Kinyoun modification of the Z-N staining procedure, heating during staining with carbol fuchsin is eliminated and a higher concentration of phenol is used in the primary stain. The primary stain consists of 4 g of basic fuchsin in 20 ml of 95% alcohol, 8 g of phenol, and 95 ml of water; the solution is filtered before use). The slide is slowly heated to steaming and maintained for 3 to 5 min at 60°C. After cooling, the slide is washed with water and decolorized with acid-alcohol (97 ml of 95% ethanol in 3 ml of HCl). The slide is counterstained for 20 to 30 s with methylene blue (0.3 g of dye in 100 ml of water). An acid-fast organism will stain red, and the background of cellular elements and other bacteria will be blue, the color of the counterstain.

In the Kinyoun modification of the Z-N staining procedure, heating during staining with carbol fuchsin is eliminated and a higher concentration of phenol is used in the primary stain. The primary stain consists of 4 g of basic fuchsin in 20 ml of 95% alcohol, 8 g of phenol, and 100 ml of distilled water. The Z-N and Kinyoun stains have the same sensitivity and specificity; however, the Kinyoun (cold) staining procedure is less time-consuming and is easier to perform.

Another modification of the acid-fast staining procedure has been the use of a weaker decolorizing agent (0.5 to 1.0% sulfuric acid) in place of the 3% acid-alcohol. This modification helps differentiate those organisms known to be partially or weakly acid-fast, particularly Nocardia, Rhodococcus, Tsukamurella, Gordonia, and Dietzia. These organisms do not stain well with the Z-N or Kinyoun stain.

Factors such as age, exposure to drugs, and a particular acid-fast organism itself may vary the acid-fast presentation. For example, while M. tuberculosis is essentially acid-fast (with the Z-N or Kinyoun stain), rapidly growing mycobacteria and Nocardia are not. Therefore, use of the modified
Kinyoun stain may be necessary for these organisms. Other modifications used in tissue preparations, such as the Fite-Faraco stain and Pottz stain, may be preferred for unusual isolates such as Mycobacterium leprae.

Detection of small numbers of acid-fast organisms in clinical specimens is generally significant. However, the use of acid-fast stains for gastric aspirates in the interpretation of pulmonary disease in adults or for stool specimens from HIV-positive patients in diagnosing M. avium-Mycobacterium intracellulare infection yields very poor specificity (false-positive smears with saprophytic organisms) as well as poor sensitivity. In addition, patients receiving adequate therapy may still have positive smears without positive cultures for a number of weeks.

### Acridine orange stain

Acridine orange is a fluorochrome that can be intercalated into nucleic acid in both the native and the denatured states. Acridine orange is useful in a number of miscellaneous infections, such as Acanthamoeba spp. or may exhibit organism “ghosts” (13). Anaerobic bacteria, older cultures, and organisms that are exhibiting the effects of antibiotics may be especially difficult to interpret.

In the conventional Gram stain procedure used in most clinical laboratories, the slide is first flooded with a primary stain of crystal violet (10 g of 90% dye in 500 ml of absolute methanol). After at least 15 s, the slide is washed with water and flooded with the mordant Gram’s iodine (6 g of I2 and 12 g of KI in 1,800 ml of H2O), which increases the affinity of the primary stain to the bacterial cell. The slide is washed with water after 15 s with the decolorizing agent acetone-alcohol (400 ml of acetone in 1,200 ml of 95% ethanol). The decolorizing agent will remove the primary stain from a Gram-negative cell. Gram-positive bacterial cells retain the primary stain. The slide is washed immediately and counterstained for at least 15 s with safranin (10 g of dye in 1 liter of distilled or deionized water). This slide is then washed, blotted dry, and examined by light microscopy at ×1,000 magnification.

For organisms such as Francisella, Legionella, and Brucella spp. that are difficult to visualize due to their tiny size and that stain only faintly with the traditional Gram stain, alternative stains may be used to enhance visualization. Substitution of safranin with basic fuchsin as a counterstain in the Gram stain has been successfully used to visualize Francisella tularensis; however, the direct fluorescent-antibody assay is more sensitive, although it is not commonly used in the clinical microbiology laboratory. The Gimenez stain can be used as an alternative to the Gram stain for the visualization of Legionella spp. This stain is difficult to prepare, is not commercially available, requires filtration before each use, and is unstable in storage; immunofluorescent staining is more sensitive but is not routinely used in the clinical microbiology setting. As with F. tularensis, replacement of safranin with basic fuchsin as the primary counterstain in the Gram stain increases the visualization of Brucella spp.

### Immunofluorescent antibody stain

Immunofluorescent staining consists of labeling antibodies with a fluorescent dye, allowing the labeled antibodies to react with their specific antigens, and observing the stained bacterial cells under a fluorescence microscope (14). These methods allow the identification of specific bacterial species and subtypes based upon the specificity of the antibody reaction, e.g., for Legionella spp. Their utility in bacteriology is primarily for culture confirmation, as their utility for direct specimen testing has been supplanted by other immunologi-
tical methods (enzyme immunoassays and PCR-immunochromatography test hybrid assays).

**Methylene blue stain**

Staining with methylene blue is used to show bacterial cell shape. This is useful for revealing the morphology of fusiform bacteria and spirochetes from oral infections (Vincent's angina). It may also establish the intracellular location of microorganisms such as *Neisseria*. Methylene blue is the stain of choice for identification of the metachromatic granules of *diphtheria*; however, one should be careful about overstaining, because this will lessen the contrast between the bacteria and the granules. Methylene blue stains organisms or leukocytes a deep blue against a light gray background. *Corynebacterium diphtheriae* appears as a blue bacillus with prominent darker blue metachromatic granules. For methylene blue staining, a 0.5 to 1.0% aqueous solution of methylene blue is applied for 30 to 60 s and up to 10 min for possible *C. diphtheriae* granules. The slide is rinsed with water, blotted dry, and examined by light microscopy at magnifications of ×100 to ×1,000.

**M’Fadyean stain**

The M’Fadyean stain is a modification of the methylene blue stain developed for detecting *Bacillus anthracis* in clinical specimens. The stain is prepared by dissolving 0.05 mg of methylene blue per ml in 20 mM potassium phosphate adjusted to pH 7.3. Slides are stained for 1 min and then washed. As a safety precaution, washing of the slide is performed using a 10% hypochlorite solution. The dried slide is examined by light microscopy. Virulent *B. anthracis* rods will be surrounded by a clearly demarcated zone giving the appearance of a reddish pink capsule (M’Fadyean reaction).

**Spore stain**

The Wirtz-Conklin spore stain is a differential stain for detection of spores. This is very useful for the identification of *Bacillus* and *Clostridium* species. Using this procedure, spores stain green while the rest of the cell stains pink. Non-spore-forming bacteria are pink. In this procedure, the slide is flooded with 5 to 10% aqueous malachite green. The stain is applied for 1 min. The slide is then washed, blotted dry, and examined by light microscopy at ×1,000 magnification.

**Wayson stain**

The Wayson stain can be used to demonstrate bipolar staining characteristics of *Yersinia pestis* but is not commonly used in clinical microbiology laboratories. It no longer is used for screening cerebrospinal fluid for bacteria now that the incidence of *Haemophilus influenzae* meningitis has decreased. The staining reagents are prepared by dissolving 0.2 g of basic fuchsin in 10 ml of 95% ethyl alcohol and 0.75 g of methylene blue in 10 ml of 95% ethyl alcohol. The two solutions are added together slowly into 200 ml of 5% phenol in distilled water. The stain is then filtered and stored in an opaque bottle at room temperature. The stain is applied for 1 min. The slide is then washed, blotted dry, and examined by light microscopy at ×1,000 magnification.

**CULTURE MEDIA**

Laboratory cultivation of pathogenic microorganisms has been central to the laboratory diagnosis of infectious diseases caused by bacteria. Louis Pasteur in 1860 was the first to use culture media for growing bacteria in the laboratory. Pasteur’s first medium consisted of sugar, ammonium salts, and yeast ash. It met the basic growth requirements of many bacteria, namely, a carbon source in the form of sugar that could be metabolized for energy and growth; a nitrogen source needed by bacteria to synthesize proteins and nucleic acids; and growth factors, including vitamins and minerals from the yeast ash.

Additional media were developed by Robert Koch and his colleagues, who used animal and plant tissues as sources of nutrients to support bacterial growth. One of the major discoveries of Fanny Hesse, who was the wife of one of the workers in Koch’s laboratory, was that agar could be used to form solidified culture media on which microorganisms would grow. Using solid media permits the isolation of pure cultures of bacteria. Extracts of plants and animal tissues were prepared as broths or mixed with agar to form a variety of solid culture media. Virtually any plant, animal, or animal organ was considered for use in preparing media. Infusions were prepared from beef heart, calf brains, and beef liver, as a few examples. From the earliest development of media, there was a balance between scientific design and chance findings regarding which media would support the growth of specific pathogens. By the early 1930s, many media were available to aid in diagnostic activities. These classic infusions still form the primary components of many media that are widely used today in clinical microbiology laboratories, such as brain heart infusion agar.

Each medium has a specific use. See Table 2 for media used to detect emerging antibiotic-resistant pathogens. Often there are pros and cons to the choice of a specific medium—the advantages and disadvantages of each must be considered and the results obtained in the clinical laboratory must be evaluated in light of the limitations of a given medium. Articles frequently appear comparing media (see, for example, references 15–18).

Several comprehensive volumes have been compiled describing in detail the formulation of these media for the culture of bacteria (15, 19–26). Additionally, the major commercial producers of microbiological culture media maintain websites that provide important information about the composition, preparation, and use of specific culture media they supply, e.g., Becton, Dickinson and Company (http://www.bd.com/), Gibco Life Technologies (http://www.lifetechnologies.com/us/en/home/life-science/cell-culture.html?_kweid=AL1365213!2610739955081!1!g!!cell%20culture%20products&ef_id=USlmGgAAAeACR0m ej:201410210135720:ns), Handy Diagnostics (http://www.hardydiagnostics.com/gclid=CMIfUec62f2jsCFR7yDAoxZIWRQg), HiMedia (http://www.himedials.com/), and Oxoid Ltd. (http://www.oxoid.com/uk/blue/index.asp). The inserts available with commercial media also provide critical information about their proper use.

**Composition of Media**

Agar is the most common solidifying agent used in microbiological media (27). Agar is a polysaccharide extract from marine algae. It melts at 84°C and solidifies at 38°C. Agar concentrations of 15.0 g/liter typically are used to form solid

Media. Lower concentrations, 7.5 to 10.0 g/liter, are used to produce soft agars or semisolid media. Lower concentrations, 7.5 to 10.0 g/liter, are used to produce soft agars or semisolid media.

Many media contain peptones as the source of nitrogen. Peptones are hydrolyzed proteins formed by enzymatic or acidic digestion. Casein most often is used as the protein substrate for forming peptones, but other substances, such as soybean meal, also are commonly employed.

Meat and plant infusions are aqueous extracts that are commonly used as sources of nutrients for the cultivation of microorganisms. Such infusions contain amino acids and low-molecular-weight peptides, carbohydrates, vitamins, minerals, and trace metals. Extracts of animal tissues contain relatively high concentrations of water-soluble protein components and glycogen. Extracts of plant tissues contain relatively high concentrations of carbohydrates.

The pH is generally maintained within a few tenths of a pH unit. For this reason, buffers are a key component of many media. Some pathogens are anaerobic, and factors such as thiglycolate are included in some media to reduce the availability of molecular oxygen so that anaerobes may be cultured. The use of specialized media for the culture of anaerobes is important for clinical microbiology (28).

Many microorganisms have specific growth factor requirements that must be included in media for their successful
cultivation. The incorporation of key growth factors began in the 1930s. Gradually new formulations were developed that incorporated vitamins, amino acids, fatty acids, trace metals, and blood components to meet the growth factor requirements of specific pathogens. Most often, mixtures of growth factors are used in microbiological media. Acid hydrolysates of casein commonly are used as sources of amino acids. Extracts of yeast cells also are employed as sources of amino acids and vitamins for the cultivation of microorganisms. Many of the media used in the clinical laboratory contain blood or blood components that serve as essential nutrients for fastidious microorganisms.

Many media contain selective components that inhibit the growth of nontarget bacteria. Selective media are especially useful in the isolation of specific pathogens from mixed populations. Selective toxic compounds are also frequently used to select for the cultivation of particular microbial species. The isolation of a pathogen from a stool specimen, for example, where there is a high abundance of nonpathogenic normal microbiota, requires selective media. Often, antimicrobials or other selectively toxic compounds are incorporated into media to suppress the growth of the background microbiota while permitting the cultivation of the organism of interest. Bile salts, selenite, tetraethionate, tellurite, azide, phenylethanol, sodium lauryl sulfate, high sodium chloride concentrations, and various dyes—such as eosin, crystal violet, and methylene blue—are used as selective toxic chemicals. Antimicrobial agents used to suppress specific types of microorganisms include many antibiotics, such as ampicillin, chloramphenicol, colistin, cycloheximide, gentamicin, kanamycin, nalidixic acid, sulfadiazine, and vancomycin. Various combinations of antimicrobials are effective in suppressing classes of microorganisms, such as enteric bacteria.

Some media contain components that permit the differentiation of specific pathogens based on key metabolic reactions. These include production of acid from various carbohydrates and other carbon sources or the decarboxylation of amino acids. Some media include indicators that permit the visual detection of changes in pH resulting from such metabolic reactions. A number of media also include chromogenic dyes that change color when specific enzymatic reactions occur. See Table 3 for sources of chromogenic media.

Some media contain components that are toxic or carcinogenic. Appropriate safety precautions must be taken when using media with such components. Basic fuchsin and acid fuchsin are carcinogens, and caution must be used in handling media with these compounds to avoid dangerous exposures that could lead to the development of malignancies. Thallium salts, sodium azide, sodium biselenite, and cyanide are among the toxic components found in some media. These compounds are poisonous, and steps must be taken to avoid ingestion, inhalation, or skin contact. Azides also react with many metals, especially copper, to form explosive metal azides. The disposal of azides must avoid contact with copper or achieve sufficient dilution to avoid the formation of such hazardous explosive compounds. Cycloheximide is toxic. Avoid skin contact or aerosol formation and inhalation. Media with human blood or human blood components must be handled with great caution to avoid exposure to HIV and other pathogens that contaminate some blood supplies. Proper handling and disposal procedures must be followed with blood-containing media as well as other media that are used to cultivate microorganisms.

### Preparation of Media

It is important to follow the manufacturers’ instructions in preparing media. The ingredients in a medium are usually dissolved, and the medium is then sterilized. When agar is used as a solidifying agent, the medium must be heated gently, usually to boiling, to dissolve the agar. In some cases where interactions of components, such as metals, would cause precipitates, solutions must be prepared and occasionally sterilized separately before mixing the various solutions to prepare the complete medium. The pH often is adjusted prior to sterilization, but in some cases sterile acid or base is used to adjust the pH of the medium following sterilization. Many media are sterilized by exposure to elevated temperatures. The most common method is to autoclave the medium. Different sterilization procedures are employed when heat-labile compounds are included in the formulation of the medium.

Autoclaving uses exposure to steam, generally under pressure, to kill microorganisms. Exposure for 15 min to steam at 15 lb/in² at 121°C is most commonly used. Such exposure kills vegetative bacterial cells and bacterial endospores. However, some substances do not tolerate such exposures, and lower temperatures and different exposure times are sometimes employed. Media containing carbohydrates often are sterilized at 116 to 118°C in order to prevent the decomposition of the carbohydrate and the formation of toxic compounds that would inhibit microbial growth.

The proper preparation of media is critical for performance. For this reason, as well as because of personnel costs, many clinical laboratories purchase prepared media. Quality control is essential regardless of whether the medium is prepared in the laboratory or purchased as a preprepared medium (29, 30). Quality control test cultures are used to periodically check the performance of the media. For general-purpose media, sufficient, characteristic growth and typical colony morphology should be obtained with all test strains. For selective media, growth of designated organisms should be inhibited and adequate growth of desired organisms must be obtained. Differential characteristics of the medium for specific bacterial strains, e.g., color and hemolytic reactions, must be met. Media must not be used past expiration dates. The Clinical Laboratory and Standards Institute issues standards for quality assurance of commercially prepared microbiological culture media (30).

### Bacteriological Media

Below are descriptions of representative media used in clinical microbiology.

#### A7 agar (Shepard’s differential agar)

A7 agar is used for the cultivation and differentiation of *Ureaplasma urealyticum* from urine based on its ability to produce ammonia from urea. The medium contains digests of casein and soybeans plus growth factors, including cysteine, NAD, cocarboxylase, vitamins, yeast extract, and penicillin as a selective factor. Manganese sulfate is included as a nutritional factor. Urea is a key component that allows the detection of *Ureaplasma* spp. Bacteria that produce ammonia from the hydrolysis of urea appear as golden to dark brown colonies.

#### A8 agar

This agar is used for the cultivation and differentiation of *U. urealyticum* from urine based on its ability to produce

*Becton Dickinson (BD) licensing agreement with CHROMagar.

*Biolog licensing agreement with FocusBiotech Sdn, Bhd. (Petaling Jaya, Malaysia).

*Gibson Bioscience (Lexington, KY) licensing agreement with CHROMagar.

ammonia from urea. This medium also supports the growth of *Mycoplasma hominis*. The medium contains digests of casein and soybeans plus growth factors, including cysteine, NAD, cocarboxylase, vitamins, yeast extract, and penicillin as a selective factor. Manganous sulfide, calcium chloride, and putrecine dihydrochloride are included as nutritional factors. Amphotericin B and penicillin G are added as selective factors. Urea is a key component that allows the detection of *Ureaplasma* species. *U. urealyticum* can be differentiated from other genital mycoplasmas on this medium due to manganous sulfate in the medium, which combines with the urease to form a golden brown pigment.

*Acetamide agar*

Acetamide agar is used for differentiating nonfermentative Gram-negative bacteria, especially *Pseudomonas aeruginosa* (31, 32). Acetamide is the key component that supports growth and forms the basis for differentiation. Most bacteria are unable to grow on acetamide as the sole source of carbon and nitrogen. Bacteria that deamidate acetamide turn the medium blue if bromthymol blue is included as the indicator or red if the medium contains phenol red. The color change is due to the liberation of ammonia from the utilization of acetamide.

*Acetate differential agar (Simmons’ citrate agar, modified)*

This agar is used for the differentiation of *Shigella* spp. from *E. coli* and also for the differentiation of nonfermenting Gram-negative bacteria (33). The medium contains acetate as the sole source of carbon. Bacteria that can utilize acetate as the sole carbon source turn the medium blue due to the increase in pH as the acidic acetate is utilized.

*Alkaline peptone water*

This medium is used for the cultivation and transport of *V. cholerae* and *Aeromonas hydrophila*. Peptone is the growth substrate. The salt concentration is 1%.

*American Trudeau Society (ATS) medium*

ATS medium is used for the isolation and cultivation of *Mycobacterium* spp. other than *M. leprae*. It is especially useful for the detection of *M. tuberculosis* from clinical specimens such as cerebrospinal fluid, pleural fluid, and tissues. The medium contains eggs, which supply the fatty acids needed for growth by mycobacteria. Potatoes are also included as a source of carbon. Malachite green is a selective factor included in the medium.

*Amies transport medium with charcoal*

This medium is used for the transport of swab specimens to prolong the survival of microorganisms between collection and culturing. The phosphate buffer and calcium and magnesium ions in the medium help protect cells against lysis. The addition of charcoal to this medium neutralizes metabolic products that may be toxic to *Neisseria gonorrhoeae*.

*Amies transport medium without charcoal*

This medium is used for the transport of swab specimens to prolong the survival of microorganisms. This medium contains phosphate buffer and calcium and magnesium ions to protect cells against lysis.

*Anaerobic colistin-nalidixic acid (CNA) agar*

This agar is used for the selective isolation of anaerobic streptococci. Digests of casein and animal tissue along with
yeast extract, beef extract, and glucose supply the carbon and nitrogen for growth. Dithiothreitol and cysteine help create anaerobic conditions. The medium contains colistin and nalidixic acid as selective factors. Blood is added to support the growth of fastidious strains and also to permit differentiation based on hemolytic reactions.

### Ashdown medium

Ashdown medium is used for the selective isolation and characterization of *Burkholderia pseudomallei* from clinical specimens such as sputum. The medium contains crystal violet and gentamicin as selective factors. It is enriched with glycerol and contains neutral red. *B. pseudomallei* produces flat, wrinkled, purple colonies on this medium. Both Ashdown agar and Ashdown broth can be modified by the addition of antimicrobials for the selective culture of *B. pseudomallei*. Modified Ashdown broth remains the standard for isolation of *B. pseudomallei* from throat swabs in patients with suspected melioidosis (34).

### Bacillus cereus medium

This medium is used for the cultivation of *Bacillus cereus*. The medium contains mannitol and eggs plus yeast extract. Bromcresol purple is included to aid in differentiation of *B. cereus*.

### Bacillus cereus selective agar base

This medium is used for the selective isolation, enumeration, and presumptive identification of *B. cereus*. The medium contains mannitol and eggs plus yeast extract. Polymyxin B is included as a selective factor. Bromthymol blue is included to aid in differentiation. *B. cereus* grows as moderate-sized (5-mm) cratered colonies, which are turquoise, surrounded by a precipitate of egg yolk, which is also turquoise.

### Bacteroides bile esculin agar

This agar is used for the selection and presumptive identification of the *Bacteroides* fragilis group and for the differentiation of *Bacteroides* spp. based on the hydrolysis of esculin and presence of catalase (4). The medium contains digest of casein and soybeans. Hemin, vitamin K₁, oxgall, and gentamicin are included in the medium as selective factors. Esulin is a key component for the differentiation of *Bacteroides* spp. *Bacteroides* colonies appear as gray, circular, raised colonies larger than 1.0 mm. Esulin hydrolysis is indicated by the presence of a blackened zone around the colonies.

### Baird-Parker medium

This medium is used for the selective isolation and enumeration of coagulase-positive staphylococci. This medium contains glycine, pyruvate digest of casein, beef extract, lithium chloride, yeast extract, eggs, and tellurite.

### Barbour-Stoenner-Kelly medium

This medium is used for the cultivation of a wide variety of microorganisms in a chemically defined medium, including *Borrelia* and *Spirochaeta* spp. This is a complex medium containing numerous vitamins and growth factors. It also contains gelatin, glucose, pyruvate, peptone, albumin, and serum.

### BCM O157:H7(+) plating medium

This proprietary medium from Biosynth International, Inc. (Itasca, IL) is used for the detection of highly pathogenic enterohemorrhagic *E. coli* serovar BCM O157:H7(+).

### Bile esculin agar

This medium is used for differentiation between group D streptococci and non-group D streptococci; for differentiation of members of the *Enterobacteriaceae*, particularly *Klebsiella*, *Enterobacter*, and *Serratia*, from other enteric bacteria; and for differentiation of *Listeria monocytogenes*. Bile tolerance and esculin hydrolysis (seen as a dark brown to black complex) are presumptive for enterococci (group D streptococci). Vancomycin can be added to identify vancomycin-resistant enterococci (VRE).

### Bile esculin agar with kanamycin

This medium is used for the selective isolation and/or presumptive identification of bacteria of the *B. fragilis* group from specimens containing a mixed biota. The medium contains beef extract and esulin. It also contains hemin and vitamin K₁ as growth factors. When examined with long-wavelength UV light, pigmented colonies of the *Bacteroides* group fluoresce red-orange. Oxgall and kanamycin are selective factors in the medium. Growth on this medium with blackening of the medium is presumptive for members of the *B. fragilis* group.

### Bile esulin azide agar

This medium is used for the isolation and presumptive identification of group D streptococci. The medium contains digest of casein, proteose peptone, iron, esulin, and yeast extract. Oxgall (bile) and sodium azide are included as selective factors. The hydrolysis of esculin in the presence of ferric citrate results in the formation of a black-brown color. *Streptococcus bovis* and *Enterococcus faecalis* produce black zones around colonies as a result of this reaction.

### Biosynth chromogenic medium for *Listeria monocytogenes*

This proprietary medium from Biosynth International, Inc. is used to differentiate *L. monocytogenes* and *Listeria ivanovii* from other *Listeria* spp. Supplements render the medium selective. Differential activity for all *Listeria* species is based on a chromogenic substrate included in the medium. This is a complete test system with a fluorogenic selective enrichment broth and a chromogenic plating medium both detecting the virulence factor phosphatidylinositol-specific phospholipase C (PI-PLC). The medium contains a substrate for PI-PLC (PlcA) enzymes. The selective enrichment broth is fluorogenic. The plating medium for rapid detection and enumeration of pathogenic *Listeria* combines cleavage of the chromogenic PI-PLC substrate with the additional production of a white precipitate surrounding the target colonies. This medium is not commonly used in clinical laboratories and is most often
used for food analysis for detection of pathogenic *Listeria spp.*

**Bismuth sulfite agar**
This medium, used for the selective isolation and identification of *Salmonella enterica* serovar Typhi and other enteric bacilli, contains digests of casein and animal tissue plus glucose, beef extract, and ferrous sulfate. Bismuth sulfite is included as a selective factor. If hydrogen sulfide is produced, a black precipitate forms as a result of the reaction with the iron. *Salmonella* Typhi produces flat, black, “rabbit-eye” colonies surrounded by a zone of black with a metallic sheen.

**Blood agar**
This medium is used for the isolation and detection of hemolytic activity of streptococci and other fastidious microorganisms. The base medium contains beef extract and peptone. Sheep blood is added to complete the medium, although rabbit blood and horse blood may be used in place of sheep blood for the characterization of some hemolytic organisms such as *Haemophilus spp.*

**Blood-free Campylobacter selectivity agar**
This medium is used for the selective isolation of *Campylobacter spp.*, especially *C. jejuni* from human feces. The medium contains digests of casein and animal tissue plus pyruvate and ferrous sulfate. Charcoal in the medium removes toxic metabolites. Sodium deoxycholate and cefazolin are included as selective factors.

**Bordet-Gengou agar**
This medium is used for the detection and isolation of *Bordetella pertussis* and *Bordetella parapertussis* from clinical specimens. The medium is rendered selective by the addition of methicillin. The medium contains digests of casein and animal tissue plus glucose, potato infusion, and rabbit blood. *B. pertussis* appears as small (<1-mm), smooth, pearl-like colonies surrounded by a narrow zone of hemolysis. *B. parapertussis* appears as brown, nonshiny colonies with a green-black coloration on the reverse side. *Bordetella bronchiseptica* appears as brown, nonshiny, moderately sized colonies with a roughly pitted surface.

**Bordetella pertussis selective medium**
This medium is used for the selective isolation and presumptive identification of *B. pertussis* and *B. parapertussis*. The medium contains Bordet-Gengou agar base, which includes digests of casein and animal tissue. It also contains blood and cephalexin. *B. pertussis* appears as small, nearly transparent, “biseected pearl-like” colonies.

**Bordetella pertussis selective medium with charcoal agar base**
This medium is used for the selective isolation and presumptive identification of *B. pertussis* and *B. parapertussis*. The medium contains charcoal agar base, which includes digests of casein and animal tissue, beef extract, nicotinic acid, starch, and charcoal. It also contains blood and cephalexin. *B. pertussis* appears as small, pale, shiny colonies.

**Bovine albumin Tween 80 medium, Ellinghausen and McCullough, modified (albumin fatty acid broth, Leptospira medium)**
This medium is used for the cultivation of *Leptospira spp.*. The medium contains glycerol, pyruvate, thiamine, and an albumin fatty acid supplement.

**Brain heart infusion**
This medium is used for the cultivation of fastidious and nonfastidious microorganisms, including aerobic and anaerobic bacteria, from a variety of clinical specimens. The medium contains digests of gelatin and animal tissue plus glucose and brain heart infusion. This medium is particularly useful for culturing streptococci, pneumococci, and meningococci. Vancomycin can be added for the detection of VRE.

**Brain heart infusion agar, 0.7%**
This medium is used for the detection of staphylococcal enterotoxin. The medium contains peptone, glucose, and infusions from beef heart and calf brains.

**Brilliance CRE Agar**
This medium is used for the presumptive identification of carbapenem-resistant *E. coli* and the Klebsiella, Enterobacter, Serratia, and Citrobacter (KESC) group, directly from clinical samples, in 18 h. The medium contains antibiotics to suppress other bacteria that are sensitive to carbapenem antibiotics and a novel chromogen to permit rapid differentiation of the target bacteria.

**Brilliance ESBL Agar**
This agar is used for the detection of extended-spectrum β-lactamase (ESBL)-producing microorganisms and for the presumptive identification of ESBL-producing *E. coli* and the KESC group, directly from clinical samples, in 24 h. ESBL-producing *E. coli* grows as either blue or pink colonies. ESBL-producing members of the KESC group produce green colonies; *Proteus*, *Morganella*, and *Providencia* do not utilize either chromogen but are able to deaminate tryptophan, resulting in tan colonies with a brown halo. The antibiotic mixture suppresses growth of β-lactam antibiotic-sensitive bacteria.

**Brilliance MRSA Agar**
This medium is used for universal methicillin-resistant *Staphylococcus aureus* (MRSA) screening. Brilliance MRSA Agar incorporates a novel chromogen that yields a blue color as a result of phosphatase activity, indicative of many staphylococci including *S. aureus*. To allow the medium to differentiate MRSA accurately, it contains a combination of antibacterial compounds designed to inhibit the growth of a wide variety of competitor organisms. Also included are compounds to suppress the expression of phosphatase activity in other staphylococci, thus ensuring a high level of sensitivity and specificity.

**Brilliance Salmonella Agar**
This medium is used for the presumptive detection and identification of *Salmonella spp.* from clinical specimens.
The inhibigen contained in this medium specifically targets E. coli, a particular benefit when testing fecal samples. Additional compounds are added to suppress growth of other competing biotas. Differentiation of Salmonella from the other organisms that grow on Brilliance Salmonella Agar is achieved through the inclusion of two chromogens that target specific enzymes: caprylate esterase and β-glucosidase. The action of the enzymes on the chromogens results in a buildup of color within the colony. The color produced depends on which enzymes the organisms possess. The action of caprylate esterase present in all salmonellae results in purple colonies, which are easy to distinguish from the purple Salmonella colonies.

**Brilliance Staph 24 Agar**
This medium is used for the isolation and enumeration of coagulase-positive staphylococci in foods within 24 h. Coagulase-positive staphylococci grow as dark blue colonies on a clear background.

**Brilliance UTI Agar**
This medium is used for the presumptive identification and differentiation of all the main microorganisms that cause urinary tract infections (UTIs). Brilliance UTI Agar contains two specific chromogenic substrates that are cleaved by enzymes produced by Enterococcus spp., E. coli, and coliforms. In addition, it contains phenylalanine and tryptophan, which provide an indication of tryptophan deaminase activity, indicating the presence of Proteus spp., Morganella spp., and Providencia spp.

**Brilliance UTI Clarity Agar**
This medium is used for the detection and differentiation of coliform bacteria and for the presumptive identification of the main pathogens that cause UTIs. Brilliance UTI Clarity Agar contains two chromogenic substrates that are cleaved by enzymes produced by E. coli, Enterococcus spp., and coliforms. Of the two chromogens included in the medium, one is metabolized by β-galactosidase, an enzyme produced by E. coli, which grows as pink colonies. The other is cleaved by β-glucosidase enzyme activity, allowing the specific detection of enterococci, which form blue or turquoise colonies. Cleavage of both the chromogens gives dark blue or purple colonies and indicates that the organism is a coliform. The tryptophan in the medium is an indicator of tryptophan deaminase activity, resulting in colonies of Proteus, Morganella, and Providencia spp. with brown halos.

**Brilliance VRE Agar**
This chromogenic agar is used for the detection of VRE and for the presumptive identification of Enterococcus faecium and E. faecalis, directly from clinical samples, in 24 h. VRE grow as either light blue colonies (E. faecalis) or as indigo-purple colonies (E. faecium), both of which are very easy to read against the new, semiopaque background.

**Brilliant green agar**
This medium is used for the selective isolation of salmonellae other than Salmonella Typhi from feces and other clinical specimens. The medium contains lactose, sucrose, and digest of casein and animal tissue plus phenol red and brilliant green. Salmonella species other than Salmonella Typhi appear as red, pink, or white colonies surrounded by a zone of red in the agar, indicating nonfermentation of lactose and sucrose. Proteus or Pseudomonas spp. may appear as small red colonies. Lactose- or sucrose-fermenting bacteria appear as yellow-green colonies surrounded by a zone of yellow-green in the agar.

**Brilliant green-phenol red agar**
This medium is used for the cultivation of Salmonella spp., with the exception of Salmonella Typhi, from feces. The medium contains lactose and peptone plus the differential indicators brilliant green and phenol red. Salmonella spp. produce pinkish white colonies.

**Bromcresol purple-deoxycholate agar**
This medium is used for the isolation and differentiation of Gram-negative enteric bacilli from clinical specimens, especially from fecal specimens. The medium contains lactose, sucrose, and sodium deoxycholate, which form the basis for differentiation. The medium also contains peptones, yeast extract, and citrate. Non-lactose- and non-sucrose-fermenting microorganisms appear as colorless or blue colonies. Lactose- and sucrose-fermenting microorganisms, such as coliform bacteria, appear as yellow-opaque white colonies surrounded by a zone of precipitated deoxycholate.

**Brucella agar**
This medium is used for the cultivation of Brucella spp. and for the isolation of both nonfastidious and fastidious microorganisms from a variety of clinical specimens. The medium contains digests of casein and animal tissue plus sodium sulfite, yeast extract, glucose, and blood. The medium can be supplemented with hemin and vitamin K₁ to improve growth. Blood can also be added for the detection of hemolytic reactions of Streptococcus and Haemophilus spp.

**Brucella agar base campylobacter medium**
This medium is used for the selective isolation and cultivation of C. jejuni from fecal specimens or rectal swabs. The medium contains digests of casein and animal tissue, yeast extract, glucose, pyruvate, sodium sulfite, and ferrous sulfate. It also includes cycloheximide, sodium cefazolin, novobiocin, bacitracin, and colistin sulfate as selective factors.

**Brucella agar base with blood and selective supplement**
This medium is used for the cultivation and maintenance of Brucella spp. and for the isolation and cultivation of nonfastidious and fastidious microorganisms from a variety of clinical specimens. This medium contains hydrolysate of casein, peptone, yeast extract, glucose, sodium sulfite, and blood. Cycloheximide, nalidixic acid, vancomycin, bacitracin, and polymyxin B are included as selective supplements.

**Brucella blood culture broth**
This medium is used for the isolation and cultivation of microorganisms from blood. This medium is especially useful
for the cultivation of anaerobes. It contains digests of casein and animal tissue plus sodium sulfite, yeast extract, sucrose, glucose, hemin, vitamin K₁, and blood. The medium can be supplemented with hemin.

■ Brucella broth (brucella Albimi broth)
This medium is used for the cultivation and maintenance of Campylobacter coli, Campylobacter falcis, and Brucella spp. It is also used for the isolation of a wide variety of fastidious and nonfastidious microorganisms. The medium contains digests of casein and animal tissue, yeast extract, glucose, sodium sulfite, and blood.

■ Brucella laked sheep blood agar with kanamycin and vancomycin
This medium is used for the selective isolation of fastidious and slow-growing, obligately anaerobic bacteria from the same specimen. The medium contains peptones, dextrose, yeast extract, sheep blood, hemin, and vitamin K₁. Kanamycin and vancomycin are included as selective factors. The laked blood improves pigmentation of the Prevotella melaninigenica-Porphyromonas asaccharolytica group.

■ Buffered charcoal-yeast extract agar with cysteine (BCYE alpha base)
This medium is used for the isolation of L. pneumophila and other Legionella spp. from clinical specimens. The medium contains cysteine, α-ketoglutarate, iron, yeast extract, N-(2-acetamido)-2-aminoethanesulfonic acid (ACES) buffer, and activated charcoal. The iron and cysteine are specific growth factors required by Legionella species for growth. The charcoal removes toxic metabolites. Antibiotics such as polymyxin B, anisomycin, and either vancomycin or cefamandole are typically included as selective factors. L. pneumophila produces light blue colonies with a pale green tint on this medium.

■ Buffered charcoal-yeast extract differential agar
This medium is used for the isolation, cultivation, and maintenance of L. pneumophila and other Legionella spp. from clinical specimens. The medium contains charcoal to reduce toxicity from metabolites. It also includes cysteine and iron, which are required growth factors for Legionella. Vancomycin and polymyxin B are included as selective factors.

■ Burkholderia cepacia agar
This medium is used for the selective isolation of B. cepacia from the respiratory secretions of patients with cystic fibrosis. Slow-growing B. cepacia can be missed on conventional media such as blood or MacConkey agar due to overgrowth caused by other faster-growing organisms found in the respiratory tract of cystic fibrosis patients, such as mucoid Klebsiella spp., P. aeruginosa, and Staphylococcus spp. This may lead to the infection being missed or wrongly diagnosed. The medium contains bile salts, gentamicin, ticarcillin, and polymyxin B as selective factors. It also contains pyruvate, peptone, and yeast extract.

■ Burkholderia cepacia selective agar
This medium is used for the selective isolation of B. cepacia. It contains digests of casein, yeast extract, sucrose, and lactose. It also contains polymyxin B, gentamicin, vancomycin, and crystal violet as selective factors.

■ Burkholderia pseudomallei selective agar
This medium is used for the selective isolation of B. pseudomallei. This medium is an improvement over Ashdown selective agar for clinical specimens from nonsterile sites. The medium contains standard agar, maltose, and neutral red.

■ Campylobacter agar, Blaser’s
This medium is used for the selective isolation of C. jejuni from fecal specimens. The medium contains cephalothin, vancomycin, trimethoprim, amphotericin B, and polymyxin B as selective factors. It also contains peptone, yeast extract, and liver digest.

■ Campylobacter agar, Skirrow’s
This medium is used for the selective isolation of C. jejuni from fecal specimens. The medium contains vancomycin, trimethoprim, and polymyxin B as selective factors. It also contains peptone, yeast extract, and liver digest.

■ Campylobacter blood agar
This medium is used for the isolation of C. jejuni from clinical specimens. It contains peptone, glucose, yeast extract, and blood. It also contains cephalothin, vancomycin, trimethoprim, amphotericin B, and polymyxin B as selective factors.

■ Campylobacter charcoal differential agar
This medium is used for the selective isolation of C. jejuni from fecal specimens. The medium contains vancomycin, trimethoprim, and polymyxin B as selective factors. It also contains peptone, yeast extract, and liver digest.

■ Campylobacter charcoal differential agar (Preston blood-free medium)
This medium is used for the cultivation of Campylobacter spp. The medium contains ceftoperazone and sodium deoxycholate as selective factors. It also contains charcoal to remove toxic metabolites. Peptone, beef extract, pyruvate, and ferrous sulfate also are included in the medium. This medium does not require blood to support the growth of Campylobacter spp.

■ Campylobacter selective medium, Blaser-Wang
This medium is used for the selective isolation of Campylobacter spp. The medium contains vancomycin, trimethoprim, and polymyxin B as selective factors. It also includes peptone, starch, and blood.

■ Campylobacter thioglycolate (Campy-Thio) medium
This medium is used for the maintenance—as a holding or transport medium—of Campylobacter spp. isolated from clinical specimens on swabs. The medium contains cephalothin, vancomycin, trimethoprim, amphotericin B, and polymyxin B as selective factors to prevent unwanted growth of contaminating organisms. It contains sodium sulfite and sodium thioglycolate to protect the cells against damage.

■ Cary-Blair transport medium
This medium is used primarily for the maintenance—as a holding medium or transport medium—of clinical speci-
mens, especially enteric pathogens, following collection or shipment. The medium contains sodium thiglycolate and calcium chloride to protect cells.

**CDC anaerobe 5% sheep blood agar**

This medium is used for the isolation and cultivation of fastidious and slow-growing, obligately anaerobic bacteria from a variety of clinical materials. The medium employs Trypticase soy agar supplemented with additional agar, yeast extract, vitamin K₁, hemin, cysteine, and 5% sheep blood. Improved growth of P. melaninogenica, Fusobacterium necrophorum, and Clostridium haemolyticum, as well as certain strains of Actinomyces israelii and Bacteroides thetaiotaomicron, has been demonstrated on this medium.

**Cefitulolin-Irgasan-novobiocin agar**

This medium is used for the selective isolation and differentiation of Yersinia enterocolitica based on mannitol fermentation. The medium contains strontium chloride, cefsulodin, novobiocin, crystal violet, neutral red, Irgasan, magnesium sulfate, mannitol, peptone, yeast extract, and pyruvate. Y. enterocolitica appears as “bull’s eye” colonies with deep red centers surrounded by a transparent periphery.

**Cellobiose-arginine-lysine agar**

This medium is used for the isolation of fastidious bacteria from clinical specimens and for the cultivation under reduced oxygen tension of fastidious microorganisms such as H. influenzae, Neisseria meningitidis, and N. gonorrhoeae. This medium contains arginine, lysine, cellobiose, deoxycholate, and neutral red.

**Cetrimide agar, non-USP**

This medium is used for the selective isolation, cultivation, and identification of P. aeruginosa and other Gram-negative, nonfermentative bacteria. The medium contains tryptose, cetrimide, and infusion from beef heart.

**Cetrimide agar, USP (Pseudosel agar)**

This medium is used for the selective isolation, cultivation, and identification of P. aeruginosa and other Gram-negative, nonfermentative bacteria. The medium contains glycerol, digest of gelatin, cetrimide, potassium sulfate, and magnesium chloride.

**Chocolate agar**

This is an enriched medium used for the cultivation of nutritionally fastidious microorganisms. The primary components of the medium are peptone, starch, digest of beef heart, and sheep blood.

**Chocolate tellurite agar (tellurite blood agar)**

This medium is used for the selective isolation of Corynebacterium spp. The medium contains extensive growth factors, including amino acids, vitamins, iron, NAD, and coenzyme. It also contains digests of casein and meat cornstarch, and tellurite. C. diptheriae appears as gray-black colonies.

**Cholera medium base with tellurite and blood**

This medium is used for the isolation of pathogenic vibrios, especially V. cholerae, and for the selective isolation of Vibrio spp. from specimens grossly contaminated with Enterobacteriaceae. This medium contains digest of animal tissue, beef extract, sucrose, sodium carbonate, sodium lauryl sulfate, blood, and tellurite.

**Cholera medium (thiosulfate-citrate-bile salts-sucrose [TCBS] agar)**

This medium is used for the isolation of pathogenic vibrios, especially V. cholerae. The medium is suitable for the growth of V. cholerae, Vibrio para-haemolyticus, and most other vibrios. Most of the Enterobacteriaceae encountered in feces are totally suppressed for at least 24 h. Slight growth of Proteus spp. and E. faecalis may occur, but the colonies are easily distinguished from vibrio colonies. While inhibiting non-vibrios, it promotes rapid growth of pathogenic vibrios after overnight incubation at 35°C. The following species form yellow colonies: V. cholerae El Tor biotype, Vibrio alginolyticus, Vibrio metschnikovii, Vibrio fluvialis, Enterococcus spp., and some strains of A. hydrophila. V. para-haemolyticus, Vibrio vulnificus, Vibrio mimicus, and Pseudomonas spp. form blue-green colonies. Proteus spp. form yellow-green colonies. Plesiomonas shigelloides does not usually grow well on this medium. This medium contains sucrose, peptone sodium thiosulfate, ox bile, ferric citrate, bromthymol blue, and thymol blue.

**Chopped meat broth**

This medium is used for the cultivation of various anaerobes. The medium contains digest of casein, yeast extract, and meat. It also contains cysteine to protect against oxygen exposure.

**Christensen agar**

See Urea agar.

**CHROMagar Acinetobacter**

Red colonies that appear on this medium are indicative of Acinetobacter spp.

**CHROMagar CTX (RambaCHROM CTX)**

This chromogenic agar is used for the detection of bacteria that produce ESBLs and carbapenemase. ESBL producers, such as Klebsiella pneumoniae, produce metallic blue colonies, while E. coli produces pink-red colonies and Proteus spp. produce brown colonies surrounded with a halo. Carbapenemase-producing organisms such as members of the KESC group produce blue-green to bluish gray colonies. E. coli produces pink to burgundy colonies or translucent colonies with a pink to burgundy center. Acinetobacter spp. produce cream, opaque colonies, and colonies of Pseudomonas spp. appear translucent or have a neutral pigment.

**CHROMagar E. coli (RambaCHROM E. coli)**

This is a proprietary medium from CHROMagar Microbiology used for the differentiation and presumptive identification of E. coli, which forms blue colonies. (CHROMagar is a Paris-based company; its products are available in the
19. Reagents, Stains, and Media: Bacteriology

CHROMagar ECC (RambaCHROM ECC)
This is a proprietary medium from CHROMagar Microbiology used for the differentiation and presumptive identification of *E. coli* and other coliform bacteria, which form red colonies.

CHROMagar ESBL (RambaCHROM ESBL)
This medium is used for the detection of Gram-negative bacteria producing ESBLs. Extended-spectrum β-lactam-resistant strains of *E. coli* form dark pink to reddish colonies. Extended-spectrum β-lactam-resistant strains of *Klebsiella*, *Enterobacter*, and *Citrobacter* form metallic blue colonies. Colonies of extended-spectrum β-lactam-resistant strains of *P. aeruginosa* have a brown halo.

CHROMagar KPC (RambaCHROM KPC)
Carbapenem-resistant strains of *E. coli* form dark pink to reddish colonies on this agar, which is used for the detection of Gram-negative bacteria with reduced susceptibility to most carbapenem antimicrobial agents. Carbapenem-resistant strains of *Klebsiella*, *Enterobacter*, and *Citrobacter* form blue colonies. Carbapenem-resistant strains of *Pseudomonas* form translucent cream colonies.

CHROMagar Listeria (RambaCHROM Listeria)
This is a proprietary medium from CHROMagar Microbiology used for the differentiation and presumptive identification of *L. monocytogenes*, which forms blue colonies surrounded by white halos.

CHROMagar MRSA (RambaCHROM MRSA)
This is a proprietary medium from CHROMagar Microbiology used for the qualitative direct detection of nasal colonization by MRSA to aid in the prevention and control of MRSA infections in health care settings.

CHROMagar O157 (RambaCHROM O157)
This is a proprietary medium from CHROMagar Microbiology used for the differentiation and presumptive identification of *E. coli* O157.

CHROMagar Orientation (RambaCHROM Orientation)
This is a proprietary medium from CHROMagar Microbiology used for the differentiation and presumptive identification of Gram-negative bacteria and *Enterococcus* spp., specifically for use in identifying these pathogens in urine. Isolates produce characteristic diagnostic colors; e.g., *E. coli* produces pinto red colonies.

CHROMagar Pseudomonas (RambaCHROM Pseudomonas)
This is a proprietary medium from CHROMagar Microbiology used for the simultaneous detection and enumeration of *P. aeruginosa* with coloring (blue colonies) that is markedly different from other microorganisms such as *S. saprophyticus*, *E. coli*, and *P. mirabilis* which are inhibited or form colorless colonies.

CHROMagar Salmonella (RambaCHROM Salmonella)
This is a proprietary medium from CHROMagar Microbiology used for the differentiation and presumptive identification of *Salmonella* spp.

CHROMagar Salmonella Plus (RambaCHROM Salmonella Plus)
This is a proprietary medium from CHROMagar Microbiology that allows for the direct detection of *Salmonella* spp., including *Salmonella Typhi*, *S. enterica* serovar *Paratyphi*, and lactose-positive *Salmonella*, by colony color according to ISO 6579:2003 norm.

CHROMagar Staph Aureus (RambaCHROM Staph Aureus)
This is a proprietary medium from CHROMagar Microbiology used for the differentiation and presumptive identification of *S. aureus*.

CHROMagar STEC (RambaCHROM STEC)
This agar is used for the detection of Shiga toxin-producing *E. coli* (STEC) in foods, environmental samples, and fecal specimens. Most common STEC serotypes form mauve colonies. Other *Enterobacteriaceae* form colorless or blue colonies.

CHROMagar StrepB (RambaCHROM StrepB)
This is a proprietary medium from CHROMagar Microbiology used for the differentiation and presumptive identification of GBS (*Streptococcus agalactiae*) based on color formation. GBS form mauve to pink colonies.

CHROMagar Vibrio (RambaCHROM Vibrio)
This is a proprietary medium from CHROMagar Microbiology used for the differentiation and presumptive identification of *V. parahaemolyticus*, which forms mauve colonies; *V. cholerae*, which forms turquoise blue colonies; and *V. alginolyticus*, whose colonies are colorless.

CHROMagar VRE (RambaCHROM VRE)
This is a proprietary medium from CHROMagar Microbiology used for the differentiation and presumptive identification of VRE (*E. faecalis* and *E. faecium*). Vancomycin-resistant Enterococcus strains form rose to mauve colonies.

CHROMagar Y. enterocolitica (RambaCHROM Y. enterocolitica)
This medium is used for the detection and direct differentiation of pathogenic *Y. enterocolitica*. Pathogenic *Y. enterocolitica* produces mauve colonies. Nonpathogenic *Y. enterocolitica* and other microbes (*Citrobacter*, *Enterobacter*, Aeromonas, etc.) produce metallic blue colonies.
■ **chromID C. difficile**
This medium is used for the identification and isolation of *Clostridium difficile*. As part of a comprehensive infection prevention program, chromID C. difficile can help institutions identify the reservoir and control the spread of this pathogenic organism.

■ **chromID CARBA agar**
This medium is used for the screening of carbapenemase-producing *Enterobacteriaceae*.

■ **chromID CPS**
This is an agar used for the isolation, enumeration, and direct identification of *E. coli*, *Proteus*, enterococci, and members of the KESC group in a single step using urine specimens. *E. coli* forms pink to burgundy colonies, *Proteus* forms dark brown colonies, and enterococci form turquoise colonies.

■ **chromID ESBL**
*E. coli* forms pink to burgundy colonies on this agar, which is used for the screening of ESBL-producing enterobacteria. KESC group members form green-blue to brown-green colonies. *Proteus* (Proteus, Providencia, and Morganella) form dark to light brown colonies of deaminase-expressing strains.

■ **chromID MRSA**
This medium was developed for use in health care facilities to actively reinforce MRSA surveillance culture and control in health care-associated infections. MRSA strains are indicated by green colonies resulting from α-glucuronidase-producing colonies in the presence of the antibiotic cefoxitin.

■ **chromID P. aeruginosa**
This medium detects *P. aeruginosa* based on the specific violet coloration of aminopeptidase-producing colonies.

■ **chromID S. aureus**
This agar is used for the direct identification of *S. aureus* and the selective isolation of staphylococci. Direct identification of *S. aureus* is based on the spontaneous green coloration of β-glucosidase-producing colonies.

■ **chromID Salmonella**
Three chromogenic substrates contained in this medium optimize the selective isolation and differentiation of all *Salmonella* serotypes. Specific detection of the esterase enzymatic activity on a colorless background yields pale pink to mauve colonies of *Salmonella* within 18 to 24 h.

■ **chromID Strepto B**
This medium is used for the screening of all *S. agalactiae* organisms. All GBS form round, pearly, pale pink to red colonies after 18 to 24 h.

■ **chromID Vibrio**
This agar is used for the selective isolation of *Vibrio* spp. and the presumptive identification of *V. cholerae* and *V. parahaemolyticus*. Presumptive identification of *V. cholerae* is through the blue-green coloration of β-galactosidase-producing colonies. *V. parahaemolyticus* forms pink colonies through arabinose assimilation.

■ **chromID VRE**
This agar is used for the rapid and reliable qualitative detection of *E. faecium* and *E. faecalis* showing acquired vancomycin resistance. As part of a comprehensive infection prevention program, chromID VRE can help institutions identify the reservoir and control the spread of these pathogenic organisms. Vancomycin-resistant *E. faecium* forms violet colonies, whereas resistant *E. faecalis* forms blue to green colonies.

■ **Clostridial agar**
This medium is used for the selective isolation of pathogenic clostridia from mixed biotas. The medium contains digests of casein and soybean meal, glucose, sodium thioglycolate, sodium formaldehyde sulfoxylate, cysteine, sodium azide, and neomycin.

■ **Coagulase-mannitol agar**
This medium is used for the cultivation and differentiation of *S. aureus* from other *Staphylococcus* spp. based on coagulase production and mannitol fermentation. The medium contains digest of casein, mannitol, brain heart infusion, digest of soybean meal, plasma, and bromcresol purple.

■ **Colistin-oxolinic acid-blood agar**
This medium is used for the isolation and cultivation of streptococci from mixed biotas in clinical specimens. The medium contains colistin sulfate and oxolinic acid as selective factors. It also contains starch, beef extract, yeast extract, and digests of animal tissue and casein plus blood.

■ **Columbia blood agar**
This medium is used for the cultivation of *Corynebacterium* spp., *Actinomyces* spp., *S. pneumoniae*, *Staphylococci* spp., and a variety of fastidious microorganisms. The medium contains starch, peptone, and blood (usually sheep blood at 5%).

■ **Columbia CNA agar**
This medium is used for the selective isolation, cultivation, and differentiation of Gram-positive cocci from clinical specimens. The medium contains starch, peptone, and blood. It also contains colistin and nalidixic acid as selective factors.

■ **Congo red acid morpholinepropanesulfonic acid pigmentation agar**
This medium is used for the cultivation of *Yersinia* spp., especially those with virulence plasmids. This medium contains morpholinepropanesulfonic acid, Casamino Acids, galactose, tricine, sodium thiosulfate, and Congo red.

■ **Congo red-brain heart infusion-agarose medium**
This medium is used for the isolation and detection of virulent strains of *Y. enterocolitica*. The medium contains
digest of gelatin, agarose (instead of agar), digest of animal tissue, infusion from brain heart, glucose, magnesium chloride, and Congo red.

**Cooked meat medium**
This medium is used for the cultivation of anaerobes, especially pathogenic clostridia. The medium contains heart tissue, glucose, and digest of animal tissue.

**Cycloserine-cefoxitin-egg yolk-fructose agar** *(Clostridium difficile agar)*
This medium is used for the selective isolation and cultivation of C. difficile from feces. The medium contains peptone, fructose, hemin, neutral red, and egg yolk emulsion. It also contains cycloserine and cefoxitin as selective factors.

**Cysteine albumin broth**
This medium is used for the transport and storage of biopsy samples for the detection of *H. pylori*. The medium contains cysteine, albumin, and glycerol.

**Cystine heart agar (cystine-glucose-blood agar)**
This medium is used for the cultivation and maintenance of *F. tularensis*. The medium contains glucose, peptone, and infusion from beef heart. It also contains hemoglobin and cystine. Without the hemoglobin enrichment, it supports excellent growth of Gram-negative cocci and other pathogenic microorganisms.

**Cystine-tellurite-blood agar**
This medium is used for the isolation, differentiation, and cultivation of *C. diphtheriae*. The medium contains infusion from beef heart, tryptose, yeast extract, cystine, blood, and potassium tellurite. *C. diphtheriae* appears as dark gray to black colonies.

**Cystine tryptic agar**
This medium is used for the cultivation and maintenance of a variety of fastidious microorganisms, including *C. diphtheriae*. It is also used for carbohydrate fermentation tests in the differentiation of *Neisseria* spp. The medium contains sodium sulfite, cystine, and digest of casein plus phenol red indicator.

**DeMan, Rogosa, Sharpe (MRS) agar** *(Lactobacillus MRS agar)*
This medium is used for the isolation and cultivation of *Lactobacillus* spp. from clinical specimens. The medium contains digest of gelatin, beef extract, yeast extract, sodium acetate, ammonium citrate, and Tween 80.

**Deoxycholate agar**
This medium is used for the selective isolation and differentiation of Gram-negative enteric microorganisms from a variety of clinical specimens. The medium contains lactose, digests of casein and animal tissue, ferric citrate, sodium citrate, sodium deoxycholate, and neutral red. *E. coli* appears as large, flat, rose red colonies. *Enterobacter* and *Klebsiella* spp. appear as large, mucoid, pale colonies with a pink center. *Proteus* and *Salmonella* spp. appear as large, colorless to tan colonies. *Shigella* spp. appear as colorless to pink colonies. *Pseudomonas* spp. appear as irregular, colorless to brown colonies.

**Deoxycholate-citrate agar**
This medium is used for the selective isolation and cultivation of enteric pathogens, especially *Salmonella* and *Shigella* spp. The medium contains citrate, lactose, digest of animal tissue, infusion of meat, deoxycholate, ferric citrate, and neutral red.

**Deoxycholate-citrate agar, Hynes**
This medium is used for the selective isolation and differentiation of enteric pathogens, especially *Salmonella* and *Shigella* spp. The medium contains lactose, citrate, peptone, beef extract, deoxycholate, ferric citrate, and neutral red. Lactose-fermenting bacteria appear as pink colonies that may or may not be surrounded by a zone of precipitated deoxycholate. Non-lactose-fermenting bacteria appear as colorless colonies that are surrounded by a clear orange-yellow zone.

**Deoxycholate-citrate-lactose-sucrose agar**
This medium is used for the selective isolation of *Salmonella* spp., *Shigella* spp., and *Vibrio* spp. from fecal specimens. The medium contains citrate, lactose, sucrose, thiosulfate, beef extract, deoxycholate, digests of casein and animal tissue, and neutral red.

**Deoxycholate-citrate-lactose-sucrose agar, Hajna**
This medium is used for the selective isolation of *Salmonella* spp., *Shigella* spp., and *Vibrio* spp. from fecal specimens. The medium contains citrate, lactose, sucrose, thiosulfate, beef extract, deoxycholate, digests of casein and animal tissue, and bromcresol purple.

**Differential agar for group D streptococci**
This medium is used for the differentiation and identification of group D streptococci. The medium contains digests of casein and animal tissue, glucose, infusion from brain heart, and bromcresol purple.

**Diphtheria virulence agar base with tellurite and diphtheria virulence supplement**
This medium is used for the detection of diphtheria toxin-producing strains of *C. diphtheriae* and for testing the toxigenicity of *C. diphtheriae*. The reaction of antitoxin forms the actual basis for the detection of the diphtheria toxin. The medium contains peptone, tellurite, horse serum, and a filter paper strip saturated with potent diphtheria antitoxin.

**DNase test agar with toluidine blue**
This medium is used for the differentiation of microorganisms, especially *Staphylococcus* spp. and *Serratia marcescens*, based on their production of DNase. The medium contains digests of casein and animal tissue, DNA, and toluidine blue.
Dubos broth (Dubos Tween albumin broth)
This medium is used for the cultivation of M. tuberculosis and other Mycobacterium spp. The medium contains asparagine, digest of casein, Tween 80, ferric ammonium citrate, and serum albumin or serum.

E. coli O157:H7 MUG agar
This medium is used for the isolation and differentiation of enterohemorrhagic E. coli O157:H7 strains from clinical specimens. The medium contains peptone, sorbitol, meat extract, thiosulfate, deoxycholate, yeast extract, ammonium ferric citrate, MUG, and bromthymol blue.

Egg yolk agar
This medium is used for the isolation and differentiation of Clostridium spp. and some other anaerobic bacteria. The medium contains peptone, glucose, hemin, and egg yolk emulsion.

Ellinghausen-McCullough-Johnson-Harris medium
This medium is used for the isolation and cultivation of Leptospira spp. Albumin and Tween 80 are included to provide lipids. Lysed erythrocytes also are included in the medium to provide iron. The medium can be rendered selective by the addition of 5-fluorouracil.

EMB agar, Levine
This medium is used for the isolation, cultivation, and differentiation of Gram-negative enteric bacteria based on lactose fermentation. The medium contains digest of casein, lactose, sucrose, esoin, dipotassium phosphate, and methylene blue. Bacteria that ferment lactose, especially the coliform bacterium E. coli, appear as colonies with a green metallic sheen or blue-black to brown color. Bacteria that do not ferment lactose appear as colorless or transparent, light purple colonies.

EMB agar, modified, Holt-Harris and Teague
This medium is used for the isolation, cultivation, and differentiation of Gram-negative enteric bacteria based on lactose fermentation. The medium contains digest of casein, lactose, sucrose, esoin, dipotassium phosphate, and methylene blue. Bacteria that ferment lactose, especially the coliform bacterium E. coli, appear as colonies with a green metallic sheen or blue-black to brown color. Bacteria that do not ferment lactose appear as colorless or transparent, light purple colonies.

Endo agar
This medium is used for the selective isolation, cultivation, and differentiation of coliform and other enteric microorganisms based on their ability to ferment lactose. The medium contains lactose, digest of animal tissue, and basic fuchsin. Lactose-fermenting bacteria appear as dark red colonies with a gold metallic sheen. Non-lactose-fermenting bacteria appear as colorless or translucent colonies.

Enterococcosel agar
This medium is used for the rapid, selective isolation of enterococci. It is also used for the cultivation of staphylococci and L. monocytogenes. The medium contains digest of casein, proteose peptone, iron, esculin, and yeast extract. Oxgall (bile) and sodium azide are included as selective factors. The hydrolysis of esculin in the presence of ferric citrate results in the formation of a black-brown color.

Enterococcosel agar with vancomycin
This medium is used for the detection of VRE, particularly for primary screening of asymptomatic gastrointestinal carriage of VRE. The medium contains digest of casein, proteose peptone, iron, esculin, and yeast extract. Oxgall (bile), sodium azide, and vancomycin (8.0 mg/liter) are included as selective factors.

Enterococcosel broth
This medium is used for the differentiation of enterococci. The medium contains digest of casein, proteose peptone, iron, esculin, and yeast extract. Oxgall (bile) and sodium azide are included as selective factors.

Esculin azide broth
This medium is used for the cultivation of enterococci from feces. The medium contains digest of animal tissue, bile salts, yeast extract, esculin, sodium citrate, ferric ammonium citrate, and sodium azide.

ESP Myco medium
This medium is used with ESP Culture System II (TREK Diagnostic Systems) for the detection of mycobacterial growth. The medium is a Middlebrook 7H9 broth enriched with glycerol, Casitone, and cellulose sponge disks. Oleic acid-albumin-dextrose-catalase (OADC) enrichment is added before use.

Eugonic agar
This medium is used for the cultivation of a variety of fastidious microorganisms, e.g., Brucella, Haemophilus, Neisseria, Pasteurella, and Lactobacillus spp. The medium contains digests of casein and soybean meal, glucose, cystine, and sodium sulfite.

Eugonic LT100 medium base without Tween 80
This medium is used for the cultivation of fastidious microorganisms such as Haemophilus, Neisseria, Pasteurella, Brucella, and Lactobacillus spp.

Feeley-Gorman agar
This medium is used for the isolation and cultivation of L. pneumophila. The medium contains acid hydrolyzed casein, beef extract, starch, cysteine, and ferric pyrophosphate.

Fildes enrichment agar
This medium is used for the isolation of H. influenzae. The medium contains peptone, beef extract, pepsin, and blood.

Fletcher medium
This medium is used for the isolation of Leptospira spp. The medium contains peptone, beef extract, pepsin, and blood.
It can be supplemented with 5-fluorouracil to render it selective.

- **GC agar**
  This medium is used for the isolation of *Neisseria* and *Haemophilus* spp. from clinical specimens. The medium contains digest of casein and starch. It may be enriched by the addition of hemin and NAD. Cysteine and antibiotics can also be added to make the medium selective.

- **GC II agar**
  This medium is used for the isolation of fastidious microorganisms, especially *Neisseria* and *Haemophilus* spp., from clinical specimens. The medium contains digest of casein, meat peptone, starch, and hemoglobin, a selective supplement of numerous growth factors, and a proprietary selective supplement. This medium is described in the *Difco & BBL Manual: Dehydrated Culture Media and Reagents for Microbiology* (22). GC-II agar is used in the Miles Laboratory JEMBEC system, which consists of a John E. Martin Biological Environmental Chamber-style plate, a carbon dioxide tablet, and resealable plastic bag.

- **GC-Lect agar**
  This medium is used for the isolation and cultivation of *N. gonorrhoeae* from clinical specimens. The medium contains digest of casein, meat peptone, starch, hemoglobin, a selective supplement of numerous growth factors, and a proprietary selective supplement. This medium is described in the *Difco & BBL Manual: Dehydrated Culture Media and Reagents for Microbiology* (22). GC-Lect Agar is used in the Miles Laboratory JEMBEC system, which consists of a John E. Martin Biological Environmental Chamber-style plate, a carbon dioxide tablet, and resealable plastic bag.

- **GN broth, Hajna**
  This medium is used for the selective cultivation of *Salmonella* and *Shigella* spp. The medium contains digests of casein and animal tissue, citrate, mannitol, glucose, and deoxycholate.

- **Gum *Listeria* medium (gum base-nalidixic acid medium)**
  This medium is used for the isolation of *L. monocytogenes* from clinical specimens. This medium contains gellan gum, digests of casein and soybean meal, glucose, and nalidixic acid.

- **H broth**
  This medium is used for the preparation of the H agglutination antigen used in the differentiation and identification of *Salmonella* spp. types and subtypes. The medium contains digest of casein, peptone, beef extract, and glucose.

- **Haemophilus test medium**
  This medium is used for antibiotic susceptibility testing of *Haemophilus* spp. The medium contains digests of casein and animal tissue, yeast extract, hematin, NAD, and growth factors.

- **HardyCHROM CRE Agar**
  This medium is used for the selection and differentiation of carbapenemase-producing Gram-negative bacteria. It is intended to serve as a supplemental medium or to be combined with other media for processing specimens. It is not intended for use in the definitive identification of colonization with carbapenem-resistant bacteria in the prevention and control of such bacteria in a health care setting. It is not cleared by the U.S. Food and Drug Administration for diagnosis of infections by carbapenem-resistant bacteria. Exposure to light during storage and incubation should be minimized.

- **HardyCHROM ESBL Agar**
  This medium is used for the selection and differentiation of *Enterobacteriaceae* that produce ESBLs. It is intended to serve as a supplemental medium to be combined with other media for processing specimens. It is not intended for use in the definitive identification of colonization with extended-spectrum β-lactam-resistant bacteria in the prevention and control of such bacteria in a health care setting. It is not cleared by the U.S. Food and Drug Administration for diagnosis of infections by extended-spectrum β-lactam-resistant bacteria. Exposure to light during storage and incubation should be minimized.

- **Hartley’s digest broth**
  This medium is used for the isolation and cultivation of actinomycetes. This medium contains ox heart, pancreatic, sodium carbonate, and hydrochloric acid.

- **Heart infusion agar**
  This medium is used for the isolation and cultivation of a wide variety of microorganisms, including *B. cereus*, *S. aureus*, *V. vulnificus*, and *V. cholerae*. The medium contains tryptose and infusion from beef heart. It can be used as a base for the preparation of blood agar in determining hemolytic reactions.

- **Hektoen enteric agar**
  This medium is used for the isolation and cultivation of Gram-negative enteric microorganisms from a variety of clinical specimens based on lactose or sucrose fermentation and H₂S production. Bacteria that ferment lactose or sucrose appear as yellow to orange colonies. Bacteria that produce H₂S appear as colonies with black centers. The medium contains lactose, digest of animal tissue, sucrose, bile salts, thiosulfate, yeast extract, salcin ferric ammonium citrate, acid fuchsine, and bromthymol blue.

- **HiCrome Aureus Agar Base with egg yolk tellurite (Staphylococcus aureus agar, HiCrome)**
  This medium is used for the isolation and enumeration of coagulase-positive *S. aureus*. Coagulase-positive *S. aureus* gives brown-black colonies, whereas *S. epidermidis* gives yellow, slightly brownish colonies. The medium contains digests of casein and gelatin, pyruvate, beef extract, lithium chloride, yeast extract, eggs, tellurite, and a chromogenic mixture.

- **HiCrome Listeria Agar Base, modified, with moxalactam (Listeria HiCrome Agar Base, modified)**
  This medium is used for the rapid and direct identification of *Listeria* spp., specifically *L. monocytogenes*. The medium contains peptone, rhamnose, lithium chloride, meat extract,
yeast extract, phenol red, and a chromogenic mixture. It also includes moxalactam as a selective supplement.

**HiCrome MeReSa Agar with methicillin**
This medium is used for the isolation and cultivation of MRSA. The medium contains a chromogenic substrate that allows differentiation of *S. aureus*. It also contains methicillin.

**HiCrome RajHans Medium (Salmonella Agar)**
This medium is used for the identification and differentiation of *Salmonella* spp. from members of the *Enterobacteriaceae*, especially *Proteus* spp. The medium contains a chromogenic mixture that permits differentiation.

**HiCrome RajHans Medium, modified (Salmonella Agar, modified)**
This medium is a selective chromogenic medium used for the isolation and differentiation of *Salmonella* spp. from members of the family *Enterobacteriaceae*, especially *Proteus* spp. The medium contains hydrolysate of casein, yeast extract, digest of animal tissue, lactose, sodium deoxycholate, neutral red, and a chromogenic mixture.

**HiCrome Salmonella Agar**
This medium is used for the identification, differentiation, and confirmation of enteric bacteria, *E. coli*, and *Salmonella* from specimens such as urine that may contain a large number of *Proteus* spp. as well as other potentially pathogenic Gram-positive organisms. The medium contains digest of animal tissue, yeast extract, bile salts, and a chromogenic mixture.

**HiCrome UTI Agar**
This medium is used for the differentiation and enumeration of thermotolerant *E. coli* from water by the membrane filtration method. It is also used for the identification, differentiation, and confirmation of enteric bacteria from specimens such as urine, water, or food that may contain large numbers of *Proteus* spp. as well as other potentially pathogenic Gram-positive organisms. The medium contains digests of casein and animal tissue, beef extract, and a chromogenic mixture.

**HiFluoro Pseudomonas Agar Base**
This medium is used for the selective isolation of *P. aeruginosa* from clinical specimens by a fluorogenic method. The medium contains digest of gelatin, potassium sulfate, glycercerol, cetrimide, and a fluorogenic mixture.

**Horie Arabinose Ethyl Violet Broth**
This medium is used for the cultivation of *Vibrio* spp. The medium contains peptone, beef extract, arabinose, ethyl violet, and bromthymol blue.

**Hoyle medium**
This medium is used for the isolation and differentiation of *C. diphtheriae* strains. It permits very rapid growth of all types of *C. diphtheriae*, so that diagnosis is possible after 18 hours’ incubation. The medium contains peptone, Lab-Lemco powder, tellurite, and laked blood.

**Kanamycin-esculin-azide agar**
This medium is used for the isolation of enterococci. The medium contains digest of casein, yeast extract, esculin, sodium citrate, ferric ammonium citrate, sodium azide, and kanamycin.

**Kligler iron agar**
The *H*$_2$S produced from thiosulfate by sulfate reductase will react with the Fe salt to produce FeS, a strong black precipitate, which for clinically relevant nonfermenters is only observed for *Shewanella* spp. The medium contains pancreatic digest of casein, ferric ammonium citrate, peptic digest of animal tissue, sodium thiosulfate, lactose, agar, glucose, phenol red, and sodium chloride.

**Lim broth**
This medium is a modification of Todd-Hewitt broth and is an enriched selective liquid medium used for the isolation and cultivation of *S. agalactiae*. Peptones, salts, and dextrose provide the nutritive base. Yeast extract provides B vitamins and additional enrichment. The antibiotics colistin and nalidixic acid inhibit Gram-negative bacteria. The effectiveness of this medium has been evaluated by Elsayed et al. (35).

**Listeria monocytogenes confirmatory agar base**
This medium is used for the selective and differential isolation of *L. monocytogenes* from clinical specimens. The medium contains peptone, lithium chloride, yeast extract, α-methyl-d-mannoside, phosphatidylinositol, polymyxin B, ceftazidime, nalidixic acid, and amphotericin B. The multiple antimicrobials make this a highly selective medium.

**Listeria Oxford medium base with antibiotic inhibitor**
This medium is used for the isolation and cultivation of *L. monocytogenes* from specimens containing a mixed bacterial biota, including from pathological specimens. The medium contains peptone, lithium chloride, starch, esculin, and ammonium ferric citrate. It also includes cycloheximide, colistin sulfate, fosfomycin, acriflavine, and cefotetan as selective factors.

**Listeria transport enrichment medium**
This medium is used for the maintenance—as a transport medium—and enrichment of *Listeria* spp. The medium contains sodium glycerophosphate, sodium thioglycolate, nalidixic acid, and acridine.

**Liver infusion agar**
This medium is used for the cultivation of *Brucella* spp. and other fastidious pathogenic bacteria. The medium contains potassium thiocyanate infusion from beef liver, peptone, and salt.

**Loeffler medium**
This medium is used for the detection of *C. diphtheriae*. The medium contains beef serum, eggs, infusion from heart muscle, glucose, and digest of animal tissue.
**Lombard-Dowell agar**

This medium is used for the identification of a variety of obligate anaerobic bacteria, including *Bacteroides* spp., *Fusobacterium* spp., and non-spore-forming Gram-positive anaerobes. The medium contains digest of casein, yeast extract, cystine, tryptophan, sodium sulfite, hemin, and vitamin K₁.

**Lombard-Dowell egg yolk agar**

This medium is used for the cultivation and differentiation of a wide variety of anaerobic bacteria based on lecithinase production, lipase production, and proteolytic ability. The medium contains digest of casein, yeast extract, cystine, tryptophan, sodium sulfite, egg yolk emulsion, hemin, and vitamin K₁. Bacteria that produce lecithinase appear as colonies surrounded by a zone of insoluble precipitate. Bacteria that produce proteolytic activity appear as colonies surrounded by a clear zone.

**Lowenstein-Gruft medium**

This medium is used for the cultivation and differentiation of *Mycobacterium* spp. The medium contains starch, asparagine, magnesium citrate, malachite green, nalidixic acid, RNA, eggs, glycerol, and penicillin. *M. tuberculosis* appears as granular, rough, dry colonies. *M. kansasii* appears as smooth to rough, photochromogenic colonies. *Mycobacterium gordonae* appears as smooth, yellow-orange colonies. *M. avium* appears as smooth, colorless colonies. *Mycobacterium smegmatis* appears as wrinkled, creamy white colonies.

**Lowenstein-Jensen medium**

This medium is used for the cultivation and differentiation of *Mycobacterium* spp. The medium contains starch, asparagine, magnesium citrate, malachite green, eggs, and glycerol. *M. tuberculosis* appears as granular, rough, dry colonies. *M. kansasii* appears as smooth to rough, photochromogenic colonies. *M. gordonae* appears as smooth, yellow-orange colonies. *M. avium* appears as smooth, colorless colonies. *M. smegmatis* appears as wrinkled, creamy white colonies.

**MacConkey agar**

This medium is used for the selective isolation and differentiation of *E. coli* O157:H7. The medium contains digest of gelatin, bile salts, digests of casein and animal tissue, neutral red, crystal violet, and sorbitol. STEC strains do not ferment sorbitol and appear as colorless colonies. Sorbitol-fermenting strains appear as pink colonies.

**MacConkey agar with sorbitol**

This medium is used for the selective isolation and differentiation of *E. coli* O157:H7. The medium contains digest of gelatin, bile salts, digests of casein and animal tissue, neutral red, crystal violet, and sorbitol. STEC strains do not ferment sorbitol and appear as colorless colonies. Sorbitol-fermenting strains appear as pink colonies.

**Malachite green broth**

This medium is used for the cultivation of *P. aeruginosa*. The medium contains peptone, beef extract, and malachite green.

**Mannitol-egg yolk-polymyxin agar**

This medium is used for the selective isolation, cultivation, and enumeration of *B. cereus* from clinical specimens. The medium contains mannitol, peptone, beef extract, phenol red, polymyxin B, and egg yolk emulsion.

**Mannitol-lysine-cresyl violet-brilliant green agar**

This medium is used for the selective isolation and cultivation of *Salmonella* spp. from fecal material. The medium contains peptone, yeast extract, lysine, sodium thiosulfate, mannitol, beef extract, ferric ammonium citrate, crystal violet, and brilliant green.

**Mannitol salt agar**

This medium is used for the selective isolation, cultivation, and enumeration of staphylococci from clinical specimens. The medium contains mannitol, digests of casein and animal tissue, beef extract, and phenol red. Mannitol-utilizing organisms turn the medium yellow.

**Mannitol salt broth**

This medium is used for the selective isolation of presumptive pathogenic staphylococci. The medium contains peptone, mannitol, beef extract, and phenol red.

**Mannitol selenite broth (selenite mannitol broth)**

This medium is used for the selective enrichment of *Salmonella* spp. from clinical specimens. The medium contains digest of animal tissue, mannitol, and sodium selenite.

**Martin-Lewis agar**

This medium is used for the isolation and cultivation of pathogenic *Neisseria* from specimens containing mixed biotas. The medium contains hemoglobin, digest of casein, meat peptone, and starch. It also contains a complex growth supplement solution with amino acids, nucleotides, and vitamins. Colistin, trimethoprim, lactate, vancomycin, and anisomycin are included as selective factors.

**McBride Listeria agar**

This medium is used for the selective isolation of *L. monocytogenes* from clinical specimens containing mixed biotas. The medium contains glycine, digests of casein and animal
tissue, beef extract, phenylethyl alcohol, and lithium chloride.

- **Methyl red-VP medium**
  This medium is used for the differentiation of bacteria based on acid production (methyl red test) and acetoin production (VP reaction). The medium contains glucose, peptone, and phosphate buffer.

- **Middlebrook albumin-dextrose-catalase (ADC) enrichment**
  This medium is used as a supplement to other Middlebrook media for the isolation, cultivation, and maintenance of *Mycobacterium* spp. It is also used as a supplement to other Middlebrook media for determining the antimicrobial susceptibility of mycobacteria. This enrichment supplement contains bovine albumin fraction V, glucose, and catalase.

- **Middlebrook 7H9 broth with Middlebrook ADC enrichment**
  This medium is used for the isolation of *Mycobacterium* spp., including *M. tuberculosis*, and also for determining the antimicrobial susceptibility of mycobacteria. The medium contains glutamate, citrate, ferric ammonium citrate, pyridoxine, biotin, glycerol, and Middlebrook ADC enrichment.

- **Middlebrook 7H10 agar with Middlebrook ADC enrichment**
  This medium is used for the isolation, cultivation, and maintenance of *Mycobacterium* spp., including *M. tuberculosis*. It is also used for determining the antimicrobial susceptibility of mycobacteria. The medium contains glutamate, citrate, ferric ammonium citrate, pyridoxine, biotin, glycerol, malachite green, and Middlebrook ADC enrichment.

- **Middlebrook 7H11 agar with Middlebrook ADC enrichment (mycobacteria 7H11 agar with Middlebrook ADC enrichment)**
  This medium is used for the cultivation of drug-resistant (isoniazid) strains of *M. tuberculosis*, and particularly for the cultivation of fastidious strains of tubercle bacilli that occur following treatment of tuberculosis patients with secondary antitubercular drugs. Generally, these strains fail to grow on 7H10 medium. The medium contains glutamate, citrate, ferric ammonium citrate, pyridoxine, biotin, glycerol, malachite green, and Middlebrook ADC enrichment.

- **Middlebrook OADC enrichment**
  This medium is used as a supplement to other Middlebrook media for the isolation, cultivation, and maintenance of *Mycobacterium* spp. It is also used as a supplement to other Middlebrook media for determining the antimicrobial susceptibility of mycobacteria. This enrichment supplement contains bovine albumin fraction V, glucose, oleic acid, and catalase.

- **MRSASelect medium**
  This is a selective and differential medium (Bio-Rad Laboratories, Redmond, WA) for the detection of MRSA from nasal swabs and wound specimens.

- **Mueller-Hinton agar**
  This medium is used for the isolation of pathogenic *Neisseria* spp., including *N. meningitidis*. It is also used for antimicrobial susceptibility testing of a variety of bacterial species. The medium contains infusion from beef, acid hydrolysate of casein, and starch.

- **Mueller-Hinton broth**
  This medium is used for antimicrobial susceptibility testing. The medium contains infusion from beef, acid hydrolysate of casein, and starch.

- **Mueller-Hinton chocolate agar**
  This medium is used for the cultivation of *N. gonorrhoeae* and *N. meningitidis* and for antimicrobial susceptibility testing of fastidious microorganisms. The medium contains infusion from beef, acid hydrolysate of casein, starch, and blood.

- **Mueller-Hinton II agar**
  This medium is used for antimicrobial disk diffusion susceptibility testing of a variety of bacteria by the Bauer-Kirby method. The medium contains acid hydrolysate of casein and starch. This medium, supplemented with 5% sheep blood, is recommended for use in antimicrobial susceptibility testing of *S. pneumoniae* and *H. influenzae*.

- **Mueller tellurite medium**
  This medium is used for the isolation, cultivation, and differentiation of *C. diphtheriae*. The medium contains casein, Casamino Acids, tryptophan, serum, sodium lactate, ethyl alcohol, calcium pantothenate, and tellurite.

- **Mycobactosel agar**
  This medium is used for the selective isolation of mycobacteria from specimens containing mixed biotas. The medium contains digest of casein, albumin, glutamate, biotin, glycerol, oleic acid, catalase, and malachite green. It also contains cycloheximide, nalidixic acid, and lincomycin as selective factors.

- **Mycobactosel L-J medium**
  This medium is used for the isolation and cultivation of *Mycobacterium* spp. from clinical specimens. The medium contains potato flour, asparagine, citrate, glycerol, malachite green, and eggs. It also contains cycloheximide, nalidixic acid, and lincomycin as selective factors. Mycobactosel L-J medium is Lowenstein-Jensen medium plus cycloheximide, lincomycin, and nalidixic acid for use with specimens likely to contain many contaminating organisms.

- **Mycoplasma agar base (PPLO agar base)**
  This medium is used for the preparation of media for the cultivation of *Mycoplasma* spp. The medium contains digest of casein, beef extract, yeast extract, infusion from beef heart, horse serum, and fresh yeast extract solution.

- **Mycoplasma broth base without crystal violet and with asctic fluid (PPLO broth base without crystal violet)**
  This medium is used for the enrichment of pleuropneumonia-like organisms (PPLOs) and *Mycoplasma* spp. from
clinical specimens. The medium contains peptone, infusion from beef, and ascitic fluid.

■ NaCl agar
This medium is used for the differentiation of Gram-positive cocci, especially Staphylococcus spp., based on salt tolerance. The medium contains various concentrations of NaCl (e.g., 6.5 or 12%) and digests of casein and soybean meal. It can be supplemented with glucose and sheep blood.

■ Neisseria meningitidis medium
This medium is used for the selective isolation and cultivation of N. meningitidis. The medium contains acid hydroxylate of casein and starch. It also contains vancomycin, colistin, and nystatin as selective factors.

■ Neomycin blood agar
This medium is used for the isolation and cultivation of group A streptococci (S. pyogenes) and GBS (S. agalactiae) from throat cultures and other clinical specimens. The medium contains digest of casein, growth factors, blood, and neomycin.

■ New York City medium
This medium is used for the isolation and cultivation of pathogenic Neisseria spp. It is also used as a transport medium for urogenital and other clinical specimens and for the isolation and presumptive identification of Mycoplasmatales, including large-colony species (Mycoplasma pneumoniae) and T-mycoplasmas from urogenital specimens. The medium contains starch, peptone, infusion from beef, and ascitic fluid. The medium contains peptone, infusion from beef, and ascitic fluid.

■ Nitrate broth
This medium is used for the differentiation of aerobic and facultative Gram-negative microorganisms based on their ability to reduce nitrate. The medium contains digest of gelatin and potassium nitrate. The test for nitrites uses sulfanilic acid and α-naphthylamine reagents. Bacteria that reduce nitrate to nitrite turn the reagents red or pink.

■ Nutrient agar, 1.5%, HiVeg with asctic fluid
This medium is used for the enrichment of PPLOs and Mycoplasma spp. from clinical specimens. The medium contains peptones and asctic fluid.

■ N-Z-Amine A glycerol agar
This medium is used for the isolation and cultivation of Actinomadura spp. The medium contains N-Z-Amine A, beef extract, and glycerol.

■ O157:H7 ID agar
This proprietary medium from bioMérieux is a chromogenic medium for the detection of E. coli O157:H7.

■ ONE Broth-Listeria (Oxoid novel enrichment broth-Listeria)
This medium is used for the selective enrichment of Listeria spp. This proprietary medium from Oxoid contains peptone, salt mix, carbohydrate mix, and a selective supplement.

■ Önöz Salmonella agar
This medium is used for the isolation and cultivation of Salmonella from feces. The medium contains sucrose, lactose, sodium citrate, meat peptone, beef extract, phenylalanine, thiosulfate, bile salts, yeast extract, ferric citrate, methylene yellow, aniline blue, neutral red, and brilliant green.

■ Oxford agar (Listeria selective agar, Oxford)
This medium is used for the isolation and cultivation of L. monocytogenes from specimens containing a mixed bacterial biota. The medium contains peptone, starch, esculin, ferric ammonium citrate, lithium chloride, and the antimicrobials cycloheximide, colistin, fosfomycin, acriflavine, and cefotetan.

■ Oxford agar, modified (Listeria selective agar, modified Oxford)
This medium is used for the isolation of L. monocytogenes from specimens containing a mixed bacterial biota. The medium contains peptone, lithium chloride, starch, esculin, ferric ammonium citrate, and the antimicrobials moxalactam and colistin sulfate.

■ Oxidation-fermentation medium, Hugh-Leifson’s
This medium is used for differentiating Gram-negative bacteria, such as Vibrio spp., based on determining the oxidative and fermentative metabolism of carbohydrates. The medium contains peptone, a carbohydrate substrate, and bromthymol blue. Bacteria that ferment the carbohydrate turn the medium yellow.

■ Oxidation-fermentation medium, King’s
This medium is used for differentiating bacteria based on determining the oxidative and fermentative metabolism of carbohydrates. The medium contains digest of casein, a carbohydrate substrate, and phenol red. Bacteria that ferment the carbohydrate turn the medium yellow.

■ Oxoid Salmonella chromogenic agar (OSCM)
This medium is used for the identification of Salmonella spp. and differentiation of Salmonella spp. from other organisms in the family Enterobacteriaceae. The medium combines two chromogens for the detection of Salmonella spp.: 5-bromo-6-chloro-3-indolyl caprylate (Magenta-caprylate) and 5-bromo-4-chloro-3-indolyl-β-D-galactopyranoside (X-gal). X-gal is a substrate for the enzyme β-D-galactosidase. Hydrolysis of the chromogen Magenta-caprylate by lactose-negative Salmonella spp. results in magenta colonies. The medium contains bile salts to inhibit the growth of Gram-positive organisms, and the addition of the selective supplement solution increases the selectivity of the medium. Novobiocin inhibits Proteus growth and cefsulodin inhibits growth of pseudomonads.
**P agar**
This medium is used for the cultivation of *Staphylococcus* spp. The medium contains peptone, NaCl, yeast extract, and glucose.

**Pasteurella haemolytica selective medium**
This medium is used for the selective cultivation of *P. haemolytica*. The medium contains digests of casein and animal tissue, glucose, peptic digest of blood, and the antimicrobials cycloheximide, novobiocin, and neomycin.

**Penicillinase-producing Neisseria gonorrhoeae medium (PPNG selective medium)**
This medium is used for the differentiation and presumptive identification of *penicillinase-producing strains of N. gonorrhoeae*. PPNG selective medium is a two-sectored plate, each containing a different Martin-Lewis agar.

**Peptone iron agar**
This medium is used for the cultivation and differentiation of microorganisms based on their ability to produce H₂S. The medium contains peptones, sodium glycerophosphate, ferric ammonium citrate, and sodium thiosulfate. Microorganisms that produce H₂S turn the medium black.

**Perfringens agar (Shahidi-Ferguson perfringens agar)**
This medium is used for the isolation and enumeration of *Clostridium perfringens* organisms, which appear as black colonies surrounded by a precipitate. The medium contains tryptose, digest of soybean meal, yeast extract, citrate, sodium sulfate, egg yolk emulsion, kanamycin, and polymyxin sulfate.

**Petragagnani medium**
This medium is used for the isolation and cultivation of *Mycobacterium* spp. from clinical specimens, particularly for the cultivation and maintenance of *M. smegmatis*. The medium contains milk, potato flour, asparagine, digest of casein, eggs, glycerol, and malachite green.

**Pfizer TB medium base with glycerol, egg yolk, glucose, and malachite green**
This medium is used for the cultivation of *M. tuberculosis*. The medium contains starch, digest of casein, beef extract, asparagine, citric acid, ferric ammonium citrate, egg yolks, glycerol, glucose, and malachite green.

**PGT medium**
This medium is used for the cultivation and maintenance of *C. diphtheriae*. The medium contains Casamino Acids, glutamic acid, maltose, cystine, tryptophan, pantothenate, ferrous sulfate, and a complex mixture of growth factors.

**Phenethyl alcohol agar (phenylethanol agar, phenylethyl alcohol agar)**
This medium is used for the selective isolation of Gram-positive bacteria, particularly Gram-positive cocci, from specimens with a mixed biota. The medium should not be used for the observation of hemolytic reactions. The medium contains digests of casein and soybean meal, blood, and phenethyl alcohol. Moxalactam and lithium chloride can be added as selective factors.

**Phenol red agar**
This medium is used for the determination of fermentation reactions. The medium contains peptone, beef extract, a carbohydrate substrate, and phenol red. Bacteria that can ferment the added carbohydrate turn the medium yellow.

**Phenol red tartrate broth**
This medium is used for the differentiation of Gram-negative bacteria of the enteric groups, particularly members of the *Salmonella* (paratyphoid) group, based on their ability to ferment tartrate. The medium contains digest of casein, tartrate, and phenol red.

**Pike streptococcal broth**
This medium is used for the isolation and enrichment of hemolytic streptococci from throat swabs and other clinical specimens. The medium contains digest of casein, tryptose, yeast extract, glucose, sodium azide, blood, and crystal violet. After incubation of bacteria for 18 to 24 h in this medium, they may be isolated by streaking the culture onto blood agar plates.

**Polymyxin B-lysozyme-EDTA-thallous acetate agar**
This medium is used for the selective isolation and cultivation of *Bacillus anthracis*. The medium contains infusion from beef heart, tryptose, EDTA, thallous acetate, and polymyxin B.

**Potassium tellurite agar**
This medium is used for the cultivation and differentiation of *E. faecalis*. The medium contains infusion from beef heart, tryptose, blood, and potassium tellurite. *E. faecalis* appears as black colonies.

**PPLO agar**
This medium is used for the isolation and cultivation of *Mycoplasma* spp. (PPLOs). The medium contains infusion from beef heart, peptone, and serum.

**Pseudomonas isolation agar base with glycerol**
This medium is used for the selective isolation and identification of *P. aeruginosa* from clinical specimens. The medium contains peptone, Ingaasan, and glycerol.

**Rainbow Agar O157**
This proprietary medium from Biolog Inc. is used for the detection and presumptive identification of verotoxin-producing strains of *E. coli*, particularly serotype O157:H7. The medium contains chromogenic substrates that are specific for two *E. coli*-associated enzymes: β-galactosidase (a blue-black chromogenic substrate) and β-glucuronidase (a red chromogenic substrate). The distinctive black or gray
coloration of *E. coli* O157:H7 colonies is easily viewed by laying the petri plate against a white background. When *E. coli* O157:H7 is surrounded by pink or magenta nontoxicogenic colonies, it may have a bluish hue. The addition of selective agents improves performance. *E. coli* O157:H7 colony coloration will be slightly bluer with these selective agents added. Tellurite is highly selective for *E. coli* O157:H7 and can reduce background biotas considerably. Novobiocin inhibits Proteus swarming and the growth of tellurite-reducing bacteria. Rare strains of O157:H7 are tellurite sensitive.

**Rainbow Agar Salmonella**

This proprietary medium from Biolog Inc. is used as a selective, chromogenic medium to aid in the detection and isolation of H₂S-producing *Salmonella* spp. Black colonies are formed even by weakly H₂S-producing strains.

**RAMBACH agar (CHROMagar Rambach)**

This medium is used for the detection of enteric bacteria, including coliforms and *Salmonella* spp. Sodium deoxycholate inhibits the accompanying Gram-positive biotas. The medium contains polypropylene glycol, peptone, deoxycholate, and a chromogenic mixture. This medium enables *Salmonella* spp. to be differentiated unambiguously from other bacteria. *Salmonella* spp. form a characteristic red color. To differentiate coliforms from salmonellae, the medium contains a chromogen indicating the presence of β-galactosidase splitting, a characteristic of coliforms. Coliform microorganisms grow as blue-green or blue-violet colonies. Other *Enterobacteriaceae* and Gram-negative bacteria, such as *Proteus*, *Pseudomonas*, *Shigella*, and *Salmonella* Typhi and Paratyphi A, grow as colorless to yellow colonies.

**Rapid fermentation medium**

This medium is used for the differentiation of *Neisseria* spp. isolated from clinical specimens. The medium contains digest of casein, cystine, sodium sulfite, and phenol red.

**Regan-Lowe charcoal agar (Regan-Lowe medium)**

This medium is used for the selective isolation of *B. pertussis* and *B. parapertussis* from clinical specimens. The medium contains beef extract, digest of gelatin, starch, charcoal, niacin, blood, and cephalaxin.

**Regan-Lowe semisolid transport medium**

This medium is used for the transport of *B. pertussis* and *B. parapertussis* isolated from clinical specimens. The medium contains beef extract, digest of gelatin, starch, charcoal, niacin, blood, and cephalaxin.

**S. aureus ID**

This proprietary medium from bioMérieux is used for the direct identification of *S. aureus* and the selective isolation of staphylococci. Direct identification of *S. aureus* is based on the spontaneous green coloration of α-glucosidase-producing colonies.

**Salmonella-shigella agar**

This medium is used for the selective isolation and differentiation of pathogenic enteric bacilli, especially those belonging to the genus *Salmonella*. The medium is not recommended for the primary isolation of *Shigella* spp. The medium contains lactose, bile salts, thiosulfate, citrate, beef extract, digests of casein and animal tissue, ferric citrate, neutral red, and brilliant green. Lactose-fermenting bacteria such as *E. coli* or *K. pneumoniae* appear as small, pink or red colonies. Non-lactose-fermenting bacteria—such as *Salmonella* spp., *Proteus* spp., and *Shigella* spp.—appear as colorless colonies. Production of H₂S by *Salmonella* spp. turns the center of the colonies black.

**Salt meat broth**

This medium is used for the isolation and cultivation of staphylococci from specimens with a mixed biota such as fecal specimens, especially during the investigation of staphylococcal food poisoning. The medium contains 10% NaCl, ox heart tissue, beef extract, and peptone.

**Salt tolerance medium**

This medium is used for the cultivation and differentiation of salt-tolerant *Streptococcus* spp., *Staphylococcus* spp., and other salt-tolerant Gram-positive cocci. The medium contains 6.5% NaCl, infusion from beef heart, tryptose, glucose, and bromcresol purple.

**SaSelect Medium**

This selective and differential medium (Bio-Rad Laboratories) detects *S. aureus* from various clinical specimens including suppurations, wounds, respiratory secretions, nasal swabs, and blood culture specimens.

**Schaeuler agar (Schaeuler anaerobic agar)**

This medium is used for the isolation of anaerobic and aerobic microorganisms. The medium contains glucose, digests of casein and soybean meal, peptone, yeast extract, Tris buffer, cystine, and hemin.

**Schaeuler CNA agar with vitamin K₁ and sheep blood**

This medium is used for the selective isolation of anaerobic Gram-positive cocci. The medium contains digests of casein, animal tissue, and soybean meal; glucose; yeast extract; cystine; hemin; colistin; nalidixic acid; blood; and vitamin K₁.

**Schleifer-Krämer agar**

This medium is used for the isolation and cultivation of *Staphylococcus* spp. The medium contains glycerol, pyruvate, digest of casein, beef extract, yeast extract, potassium thiocyanate, lithium chloride, glycine, and sodium azide.

**Selenite broth (Selenite-F broth)**

This medium is used for the isolation and enrichment of *Salmonella* spp. from clinical specimens. The medium contains digest of casein, lactose, and sodium bisulfite.
Selenite broth base, mannitol
This medium is used for the isolation and cultivation of Salmonella Typhi and Salmonella Paratyphi. The medium contains peptone, mannitol, and sodium selenite.

Selenite cystine broth
This medium is used for the isolation and cultivation of Salmonella spp. from feces. The medium contains digest of casein, lactose, cystine, and sodium selenite.

Serum glucose agar (serum dextrose agar)
This medium is used for the maintenance of Brucella spp. and as a transport medium for S. pyogenes. The medium contains peptone, beef extract, serum, and glucose.

Serum tellurite agar
This medium is used for the isolation and cultivation of Corynebacterium spp., especially in the laboratory diagnosis of diphtheria. The medium contains digest of casein and animal tissue, glucose, lamb serum, and tellurite.

Simmons’ citrate agar (citrate agar)
This medium is used for the differentiation of Gram-negative bacteria on the basis of citrate utilization. The medium contains citrate, phosphate buffer, and bromthymol blue. Bacteria that can utilize citrate as sole carbon source turn the medium blue. The medium is yellow at pH 6.0, green at pH 6.9, and blue at pH 7.6.

Skirrow brucella medium
This medium is used for the selective isolation and cultivation of Campylobacter spp. The medium contains peptone, yeast extract, liver digest, and blood. It also contains vancomycin, trimethoprim, and polymyxin B as selective factors.

Sodium hippurate broth (hippurate broth)
This medium is used for the identification and differentiation of beta-hemolytic streptococci based on hippurate hydrolysis. The medium contains infusion from beef heart, tryptose, and sodium hippurate. After inoculation and incubation, tubes are treated with FeCl₃ reagent. A heavy precipitate remaining after 10 to 15 min indicates that hippurate has been hydrolyzed.

Sorbitol-MacConkey agar with 5-bromo-4-chloro-3-indolyl-β-d-glucuronide (BCIG)
This agar is used as a selective and differential medium for the detection of E. coli O157:H7 incorporating the chromogen BCIG. The medium combines two different screening mechanisms for the detection of E. coli O157:H7, the failure to ferment sorbitol and the absence of β-glucuronidase activity. The non-sorbitol-fermenting and β-glucuronidase-negative E. coli O157:H7 will appear as straw-colored colonies. Organisms with β-glucuronidase activity will cleave the substrate, leading to a distinct blue-green coloration of the colonies.

Soybean medium with 0.1% agar (tryptone soya HiVeg broth with 0.1% agar)
This medium is used for the cultivation of anaerobes from root canals, blood, and other clinical specimens. The medium contains 0.1% agar, casein hydrolysate, and digest of soybean meal.

Special infusion broth with blood
This medium is used for the propagation of pathogenic coccii and other fastidious organisms associated with blood culture work and allied pathological investigations. The medium contains infusion from animal tissues, peptones, glucose, and blood.

Specimen preservative medium
This medium is used for the preservation and transport of viable microorganisms in stool specimens. The medium contains glycerol, citrate, yeast extract, and deoxycholate.

Standard fluid medium 10B (Shepard’s M10 medium)
This medium is used for the isolation and cultivation of U. urealyticum from clinical specimens. The medium contains numerous growth factors, including serum yeast extract, glucose, amino acids, cocarboxylase, NAD, vitamins, and serum. It also contains infusion from beef heart, peptone, and phenol red. Penicillin is included as a selective factor.

Staphylococcus agar no. 110
This medium is used for the isolation of staphylococci from clinical specimens. The medium contains gelatin, mannitol, digest of casein, yeast extract, and lactose.

Staphylococcus-Streptococcus selective medium
This medium is used for the selective isolation of S. aureus and streptococci from clinical specimens. The medium contains peptone, starch, and blood. It also contains nalidixic acid and colistin sulfate as selective factors.

Streptococcus selective medium
This medium is used for the selective isolation of streptococci from clinical specimens. The medium contains peptone, starch, and blood. It also contains colistin sulfate and oxolinic acid as selective factors.
- **Streptosel agar**
  This medium is used for the selective isolation, cultivation, and enumeration of streptococci from specimens containing a mixed biota. The medium contains digest of casein, glucose, digest of soybean meal, sodium citrate, cystine, sodium azide, sodium sulfite, and crystal violet.

- **Stuart transport medium, modified**
  This medium is used for the preservation of Neisseria spp. and other fastidious organisms during their transport from clinic to laboratory. The medium contains sodium glycero-phosphate, cysteine, sodium thioglycolate, and methylene blue.

- **Sucrose-Teepol-tellurite agar**
  This medium is used for the selective isolation and differentiation of Vibrio spp. based on their ability to ferment sucrose. The medium contains beef extract, peptone, sucrose, Teepol, tellurite, and bromthymol blue. V. cholerae appears as flat, yellow colonies. V. parahaemolyticus appears as elevated, green-yellow, mucoid colonies.

- **Sulfide-indole-motility medium**
  This medium is used for the differentiation of members of the Enterobacteriaceae based on H$_2$S production, indole production, and motility. The medium contains peptone, beef extract, peptonized iron, and sodium thiosulfate.

- **TCBS agar**
  This medium is used for the selective isolation of V. cholerae and V. parahaemolyticus from a variety of clinical specimens. The medium contains sucrose, citrate, thiosulfate, yeast extract, digests of casein and animal tissue, oxgall (bile), sodium cholate, ferric citrate, thymol blue, and bromthymol blue.

- **Tetrathionate broth, Hajna**
  This medium is used for the isolation of Salmonella spp., except Salmonella Typhi and S. enterica subsp. arizonae, from fecal specimens and urine. The medium contains thiosulfate, peptones, mannitol, yeast extract, glucose, sodium deoxycholate, brilliant green, and iodine.

- **Tetrazolium tolerance agar**
  This medium is used for the differentiation of bacteria based on the ability to tolerate and grow in the presence of tetrazolium. The medium contains digests of casein and soybean meal plus triphenyltetrazolium chloride. E. faecalis rapidly reduces tetrazolium.

- **Thayer-Martín medium**
  This medium is used for the isolation and cultivation of fastidious microorganisms, especially Neisseria spp. The medium contains peptone starch, hemoglobin, and a complex mixture of amino acids, glucose, nucleotides, iron, and vitamins. The glucose and agar concentrations are lower than in the original formulation, which improves growth. The medium also contains trimethoprim.

- **Thioglycolate bile broth**
  This medium is used for the cultivation of B. fragilis and C. perfringens from clinical specimens. The medium contains digest of casein, glucose, yeast extract, cystine, sodium thioglycolate, and bile.

- **Thioglycolate medium, enriched (thioglycolate medium with vitamin K$_1$ and hermin, anaerobic thioglycolate medium)**
  This medium is used for the isolation, cultivation, and identification of a wide variety of obligate anaerobic bacteria. The medium contains digest of casein, glucose, yeast extract, cystine, sodium thioglycolate, bile, hemin, and vitamin K$_1$.

- **Tinsdale agar**
  This medium is used for the primary isolation and identification of C. diphtheriae. The medium contains peptone, yeast extract, cystine, sodium sulfite, and potassium tellurite.

- **Todd-Hewitt broth**
  This medium is used for the cultivation of group A streptococci used in serological typing and for the cultivation of a variety of pathogenic microorganisms. The medium contains infusion from beef heart, neopeptone, and glucose. Gentamicin and naladixic acid may be added to render the medium selective.

- **Transport medium, Stuart**
  This medium is used for the transportation of swab specimens for the recovery of a wide variety of microorganisms, including N. gonorrhoeae. The medium contains sodium glycerophosphate, sodium thioglycolate, and methylene blue.

- **Tryptic soy blood agar (tryptose blood agar, TSA blood agar)**
  This medium is used for the cultivation of a wide variety of fastidious microorganisms and for the observation of hemolytic reactions of a variety of bacteria. It may be used to perform the CAMP test for the presumptive identification of GBS (S. agalactiae). The medium contains digests of casein and soybean meal, and blood.

- **Trypticase soy agar (tryptic soy agar, soybean-casein digest medium)**
  This medium is used as a base for the general culture of numerous bacteria or, when supplemented, for the cultivation of fastidious microorganisms. The medium contains digests of casein and soybean meal. It can be supplemented with glucose, various amino acids (e.g., glutamine), and vitamins. It can also be supplemented with various antimicrobials as selective factors. When supplemented with sheep
blood, this medium is useful for the observation of hemolytic reactions of a variety of bacteria.

- **Trypticase soy agar with sheep blood and gentamicin (TSA II with sheep blood and gentamicin)**
  This medium is used for the isolation of *S. pneumoniae* from a variety of clinical specimens. The medium contains digests of casein and soybean meal, growth factors, blood, and gentamicin.

- **Trypticase soy agar with sheep blood, sucrose, and tetracycline**
  This medium is used for the isolation of *S. pneumoniae* from a variety of clinical specimens. The medium contains digests of casein and soybean meal, growth factors, sucrose, blood, and tetracycline.

- **Trypticase soy agar with sheep blood and vancomycin**
  This medium is used for the isolation of VRE from a variety of clinical specimens. The medium contains digests of casein and soybean meal, blood, and vancomycin.

- **Trypticase tellurite agar base**
  This medium is used for the selective isolation of microorganisms from clinical specimens, especially from the nose, throat, and vagina. The medium contains digests of casein and soybean meal, blood, glucose, serum, and tellurite.

- **U9B broth**
  This medium is used for the isolation and identification of T-strain mycoplasmas from clinical specimens, especially *U. urealyticum*. T-mycoplasmas are the only members of the *Mycoplasma* group known to contain urease. Bacteria with urease activity turn the medium dark pink. The medium contains digests of casein and soybean meal, glucose, cysteine, penicillin, phenol red, and urea.

- **Urea agar (urease test agar; urea agar base, Christensen)**
  This medium is used for the detection of *Proteus* spp. and other members of the *Enterobacteriaceae* based on rapid urease activity. Urease-positive bacteria turn the medium pink. The medium contains urea, peptone, glucose, and phenol red.

- **Urinary Tract Infections Chromogenic Agar (UTIC Agar)**
  This medium is used for the presumptive detection and differentiation of bacteria that cause UTIs.

- **Urogenital Mycoplasma broth base**
  This medium is used for the selective culture of *M. hominis* and *U. urealyticum*. The medium contains heart infusion, digest of casein, yeast extract, arginine, cysteine, phenol red, serum, vitamins, and urea. It also contains penicillin and amphotericin B as selective factors.

- **UVM (University of Vermont) Modified Listeria Enrichment Broth**
  This medium is used for the selective isolation of *L. monocytogenes*. The medium contains 2% NaCl, digests of casein and animal tissue, beef extract, yeast extract, esculin, nalidixic acid, and acriflavine.

- **V agar**
  This medium is used for the isolation and differentiation of *G. vaginalis* from clinical specimens. The medium contains digests of casein and animal tissue, peptone, beef extract, yeast extract, starch, and blood. Plates are incubated under an atmosphere with 3 to 10% CO₂. *G. vaginalis* appears as small white colonies with diffuse beta-hemolysis.

- **VACC agar (Remel VACC Agar)**
  This medium is used for the primary isolation, selection, and differentiation of *Enterobacteriaceae* that produce ESBLs.

- **Vibrio parahaemolyticus agar**
  This medium is used for the isolation, cultivation, enumeration, and presumptive identification of *V. parahaemolyticus*. Sucrose-fermenting bacteria appear as yellow colonies with pale yellow peripheries. Non-sucrose-fermenting bacteria appear as mucoid, green colonies with a dark green center. The medium contains sucrose, citrate, thiosulfate, peptone, sodium taurocholate, yeast extract, sodium lauryl sulfate, bromthymol blue, and thymol blue.

- **Vibrio parahaemolyticus sucrose agar**
  This medium is used for the isolation, cultivation, and differentiation of *V. parahaemolyticus*. *V. parahaemolyticus* and *V. vulnificus* appear as blue to green colonies. Other *Vibrio* spp. appear as mucoid, green colonies with sucrose positive. This medium contains sucrose, yeast extract, tryptose, digest of casein, bile salts, and bromthymol blue.

- **Vogel and Johnson agar**
  This medium is used for the detection of coagulase-positive *S. aureus*. The medium contains digest of casein, mannitol, glycerine, yeast extract, lithium chloride, phenol red, and tellurite.

- **VRE agar**
  This medium is used for the isolation of VRE and high-level-aminoglycoside-resistant enterococci from clinical samples. Nonresistant enterococci containing the *vanC* genes will not grow on this medium. The medium contains tryptone, yeast extract, citrate, esculin, ferric ammonium citrate, sodium azide, and a selective supplement of meropenem and vancomycin. The selective supplement suppresses growth of Gram-negative bacteria and *Enterococcus gallinarum*. The medium contains an indicator system to detect the growth of esculin-hydrolyzing organisms. Enterococci produce black zones around the colonies from the formation of black iron phenolic compounds derived from esculin hydrolysis products and ferrous iron.
VRESelect medium
This is a selective and differential medium (Bio-Rad Laboratories) for vancomycin-resistant E. faecium and E. faecalis for use with rectal swabs and fecal specimens.

Wallenstein medium
This medium is used for the isolation of Mycobacterium spp. other than M. leprae. The medium contains egg yolks, glycerol, and malachite green.

Wilkins-Chalgren anaerobe broth (anaerobe broth, MIC)
This medium is used for the cultivation and antimicrobial susceptibility (MIC) testing of anaerobic bacteria. The medium contains digest of casein, gelatin peptone, yeast extract, glucose, arginine, sodium pyruvate, hemin, and menadione.

Xylose-lactose-Tergitol 4
This medium is used for the isolation and identification of salmonellae from clinical samples. The medium contains lactose, sucrose, thiglycollate, lysine, xylose, yeast extract, peptone, phenol red, and a selective supplement containing Tergitol. The presence of the selective agent, Tergitol 4, in this medium inhibits many organisms that can be problematic on other plating media. In addition, biochemical and pH changes within the medium allow Salmonella spp. (black colonies) to be differentiated from organisms such as E. coli (yellow colonies) and Shigella spp. (red colonies). The enhanced selectivity of this agar reduces the need for further identification procedures, saving time and money, and results in fewer false presumptive positive colonies than do other Salmonella plating media.

Xylose-lysine-deoxycholate agar
This medium is used for the isolation and differentiation of enteric pathogens, especially Shigella and Providencia spp. The medium contains lactose, sucrose, thiglycollate, lysine, xylose, sodium deoxycholate, ferric ammonium citrate, and phenol red. Bacteria that do not ferment xylose, lactose, or sucrose appear as red colonies. Xylose-fermenting, lysine-decarboxylating bacteria appear as red colonies. Xylose-fermenting, non-lysine-decarboxylating bacteria appear as opaque yellow colonies. Lactose- or sucrose-fermenting bacteria appear as yellow colonies.

Xylose-sodium deoxycholate-citrate agar
This medium is used for the cultivation of Salmonella spp. and some Shigella spp. The medium contains xylose, citrate, thiosulfate, beef extract, peptone, ferric ammonium citrate, deoxycholate, and neutral red.

Yersinia selective agar base
This medium is used for the isolation and enumeration of Y. enterocolitica from clinical specimens. The medium contains mannitol, peptones, yeast extract, sodium pyruvate, deoxycholate, neutral red, and crystal violet. It also contains cefsulodin, Irgasan, novobiocin, and selective factors.

APPENDIX

Medium Additives
Many media contain additives that have specific functions ranging from selection to differentiation to protection of certain bacterial species. Below are descriptions of some of the commonly used medium additives.

ACES: allows optimal pH buffering capacity without inhibition of bacteria as seen with other inorganic buffers

Acriflavine: selective agent; suppresses Gram-positive organisms

ADC enrichment: a supplement added to mycobacteriology media that includes albumin, dextrose, catalase, and sodium chloride; catalase destroys peroxides that may be in the medium

Agar used in broth medium (0.05 to 0.1%): used to reduce O2 tension

Albumin: protects against toxic by-products in medium; binds free fatty acids

Antibiotics: one or many may be added to make a medium selective; inhibitory capacity may vary depending on the concentration used

Bicarbonate-citric acid pellet: used to generate CO2 gas within a closed environment after exposure to moisture; used in transport devices for isolating N. gonorrhoeae

Bismuth sulfite: heavy metal that is inhibitory to commensal organisms

Carbohydrates: energy source; used to make medium differential when combined with an indicator

Cetriramide: acts as a quaternary ammonium cationic detergent that causes nitrogen and phosphorus to be released from bacterial cells other than P. aeruginosa

Charcoal: detoxifying agent, surface tension modifier, scavenger of radicals and peroxides

Cornstarch: works as a detoxifying agent; may provide additional nutrients as an energy source

Dent’s supplement (Oxoid): vancomycin, trimethoprim, cefsulodin, and amphotericin B added to Columbia blood agar and laked horse blood for isolation of Helicobacter

Dextrose (glucose): makes the medium hypertonic; energy source

Egg yolk: used to demonstrate lecitihinase, lipase, and proteolytic activities and fatty acids

Ferric ammonium citrate: iron salt used in combination with other agents (esculin and sodium thiosulfate) to make medium differential by producing a black precipitate

Fildes enrichment: peptic digest of sheep blood that provides a rich source of nutrients, including X (hemin) and V (NAD) factors; X originally stood for “unknown” and V originally stood for “vitamin”

Glycerol: a purified alcohol and an abundant source of carbon; used in culture, transport, and storage medium and reagent preparation

Glycine: a selective agent that is inhibitory to organisms

Horse serum: an enrichment used in growth media for such organisms as Mycoplasma and Ureaplasma

IsoVitaleX (BBL): provides V factor (NAD) and additional nutritive ingredients, such as vitamins, amino acids, ferric ion, and dextrose, to stimulate growth of fastidious organisms

Laked blood: used for isolation and antimicrobial testing of anaerobes and used in susceptibility testing of fastidious organisms

Lithium chloride: a selective agent that inhibits organisms

Malachite green: a dye that partially inhibits bacteria

NAD (V factor): necessary for growth of some fastidious organisms

OADC enrichment: a supplement added to mycobacteriology media that includes oleic acid, albumin, dextrose, catalase, and sodium chloride; the oleic acid provides fatty acids utilized by mycobacteria, and the catalase destroys peroxides that may be in the medium

The majority of aerobic, or facultatively anaerobic, Gram-positive cocci isolated from clinical specimens are distributed among the genera *Staphylococcus*, *Streptococcus*, and *Enterococcus*. Molecular taxonomic studies of this group of bacteria have revealed additional genera and species that are phenotypically similar to the commonly encountered organisms but are infrequently isolated from clinical specimens. Tables 1 and 2 and chapters 21 to 24 describe basic phenotypic tests that can be used to distinguish these infrequent isolates from staphylococci, streptococci, and enterococci. It should be noted that the reactions listed in Tables 1 and 2 represent those of the majority of strains in each group; isolates with variant reactions may be encountered. Each of the tables contains organisms with similar cellular morphologies, either "streptococcal," consisting of Gram-positive cocci or coccobacilli arranged primarily in pairs and/

*See chapters 19, 21, 24, and 28 for methods for performing the phenotypic tests referred to in this table. Reactions shown are typical; exceptions may occur. Abbreviations and symbols: PYR, production of pyrrolidonyl arylamidase; LAP, production of leucine aminopeptidase; NaCl, growth in the presence of either 5 or 6.5% NaCl (see footnotes b and d); ESC, esculin hydrolysis; BGUR, production of β-glucuronidase; +, most strains positive; −, most strains negative; V, variable reactions are observed; NA, not applicable; α, alpha-hemolysis on sheep blood agar; γ, nonhemolytic reaction on sheep blood agar; S, susceptible; R, resistant.

b Growth in the presence of 5% sodium chloride.

c Kocuria, a related genus infrequently isolated from clinical specimens, is distinguished from Micrococcus by its ability to produce acid aerobically from D-glucose and glycerol (see chapter 21).

d Growth in the presence of 6.5% sodium chloride.

e R. mucilaginosa isolates are usually catalase negative or weakly positive but may be strongly catalase positive. Rothia aeria and Rothia dentocariosa are usually catalase positive.

f Ignavigranum ruoffiae (Table 1) exhibits reactions identical to those of F. languida in the PYR, ESC, and NaCl tests. However, I. ruoffiae cells are arranged primarily in chains, while F. languida cells usually form clusters. Other Facklamia species form cells arranged in pairs and chains (Table 1).

g G. haemolysans cells tend to be arranged in pairs, tetrads, and groups, in contrast to the cells of other Gemella species, which usually occur in pairs and short chains (Table 1).

h H. kunzii strains form tiny pinpoint nonhemolytic colonies on blood agar after 24 h of aerobic incubation at 35°C, while A. viridans isolates form larger alpha-hemolytic colonies under similar incubation conditions. In contrast to H. kunzii, A. viridans prefers aerobic incubation atmospheres. Two additional species of Helcococcus isolated from human sources have been described, each based on a single isolate. In contrast to H. kunzii, the new species Helcococcus sueciensis and the proposed species “Helcococcus pyogenes” are PYR negative (see chapter 24).

i The genera Pediococcus and Tetragenococcus have similar phenotypic characteristics, except that tetragenococci are vancomycin susceptible. The bile esculin test can differentiate between tetragenococci (positive) and Aerococcus urinae (negative) (see chapter 24).
or chains, or “staphylococcal,” signifying that cells appear as cocci arranged in pairs, tetrads, clusters, and irregular groups. No taxonomic kinship is implied by division of these bacteria into two groups based on cellular morphology.

The commonly isolated aerobic Gram-positive cocci (staphylococci, streptococci, and enterococci) can usually be accurately identified by determining a few basic phenotypic traits (cellular morphology, catalase reaction, production of pyrrolidonyl arylamidase [PYR], etc. [see reference 1, Tables 1 and 2 herein, and chapters 21 to 24]). Reliance on a single or only a few phenotypic tests can, however, lead to misidentification. For example, optochin-resistant *Streptococcus pneumoniae* strains (2) might be incorrectly identified as alpha-hemolytic (viridans) streptococci (chapter 22). Clumping factor (slide coagulase)-positive *Staphylococcus* lugdunensis, a coagulase-negative species, could be misidentified as *Staphylococcus aureus* (see reference 3 and chapter 21). PYR-positive *Lactococcus* isolates might be incorrectly identified as members of the genus *Enterococcus* (see reference 4 and chapter 23).

As new genera and species of aerobic Gram-positive cocci are described and characterized, it becomes increasingly difficult to identify some of the less frequently isolated organisms solely on the basis of phenotypic traits. A variety of automated and manual systems have proven to be fairly accurate for identification of commonly encountered staphylococcal, streptococcal, and enterococcal species (see the “Identification” sections in chapters 21 to 24 and references 5–10). These systems are less effective for identification of infrequently isolated aerobic Gram-positive cocci (see chapter 24). The less commonly isolated organisms may not be identified by these systems or may be misidentified as other genera or species. Basic phenotypic tests can usually suggest a possible identity for strains of infrequently encountered aerobic Gram-positive cocci, but evaluation with a larger battery of phenotypic tests, molecular identification methods, and, more recently, matrix-assisted laser desorption ionization–time-of-flight mass spectrometry (MALDI-TOF MS) is often valuable, if not indispensable, for accurate identification.

Nucleic acid probe tests and amplification methods for identification of some of the commonly isolated aerobic Gram-positive cocci are commercially available and designed for use in medium- to large-volume clinical microbiology laboratories. These methods may also be useful for ruling out enterococcal, streptococcal, or staphylococcal strains when attempting to identify phenotypically similar, infrequently isolated organisms. One of the most useful methods for molecular characterization of the aerobic Gram-positive cocci of clinical interest is comparison of 16S rRNA gene sequences (11, 12), although sequence comparison of other genes may also be helpful for identification. Genes that have been examined for this purpose include the *rpoB*, *tuf*, and sodA genes of staphylococci (13–15); the *rpoB* gene of streptococci (16); the *atpA* gene of enterococci (17); and the sodA gene of lactococci (4). Other identification methods, such as multilocus sequence analysis of enterococci (*rpoA* and *pheS* genes) (18) and melting-curve analysis of restriction fragments obtained from amplified regions of the sodA gene and the 16S-23S intergenic spacer region (enterococci) (19), have also been reported.

MALDI-TOF MS is increasingly used for routine identification of bacterial strains, and its usefulness is steadily expanding due to new developments and improvements (20). The commercially available MS instruments and software packages have many strengths in common. However, the packages do have different strengths and weaknesses, and improvements are steadily introduced. Comparisons of MALDI-TOF MS results to those obtained with other methods, phenotypic as well as genotypic, have been very encouraging. In general, quite reliable identifications have been obtained when examining strains from the genera *Enterococcus*, *Streptococcus*, and *Staphylococcus* and the taxa of catalase-negative, Gram-positive cocci not belonging to the streptococci or enterococci, though some species may be difficult to separate with the currently available MALDI-TOF MS database and software options (21–28). More information on the use of molecular methods for identification of this group of organisms can be found in chapters 21 to 24.

Each microbiology laboratory needs to establish criteria for the extent of identification of routinely isolated aerobic Gram-positive cocci. Efforts should be made to recognize and report organisms described as pathogens in various clinical scenarios or organisms with well-known susceptibility patterns, since identification should, in these cases, play an important role in guiding patient treatment. For example, in one scenario, all staphylococcal isolates could be fully identified to the species level with an automated system; alternatively, in a different setting, staphylococci might be examined initially with the coagulase test to identify *S. aureus*. Coagulase-negative strains could then be subjected to a few simple screening tests and be identified simply as coagulase-negative staphylococci, presumptively as *Staphylococcus saprophyticus*, or presumptively as *S. lugdunensis*. An identification of “viridans streptococci” might be sufficient when these organisms are isolated in mixed culture, but species identification of important isolates can offer clinically relevant information (e.g., “*Streptococcus bovis* group” in endocarditis cases or “*Streptococcus anginosus* group” ["milleri" group] in cases of brain or hepatic abscesses). Procedures for identification should reflect laboratory resources, workflow, the composition of patient populations served by the laboratory, and the clinical utility of results for the laboratory’s users.

Staphylococcus, Micrococcus, and Other Catalase-Positive Cocci

KARSTEN BECKER, ROBERT L. SKOV, AND CHRISTOF VON EIFF

TAXONOMY
Historically, the genera Staphylococcus and Micrococcus were placed together with the genera Stomatococcus and Planococcus in the family Micrococccaceae, containing Gram-positive, catalase-positive cocci. However, molecular phylogenetic and chemotaxonomic analyses revealed that staphylococci and “micrococci” are not closely related (1). Staphylococci belong to the Bacillus-Lactobacillus-Streptococcus cluster, which consists of Gram-positive bacteria with DNA of a low G+C content. In the taxonomic outline (2004) of the 2nd edition of Bergey’s Manual of Systematic Bacteriology (2), a classification of the Staphylococcus genus together with the genera Leuotoquoccus, Macroccocus, Salminococcus, and Gemella was outlined in a newly established family, Staphylococcaceae, which has since been supplemented with Nosocomcococcus and diminished by Gemella (now Bacillales family XI, incertae sedis) (3). The Staphylococcaceae combined with the Bacillales, Planococccaceae, Listeriaceae, and other families are now part of the order Bacillales of the class Bacilli (3).

The Micrococcus genus was sustained, but certain micrococal species previously belonging to this genus were reclassified into the newly established genera Kocuria, Nesterenkonia, Kytococcus, and Deracoccus. These genera were rearranged into two families, the redefined Micrococcaceae and the newly established Dermacoccaceae, both consisting of Gram-positive cocci with high G+C-content DNA (4, 5). Both families are assigned to the suborder Micrococccineae (class Actinobacteria) (1). The type genus Micrococcus and the genera Kocuria and Nesterenkonia as well as the genera Acariomes, Arthrobacter, Citrococcus, Enterococccus, Renibacterium, Rothia, Sinomonas, Yaniella, and Zhihengniella now constitute the Micrococccaceae family. The only species of the former genus Stomatococcus, S. mucilaginosus, was reclassified as Rostha mucilaginosa (6). The other family of the Micrococcineae also containing previous Micrococcus species, designated Dermacoccaceae, contains the type genus Dermacoccus as well as the genera Branchiibius, Calidifontibacter, Demetria, Flexivirga, Kytococcus, Luteipulveratus, and Yimella.

An unrelated species of Gram-positive cocci exhibiting a positive catalase reaction and occurring in human specimens is Alloleucoccus otitis, the only species of this genus, which is a member of the Carnobacteriaceae family belonging to the order Lactobacillales (class Bacilli) (3).

For further taxonomic details and references, see the taxonomic outline of the 2nd edition of Bergey’s Manual of Systematic Bacteriology (2) and the List of Prokaryotic Names with Standing in Nomenclature (http://www.bacterio.net).

DESCRIPTION OF THE FAMILIES

Staphylococcaceae
Staphylococci are characterized by Gram-positive, nonmotile, non-spore-forming, spherical cells of 0.5 to 1.5 μm in diameter, occurring as single cocci, in pairs, as tetrads, or as short chains, which characteristically divide in more than one plane, thereby forming irregular clusters like a bunch of grapes. With the exception of the anaerobic species Staphylococcus saccharolyticus (formerly Peptococcus saccharolyticus) and Staphylococcus aureus subsp. anaeobius, the staphylococci are facultative anaerobes (Table 1). Although staphylococci are usually catalase positive, rare catalase-negative strains have been reported (7). Most Staphylococcus species are cytochrome oxidase negative in the modified oxidase test, with the exception of S. fleuretii, S. lentus, the three subspecies of S. sciuri, S. stepanovicii, and S. vitulinus. Staphylococci grow in the presence of 10% NaCl between 18°C and 40°C. The metabolism is respiratory and fermentative. The cell wall contains peptidoglycan and teichoic acid. Staphylococci are susceptible to lysostaphin.

A major genotypic criterion of the members of the genus Staphylococcus is a G+C content of 30 to 39 mol%. Whole-genome sequencing has been performed for many staphylococcal strains, and completed genome sequences are available for S. aureus (e.g., COL, Mu3, Mu50, MW2, N315, NCTC8325, Newman, USA300-FPR3757, MRSA252, LGA251), Staphylococcus pseudintermedius (HKU10-03, ED99), and some coagulase-negative staphylococci (CoNS), such as S. carnosus (TM300), S. epidermidis (ATCC 12228, RP62A), S. haemolyticus (JCS1435), and S. lugdenensis (N920143, HKU09-01). The S. aureus genome is composed of a single chromosome ranging in size from approximately 2.8 to 2.9 Mbp. In comparative genomic analyses, the species’ pan-genome (supragenome) was found to comprise 3,221 genes, with 2,245 core genes (8). A wide range of mobile DNA elements have been identified. Most naturally occurring staphylococcal strains contain small multicopy and/or large, conjugative multiresistance plasmids (classes I to III). For more details and other staphylococcal species,

</tbody>
</table>
activity and novobiocin susceptibility are still used for pre-
Staphylococcus cohnii
subspecies, several CoNS species are novobiocin resistant
S. saprophyticus

The genus Macroccocus was established by delimiting the
genus Staphylococcus through description of Macroccocus
caseolyticus, the former Staphylococcus (Micrococcus) caseoly-
ictus, and the description of novel species. The macroccocal
cells are similar to those of staphylococci, with the exception
of their larger cell diameter, reaching 2.5 μm in some species,
hence their genus name. Recently, Macroccocus was consid-
ered to reflect the genome of ancestral bacteria before the
speciation of staphylococcal species (12). As shown for the
fully sequenced strain JCSC5402, Macroccocus caseolyticus
has a G+C content of 36.9 mol% (12). In contrast to the
cell walls of other macroccoci, the cell wall of M. caseolyticus
contains teichoic acid. With the exception of Nosocomiicoc-
cus, the other genera, Salinicoccus and Jeotgalicoccus, have a
G+C content that is generally higher than those of staphy-
lococci. Whereas salinicocci are strictly aerobes, the other
genera comprise facultative anaerobes.

**Micrococaceae and Dermcocaceae**

Most species of the Gram-positive, non-spore-forming fam-
ilies Micrococaceae and Dermcocaceae are characterized by
nonmotile and spherical cells that are 0.5 to 1.8 μm in
diameter and arranged in tetrads and clusters. Deviating from
this, rod-shaped species are found in some genera. Arthrobacter
and Rothia species may display coccoid forms. Except for Rothia mucilaginosa,
both genera are discussed in chapter 28. Members of the Micrococaceae and Dermcocaceae
have G+C contents within the range of 52 to 75%.

The Micrococcaceae family covers mostly strictly aerobic
and mesophilic species. The type genus Micrococcus contains
the classical microccocal species M. luteus and M. lylae.
Other former Micrococcus members are now part of the
Kocuria genus, such as K. (Micrococcus) kristinae, K. (Mi-
icrococcus) varians, and K. roseus (formerly Micrococcus roseus,
now united with the former Pelczaria aurantia) (4). The
former Micrococcus halobius was transferred into the novel
genus Nesterenkonia as N. halobia. For all these genera, sev-
eral novel species have been described. In this chapter, the
term "micrococcii" in quotes is used to indicate the members
of the genus Micrococcus as understood before the emenda-
tion, reflecting most of the clinically relevant species (4).

Two of the former "micrococcii" species are now assigned
to the Dermcocaceae family, either to the genus Dermcococcus
containing D. (Micrococcus) nishinomyaensis and other species or
to the genus Kytococcus, comprising, besides K. (Micrococcus) sedentarius, the recently described species K.
schroeteri and K. aerolatus.

**Alloiococcus**

The name of the only species of the genus Alloiococcus
(family Carnobacteriaceae) still standing in nomenclature is
A. otitidis; however, the proposed emended name, A.
otitidis, is frequently used in the literature. This slow-growing
species is characterized by Gram-positive ovoid cocci, occur-
ing mostly in clusters and pairs. Alloiococci show aerobic
atmospheric requirements, but they are able to grow sparsely
in a candle jar atmosphere (13). Their G+C content is 44
to 45%.

**Epidemiology and Transmission**

**Staphylococcus**

The major habitats of most staphylococcal species are the
skin and mucous membranes of mammals and birds. S. aureus
subsp. aureus is considered to be the most important human
pathogen among staphylococci, followed by S. epidermidis,
S. haemolyticus, S. saprophyticus subsp. saprophyticus, and S.
ludanensis. S. auricularis, S. capitis subsp. capitis and subsp.
urealyticus, S. caprae, S. cohnii subsp. cohnii and subsp. urealy-
ticus, S. hominis subsp. hominis and subsp. novobiosepticus, S.
pasteuri, S. pettenkoferii, S. saccharolyticus, S. schleiferi subsp.
schleiferi, S. simulans, S. varians, S. warneri, and S. xylosus are also encountered in human specimens (14). These
species are found mainly as part of the resident microbiota.
For references concerning species description, see the List
of Prokaryotic Names with Standing in Nomenclature (http://
www.bacterio.cict.fr/).

S. aureus and Other Coagulase-Positive Species

The anterior nares (vestibulum nasi) are the principal habitat
for S. aureus. Approximately 50% of people are either per-
manently or intermittently colonized. As determined in
longitudinal studies, three types of S. aureus nasal carriers
have been historically distinguished: persistent carriers (10
to 35%, carrying one strain over a prolonged period), inter-
mittent carriers (20 to 75%, carrying different strains), and
noncarriers (5 to 50%) (15). Since intermittent carriers and
noncarriers have similar S. aureus nasal elimination kinetics,
it was recently proposed that there are only two types of
nasal carriers: persistent carriers and others (16). From the
vestibulum nasi, S. aureus can be transferred to skin and
other body areas. Whether health care personnel, patients
with insulin-dependent diabetes mellitus, patients receiving
long-term hemodialysis, and users of illegal intravenous
drugs may have higher-than-normal S. aureus nasal carriage
rates (17–19) is a matter of debate because certain studies do
not support earlier findings (20–22). Of particular interest,
nasal colonization plays a crucial role as a source of invasive
infections (23–26). The throat, the intestine, the vagina,
the intertriginous skin folds, the axillae, and the perineum
are also found to be regularly colonized.

The population of S. aureus stains presents a highly
clonal structure. By multilocus sequence typing (MLST),
S. aureus stains can be grouped in sequence types (STs)
(about 2,400 [www.mlst.net]) that can be arranged in clonal
complexes (CCs) (27). Common S. aureus lineages comprise
CCs 1, 5, 8, 15, 22, 30, 45, 59, 80, 97, 121, and 398 (28,29).
The S. aureus populations are also divided into four
distinct groups based on agr (accessory gene regulator sys-
tem) allelic variation (30).

Within health care facilities, S. aureus stains are trans-
mitted from patient to patient primarily via hand carriage of
medical personnel but also by means of contaminated objects.
This is of utmost importance for the transmission of methicillin-
resistant S. aureus (MRSA) strains (MRSA and their
clonal lineages are further discussed under Antimicrobial
Susceptibilities below). The role of the external environment
is less important, except in certain areas, such as intensive
care units and burn units. Colonized or infected health care
personnel may act as reservoirs (31). Until recently, direct or
indirect human-to-human transmission has been the primary
route for the transmission of both methicillin-susceptible S.
aureus (MSSA) and MRSA strains, but now animals have
become a significant additional reservoir. For companion ani-
This makes sense, humans infect the animals, which then can transmit the organism

Coagulase-Negative Staphylococci

In humans, *S. epidermidis* is the most frequently recovered staphylococcal species colonizing the body surface, where it is particularly prevalent on moist areas, such as the axillae, inguinal and perineal areas, anterior nares, and toe webs. *S. aureus* is part of the healthy human external auditory canal microbiota exclusively colonizing this region; *S. capitis* is found surrounding the sebaceous glands on the forehead and scalp following puberty; *S. haemolyticus* and *S. hominis* are preferentially isolated from axillae and pubic areas high in apocrine glands; and *S. saprophyticus* subsp. *saprophyticus* frequently colonizes the rectum and the genitourinary tract of young women (14, 36, 37). *S. lugdunensis* is frequently found on the lower extremities and the groin (38). However, these species may be found occasionally on other body sites. Some recently described staphylococcal species, such as *S. massilesens*, *S. pettenkoferi*, and *S. petrasii* are also likely to be part of the human skin microbiota (39–41).

*S. sciuri* and *S. xylosus* are commensals of the skin and the mucous membranes of many animals and, occasionally, of humans (14, 42). Both species are also found in food; *S. xylosus* represents one of the major starter cultures used for meat fermentation. *S. sciuri* subsp. *carnaticus* is recovered mainly from bovine hosts, and subsp. *rodenium* is found mainly in rodents. *S. klössii*, *S. equorum* subsp. *equorum*, and *S. gallinarum* are found on several mammals and food products (43, 44). *S. chromogenes* and *S. lentus* are common residents of cloven-hoofed animals and, in addition, may be isolated from their food products. *S. vitulinius* (synonym, *S. pulvereri*) is found preferentially on horses and whales. *S. arlettae* is found on mammals and birds. *S. netakensis* has been isolated from a variety of avian species (49). *S. saprophyticus* has been described on flies. *S. rostri* was isolated from the noses of pigs. *S. devriesei* from bovine udder, *S. microti* from free-living common voles, and *S. stepanovicii* from rodents and mammalian insectivores. *S. carnosus* subsp. *carnosus* and subsp. *utilis*, *S. condimenti*, *S. devriesei*, *S. equorum* subsp. *linens*, *S. fleurettii*, *S. pisefermentans*, and *S. succini* subsp. *casei* have been associated with fermented food and dairy products, and *S. succini* subsp. *succinis* was isolated from an amber fragment (45). However, the complete and/or true natural habitat for many of these species is still unclear.

**Macrococcus, Salinicoccus, Jeotgalicoccus, and Nosocomicoccus**

The *Macrococcus* genus comprises seven hoofed-animal-adapted species, including *M. caseolyticus*, first described as *Staphylococcus caseolyticus* (46). This species is found on food such as sausages and meat products. The halotolerant/halophilic *Jeotgalicoccus* and *Salinicoccus* species are recovered from fermented seafood and salted fish or found in saline and desert soil or salt mines. Thus far, the only reported recovery of *Nosocomicoccus ampullaceus* has been isolation from surfaces of bottles of saline solution used in wound cleansing (47).

**Micrococcaceae and Dermacoccaceae**

The skin of humans and other mammals is the primary habitat for most *Micrococcaceae* and *Dermacoccaceae* recovered from clinical specimens. Cutaneous populations of micrococci are carried by most people (ca. 96%), with *M. luteus* being the most frequent species, followed by *Kokkia varians* (48). *Rothis mucilaginosus* is probably a normal inhabitant of the mouth and upper respiratory tract. Animal and dairy products may be considered secondary sources of “micrococi.” Many of the recently discovered members of the *Micrococcaceae* and *Dermacoccaceae* are associated with different environmental habitats.

**Alloiococcus**

*A. otitis* was detected in the outer ear canal of healthy persons at a high incidence, suggesting that *alloiococci* are part of the normal bacterial microbiota (49).

**CLINICAL SIGNIFICANCE**

**Staphylococcus**

Many staphylococcal species are classical opportunists colonizing skin and mucous membranes but may become pathogenic in a species- and strain-dependent manner following breaks in the cutaneous epithelial barrier through trauma or medical interventions. The recovery of a staphylococcal isolate always requires assessment of clinical significance to determine whether it is a contaminant, colonizer, or pathogen.

*S. aureus* is the clinically most important species, as it is capable of causing a wide range of human and animal diseases. *S. aureus* possesses an extensive arsenal of often redundant and overlapping virulence factors, such as adhesins, enzymes, and toxins, and has various strategies to evade the host immune response. In addition, the pathogen has become resistant to many of the therapeutic agents available. National Nosocomial Infection Surveillance and National Healthcare Safety Network data indicate that *S. aureus* is the most common cause of nosocomial pneumonia and skin and soft tissue infections (SSTIs). *S. aureus* is second only to CoNS as a cause of primary bacteremia in hospitals (50, 51).

Disease entities caused by *S. aureus* can be broadly divided into toxin-mediated diseases and supplicative infections, comprising SSTIs, organic and systemic infections, and foreign-body-related infections (FBRIs). SSTIs are the most frequent infections in community-associated *S. aureus* infections, including those caused by community-associated MRSA (CA-MRSA). The spectrum of SSTIs ranges from superficial (impetigo, folliculitis, furuncles/carbuncles, hydraenitidis suppurativa, pyoderma, and wound infections) to deep entities (absceses, mastitis, cellulitis, and pyomyositis).

to acute life-threatening necrotizing fasciitis and myositis. Infection of deep sites may involve any body compartments and organ systems resulting in empyemas, osteomyelitis, arthritis, endocarditis, pneumonia, otitis media, sinusitis, mastoiditis, and parotitis. Any localized Staphylococcus aureus infection can become invasive and lead to bacteremia. Systemic infections comprise primary and secondary bacteremia, meningitis, and endocarditis. Bacteremia may be complicated by metastatic foci (e.g., vertebral osteomyelitis). Congenital or acquired defects in host defense and the presence of foreign bodies may predispose patients to serious infections.

Besides an acute, aggressive course of infection, S. aureus may cause chronic, persistent, and relapsing infections often due to a phenotypic subpopulation designated small-colony variants (SCVs), which present adapted phenotypes for intracellular persistence (52, 53). Rapid switching between the normal and the SCV phenotype seems to be a highly dynamic process in both directions for adaptation to intra- and extracellular conditions, respectively; this phenotype switching also challenges accurate detection in the routine laboratory (see below) (54-56). SCVs of S. aureus and other staphylococcal species (e.g., S. epidermidis and S. lugdunensis) have been isolated from patients with chronic osteomyelitis, abscesses, and FBRIs as well as from cystic fibrosis patients with chronic airway infection (57-59).

Classical toxin-mediated diseases due to S. aureus include staphylococcal toxic shock syndrome (TSS), staphyloccocal food poisoning, and staphylococcal scalded skin syndrome (SSSS). TSS is associated with colonization by or infection with an isolate of S. aureus that is positive for TSS toxin-1 (TSST-1) or, less frequently, for other members of the staphylococcal pyrogenic toxin superantigen (PTSAg) family (primarily staphylococcal enterotoxin B or C). TSS is diagnosed on clinical grounds and is characterized by high fever, rapid-onset hypotension, a diffuse erythematous rash that becomes desquamating 1 to 2 weeks after onset, and involvement of three or more organ systems. After its initial description in children, it was associated with menstruating women who were using highly absorbent tampons. While the incidence of menstrual TSS decreased due to changes in the tampons’ absorbency and chemical composition, the frequency of nonmenstrual TSS entities has remained constant since the 1980s (60). Even though normally no source of infection is confirmed, nonmenstrual TSS is usually associated with focal postoperative wound or soft tissue infections.

Staphylococcal food poisoning is caused by consumption of food contaminated with one or more preformed, relatively heat-stable enterotoxins. Nausea, vomiting, abdominal cramps, and diarrhea occur 2 to 6 h after food ingestion. Symptoms usually subside 8 to 12 h later.

Blisters in bullous impetigo and SSSS are caused by exfoliative (epidermolytic) toxins (ETA and ETB). SSSS is typically found in neonates and young children (61). In addition to severe exfoliation affecting up to 90% or more of the entire body surface (Ritter’s disease), a localized form (pemphigus neonatorum) with a few blisters is known. Diagnosis is made on the basis of clinical features, including Nikolsky’s sign, in which the skin wrinkles on gentle pressure.

The other coagulase-positive or -variable staphylococci are members of the skin microbiota of various animal species and occasionally cause infections in their hosts. The members of the S. intermedius/S. pseudointermedius/S. delphini cluster are the most common etiologic agents of the canine pyoderma. S. hyicus is predominantly associated with the exudative epidermitis (greasy pig syndrome) in pigs, S. schleiferi subsp. coagulans is found in dogs suffering from external otitis, and S. aureus subsp. anaeorobius is the etiologic agent of abscess disease, a specific lymphadenitis of sheep and goats. In humans, S. intermedius/S. pseudintermedius appears to be occasionally responsible for canine-inflicted wound infections, FBRIs, food poisoning, and invasive infections in immunocompromised patients (62, 63). Only a few human infections due to S. schleiferi subsp. coagulans and S. hyicus are known. For S. agnetis, isolates have been recovered from bovine intramammary infections (64).

Since 1980, CoNS have been increasingly recognized as nosocomial pathogens, especially S. epidermidis. S. epidermidis and S. haemolyticus are often referred to as “medium-pathogenicity” staphylococci, as they cause nosocomial infections mainly in patients with predisposing factors, such as immunodeficiency and/or the presence of indwelling or implanted foreign polymer bodies (51, 65-67). Also, S. lugdunensis and S. saprophyticus may be categorized into this group. CoNS are less often implicated as the cause of infections of natural tissue. Overall, the clinical appearance of infections caused by CoNS has been characterized as subtle (associated with subacute or chronic clinical courses without fulminant signs), and they are seldom life-threatening (68). CoNS are the most common cause of nosocomial bloodstream infections typically associated with central and peripheral intravascular catheters (50). Most important in the pathogenesis of FBRIs is the ability of CoNS to colonize the surface of a device by the formation of a thick, multilayered biofilm (69). S. epidermidis is the predominant cause of infections associated with prosthetic vascular grafts, prosthetic orthopedic devices, and cerebrospinal fluid shunts. CoNS are frequently isolated as causative agents of prosthetic-valve endocarditis; rarely (ca. 5% of the time), they are involved in infections of (previously damaged) native valves (70). Right-sided native-valve endocarditis is observed in intravenous drug abusers. Virtually any other surgically inserted materials and devices may become infected by CoNS. CoNS also account for 45 to 75% of all late-onset bloodstream infections in preterm and low-birthweight neonates in neonatal intensive care units (71).

Of all CoNS, S. lugdunensis holds a special position because its infections generally resemble those caused by S. aureus rather than those caused by other CoNS. It is especially renowned for causing unusually fulminant cases of native-valve endocarditis in addition to prosthetic-valve endocarditis (72). Thus, patients with S. lugdunensis bacteremia should be carefully examined for signs of endocarditis. Besides causing other invasive infections, this organism is a common pathogen involved in FBRIs (59). In addition, S. lugdunensis is not a rare cause of skin abscesses and wound infections, especially below the waist (73).

Based on special urotropic and ecologic characteristics, S. saprophyticus subsp. saprophyticus is a well-documented causative agent of acute, commonly recurrent, urinary tract infections in young, otherwise healthy, sexually active women and, less frequently, in young men or boys. This pathogen is the second-most-common (after Escherichia coli) cause of uncomplicated cystitis among young women. While colony counts of ≥100,000 CFU/ml in two or more cultures of midstream urine usually indicate significant bacteriuria; lower counts may be significant in the symptomatic patient. Infections due to the recently described subspecies S. saprophyticus subsp. bovis have not been reported.

For various other CoNS species (e.g., S. capitis, S. chromogenes S. cohnii, S. hominis, S. pasteuri, S. pettenkofleri, S. warneri, and S. xylosus), case reports and series predominantly reporting on FBRIs have been published. In contrast, S. carnosus, S. condimenti, S. piscifermentans, S. equorum subsp. linens, and other staphylococcal species involved
mainly in food production have been regarded as nonpathogenic staphylococci. Since human infections due to *Micrococcus*, *Jeotgallius*, *Nosocomicoccus*, and *Salinicoccus* have not been described, these genera are not discussed further in this chapter.

**Micrococcaceae and Dermacoccaceae**

While "micrococc" are generally acknowledged as harmless saprophytes, they can also act as opportunistic pathogens. *Micrococcus*, *Kocuria*, and *Kyotoroccus* species have been found to cause infections such as endocarditis, pneumonia, and sepsis or FBRIs predominantly in immunocompromised patients (74–76). Recovery of the more recently described "micrococc" species associated primarily with the environment must be assessed for clinical significance, as reported for *K. rhizophila* (77).

*R. mucilaginosus* has been implicated in cases of bacteremia, endocarditis, endophthalmitis, intravascular catheter-related and central nervous system infections, pneumonia, pneumonia, peritonitis, septicemia, and cervical necrotizing fasciitis (78–80).

Since human infections due to *Acacriomes*, *Citrococcus*, *Luteococcus*, *Nesterenkonia*, *Renibacillus*, *Sinomona*, *Yimella*, and *Zhihengliuella* have not been reported, these genera are not discussed further in this chapter.

**Alloiococcus**

*A. otitidis* has been associated with infections of the middle ear (81). While its immunostimulatory capacity suggests that *A. otitidis* has pathogenic potential (82), other studies revealed that *A. otitidis* may be a commensal rather than a cause of otitis media (49).

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

The general principles of collection, transport, and storage of specimens as given in chapter 18 of this Manual are applicable to the microorganisms listed in this chapter. No special methods or precautions are usually required for these organisms because they are easily obtained from clinical material of most infection sites and are relatively resistant to drying and to moderate temperature changes. While some staphylococcal species may require anaerobic conditions or *CO₂* supplementation for satisfactory growth, they survive transport and limited storage in air.

**DIRECT EXAMINATION**

**Microscopy**

Direct microscopic examination of normally sterile fluids, such as cerebrospinal fluid and joint aspirates, may be helpful. For nonsterile fluids, microscopy may also be useful; however, the presence of inflammatory cells versus epithelial cells has to be taken into consideration.

Cells of microorganisms discussed here are Gram-positive, nonmotile, non-spore-forming cocci that are arranged mostly in pairs and tetrads but also occur singly, in irregular (grape-like) clusters, or in short chains (three or four cells). However, within the *Micrococcaceae* and *Dermacoccaceae*, some species exhibit rod-shaped cells and have been shown to be motile. Positive findings of direct microscopic examination should be reported as "Gram-positive cocci resembling staphylococci."

**Antigen Detection**

Direct antigen detection plays no role in the detection of catalase-positive cocci.

**Nucleic Acid Detection**

Rapid amplification-based approaches have been introduced for the detection of MRSA directly from surveillance swabs. The multiple-locus approach, which detects the *mecA* gene and additionally an *S. aureus*-specific target (see "Species Identification by Nucleic Acid-Based Approaches" below), may be influenced by the coexistence of MSSA and methicillin-resistant CoNS (MR-CoNS) in a patient's physiological microflora and thus may lead to false-negative MRSA findings (83). Nevertheless, the fundamental advantage of this approach is the direct detection of the methicillin resistance-encoding *mec* gene and, if additionally targeted, its diagnostically relevant, recently detected homolog, mecC.

Tests applying this principle, such as hyclpex StaphyloResist (plus) (BAG Health Care, Lieh, Germany) and the StaphPlex panel (Quagen), are commercially available. Some mecA-targeting assays, such as hyclpex MRSA plus (Amples Diagnostics, Gars-Buinheh, Germany), the BD MAX StaphSR test (BD Diagnostics, Sparks, MD), a MRSA/SA ELITe MGB kit (Nanogen Advanced Diagnostics, Italy), and the RIDA Gene MRSA system (R-Biochem, Darmstadt, Germany) have already been refined by including mecC as a target (84).

The alternative single-locus amplification strategy overcomes the MSSA/MR-CoNS coexistence drawback by using oligonucleotide primers that bind the right extremity of the staphylococcal cassette chromosome (SCCmec) and the neighboring *orfX* region of the *S. aureus* chromosome. This amplification amplifies both a taxonomic marker and a resistance marker in one step (85). This principle is the basis for several rapid test systems (e.g., BD GeneOhm MRSA assay [BD, Franklin Lakes, NJ]; GenoType MRSA Direct, GenoQuick MRSA, and FluoroType MRSA [Hain Lifescience]; Xpert MRSA [Cepheid, Sunnyvale, CA]; and LightCycler MRSA advanced test [Roche, Basel, Switzerland]). However, the use of the SCCmec region as a surrogate marker instead of direct detection of mecA may lead to false-negative results due to the high variability of the SCCmec primer binding sites, a situation that is particularly problematic in the case of rare or still-unknown SCCmec (sub)types. On the other hand, false-positive results may occur due to the replacement of the mecA gene within the cassette by other genes (e.g., resistance or capsule-encoding genes) and, particularly, by partial excision of the cassette, leading to remnants that lack the mec gene complex but still contain the primer binding sites on the 3' end of the SCC cassette ("drop-out" isolates) (86–89). The Detect-Ready MRSA panel (Molecular Detection Inc., Wayne, PA) combines the detection of an *S. aureus*-specific gene target, the SCCmec:orfX junction, and the mecA gene. The same holds true for the BD MAX StaphSR nasal kit, which also targets mecC and is designed to detect both MRSA and MSSA.

Overall, these amplification-based rapid MRSA screening assays, not designed to identify MRSA or MSSA infections, are characterized by very good negative predictive values (approximately 97 to 99%) but are hampered by moderate positive predictive values (approximately 65 to 95%). To date, MRSA cultures remain essential for confirming molecular results, for typing purposes, and for determination of the complete susceptibility profile.

The Xpert MRSA/SA SSTI test (Cepheid) was launched to detect the presence of *S. aureus* or MRSA in skin and soft tissue infections; however, it has been applied in a
preclinical evaluation to lower respiratory tract secretions (90) and to perioperative bone and joint samples (91).

**ISOLATION PROCEDURES**

Considering the widespread distribution of staphylococci and "micrococci" on the skin and mucous membranes, careful procedures should be used to isolate organisms from the presumed focus of infection without collecting surrounding microbiota. The basic procedures for culture and isolation described in chapters 18 and 20 of this Manual should be followed.

The primary culture plate used for the isolation of staphylococci from clinical specimens is Columbia or tryptic soy blood agar containing 5% defibrinated sheep (or horse) blood (see also chapter 19). The abundant growth of most staphylococcal species occurs within 18 to 24 h. The simultaneous use of an enrichment broth (i.e., dextrose broth) streaked after 24 and 48 h on Columbia blood agar may enhance the recovery rate of *S. aureus* and other staphylococci.

The use of selective agars for *S. aureus*, such as mannitol salt agar, egg yolk-tellurite pyruvate-containing Baird-Parker medium, Columbia colistin-nalidixic acid agar, lipase-salt-mannitol agar (Remel, Lenexa, KS), and phenylethyl alcohol agar, may be appropriate for specimens from heavily contaminated sources, such as feces and respiratory cultures from patients with cystic fibrosis. It is mandatory to confirm putative *S. aureus* isolates recovered on these media.

Various selective agars using chromogenic enzyme substrates specifically for *S. aureus*, such as CHROMagar Staph aureus (CHROMagar, Paris, France), BBL CHROMagar Staph aureus (BD Diagnostics, Sparks, MD), Brilliance Staph 24 (Oxoid, Cambridge, United Kingdom), and chromID S. aureus (bioMérieux, La Balme Les Grottes, France), are commercially available with chromogen-dependent coloration of the colonies. In particular, for screening purposes, the chromogenic agars have been proven to be suitably sensitive and specific, allowing a presumptive but not final identification (92). Chromogenic agars designed for MRSA detection are discussed in Antimicrobial Susceptibilities below.

The diagnosis of catheter-related bloodstream infections by CoNS and other organisms remains a major challenge. One of the most frequently studied diagnostic techniques is represented by the semiquantitative roll plate catheter culture. With this technique, the distal segment of the central venous catheter is cut and rolled across the surface of a Columbia blood agar plate at least four times, followed by overnight incubation. A colony count of 15 CFU/ml or more may indicate catheter colonization (93). Examination of paired quantitative blood cultures drawn simultaneously from the catheter and a peripheral vein enhanced by the analysis of differential time to positivity represents an example of an approach that does not require catheter removal (94) (see also Evaluation, Interpretation, and Reporting of Results below).

Cultivation of "micrococci" and *R. mucilaginosa* should be performed as described for staphylococci on Columbia blood agar at 35°C to 37°C under aerobic conditions. However, abundant growth of Micrococccae and Dermacoccaceae needs consistent incubation times of 36 to 48 h. Because of the low growth rate, it is difficult to isolate *A. otitis* by conventional nonselective culture methods (95).

Blood agar plates with 6% NaCl were shown to be useful.

**IDENTIFICATION**

The basic criteria distinguishing catalase-positive Gram-positive cocci and their relatives from among themselves and from other microbial taxa are given in Description of the Families above and in Table 1. Misidentification is likely to occur if automated test system results are accepted without critical review by skilled lab personnel. In specialized settings, species can also be identified by chemotaxonomic procedures. Nucleic acid-based molecular methods have become standard in particular for verification of ambiguous identification results. The recent introduction of matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) mass spectrometry (MS) instruments in clinical microbiology laboratories has the potential to accelerate and ease the routine identification of staphylococci and other catalase-positive cocci.

**Staphylococcus and Related Genera**

*Staphylococcus* species can be identified phenotypically on the basis of a variety of conventional characteristics (Tables 1 to 3). The most clinically significant species in human and veterinary medicine can be identified on the basis of several key characteristics (Table 3). The application of the extensive scheme originally published by Kloos and Schleifer in 1975 (96) has been mostly replaced by the use of commercial identification systems.

**Colony Morphology**

Most staphylococcal colonies are 1 to 3 mm in diameter within 24 h and 3 to 8 mm in diameter after 72 h of incubation in air at 34 to 37°C. Exceptions are those of *S. aureus* subsp. *aeruginosus*, *S. saccharolyticus*, *S. uricollis*, *S. eqorum*, *S. vitulinus*, and *S. lentus*, which grow more slowly and usually require 24 to 36 h for detectable colony development. Further incubation of agar plates for a period of up to 48 to 72 h (optimally followed by a 2-day incubation at room temperature) enhances morphologic differences.

On routine blood agar, the typical *S. aureus* colony is pigmented (gray/gray-white with a yellowish tint through yellow to orange), smooth, entire, slightly raised, and hemolytic (Fig. 1). Mucoid colonies due to highly encapsulated strains are rarely encountered. A number of isolates of *S. aureus* as well as some CoNS species (e.g., *S. haemolyticus* and *S. lugdunensis*) may have a hazy or distinct zone of beta-hemolysis around the colonies, ranging from weak to strong. SCVs of *S. aureus* or other staphylococcal species are characterized by pinpoint colonies (1/10 the size of the wild type), mostly nonpigmented and nonhemolytic after 24 to 72 h of incubation (Fig. 1) (52, 97). SCVs are often mixed with colonies displaying the normal phenotype, thus giving the appearance of a mixed culture. Upon subculture, they may remain stable or revert to the wild type. Depending on their aurotyrophy, normal growth may be restored if the isolate is grown in the presence of hemin, menadione, or thymidine and/or CO₂ supplementation (52).

The typical colony appearance of most CoNS species is nonpigmented, smooth, entire, glistening, and opaque. Rare strong slime producers display mucoid colony morphology. Colony diameters reach 3 to 6 mm after 3 days of incubation. Colonies of *S. chromogenes*, *S. devriesii*, *S. lugdunensis*, *S. sciuri*, *S. vitulinus*, *S. warneri*, and *S. xylosus* are found to be more or less regularly gray to yellow, yellow, or yellow to orange. Other CoNS species may show pigmentation that is usually yellowish (Table 2).

**Coagulase Production**

A widely used criterion for the identification of *S. aureus* in the clinical laboratory is the clotting of plasma proven by two different tests: (i) detection of the extracellular free coagulase by the tube test due to staphylococcal coagulase,
which converts fibrinogen to fibrin, and (ii) detection of the cell wall-bound coagulase (i.e., the clumping factor) by the slide agglutination test (see below).

The tube coagulase test is performed by transferring a large, well-isolated colony from a noninhibitory agar into 0.5 ml of reconstituted rabbit plasma. It is crucial to incubate the tube at 37°C for 4 h and to observe the tube for clot formation by slowly tilting the tube 90° from the vertical. Any degree of clotting represents a positive test. A flocculent or fibrous precipitate is not a true clot and should be recorded as negative. If no clot is formed by 4 h, the tube should be read again after 18 h of incubation at 37°C. False-negative results may occur for some strains producing staphylokinase, which may lyse the clot after formation (usually after prolonged incubation) and if SCVs are tested (often with no or delayed clotting). Inaccurate results may occur if nonsterile plasma is used or the colony tested is not pure.

Particularly in veterinary microbiological laboratories, the other coagulase-positive or variable species (Table 1) must not be disregarded. The detection of free coagulase in staphylococci obtained from human specimens is usually equated with the species identification of *S. aureus*. However, for animal-inflicted wounds, additional testing should be performed to provide identification beyond “coagulase-positive staphylococci.”

**Agglutination Assays**

To overcome the low sensitivity and specificity of the classical slide agglutination test (see previous editions of this Manual) and of the long incubation time of the tube coagulase test, rapid latex and hemagglutination assays allowing presumptive identification of *S. aureus* have been developed. Besides detecting protein A and clumping factor A, third-generation assays include monoclonal antibodies recognizing the clinically most prevalent capsular polysaccharide serotypes, 5 and 8, or other structures (e.g., Pastorex Staph-Plus [Bio-Rad Laboratories, Hercules, CA]; Slidex Staph Plus [bioMérieux, Marcy l’Étoile, France]; and Staphaurex Plus and Staphytec Plus [Oxoid]). The higher sensitivity (>98 to 100%) of the third-generation tests has reduced their specificity (72 to 99%). False-positive reactions occur with some CoNS strains (*S. haemolyticus* and *S. hominis*) possessing type 8 capsular polysaccharide or a cell wall hemagglutinin (*S. saprophyticus*). When an isolate is suspected

### TABLE 3  Key tests for identification of the most clinically significant *Staphylococcus* species

| Species                              | Colonial pigmentation | Staphylococcal coagulase | Clumping factor | Heat-stable nuclease | Alkaline phosphatase | Petridesky l-lysine | Ornithine decarboxylase | Urease | β-Galactosidase | Acid production | Acid production | Acid production | Acid production | Acid production | Acid production | Acid production | Acid production | Acid production | Acid production | Acid production | Acid production | Acid production | Acid production |
|--------------------------------------|-----------------------|--------------------------|------------------|---------------------|----------------------|---------------------|-----------------------|--------|----------------|----------------|-----------------|----------------|----------------|----------------|----------------|----------------|----------------|----------------|----------------|
| *S. aureus* subsp. *aureus*           | +                     | +                        | +                 | +                   | +                    | −                   | −                     |          | −              | −              | −               | −              | −              | −              | −              | −              | −              | −              | −              | −              |
| *S. epidermidis*                      | −                     | −                        | −                 | −                   | −                    | −                   | +                     |          | −              | −              | −               | −              | −              | −              | −              | −              | −              | −              | −              |
| *S. haemolyticus*                     | d                     | −                        | −                 | −                   | +                    | −                   | +                     |          | −              | −              | −               | −              | −              | −              | −              | −              | −              | −              | −              |
| *S. pyogenes* (veterinary)            | −                     | +                        | −                 | −                   | −                    | −                   | +                     |          | −              | −              | −               | −              | −              | −              | −              | −              | −              | −              | −              |
| *S. intermedius* (veterinary)         | −                     | +                        | +                 | −                   | +                    | +                   | +                     |          | −              | −              | −               | −              | −              | −              | −              | −              | −              | −              | −              |
| *S. lugdunensis*                      | d                     | −                        | +                 | −                   | −                    | −                   | +                     |          | −              | −              | −               | −              | −              | −              | −              | −              | −              | −              | −              |
| *S. pseudintermedius* (veterinary)    | −                     | +                        | +                 | +                   | +                    | +                   | −                     |          | −              | −              | −               | −              | −              | −              | −              | −              | −              | −              | −              |
| *S. schleiferi* subsp. *schleiferi*    | −                     | +                        | +                 | −                   | −                    | −                   | +                     |          | −              | −              | −               | −              | −              | −              | −              | −              | −              | −              | −              |
| *S. saprophyticus* subsp. *saprophyticus* | +                 | +                        | +                 | −                   | +                    | +                   | −                     |          | +              | +              | −               | −              | −              | −              | −              | −              | −              | −              | −              |

*a* Symbols and abbreviations (unless otherwise indicated): +, 90% or more strains positive; ±, 90% or more strains weakly positive; −, 90% or more strains negative; d, 11 to 89% strains positive; ND, not determined. Parentheses indicate a delayed reaction.

*b* Descriptions are the same as those in Table 2.

*c* Alkaline phosphatase reactions tested positive in the STAPH-ZYM gallery but negative in the API STAPH gallery.

---

**FIGURE 1** Columbia blood agar plate with 5% sheep blood showing *S. aureus* subsp. *aureus* after 24 h of incubation. The normal phenotype is grayish colonies with a yellowish tint surrounded by a hemolysis zone (arrows), and the small-colony phenotype is characterized by tiny, nonhemolytic, and nonpigmented colonies (dashed arrows).

doi:10.1128/9781555817381.ch21.f1
of being *S. aureus*, negative slide tests should be confirmed either by the tube coagulase test or a nucleic acid-based assay for identification of *S. aureus*.

**Identification of Species by Susceptibility Tests**

Resistance to novobiocin is intrinsic to *S. saprophyticus* and other CoNS species (Table 2) but is uncommon in the other clinically important CoNS species of the “*S. epidermidis* group.” A disk diffusion test for estimating novobiocin susceptibility can be performed using a 5-μg novobiocin disk on Mueller-Hinton agar or tryptic soy sheep blood agar. With an inoculum suspension equivalent in turbidity to a 0.5 McFarland opacity standard and incubation at 35 to 37°C overnight or for up to 24 h, novobiocin resistance is indicated by an inhibition zone diameter of ≤16 mm with any of these media.

Resistance to polymyxin B is usually observed for isolates of *S. aureus*, *S. epidermidis*, *S. hyicus*, *S. chromogenes*, and, to a lesser extent, for some strains of *S. lugdunensis*. A disk diffusion test may be performed using a 300-U polymixin B disk on tryptic soy sheep blood agar with the same test conditions as those described for novobiocin. Polymycin B resistance is indicated by an inhibition zone diameter of <10 mm.

**Identification of Species by Biochemical Procedures**

For speed, standardization, cost reduction, and convenience, the classical tests for fermentation, oxidation, degradation, and hydrolysis of various substrates (details are available in chapter 19) have been incorporated into commercial manual and automated biochemical test systems (see below and chapter 4). They are often complemented by simultaneously performed antimicrobial susceptibility testing using an advanced expert system and an interface with the laboratory informatics software. Results from conventional tests (Tables 2 and 3) may be slightly different from those obtained with rapid biochemical test systems due to the use of alternative, more sensitive indicators. Commercial identification systems identify the staphylococci (and some other aerobic Gram-positive cocci) of clinical importance with an accuracy of 70 to >90%. For some systems, reliability depends on additional testing as suggested by the manufacturer. Uncommon strains or phenotypic variants (e.g., SCVs) may have altered patterns of biochemical reactions requiring molecular testing for identification.

The API Staph (bioMérieux) strip represents an overnight method for manual identification of (primarily) staphylococci for health care and product safety applications. Necessitating the same incubation time as the API Staph and also fashioned in the strip format, the ID32 Staph (bioMérieux) may be read manually as well as automatically by the bioMérieux ATB system. The databases of both systems comprise more than 20 staphylococcal species with clinical significance, some “micrococcals” species, and *R. mucilaginosa*. A rapid version allowing 2-h identification of *S. aureus*, *S. epidermidis*, and *S. saprophyticus* is provided by the same manufacturer (Rapidec Staph). The Vitek 2 (bioMérieux) system is a fully automated platform that performs bacterial identification and antibiotic susceptibility testing. The VITEK 2 Gram-positive identification card encompasses a total of more than 100 species, including 26 staphylococcal species, a small spectrum of “micrococcals,” and *R. mucilaginosa*; identification of CoNS usually requires 10 h.

The MicroScan product Pos ID family (Siemens Healthcare Diagnostics, Deerfield, IL) includes a conventional panel (overnight identification time), a rapid panel (2.5-h identification time), and a Synergies plus panel (2- to 2.5-h identification time, with key antimicrobial results in as little as 4.5 h) in a microtiter format. Identification of 19 clinically important staphylococcal species, some “micrococcals” species, and *R. mucilaginosa* is available with either manual or automated processing on the autoSCAN-4 and WalkAway systems.

The BD BBL Crystal rapid Gram-positive identification kit (BD Diagnostic Systems, Sparks, MD) is a three-row panel that may be read manually or with the BBL Crystal AutoReader, requiring a 4-h incubation period. The database encompasses, besides 14 staphylococcal species, a total of 88 taxa, including *M. caseolyticus*, *R. mucilaginosa*, and several “micrococcals.” The BBL Crystal Gram-positive identification system represents the overnight incubation (18-h) version with an extended taxon profile of 121 Gram-positive organisms. A further enhanced profile (covering about 200 taxa) is covered by the automated nephelometry-based BD Phoenix automated microbiology system, which uses one combination panel with the identification substrates on one side and the antimicrobial agents on the other side of the panel. For staphylococci, about 10 to 15.5 h is required for complete results (identification and antimicrobial susceptibility testing) (98).

The Sensititre GPID identification plate (TREK Diagnostic Systems, Oakwood Village, OH) includes biochemical media reformulated for fluorometric reading and has been designed for the automated identification of Gram-positive organisms after 18 or 24 h of incubation. Overall, a limited number of staphylococcal species (*n = 8*) and a few “micrococcals” species are part of the database. The differentiation of *S. hominis*, *S. saprophyticus*, and *S. warneri* may need additional tests.

The Gram-positive aerobacterium database (339 taxa) of the Biolog Systems family (Biolog, Hayward, CA) comprises 34 staphylococcal and 4 macrococcal (sub)species and many members of the *Micrococcaceae* and *Dermacoccaceae* families not found in other commercial phenotype-based systems. The system’s redox chemistry, based on the utilization of a wide variety of carbon sources, is used to generate a “metabolic fingerprint,” providing results in 4 h or less, and is available with different automation levels. This system requires subculture of the isolate to be tested with a proprietary medium called Biolog Universal Growth (BUG) or Bug+blood (BUG+B) agar.

The Sherlock microbial identification system (MIDI, Newark, DE) automates microbial identification by combining cellular fatty acid analysis with computerized high-resolution gas chromatography. In addition to a multitude of other species, 30 staphylococcal species, *M. caseolyticus*, and several “micrococcals” are listed in the database of fatty acid profiles. A new sample preparation method (Instant FAME) allows for rapid identification from pure cultures in less than 15 min.

Most systems are fairly successful in differentiating *S. aureus*, *S. epidermidis*, and *S. saprophyticus*, while the accurate identification of less common species is more variable (99). Systems may fail in distinguishing commonly encountered staphylococcal species, in particular if phenotypic variants or isolates recovered from livestock and food are tested (100, 101). A verification of the identification result by a second, independent approach is recommended for isolates presumptively identified as *S. aureus*, particularly for oxacillin-resistant strains. Additional tests should be performed on clinically significant isolates with questionable identification results that impact patient management.
Species Identification by Nucleic Acid-Based Approaches

Extraction of staphylococcal nucleic acids may be challenging due to the Gram-positive nature of staphylococci, which necessitates special conditions for lysis of the cell wall. For this purpose, lysespin, lysozyme, protease K, and achromopeptidase have been used.

PCR fingerprinting techniques based on DNA sequence polymorphisms may be used, and species-specific variable regions of universal genes or genes unique to S. aureus or other staphylococcal species may serve as targets for identification and differentiation of staphylococcal isolates. Assays based on the specific amplification of fragments of the universal 16S and 23S rDNA genes and of their spacer sequences have been published (101–107). The 16S rDNA gene is also used as a target for the in situ detection and identification of S. aureus and S. epidermidis (108). Other universal DNA targets shown to be useful for identification of staphylococci include the elongation factor gene (tau), the gyr gene (gyrA), the manganese-dependent superoxide dismutase gene ( sodA), the glycolaldehyde-3-phosphate dehydrogenase-encoding gene (gap), and a 60-kDa heat shock protein (HSP60/GroE) (109–113).

Sequencing of selected universal phylogenetic marker genes represents the ultimate approach to identify known and not-yet-described staphylococcal species. For 16S rDNA gene sequencing, the regions between bp 70 to 300, 420 to 500, 1000 to 1050, and 1250 to 1290 (corresponding to nucleotides of the Escherichia coli 16S rDNA gene) are useful to determine sequence differences among the staphylococcal species. For differentiation of staphylococcal subspecies, sequencing of partial tpoB gene sequences seems to be superior to partial 16S rDNA gene sequencing (114). The recognized limitations of currently available public sequence databases apply to sequencing of staphylococcal isolates (101).

The most popular and well-studied specific target for S. aureus identification is the nuc gene, which encodes thermostable nucleas (theronuclease or Tnase) (115, 116). PCR methods targeting nuc are highly specific for S. aureus. A specific PCR for the S. intermedius nuc gene has also been described (117). Further specific targets used for the identification of S. aureus include the genes encoding clumping factor (clfA), coagulase (coa), manganese-dependent superoxide dismutase ( sodA), and the factors essential for the expression of methicillin resistance ( femA and -B), and (for MRSA only) the staphylococcal insertion element 431 (112, 118–121). Misidentification using the fem factors may occur due to fem-negative S. aureus strains and CoNS with a gene structurally related to femA.

For molecular identification of S. aureus and some other staphylococcal species isolated from culture, several commercial tests (e.g., GenoType Staphylococcus and Geno-Type MRSA [Hain Lifescience, Nehren, Germany], StaphyPlex panel [Qiagen, Germantown, MD], and Accu-Probe S. aureus culture [Gen-Probe, San Diego, CA]) are available. Some assays also detect resistance genes and/or toxin genes. The GeneXpert (Xpert MRSA/SA BC; Cepheid) and BD GeneOhm (StaphSR assay; BD Diagnostics) instruments offer assays to detect MSSA and MRSA directly from positive blood cultures. Other assays, such as the BioFire FilmArray blood culture identification (BCID) assay (BioFire Diagnostics, Salt Lake City, UT) and the Verigene Gram-positive blood culture (BC-GP) assay (Nanosphere, Northbrook, IL), include MSSA/MRSA detection as part of a broader panel that identifies bacteria directly from positive blood culture bottles. The Riboprinter microbial characterisation system (DuPont Qualicon, Wilmington, DE) utilizes ribotype pattern analysis for the differentiation of staphylococcal species with patterns in the database.

The S. aureus/CNS PNA FISH and the faster Staphylococcus QuickFISH BC kit (AdvancDx, Woburn, MA) are qualitative nucleic acid hybridization assays targeting rRNA sequences based on peptide nucleic acid (PNA) fluorescence in situ hybridization (FISH). These assays are intended for rapid identification of S. aureus and several CoNS species in a smear prepared from a positive blood culture (122).

Diagnostic DNA oligonucleotide microarrays that identify the genus Staphylococcus, clinically important staphylococcal species, other pathogens, drug resistance genes, and toxin genes have been designed and successfully tested on clinical isolates, indicating their potential for array-based high-throughput screening (123, 124).

Species Identification by Spectroscopic Approaches

An alternative high-throughput approach is represented by identification of staphylococci based on peptide spectra obtained by MALDI-TOF MS. In the past few years, commercially available mass spectrometers adapted to routine diagnostic requirements have become available (Microflex LT [Bruker Daltonics, Billerica, MA] and VITEK MS [bioMérieux]). The usefulness of this approach has been evaluated for routine identification of staphylococcal isolates (125–129). Most studies reported on identification of staphylococci at the species level with >97%. Investigating a large collection of clinical, molecularly defined strains of S. aureus and CoNS, the MALDI-TOF MS approach was shown to be faster than and equivalent to the molecularly defined reference methods irrespective of the methicillin resistance of the included strains (129). Nevertheless, for non-human-associated and/or newly described CoNS species, expansion of the MALDI-TOF MS databases is needed (128). There are few or incomplete data for MALDI-TOF MS identification of other catalase-positive cocci. Some “micrococci” and A. otitidis are part of the databases of both Microflex LT and VITEK MS. Of note, the content and quality of the database and the standardization of variable parameters, such as culture conditions and length of incubation, are crucial to achieve reproducible results.

By compiling universal and target gene-specific primer sets, PCR coupled to electrospray ionization-mass spectrometry (ESI-MS) gives the opportunity for high-throughput species identification and further molecular characterization (e.g., toxin gene detection) in parallel (130).

Nondestructive techniques, such as Fourier transform infrared (FTIR) and Raman spectroscopy, are currently being developed as alternative methods for the rapid identification of staphylococci (131). This approach also allows discrimination between the SCV and the normal S. aureus phenotype (55).

Diagnosis of Toxin-Mediated Staphylococcal Syndromes

The diagnosis of TSS and SSSS is based on clinical signs (supplemented by serologic tests) and the detection of toxin production by staphylococcal isolates (S. aureus but rarely other species). While the skin manifestations are mostly culture negative, isolates are usually recovered from the suspected site of infection. Blood cultures are positive in fewer than 5% of cases of staphylococcal TSS. In patients with TSS, protective antibodies against causative PTSAgs are absent or present at very low levels. However, secocon-
version after onset of the disease and during convalescence may be observed. The same phenomenon holds true for exfoliatin antibodies in patients with SSSS. Currently available immunoassays for antibody detection are for research use only. Beyond the recognition of the characteristic rapid onset and the clinical signs, staphylococcal food poisoning is difficult to verify because the incriminated food source may not contain cultivable staphylococcal cells and detection of staphylococcal enterotoxin is required.

Traditional immunological procedures may be used to measure the toxin in culture supernatants of isolated strains, in contaminated food extracts, or in patient specimens. Kits for the detection of strains producing TSST-1 (TST-RPLA [Oxoid], TST-RPLA Seiken [Denka Seiken, Tokyo, Japan], and TSST-1 Evigene [AdvantDx, Woburn, MA]), staphylococcal enterotoxins (Ridascreen sets A, B, C, D, and E [R-Biopharm, Darmstadt, Germany], SET-RPLA Seiken [Denka Seiken], and SET-RPLA kit toxin detection kit [Oxoid]), and ETA/ETB (EXT-RPLA Seiken [Denka Seiken]) are offered. A quantitative real-time immuno-PCR was recently described for the detection of small amounts of enterotoxins (132). An adaptation of a flow cytometry-assisted multiplex immunoassay (Bio-Plex system; Bio-Rad, Hercules, CA) for the detection of ETA and ETB has been recently reported (133). Since phenotypic methods may be hampered by low sensitivity and specificity (cross-reactivity between PTSAgs) and in vitro expression of PTSAgs might be negatively influenced by various factors, detection of PTSAg/ET-encoding sequences by nucleic acid-based methods has come into favor (134–137).

Due to renewed interest in Panton-Valentine leukocidin (PVL), PCR procedures targeting leukocidal (synergohemotropic) pore-forming toxins produced by S. aureus were established (138). The detection of PVL-encoding genes is included in the GenoType Staphylococcus and MRSA test systems (Hain Lifescience) and offered by the PVL Evigene kit (AdvantDx, Woburn, MA). A rapid phenotypic assay for PVL toxin detection in S. aureus cultures using recombinant monoclonal antibodies was developed as an immunochromatographic membrane-based lateral-flow assay (139).

**Micrococcaceae and Dermacoccaceae**

“Micrococi” and staphylococci might be easily confused with one another on the basis of similar cellular morphologies, Gram stain appearance, and positive catalase activities. The exact species affiliation of “micrococi” may frequently be misjudged. The frequent pigmentation of “micrococal” colonies with a high convex profile leads to their presumptive identification as members of the Micrococcaceae and Dermacoccaceae families (Fig. 2). Colonies of M. luteus, K. varians, and the kytococcal species are characterized by yellowish tints. K. kristinae and D. nishinomiyaensis appear orange-like, and K. rosea shows pink-to-red colonies. Some species (e.g., M. lylae) or strains of the usually pigmented species are nonpigmented. On routine blood agar, R. mucilaginosa colonies are mucoid or sticky, transparent to white, and nonhemolytic and in the majority of cases adhere to the agar (differentiation from streptococci). This organism may be distinguished from other similar organisms by its weak catalase reaction and its inability to grow in the presence of 5% NaCl.

In the clinical laboratory, “micrococal” species can be preliminarily distinguished from staphylococci by their resistance to furazolidone (100 μg/disk [Oxoid, United

Kingdom]; resistance is indicated by a ≤9-mm zone diameter) and lysostaphin (200 μg/disk [Mast, Bootle, United Kingdom]; resistance, no zone) and susceptibility to bacitracin (0.04 U/disk [Oxoid]; susceptibility, ≥10-mm zone diameter), in contrast to members of the Staphylococcus genus, which show inverse susceptibility patterns (zone diameters as follows: furazolidone, ≥15 mm; lysostaphin, 10 to 16 mm; bacitracin, no zone) (Table 1). Details are available in previous editions of this Manual. In contrast to most staphylococci, “micrococci” are positive by the modified oxidase test (140). Regarded as a reference method to distinguish “micrococal” species from staphylococci, the fermentation of glucose in a manner similar to that of the oxidation-fermentation test for nonfermenters requires a specific oxygenation and prolonged incubation. In contrast to staphylococci, “micrococci” are characterized by the lack of acid production from glucose under anaerobic conditions.

Key features for differentiation of species reported to occur in human specimens are given in Table 4. Data concerning the applicability of manual and automated identification systems for members of Micrococcaceae and Dermacoccaceae are given in the respective Staphylococcus sections; however, their use is limited to a small spectrum of the clinical “micrococal” species. In cases of doubt and extraordinary clinical relevance, the use of sequencing-based approaches is recommended for definite species recognition.

**Alloiococcus**

After 48 h of incubation at 37°C, alloiococci form small alpha-hemolytic colonies on blood agar. Colonies formed on brain heart infusion agar with 5% rabbit blood are small, moist, and slightly yellow at 72 h, and the blood is partially hemolyzed. Growth occurs in the presence of 6.5% NaCl and on bile esculin agar. No growth occurs at 10°C or 45°C. A. otitis can be distinguished from similar organisms by its positive catalase and negative oxidase activities, its obligate aerobic nature, and its inability to produce acid from glucose or other carbohydrates (Table 1). Arginine dihydrolase is not produced. Pyrrolidonyl arylamidase, leucine aminopeptidase, and P-galactose are produced. Starch and esculin are not hydrolyzed; hippurate is mostly hydrolyzed (95). A. otitis is included in the database of the API Strep gallery (bioMérieux).

As the bacterium is quite inert biochemically, molecular methods are often necessary to confirm the identification. For the molecular verification of suspected colonies, an A. otitis-specific PCR assay has been described (141). A PCR assay for direct detection of this microorganism in clinical specimens has been reported as part of a multiplex approach targeting pathogens that cause otitis media with effusion (142).

**Typing Systems**

Traditional phenotyping techniques, such as phage typing, capsule serotyping, antibiotic susceptibility pattern analysis, and other biotyping methods, have been replaced by molecular-hand-based and sequence-based typing methods (143).

For local MRSA outbreak investigations as well as for long-term MRSA surveillance, Small macrorestriction pattern analysis by PFGE still represents a highly discriminatory “gold standard” tool with detailed performance and interpretation guidelines (144, 145). However, PFGE is technically demanding, with low throughput, limited portability, and problems with intercenter reproducibility. In addition, the

use of different national nomenclatures and attribution of PFGE clusters to genetic lineages may be problematic (143). Since no digestion occurs due to methylation of the respective restriction endonuclease site, the emerging livestock-associated CC398 isolates are mostly nontypeable by standard PFGE protocols applying Smal (NT$_{SmaI}$) (146–148). Those NT$_{SmaI}$ MRSA can be PFGE typed by neochozimers, such as Xmal or Cfr9I, that are partially or fully insensitive for the DNA methylase (148–150).

The reference method for defining the core genetic population structure of S. aureus is MLST (151). In a standardized manner, the allelic polymorphisms of seven housekeeping genes are indexed. A Web-based database is available (http://saureus.mlst.net/). MLST has limited discriminatory power and a low-throughput capacity in the context of MRSA outbreak investigation and surveillance. In the case of common ancestry but assumed distinct epidemiological origins of MRSA isolates, subtyping of SCCmec may provide additional information (http://www.sccmec.org/) (152).

spa typing, based on the number of polymorphisms and the sequence of tandem repeat elements of the hypervariable X region of the S. aureus protein A (spa) gene, is the basis of a single-locus sequence typing approach that has become one of the primary genotyping methods for MRSA surveillance (153, 154). Beside excellent reproducibility, other advantages include low costs, high throughput, a standardized nomenclature, and complete portability of data transferable into an international database (http://spaserver.med.unimelb.edu/) curated by SeqNet.org (http://www.seqnet.org/) (155). For particular genetic lineages, misclassification may occur, necessitating the use of additional tests for reliable inference.

Other molecular typing techniques used for typing of staphylococci include several other band-based molecular-fingerprinting approaches, ribotyping, and, more recently, multiple-locus variable-number tandem-repeat analysis (MLVA) and microarray-based approaches (156–158).

In the near future, whole-genome sequencing may supersede traditional molecular typing methods, serving as a universal approach that may provide information useful for outbreak investigation, surveillance purposes, detection of unknown and/or emerging strains, and prediction of the clinical importance of a given isolate (159). However, costs (although rapidly declining), bioinformatic processing issues, missing universal nomenclature, and challenging interpretation of sequence data still hamper its use.

Modern approaches based on phenotype structures applied to staphylococci include the MALDI-TOF MS and whole-cell fingerprinting techniques, such as FTIR spectroscopy (160).

While many typing systems have been developed and evaluated for S. aureus, fewer applications are available for CoNS. These include antibiotic resistance analysis, phase typing, slime production, and some modern genotyping procedures (PFGE and ribotyping) (161, 162).

For “micrococcus” species, phase typing and PFGE approaches applying phase sets and restriction enzymes, respectively, different from those used for staphylococci (163) have been described. PFGE and restriction fragment length polymorphism approaches have been described for Allolablabus (95, 164).

### SEROLOGIC TESTS

Because serological testing for antistaphylococcal antibodies lacks specificity and predictive accuracy, it plays no role in the diagnosis of most staphylococcal diseases. The one exception is the determination of protective antibodies in the case of toxin-mediated syndromes such as TSS and SSSS (see above). For the other microorganisms discussed in this chapter, detection of antibodies is in fact not clinically useful.

### ANTIMICROBIAL SUSCEPTIBILITIES

**Staphylococcus and Related Genera**

**Genetic Basis and Prevalence of Antimicrobial Susceptibilities**

A number of studies and reviews describing the antimicrobial and biocide susceptibilities of clinically important staphylococcal species have been published (165–167). Networks that provide online or published resistance data for staphylococci have also been established, namely, the National Healthcare Safety Network (NHSN) (http://www.cdc.gov/hai/), the European Antimicrobial Resistance Surveillance System (EARS) (http://www.ecdc.europa.eu/en/activities/surveillance/EARS-Net/Pages/index.aspx), the Asian Network for Surveillance of Resistant Pathogens (ANSORP) (http://www.ansorp.org/), and the International Nosocomial Infection Control Consortium (INICC) (http://www.inicc.org/espanol/esp_index.php).

Methicillin resistance mediated by the mecA gene or the newly described mecC gene is the most important resistance mechanism, as it has a profound impact on patient management by excluding all traditional β-lactam antibiotics (penicillins, group 1 to 4 cephalosporins, and carbapenems) from the antibiotic armamentarium. Since the early 1980s, the prevalence of health care-associated MRSA (HA-MRSA) has increased in many regions. In some areas of the United States, the prevalence of MRSA is >50% (168, 169). In Europe, the prevalence of MRSA ranges from 10 to 50%, except in The Netherlands and the Scandinavian countries, where MRSA rates are very low (170). In Asia, Australia, and Africa, high MRSA rates (approximately 20 to 80%) have also been noted (171–173). The worldwide burden of infections caused by MRSA has further increased due to the advent of CA-MRSA in the past decade and recently by livestock-associated S. aureus infections (174–176). However, in some parts of the world (the United States and several European countries), there are signs of stabilization or even a decrease in the incidence of MRSA infections (177, 178).

The mecA gene and its homologs acquired by S. aureus and other staphylococcal species on a foreign, mobile DNA element (SCCmec) encode an additional penicillin-binding protein (PBP), PBP2a or PBP2c, responsible for the reduced activities of traditional β-lactam antibiotics. Homologs of the mecA gene have been described for S. sciuri (mecA1) and S. vitulinus (mecA2), Micrococcus caseolyticus (mecB), S. aureus (mecC), and S. xylosus (mecC1) (179). mecC possesses, so far associated with SCCmec type XI, may result in the expression of a functional PBP2a homolog, likewise leading to methicillin resistance (180–182). Eleven major variants of SCCmec, types I to XI, and many subtypes have been recognized (178, 181–189). SCCmec types I, II, III, VI, and VIII are predominantly associated with HA-MRSA, and types IX and X are associated with LA-MRSA (190).

Multidrug resistance is regularly observed in HA-MRSA and usually includes resistance to aminoglycosides, fosfo- mycin, fusidic acid, ketolides, lincosamides, macrolides, quinolones, rifampin, tetracyclines, and trimethoprim-sulfamethoxazole (166, 167, 191). While reports are still rare,
an increasing number of reports of S. aureus and CoNS isolates resistant to newer agents, such as daptomycin, tigecycline, and linezolid, has to be noted, including plasmid-mediated resistance to linezolid based on the acquisition of the cfr gene (192–194). The transferable multiresistance gene cfr confers resistance not only to oxazolidinones but also to spectogramin A, lincomamides, phenicols, and pleuromutins (195).

In contrast to HA-MRSA, CA-MRSA strains are mostly susceptible to non-β-lactam antibiotic classes. They harbor different SCCmec types (mostly types IVa, V, and VII) (185–187, 196). CA-MRSA isolates are more likely to carry PVL, a pore-forming toxin with potent cytolytic and inflammatory activities (197). Whereas in Europe, an array of diverse CA-MRSA clones (e.g., the “European” ST-80, spa type t044) have been reported, in the United States, CA-MRSA infections are dominated by a single clone, i.e., the PFGE type USA300 (ST-8, spa type t008); PFGE type USA400 (ST-1) was most prominent before 2001 (190, 198–200). However, also in Europe and other parts of the world, an increase in USA300 strains has been reported (201–204). Outside North America, other CA-MRSA clones are prevalent, e.g., ST80 in Europe, ST59, ST30 (Southwest Pacific clone), and ST5 in the Asia and Pacific regions, ST88 and ST1797 in Africa, and ST772 (Bengal Bay clone) in South Asia (199, 201, 205–207). Of note, PVL possession is not restricted to CA-MRSA. Isolates of many pandemic MSSA lineages may carry PVL genes. Particularly in African populations, a high prevalence of PVL-positive MSSA has been reported (208–210). Populations at increased risk for CA-MRSA colonization and/or infections include children in day care centers, athletes, military recruits, jailed inmates, and men who have sex with men (211–215). CA-MRSA causes superficial skin and soft tissue infections and can also be associated with necrotizing fasciitis and myositis, necrotizing pneumonia, and other severe entities (138). Infections by PVL-positive MRSA and MSSA in young, otherwise healthy children following a respiratory viral infection (most frequently influenza) can be a devastating disease (197). However, some of the distinctions between HA-MRSA and CA-MRSA strains may disappear, since CA-MRSA is now becoming endemic in hospitals and acquiring additional resistance phenotypes (212, 216, 217).

For LA-MRSA, the possession of various SCCmec types has been reported. Most LA-MRSA belong to CC398, as defined by MLST, with t011 and t034 as the most frequent spa types (218). LA-MRSA isolates may exhibit resistance to antibiotic classes other than the tetracyclines, resistance to which is found in almost all isolates, but so far, LA-MRSA isolates exhibit this trait to a less frequent extent than HA-MRSA isolates (175).

Vancomycin-intermediate S. aureus (VISA) isolates (MIC of 4 to 8 μg/ml) (219) and their putative precursors, termed heterogeneous VISA (hVISA) strains, were identified first (1996) in Japan and then in the United States and other regions (220–222). The mechanism of resistance for hVISA and VISA strains is not due to a single gene but is complex and can be obtained by several pathways, all of which, however, include cell wall alterations resulting in reorganization and thickening in addition to reduced autolytic activity (223–225). Moreover, current data may suggest that hVISA and VISA strains represent a bacterial evolutionary state favoring persistence in the host environment (226). In 2002, the first of multiple vancomycin-resistant S. aureus (VRSA) strains containing the vanA gene were reported in the United States (227). The MICs for S. aureus isolates currently defined as vancomycin resistant according to the CLSI are ≥16 μg/ml (228). Since most VISA strains are also resistant to teicoplanin, the acronym GISA (glycopeptide-intermediate S. aureus) is preferred by some authors. A few clinical isolates that are resistant to teicoplanin but fully susceptible to vancomycin have been reported (229). For hVISA and VISA isolates, heteroresistance to daptomycin has been rarely reported (230).

For S. pseudintermedius/S. intermedius, a significant emergence of methicillin resistance has been observed (231).

More than 90% of all nosocomial CoNS (mainly S. epidermidis and S. haemolyticus) are resistant to penicillin due to β-lactamase production, and resistance to methicillin and other agents can be as high as 60 to 80% for nosocomial isolates (167, 232, 233). In terms of glycopeptides, resistant CoNS isolates have been described primarily as resistant to teicoplanin.

Determination of Antimicrobial Susceptibilities

Antimicrobial susceptibility testing of staphylococci may be performed conventionally by Clinical and Laboratory Standards Institute (CLSI) or European Committee on Antimicrobial Susceptibility Testing (EUCAST) reference methods or commercial systems as described in chapters 70 to 73 of this Manual. Direct detection of MRSA is discussed in Direct Examination above. For SCVs, no approved method has been developed to determine the susceptibility (97, 234).

Detection of MRSA represents the most important task in determining the antimicrobial susceptibilities of staphylococci. Of note, traditional methods have reduced sensitivity and specificity in distinguishing MRSA from MSSA due to heteroresistance and the borderline oxacillin resistance of S. aureus strains characterized by β-lactamase hyperproduction. With the enhanced discriminatory power of applying cefoxitin as the agent for detecting MRSA (both mecA and mecC mediated), most of these problems have disappeared. The use of cefoxitin obviates the need for specific assay conditions (see previous editions of this Manual). However, oxacillin MIC determination continues to require the addition of 2% NaCl to the media, a maximum incubation temperature of 35°C, and a full 24 h of incubation. Even when these optimal expression conditions are present, MICs below the breakpoint, indicating false susceptibility, can still be obtained for some mecA- or mecC-positive isolates. This phenomenon is due to heterogeneous PBP2a expression of some MRSA isolates, where only a small fraction of the bacterial cell population (10−2 to 10−3) expresses the resistance phenotype under in vitro test conditions. The resistant subpopulation may thus be overlooked because it usually grows more slowly than the susceptible population. The cefoxitin disk (30 μg) is today the disk diffusion method recommended by the CLSI for testing of S. aureus and S. lugdunensis (resistance is indicated by a zone diameter of ≤21 mm) and can be used for other CoNS (resistance, ≤24 mm) for mecA-mediated resistance. According to EUCAST (http://www.eucast.org), S. saprophyticus should be tested like S. aureus and S. lugdunensis. Isolates of these species are categorized as resistant if cefoxitin disk zone diameters are less than 22 mm (235, 236). For other CoNS, resistance is indicated by a zone diameter of <25 mm. It should be noted that these cefoxitin breakpoints are inappropriate for S. pseudintermedius in cases where, e.g., oxacillin is recommended (237). For this species, EUCAST now recommends a cefoxitin screen zone diameter breakpoint of <35 mm as resistant.
For broth microdilution testing, oxacillin or cefoxitin may be used to detect mecA-mediated resistance in S. aureus and S. lugdunensis (resistance to cefoxitin, MIC ≥ 8 μg/ml; oxacillin, MIC ≥ 4 μg/ml). For other CoNS isolates, the presence of mecA is predicted by applying lower oxacillin MIC breakpoints (resistance to oxacillin, MIC ≥ 0.5 μg/ml). Cefoxitin has also improved the detection of MRSA by automated susceptibility testing systems (238). The low growth rate of SCVs prevents the use of disk diffusion and automated methods to determine the susceptibilities of these strains (52).

An alternative method for the detection of methicillin resistance is the use of anti-PBP2a monoclonal antibodies available in a latex agglutination assay (MRSA screen; Denka Seiken, Tokyo, Japan, and other suppliers) or immunochromatographic assay (PBP2a culture colony test; Alere, Waltham, MA) that may be performed on isolated colonies from a pure culture (239). These assays, however, do not detect mecC isolates. If the latex test is used for SCVs, then the number of colonies must be increased 100-fold (240).

For a definite verification of a given MRSA isolate, the occurrence of both the oxacillin resistance-determining gene and an S. aureus species-specific marker (see above) has to be proven as a matter of principle, representing the gold standard. The use of pure colony material is a vital premise for this approach. In particular, for heterogeneous methicillin-resistant staphylococci, strains displaying growth-impaired phenotypes (SCVs), or S. aureus strains with borderline oxacillin resistance, the methicillin resistance of cultivated staphylococcal isolates may be determined by detection of the mecA gene (241). At least in the case of unexplainable discrepancies between a positive MRSA result obtained by culture-based approaches and a negative result obtained by molecular approaches targeting mecA and/or the SCCmec/orfX junction, testing of mecA homologues should be included. The same holds true for CoNS if molecular verification of oxacillin resistance is desired. For the detection of mecC and other mecA alleles, specific oligonucleotide primers have been described and a microarray-based approach has been published (180, 182, 242).

For MRSA screening to detect colonization (preferentially nasal but also pharyngeal), selective agar media (e.g., mannitol salt agar) supplemented with oxacillin or, preferably, cefoxitin are widely used. Inclusion of a broth enrichment step prior to plating enhances sensitivity but delays results. A commercial MRSA screening broth is supplied by Oxoid (Contrast MRSA broth). Agar media containing chromogenic enzyme substrates (e.g., chromID MRSA [bio-Mérieux], BBL CHROMagar MRSA II [BD], and Brilliance MRSA 2 agar [Oxoid]) have better specificity; however, confirmation of MRSA with a coagulase test is recommended for some products (243–245). A semiselective tryptic soy broth with 2.5% salt containing cefoxitin and aztreonam (TSB-SSI; SSI Diagnostica, Hillerød, Denmark) was shown to be superior to both nonselective enrichment broth and direct plating on a chromogenic agar or Columbia blood agar (246).

Regarding glycopeptide susceptibility testing, differences between CLSI and EUCAST interpretative criteria have to be taken into account. Applying EUCAST criteria, the different underlying mechanisms leading to glycopeptide nonsusceptibility are not addressed. The disk diffusion test is unreliable and not recommended for glycopeptide susceptibility testing either by the CLSI or by EUCAST.

According to CLSI guidelines, VRSA strains (MIC ≥ 16 μg/ml) are reliably detected by screening tests such as the broth microdilution reference method (for screening, the MIC is ≥8 μg/ml), most FDA-cleared automated systems, and a brain heart infusion vancomycin (6 μg/ml) agar screen plate (219). Detection of the VISA phenotype is unreliable and underreported by routine susceptibility testing methods, including automated methods (247). According to current CLSI recommendations, S. aureus isolates for which vancomycin MICs are 4 to 8 μg/ml are classified as VISA (219). These vancomycin MIC breakpoints were lowered for S. aureus (the intermediate category remained defined as 8 to 16 μg/ml for CoNS) in order to better detect VISA strains (248). The CLSI recommends sending S. aureus isolates for which the vancomycin MIC is ≥8 μg/ml to a reference laboratory (219). The glycopeptide MIC breakpoints have been considerably lowered by EUCAST (resistance to vancomycin and teicoplanin, >2 μg/ml for S. aureus and >4 μg/ml for CoNS [http://www.eucast.org]) to avoid reporting VISA/GISA isolates as “intermediate” (249) and to address the finding that strains of the hVISA/VISA phenotypes appear to be associated with impaired clinical responses to vancomycin (250). The poor clinical outcome of infections with S. aureus isolates for which the vancomycin MICs are 1.5 or 2.0 (studies listed in reference 249) as well as the “vancomycin MIC creep” phenomenon are matters of debate (251).

Detection of hVISA requires a modified population analysis profile-area under the curve method (252, 253). As this method is laborious, complicated, and not suited for routine use, a number of screening assays including antibiotic-incorporated agar media and specialized gradient tests (macroEtest) have been developed (225). Recently, FTIR spectroscopy was successfully applied for rapid and accurate identification of VISA and hVISA among isolates of MRSA (254).

Additional information on the determination of antimicrobial susceptibilities is contained in chapters 70 to 73 of this Manual. There are no CLSI methods for susceptibility testing of “micrococci” and alloilococci.

**Treatment**

For additional and annually updated information regarding treatment, the reader should consult the current edition of The Sanford Guide to Antimicrobial Therapy (255) or other guidelines, such as the IDSA practical guideline for the treatment of MRSA infections (256). Effective treatment of focal infections, such as abscesses, requires incision and drainage. Penicillin G is the most effective compound for the treatment of the uncommon penicillin-susceptible S. aureus strain. In general, penicillin-resistant, oxacillin-susceptible staphylococcal strains should be treated with penicillin-stable penicillins, β-lactam/β-lactamase inhibitor combinations, and cephaparsins (255, 257). For patients with penicillin allergy or chronic renal failure, clindamycin or vancomycin may be an option in the case of MSSA. However, the use of vancomycin, known to be poorly bactericidal against staphylococci, is not recommended for severe infections due to MSSA, as it is inferior to β-lactams in terms of mortality and bacteriological outcome.

Strains that are oxacillin and cefoxitin resistant (MRSA) should be considered resistant to all β-lactams, including penicillins, carabepens, and cephalosporins (except for the new “fifth-generation” cephalosporins with anti-MRSA activity) (258). Vancomycin and the newer agents, such as linezolid, daptomycin, telavancin, tigecycline, and the anti-MRSA cephalosporins (ceftobiprole and ceftaroline), are suitable options for empirical therapy of MRSA infections (note the different spectra and the
approved indications of these compounds) (256, 259–265). For the treatment of MRSA nosocomial pneumonia, it was shown in a prospective multicenter trial that clinical responses at the end of the study in the per-protocol population were significantly higher with linezolid than with vancomycin, while all-cause 60-day mortalities were similar (266). Occasionally, trimethoprim-sulfamethoxazole may be helpful, but it should be used with caution (267). In particular, in terms of “collateral damage” (referring to ecological adverse effects, such as subsequent MRSA colonization/infection after receipt), quinolones should be avoided for the therapy of staphylococcal infections (268).

While there are only a few, partly uncorroborated studies and case reports available supporting combination therapy for treatment of severe staphylococcal infections, aminoglycosides, rifampin, fosfomycin, co-trimoxazole, and fusidic acid in combination with glycopeptides and β-lactams have been recommended (269). A careful risk-benefit assessment concerning drug-drug interactions and side effects should be performed. Since resistance to rifampin, fusidic acid, and fosfomycin develops rapidly, these compounds must not be administered alone.

Despite the challenges for S. aureus universal vaccines, they are urgently needed and being actively pursued in health care settings (270). Within the past several years, the S. aureus vaccine field has witnessed vaccine failures in clinical trials designed to prevent infections in either patients undergoing surgery or patients with end-stage renal disease undergoing hemodialysis. For patients undergoing cardiothoracic surgery with median sternotomy, the use of a vaccine against S. aureus compared with a placebo did not reduce the rate of serious postoperative S. aureus infections and was associated with increased mortality among patients who developed S. aureus infections (271).

Since the majority of clinically recovered CoNS strains are methicillin resistant, most infections by CoNS require treatment with vancomycin or, where appropriate, the new agents described above. Replacement of these by β-lactamase-resistant penicillins is advisable for methicillin-susceptible isolates. When used simultaneously, antibiotics with cell wall activity (β-lactams and vancomycin) combined with rifampin were shown to act synergistically; however, this combination is not recommended for catheter-related bloodstream infections (272). FBRLs remain a therapeutic challenge and frequently require removal of the device (65, 273).

Prospective studies on the most appropriate treatment for patients infected with staphylococcal SCVs are unavailable. A reduced susceptibility to aminoglycosides can be expected (274). Resistance to trimethoprim-sulfamethoxazole is observed in thymidine-auxotrophic SCVs (58). Due to the fact that SCVs may persist intracellularly, a combined treatment regimen of rifampin (intracellular activity) with either β-lactam antibiotics or vancomycin (for methicillin-resistant SCVs) may be effective.

**Micrococcaceae and Dermacoccaceae**

Systematic data on susceptibilities of the two families Micrococcaceae and Dermacoccaceae are rare, and the real species affiliation in older reports is often unclear. Members of the genera Micrococcus and Kocuria appear to be susceptible to β-lactams, macrolides, tetracycline, linezolid, rifampin, and the glycopeptides; however, clinical isolates resistant to these agents have been reported (74, 275, 276).

While most kytooccal isolates have been susceptible to carbapenems, gentamicin, ciprofloxacin, tetracycline, rifampin, and glycopeptides, kytoocci are usually resistant to penicillin G, cephalosporins, and oxacillin (not mecA based) (4, 74, 275). An antibiotic regimen that has been suggested for the treatment of infection by members of both families is a combination of vancomycin with rifampin and gentamicin (277). R. mucilaginosa appears to be variable in its antimicrobial susceptibilities (276, 278). The observation that R. mucilaginosa exhibits poor to no growth on Mueller-Hinton agar makes susceptibility testing a challenge for clinical laboratories. Supplementation with 5% sheep blood and incubation in 6% CO₂ may enhance susceptibility testing (276, 278).

**Alloccoccus**

A. otitis has been reported as susceptible to ampicillin, cefotaxime, tetracycline, and vancomycin but resistant to macrolides, azithromycin, and co-trimoxazole (95, 279, 280).

In addition to gentamicin-resistant isolates, some A. otitis isolates with intermediate levels of resistance to β-lactams have been reported, although they are β-lactamase negative.

**Evaluation, Interpretation, and Reporting of Results**

Distinguishing contaminants and colonizers from staphylococcal and “micrococal” isolates causing infection continues to be an important challenge for laboratorians and clinicians. It is imperative to have an appreciation of the quality of the specimen under consideration. Clinical features and the results of other investigations should be taken into account during the interpretative process. There is no replacement for good communication between laboratory staff and primary physicians.

Cultivation and identification of the causative pathogen to the species level represent the gold standard for the diagnosis of staphylococcal infections. The most critical step when interpreting a culture that is suspect for staphylococci is to distinguish between S. aureus and other species. Due to the importance of a report of “S. aureus” and, in particular, of “MRSA” for prognosis, therapy, hospital hygiene, and infection control, any uncertainty regarding the species identification or the susceptibility to oxacillin (cefotaxin) should be investigated via a second independent method. Considering costs and rapidity, applicable routine proceedings may comprise the use of respective latex agglutination tests combined with the use of automated systems for identification and susceptibility testing. In case of doubt, further tests, preferentially nucleic acid-based approaches, should be applied. However, the need for additional procedures must be weighed against delay in informing the physician concerning a preliminary S. aureus identification as the putative causative agent.

Species-level identification of CoNS associated with infection, especially in the case of a pure culture, has become customary. In particular, in the case of S. lugdunensis, species identification is mandatory for interpretation of the results of susceptibility testing. The same holds true for coagulase-positive S. pseudintermedius, which is often misidentified as CoNS due to negative results in latex agglutination assays. To rule out S. saprophyticus for urine isolates, the novobiocin test may be used. Isolates from deep-tissue infections and blood cultures of patients with suspected endocarditis should be differentiated to the species level, since the identification of S. lugdunensis raises the index of suspicion for aggressive disease. To identify S. lugdunensis from cultures of invasive and sterile sites or from abscesses and wound infections, its positivity for pyrroldonase and ornithine decarboxylase may be considered (Tables 2 and 3). Other CoNS have also
been increasingly described as causative pathogens of severe infection. Contaminants and colonizing CoNS do not require susceptibility testing or identification. Several reports suggest that cultures of colonially indistinguishable CoNS may contain multiple different strains (281). Extending the incubation period of the initial cultures to 72 h may enable different colony types to be more readily identified but also delays the time to the final culture result.

Unless there is strong evidence to the contrary, isolation of S. aureus from a sterile-site culture (such as aspirated pus, blood, or cerebrospinal fluid) should be considered clinically significant. Contamination of high-quality samples by S. aureus is rare, and further samples should be taken if there is clinical doubt. Interpreting the isolation of S. aureus from specimens contaminated with elements of a normal microbiota requires consideration of setting, clinical features, and recent interventions. Quantitative culture may be helpful, for example, when interpreting a bronchoalveolar lavage or urine sample. In patients with S. aureus endocarditis, bacteremia is continuous and associated with higher loads, while in cases with transient bacteremia (e.g., manipulations with mucous membrane trauma), bacteremia is associated with lower loads and typically has a short duration. Because quantitative blood cultures are not routinely performed, the time between incubation onset and growth detection (defined as the time to positivity) may provide additional information in continuous blood culture monitoring systems. Rapid growth of S. aureus (within 14 h after the initiation of incubation) has been associated with a high likelihood of endovascular infection, delayed clearance, and complications (282). Isolation of S. aureus from surgical wounds and other sites, such as ulcers, may represent infection or colonization, and the clinician’s response to the culture report should be guided by a bedside assessment of signs and symptoms of infection. Colonization alone is an insufficient reason to treat, unless the patient is colonized by MRSA and decolonization is undertaken as part of a specific infection control policy.

Interpreting the significance of cultures that are positive for CoNS is more challenging than for S. aureus. CoNS are an important cause of nosocomial bloodstream infections, but they are also the most common contaminants of blood cultures (283). It is obvious that samples taken from colonized sites will contain members of these species. Blood samples or biopsy specimens taken without careful skin cleaning and disinfection will become contaminated with the microbiota of the skin or mucous membranes. However, even careful attention to collection techniques will not prevent all episodes of contamination. Interpretation of blood cultures positive for CoNS requires knowledge of the presence of prosthetic material in the intravascular compartment, risk factors for true CoNS sepsis, such as prematurity or the presence of an impaired immune system, and clinical features of sepsis. Factors helpful in distinguishing between true-positive cultures with clinical impact and therapeutic consequences and contaminated specimens taken from a patient with clinical features of infection include (i) isolation of a strain in pure culture from the infected site or body fluid and (ii) the repeated isolation of the same strain or combination of strains over the course of the infection (284, 285). An algorithm to reduce misclassification of nosocomial bloodstream infections due to CoNS was defined as at least two blood cultures positive for CoNS within 5 days or one positive blood culture plus clinical evidence of infection (286).

The presence of the same CoNS strain on an intravenous catheter tip and in a blood culture is supportive evidence for intravenous catheter-associated bacteremia. Measurement of differential times to positivity between blood cultures drawn through the central venous catheter and those drawn from the peripheral vein was reported as highly sensitive and specific for the in situ diagnosis of catheter-related bloodstream infection in patients with short- and long-term catheters; however, other studies did not show that this method was of major diagnostic value (287–289). Isolation of CoNS from peritoneal dialysis fluid or cerebrospinal fluid taken from ventricular shunts in a patient suspected of having infection is usually significant. While most contaminated clinical samples produce mixed cultures of different strains and/or species, some infections may be attributable to more than one strain or species (281).

For patients with complicated cases who probably have a true CoNS infection, it is advisable to develop a sampling strategy. This is particularly pertinent when dealing with patients with low-grade infection associated with implanted prosthetic material, such as from a joint replacement or vascular graft. Samples should include those from each anatomical layer or region, and fresh instruments should be used to gather deep-site samples (290).

Susceptibility testing, and in particular the detection of methicillin resistance, should always be carried out following the identification of S. aureus. For surveillance cultures to detect MRSA colonization, susceptibility testing beyond the determination of methicillin resistance may be needed only for patients undergoing decolonization to predict the success of mupirocin therapy. All CoNS associated with true infection require susceptibility testing.

The considerations of clinical significance discussed for CoNS are also appropriate for members of the Micrococcaeae and Dermacoccaceae families; however, the criteria used for distinguishing etiologically relevant isolates from contaminants and colonizers, respectively, should be applied much more strictly. Since species of the Kytococcus genus are resistant to some β-lactams, they should be (if clinically relevant) carefully distinguished from other “micrococci” that are usually susceptible.

BACTERIOLOGY

TAXONOMY
The genus *Streptococcus* comprises currently more than 100 recognized species—a number that can certainly be expected to rise with the increasing availability of next-generation sequencing technologies. More than 10 novel species have been validly published in the last 5 years alone. Most of these were found in the oral cavity and gastrointestinal tract of various mammals and have so far not been shown to play a role in human infections. This chapter focuses on well-known and novel streptococcal species found in human specimens and covers changes that were applied to the taxonomy of streptococci during recent years. Streptococci are fimbriated of the order Lactobacillales and belong to the family of *Streptococaceae*. Among the currently established 17 different genera of catalase-negative Gram-positive cocci are several genera that were split off from the genus *Streptococcus* some time ago, such as *Enterococcus* and *Lactococcus*, or more recently *Abiotrophia*, *Granulicatella*, *Facklamia*, and *Globicatella*. For excellent reviews on the topic, see references 1 and 2. While streptococcal species designation based solely on the hemolysis reaction, colony size, and the presence of Lancefield antigens has several limitations for correct species identification, this traditional streptococcal classification system is well established and still of value to the clinical microbiologist and health care provider. It correlates with clinical syndromes caused by different species and enables a first distinction of broad categories of streptococci that is useful for the choice of further tests and guidance of empirical treatments. The information and the identification schemes presented in this chapter therefore adhere in many aspects to the phenotypic classification system.

The classical differentiation of streptococci separates the group of beta-hemolytic streptococci from the group of non-beta-hemolytic streptococcal species. Beta-hemolytic streptococci, also referred to as pyogenic streptococci, include the human-pathogenic species *S. pyogenes*, *S. agalactiae*, *S. dysgalactiae* subsp. *equisimilis*, and a number of primarily veterinary pathogens. The designation "pyogenic streptococci" is more precise, since the group includes species that are non-beta-hemolytic like *S. dysgalactiae* subsp. *dysgalactiae* and the term excludes beta-hemolytic strains of the *S. anginosus* group, which belong to the viridans group streptococcal group. The small colony size of streptococci from the anginosus group (≤0.5 mm) helps to distinguish them from the large-colony-forming (>0.5-mm colonies) streptococci of the pyogenic group. Species from the pyogenic or beta-hemolytic group are further characterized by the presence of Lancefield antigens, which correlate to some extent with the proper streptococcal species designations. While the B antigen is limited to *S. agalactiae*, the Lancefield group A antigen has been detected not only in *S. pyogenes* but also in *S. dysgalactiae* subsp. *equisimilis* isolates (3) and in species from the *S. anginosus* group (Table 1). Correlation with other Lancefield antigens is even more complicated, and molecular taxonomic studies led to novel species designations, presented below and in Table 1.

The group of nonpyogenic streptococci includes mostly alpha-hemolytic as well as nonhemolytic and even beta-hemolytic streptococcal species from the large category of viridans group streptococci. In a study of the genus *Streptococcus* based on sequence comparisons of small-subunit (16S) rRNA genes, five species groups of viridans group streptococci were demonstrated (4) in addition to the pyogenic group (beta-hemolytic, large-colony formers). These nonpyogenic groups were designated the *S. mitis* group, the *S. anginosus* group, the *S. mutans* group, the *S. salivarius* group, and the *S. bovis* group. Several streptococcal species were not unequivocally assigned and remain ungrouped (1, 2). Among alpha-hemolytic streptococci, *S. pneumoniae* can be separated from other streptococci of the viridans group through bile solubility and optochin susceptibility. However, phenotypic characterization and taxonomic considerations place *S. pneumoniae* into the *S. mitis* group (4). The relationship of *S. pneumoniae* to other species of the *S. mitis* group is so close that 16S rRNA gene analysis reveals greater than 99% identity to the nucleotide sequences of *S. mitis* and *S. oralis* and the current concept of separate species in this group has been challenged (5). A closely related species, *S. pseudopneumoniae*, was split off from *S. pneumoniae* several years ago (6). Strains are nonencapsulated, insoluble in bile, and optochin susceptible only when incubated in ambient air. Strains are often isolated from respiratory tract infections in patients with pre-disposing conditions such as chronic obstructive pulmonary disease (COPD) (7).

*Streptococcus* comprises currently more than 100 recognized species—a number that can certainly be expected to rise with the increasing availability of next-generation sequencing technologies. More than 10 novel species have been validly published in the last 5 years alone. Most of these were found in the oral cavity and gastrointestinal tract of various mammals and have so far not been shown to play a role in human infections. This chapter focuses on well-known and novel streptococcal species found in human specimens and covers changes that were applied to the taxonomy of streptococci during recent years. Streptococci are fimbriated of the order Lactobacillales and belong to the family of *Streptococaceae*. Among the currently established 17 different genera of catalase-negative Gram-positive cocci are several genera that were split off from the genus *Streptococcus* some time ago, such as *Enterococcus* and *Lactococcus*, or more recently *Abiotrophia*, *Granulicatella*, *Facklamia*, and *Globicatella*. For excellent reviews on the topic, see references 1 and 2. While streptococcal species designation based solely on the hemolysis reaction, colony size, and the presence of Lancefield antigens has several limitations for correct species identification, this traditional streptococcal classification system is well established and still of value to the clinical microbiologist and health care provider. It correlates with clinical syndromes caused by different species and enables a first distinction of broad categories of streptococci that is useful for the choice of further tests and guidance of empirical treatments. The information and the identification schemes presented in this chapter therefore adhere in many aspects to the phenotypic classification system.

The classical differentiation of streptococci separates the group of beta-hemolytic streptococci from the group of non-beta-hemolytic streptococcal species. Beta-hemolytic streptococci, also referred to as pyogenic streptococci, include the human-pathogenic species *S. pyogenes*, *S. agalactiae*, *S. dysgalactiae* subsp. *equisimilis*, and a number of primarily veterinary pathogens. The designation “pyogenic streptococci” is more precise, since the group includes species that are non-beta-hemolytic like *S. dysgalactiae* subsp. *dysgalactiae* and the term excludes beta-hemolytic strains of the *S. anginosus* group, which belong to the viridans group streptococcal group. The small colony size of streptococci from the anginosus group (≤0.5 mm) helps to distinguish them from the large-colony-forming (>0.5-mm colonies) streptococci of the pyogenic group. Species from the pyogenic or beta-hemolytic group are further characterized by the presence of Lancefield antigens, which correlate to some extent with the proper streptococcal species designations. While the B antigen is limited to *S. agalactiae*, the Lancefield group A antigen has been detected not only in *S. pyogenes* but also in *S. dysgalactiae* subsp. *equisimilis* isolates (3) and in species from the *S. anginosus* group (Table 1). Correlation with other Lancefield antigens is even more complicated, and molecular taxonomic studies led to novel species designations, presented below and in Table 1.

The group of nonpyogenic streptococci includes mostly alpha-hemolytic as well as nonhemolytic and even beta-hemolytic streptococcal species from the large category of viridans group streptococci. In a study of the genus *Streptococcus* based on sequence comparisons of small-subunit (16S) rRNA genes, five species groups of viridans group streptococci were demonstrated (4) in addition to the pyogenic group (beta-hemolytic, large-colony formers). These nonpyogenic groups were designated the *S. mitis* group, the *S. anginosus* group, the *S. mutans* group, the *S. salivarius* group, and the *S. bovis* group. Several streptococcal species were not unequivocally assigned and remain ungrouped (1, 2). Among alpha-hemolytic streptococci, *S. pneumoniae* can be separated from other streptococci of the viridans group through bile solubility and optochin susceptibility. However, phenotypic characterization and taxonomic considerations place *S. pneumoniae* into the *S. mitis* group (4). The relationship of *S. pneumoniae* to other species of the *S. mitis* group is so close that 16S rRNA gene analysis reveals greater than 99% identity to the nucleotide sequences of *S. mitis* and *S. oralis* and the current concept of separate species in this group has been challenged (5). A closely related species, *S. pseudopneumoniae*, was split off from *S. pneumoniae* several years ago (6). Strains are nonencapsulated, insoluble in bile, and optochin susceptible only when incubated in ambient air. Strains are often isolated from respiratory tract infections in patients with pre-disposing conditions such as chronic obstructive pulmonary disease (COPD) (7).
type strain as an S. gordonii strain and the subsequent replacement by a new S. mitis type strain (NCTC12261') (14).

The small-colony-forming S. anginosus group consists of the three distinct species S. anginosus, S. constellatus, and S. intermedius (15) and the two recently described species S. anginosus subsp. whileyi and S. constellatus subsp. viroergensis (16). It includes streptococcal species previously referred to as Lancefield group F streptococci, “S. milleri” group or “S. milleri,” but “S. milleri” has no standing taxonomically. The S. mutans group comprises the species S. mutans, S. sobrinus, S. criceti, S. rattii, S. downei, and numerous other species that have been identified only from animals thus far (S. ferus, S. macacae, S. hyovaginalis, and S. devriesi).

The human species S. salivarius, S. vestibularis, and S. thermophilus, which is found in dairy products, belong to the S. salivarius group. The whole S. salivarius group is closely related to the S. bovis group. Some streptococcal species that are currently part of the S. bovis group (S. infantarius and S. alactolyticus) (17) were formerly part of the S. salivarius group (1).

The S. bovis group has experienced extensive taxonomic changes (17–19) in the past. These changes were made because DNA-DNA reassociation studies revealed considerable heterogeneity among the human isolates described as S. bovis biotypes. Four DNA clusters are currently recognized. DNA cluster I consists of animal strains of S. bovis and S. equinus, which were shown to belong to a single species. The earlier species name S. equinus has been formally adopted. DNA cluster II consists of S. gallopyricus, with three subspecies: subsp. gallopyricus (formerly S. bovis biotype 1), subsp. pasteurianus (formerly S. bovis biotype II.2), and subsp. macedonicus. DNA cluster III consists of S. infantarius (formerly S. bovis biotype II.1), with two subspecies: subsp. infantarius and subsp. coli (formerly called S. lacticiensis). DNA cluster IV consists of S. alactolyticus.

**DESCRIPTION OF THE GENUS**

Bacterial species belonging to the genus Streptococcus are catalase-negative, Gram-positive cocci of less than 2 μm that tend to grow in chains in liquid medium. Most species of the genus Streptococcus have a low G+C content of DNA ranging between 34 and 46%. The cell wall composition is typical for Gram-positive bacteria and consists mainly of peptidoglycan with glucosamine and muramic acid as amino sugars and galactosamine as a variable component. A variety of carbohydrates, surface protein antigens, and teichoic acid are attached to the cell wall and are, among other characteristics, responsible for intra- and interspecies differences among streptococci. Streptococci are facultative anaerobic bacteria. Due to a lack of heme compounds, streptococci are incapable of respiratory metabolism. Some species of the viridans streptococcal group and S. pneumoniae require 5% CO₂ levels for adequate growth, and the growth of many streptococcal species is enhanced in the presence of 5% CO₂. The optimum temperature for growth of most streptococci is around 37°C, while some species, like S. uberis, also grow at temperatures as low as 10°C. The complex nutritional requirements of streptococci are usually provided by the addition of blood or serum to the growth medium. Glucose and other carbohydrates are metabolized fermentatively with lactic acid as the major metabolic end product. The addition of glucose or other carbohydrates to liquid medium enhances growth but lowers the pH, resulting in growth inhibition unless the medium is highly buffered (e.g., Todd-Hewitt broth [THB]). Leucine aminopeptidase (LAP) is produced by all streptococci and enterococci but can

*Symbols and abbreviations: +, positive; −, negative; v, variable.
*²S. dysgalactiae subsp. dysgalactiae is alpha-hemolytic on sheep blood agar plates.
*²S. equi subsp. zoopneumoniae, S. canis, and S. porcinus are primarily animal pathogens that are only rarely isolated from humans.
*²Species included in the S. anginosus group can be beta-hemolytic, alpha-hemolytic, or nonhemolytic on sheep blood agar plates.
*²Size: large, >0.5 mm after 24-h incubation; small, <0.5 mm.
*²Presence of the enzyme pyrrolidonyl aminopeptidase.
*²CAMP factor reaction (cohemolysis in the presence of the Staphylococcus aureus CAMP factor).
*²Voges-Proskauer test (formation of acetoin from glucose fermentation).
*²Parenthetical entries represent hosts from which the organism is only rarely isolated.
also be found in lactococci, pediococci, and other catalase-negative Gram-positive cocci. LAP production helps to distinguish these species from the LAP-negative Aerococcus species and Leuconostoc. All streptococci are catalase negative upon exposure to 3% hydrogen peroxide with the exception of \textit{S. didelphis}, a veterinary pathogen (20). False-positive catalase reactions may occur if bacteria are grown on blood-containing medium.

**EPIDEMIOLOGY AND TRANSMISSION**

Streptococci can cause infections in humans and in many different animal species, including mammals and fish. Different species exhibit a high virulence potential, but even the highly pathogenic streptococcal species are frequently found as colonizing strains. \textit{S. pneumoniae} was responsible for approximately 31,600 invasive infections in the United States in 2012, leading to an estimated 3,300 deaths (http://www.cdc.gov/abcs/reports-findings/surv-reports.html) and was found as a colonizing bacterial species in many asymptomatic carriers. The asymptomatic carriage rate for \textit{S. pneumoniae} differs considerably between children and adults. Detection rates of 30 to 70% have been reported for young children, depending on the sampling method, while carriage rates among healthy adults are often reported to be below 5% (21, 22). Significantly higher colonization rates for adults living in households with preschool children suggests the occurrence of household transmission between parents and their children (23).

Due to active bacterial surveillance in the emerging infections program network (24), reliable epidemiologic data on invasive infections due to \textit{S. pneumoniae} (described above), \textit{S. pyogenes} (group A), and \textit{S. agalactiae} (group B) have been obtained for a population of more than 30 million people in the United States during 2012. National estimates are that \textit{S. pyogenes} caused 10,700 cases of invasive disease and 1,100 deaths with the peak of infections in people older than 65 years. Invasive infections due to \textit{S. agalactiae} were second to those due to \textit{S. pneumoniae}, with an estimated 28,150 cases and 1,865 deaths in 2012. Reflecting the ongoing changes in the epidemiology of group B streptococcal (GBS) disease, the highest attack rates were observed in patients less than 1 year and adults greater than 65 years of age. Apart from causing invasive infections, pyogenic streptococci are frequently encountered as colonizing strains. While asymptomatic pharyngeal colonization with \textit{S. pyogenes} occurs in less than 5% of the adult population, \textit{S. agalactiae} colonization rates of the urogenital and gastrointestinal tracts can be demonstrated in 10 to 30% of the female as well as the male population. No significant differences are observed in the colonization rates of pregnant and nonpregnant women.

Transmission of streptococcal infections can occur by different routes. Pathogenic species like \textit{S. pyogenes} and \textit{S. pneumoniae} are primarily transmitted through droplets or direct contact. Transmission can first lead to colonization with the potential for the development of a subsequent infection. Transmission from mother to child is typical for neonatal invasive \textit{S. agalactiae} infections. Newborns acquire the bacteria usually during delivery, although prenatal transmissions leading to stillbirths occur. Postnatal transmissions, from the mother or health care personnel to infants, are probably responsible for the majority of late-onset neonatal infections. Another streptococcal species transmitted from mother to child is the tooth decay-causing species \textit{S. mutans}; transmission occurs during early infancy most probably through oral secretions. Infections due to viridans group streptococci, which are part of the oral microbiota, do not require a prior transmission; they most often occur as endogenous infections.

Streptococcal infections do not represent classical zoonoses. Most species have a preferred host, while occasional animal-to-human transmissions do occur, as in the case of \textit{Streptococcus suis} (25). Genotypic and phenotypic analyses of animal and human strains show distinct differences between strains causing human infections and veterinary isolates. For large-colony-forming group C and G streptococci, such an analysis led to an important change in species designations (26, 27). Currently, all beta-hemolytic group C and L and human group G streptococci are defined as \textit{S. dysgalactiae} subsp. \textit{equisimilis}, while alpha-hemolytic group C streptococcal animal isolates are classified as \textit{S. dysgalactiae} subsp. \textit{dysgalactiae} and animal group G streptococcal strains as \textit{S. canis} (28). Other closely related veterinary species are \textit{S. equi} subsp. \textit{equi} and \textit{S. equi} subsp. zoopneumoniae. The predominant reservoir for \textit{S. dysgalactiae} subsp. \textit{equisimilis} strains is the human host, and transmission usually occurs among humans.

**CLINICAL SIGNIFICANCE**

**Streptococcus pyogenes** (Group A Streptococci)

\textit{S. pyogenes} colonizes the human throat and skin and has developed complex virulence mechanisms to avoid host defenses (29, 30). The upper respiratory tract and skin lesions serve as primary focal sites of infections and principal reservoirs of transmission. \textit{S. pyogenes} can cause superficial or deep infections due to toxin-mediated and immunologically mediated mechanisms of disease. \textit{S. pyogenes} is the most common cause of bacterial pharyngitis and impetigo. In the past, \textit{S. pyogenes} was a common cause of childhood fever or puerperal sepsis. \textit{S. pyogenes} is responsible for deep or invasive infections, especially bacteremia and sepsis, and deep soft tissue infections, such as erysipelas, cellulitis, and necrotizing fasciitis. Less common presentations include myositis, osteomyelitis, septic arthritis, pneumonia, menigitis, endocarditis, pericarditis, and severe neonatal infections following intrapartum transmission. One or more erythrogenic exotoxins produced by \textit{S. pyogenes} may cause a confluent erythematous sandpaper-like rash characteristic of scarlet fever. While systemic toxic effects occur rarely with scarlet fever, severe clinical manifestations in streptococcal toxic shock syndrome (STSS) may result from massive superantigen-induced cytokine and lymphokine production. Nonsuppurative complications include poststreptococcal glomerulonephritis and acute rheumatic fever. While either of these conditions may follow pharyngitis, only glomerulonephritis is linked with skin infections due to \textit{S. pyogenes}. \textit{S. pyogenes} has also been associated with pediatric autoimmune neuropsychiatric disorders (31).

The causes of the emergence of STSS, frequently accompanied by necrotizing fasciitis, and the resurgence of invasive \textit{S. pyogenes} infections since the mid-1980s are mostly unexplained (32). \textit{S. pyogenes} remains exquisitely susceptible to penicillin. Efforts to find highly virulent clones include subtyping of \textit{S. pyogenes} by serological determination of the surface M protein or genetic detection of the emm genes, encoding the M protein. However, despite the continuous exposure and subsequent type-specific immunity, the most prevalent M types associated with STSS continue to be M1
and M3, together accounting for approximately 50% of invasive infections. Since identical strains have accounted for less serious infections (33), host factors and comorbid conditions account for different diseases. The incidence of STSS seems highest among young children, particularly those with varicella, and the elderly. Other persons at risk include those with diabetes mellitus, chronic cardiac or pulmonary diseases, HIV infection, and intravenous drug or alcohol abuse. The risk for severe invasive infection in contacts has been estimated to be 200 times greater than for the general population, but most contacts are asymptptomatically colonized (34).

**Streptococcus agalactiae (Group B Streptococci)**

*S. agalactiae* was first identified as the cause of bovine mastitis at the end of the 19th century. Since the 1970s, it has been reported as the cause of invasive neonatal infections. Neonatal infections present as two different clinical entities: early-onset neonatal disease, characterized by sepsis and pneumonia within the first 7 days of life; and late-onset disease with meningitis and sepsis between 7 days and 3 months of age. The most important risk factor for the development of invasive neonatal disease is the colonization of the maternal urogenital or gastrointestinal tract by *S. agalactiae*, which is found in 10 to 30% of pregnant women. Prevention of early-onset neonatal infections can be achieved in the majority of cases by administration of intrapartum antibiotic prophylaxis starting at least 4 hours before delivery. Official CDC recommendations for the prevention of neonatal *S. agalactiae* infections were first issued in 1996 and then revised in 2002 and 2010 (35). These guidelines resulted in a substantial decline of early-onset neonatal GBS disease. Invasive *S. agalactiae* infections of adult patients may be observed as postpartum infections or in immunocompromised adult patients with alcoholism, diabetes mellitus, cancer, or HIV infection (36). The spectrum of infections in adult patients includes pneumonia, bacteremia, meningitis, endocarditis, urinary tract infections, skin and soft tissue infections, and osteomyelitis.

**Streptococcus dysgalactiae subsp. equisimilis (Human Group C and G Streptococci)**

Human isolates of large-colony-forming beta-hemolytic streptococci harboring the Lancefield group C or group G antigens belong to this novel species (26, 27). While most isolates of this species possess either the Lancefield group C or G antigen, strains harboring the Lancefield group L as well as the group A antigen (3) have been described. The clinical spectrum of disease caused by *S. dysgalactiae* subsp. *equisimilis* resembles infections caused by *S. pyogenes* (28). The responsible strains harbor genes similar to virulence factor genes of *S. pyogenes*, such as *emm*-like genes, and can be isolated from upper respiratory tract infections, skin infections, soft tissue infections, and invasive infections, such as necrotizing fasciitis, STSS, bacteremia, and endocarditis. However, convincing reports about scarlet fever due to *S. dysgalactiae* subsp. *equisimilis* have so far not been published. Similar to what has been seen with *S. pyogenes*, cases of glomerulonephritis (GN) and acute rheumatic fever (ARF) have been reported (37, 38) following *S. equi* subsp. *zooepidemicus* (GN) and *S. dysgalactiae* subsp. *equisimilis* (GN and ARF) infections.

**Streptococcus pneumoniae**

*S. pneumoniae* is described separately in this section due to its clinical features that distinguish it from other species of the *S. mitis* group. *S. pneumoniae* is the most frequently isolated respiratory pathogen in community-acquired pneumonia (CAP). In as many as 30% of CAP cases, *S. pneumoniae* can be found in blood cultures of patients. *S. pneumoniae* is also a major cause of meningitis, leading to high morbidity and mortality in pediatric and adult patients. The most frequently observed infection due to *S. pneumoniae* is otitis media, with an estimate of one infection for every child up to the age of 6 in the United States. Other infections due to *S. pneumoniae* include sinusitis, parotitis, and rare cases of endocarditis. *S. pneumoniae* colonizes the upper respiratory tract especially in children, without evidence of infection. Prevention of pneumococcal infections can be achieved by immunization with a 23-valent capsular polysaccharide vaccine in adults or the 13-valent conjugate vaccine in children. Widespread use of vaccines has resulted in a reduction of invasive pneumococcal infections during the past several years but also in changes of the serotypes responsible for invasive and noninvasive infections (39–41). The recent introduction of the 13-valent conjugate vaccine resulted in a general decrease of nasopharyngeal colonization rates with the vaccine-included serotypes in vaccinated children (42, 43). First data on the impact of the 13-valent vaccine on the burden of invasive disease in children are also promising (44, 45).

**Streptococcus mitis Group**

*S. mitis*, *S. sanguinis*, *S. parasanguinis*, *S. gordoni*, *S. crista tus*, *S. oralis*, *S. infantis*, *S. peroris*, *S. australis*, *S. sinensis*, *S. orisvati*, *S. oligofermentans*, *S. massiliensis*, *S. pseudopneumoniae*, and *S. pneumoniae* are members of this group. Members of the *S. mitis* group are regular commensals of the oral cavity, the gastrointestinal tract, and the female genital tract. The *S. mitis* group organisms can be found as members of the transient microbiota of the normal skin and may represent contaminants when isolated from blood cultures. At the same time, these species are the most frequently isolated bacteria in bacterial endocarditis in native valve and, less frequently, in prosthetic valve infections. Careful evaluation of the clinical situation is therefore crucial to correctly interpret the clinical significance of blood culture isolates from the *S. mitis* group. In neutropenic patients, *S. mitis* species found in a patient’s blood are often responsible for life-threatening sepsis and septic shock cases following immunosuppression by chemotherapy (46). Treatment of these infections is further complicated by high penicillin resistance rates.

**Streptococcus anginosus Group**

Species from this group (S. anginosus, S. constellatus, and S. intermedius) are commensals of the oropharynxal, urogenital, and gastrointestinal microbiota. While these organisms are strongly associated with abscess formation in the brain, oropharynx, or the peritoneal cavity, their role as invasive pathogens may be underrecognized (47). In addition, the *S. anginosus* group has recently been implicated as an emerging pathogen in the respiratory tract of cystic fibrosis patients (48). All species of this group are small-colony-forming bacteria (colony size, ≤0.5 mm) that can display variable patterns of hemolysis (alpha, beta, or gamma). Since they are strongly associated with abscess formation in the brain, oropharynx, or the peritoneal cavity, their role as invasive pathogens may be underrecognized (47). In addition, the *S. anginosus* group has recently been implicated as an emerging pathogen in the respiratory tract of cystic fibrosis patients (48). All species of this group are small-colony-forming bacteria (colony size, ≤0.5 mm) that can display variable patterns of hemolysis (alpha, beta, or gamma). Since they are strongly associated with abscess formation in the brain, oropharynx, or the peritoneal cavity, their role as invasive pathogens may be underrecognized (47). In addition, the *S. anginosus* group has recently been implicated as an emerging pathogen in the respiratory tract of cystic fibrosis patients (48). All species of this group are small-colony-forming bacteria (colony size, ≤0.5 mm) that can display variable patterns of hemolysis (alpha, beta, or gamma). Since they are strongly associated with abscess formation in the brain, oropharynx, or the peritoneal cavity, their role as invasive pathogens may be underrecognized (47). In addition, the *S. anginosus* group has recently been implicated as an emerging pathogen in the respiratory tract of cystic fibrosis patients (48).
tract, and *S. intermedius* is most often identified in abscesses of the brain or liver.

**Streptococcus salivarius Group**

Streptococcal species that belong to the *S. salivarius* group include *S. salivarius* and *S. vestibularis*. They have been primarily isolated from the oral cavity and blood. Another species of this group, *S. thermophilus*, is found only in dairy products. *S. salivarius* has been repeatedly reported as a cause of bacteremia, endocarditis, and meningitis (sometimes in a neonate), while *S. vestibularis* has not been clearly associated with human infection. Isolation of *S. salivarius* from blood cultures does correlate to some extent with neonoplasia (49, 50).

**Streptococcus mutans Group**

*S. mutans* and *S. sobrinus* belong to the *S. mutans* group. They are the most commonly isolated species of the group that originate from human clinical specimens, usually obtained from the oral cavity. *S. criceti*, *S. ratti*, and *S. downei* have occasionally been identified from human sources, while the other streptococcal species of the *S. mutans* group (*S. ferus*, *S. macacae*, *S. hyovaginalis*, and *S. deviresei*) have been identified only in animals. *S. mutans* is the primary etiologic agent of dental caries, and infection is transmissible. By 18 years of age, 85% of the population have at least one carious lesion (51). Permanent colonization with *S. mutans* occurs under normal living conditions in the Western world between the second and the end of the third year of life (51). Molecular analysis of mother and infant isolates reveals that strains are usually acquired from the mother and that the colonization rate of infants depends on the bacterial load of the mother (52). Analyses of streptococcal blood culture isolates show that *S. mutans* is the most frequently isolated species of this group in cases of bacteremia (1).

**Streptococcus bovis Group**

Extensive taxonomic changes have occurred in this group, and strains formerly known as human *S. bovis* isolates are designated as different species (see “Taxonomy” above). The group now includes *S. equinus*, *S. gallolyticus*, *S. infantarius*, and *S. lactolyticus*. Species from this group are frequently encountered in blood cultures of patients with bacteremia, sepsis, and endocarditis. The clinical significance of blood cultures growing streptococci from the *S. bovis* group lies in the association of (i) *S. gallolyticus* subsp. *gallolyticus* with gastrointestinal disorders, including colon cancer and chronic liver disease, and (ii) *S. gallolyticus* subsp. *pasteurianus* with meningitis (53–55).

**Other Streptococci Infrequently Isolated from Human Specimens**

Streptococcal species that are primarily animal pathogens are sometimes isolated from human hosts, in most cases from humans that are in close contact with animals. *S. suis*, *S. porcinus*, and *S. iniae* belong to this category. *S. suis* is a swine pathogen that has occasionally been isolated from cases of human meningitis and bacteremia. *S. suis* is encapsulated and appears to be alpha-hemolytic on sheep blood agar plates, although some strains are beta-hemolytic on horse blood agar. *S. suis* strains are positive for the Lancefield group antigen R, or T, which helps to distinguish them from the phenotypically similar species *S. gordoni*, *S. sanguinis*, and *S. parasanguinis*. Similar to *S. suis*, *S. porcinus* (Lancefield groups E, P, U, and V) is primarily a swine pathogen. Beta-hemolytic *S. porcinus* strains have rarely been isolated from human sources such as peripheral blood, wounds, and the female genital tract (56). Molecular studies of *S. porcinus* isolates from the female genital tract, however, indicate that these isolates belong to a novel species designated *S. pseudoporcinus* (57). *S. pseudoporcinus* may be more prevalent in the female genital tract than previously assumed (58). Strains can easily be misidentified as *S. agalactiae* due to isolation from the female genital tract, false-positive reactions with commercially available group B antisera, and a positive CAMP test reaction. *S. porcinus* and *S. pseudoporcinus* can be l- pyrrolidonyl-beta-naphthylamide (PYR) positive and do not hydrolyze hippurate, in contrast to *S. agalactiae*. *S. iniae* is a fish pathogen that is beta-hemolytic but does not possess any Lancefield group antigens. It has been isolated from soft tissue infections, bacteremia, endocarditis, and meningitis in people handling fish (59, 60). *S. iniae* isolates resemble *S. pyogenes* strains due to the fact that both are PYR positive. Beta-hemolysis of the species can be observed only around agar stabs or under anaerobic culture conditions. Commercial identification systems do not correctly identify the species; the failure to react with Lancefield group antisera is important to notice, since it is rare among beta-hemolytic streptococci. Very recently, a novel streptococcal species associated with the handling of fish has been reported as a human pathogen. The species has been designated *S. hongkongensis*; it is closely related to *S. iniae* and *S. parauberis* (61).

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

Specimens suspected of harboring streptococci should be collected by the methods outlined elsewhere in this Manual (chapter 18). Since many streptococcal species lose viability fairly quickly, it is best to place swabs in an appropriate moist transport medium and process specimens rapidly. If transport time is below 1 to 2 h, a special transport system is not absolutely necessary. *S. pyogenes* can safely be transported on dry swabs; desiccation enhances recovery from mixed cultures by suppression of the accompanying microbiota (62). Detailed recommendations for collection and storage of swabs from pregnant women to detect *S. agalactiae* colonization have been issued by the U.S. Centers for Disease Control and Prevention (35). These recommendations are summarized below under “Special Procedures for *Streptococcus agalactiae* Screening.”

**DIRECT EXAMINATION**

**Microscopy**

Microscopic examination shows streptococci as Gram-positive bacteria growing in chains of various lengths. *S. pneumoniae* isolates most often present as Gram-positive diplococci with an elongated appearance, but a reliable microscopic distinction of *S. pneumoniae* from enterococci and other streptococci is not possible. In blood culture specimens, *S. pneumoniae* tends to form chains of varying lengths, similar to other streptococci. Direct identification of streptococci by microscopic methods is most helpful in the case of clinical specimens from sterile body sites, such as cerebrospinal fluid. Tiny, irregular cocci in clumps of chains seen in abscess- or peritonitis-associated aspirates are suggestive of the *S. anginosus* group. Interpretation of Gram stain results from nonsterile body sites is difficult due to the resident microbiota, which frequently includes streptococci. Thus, for example, throat
swabs should not be examined by Gram stain for diagnosis of "strep" throat.

**Direct Antigen Detection of *S. pyogenes* from Throat Specimens**

*S. pyogenes* is the most common cause of acute pharyngitis and accounts for 15 to 30% of cases of acute pharyngitis in children and 5 to 10% of cases in adults. If the diagnosis can be provided rapidly, antibiotic therapy can be initiated promptly to relieve symptoms, to avoid sequelae, and to reduce transmission. Numerous assays for direct detection of the group A-specific carbohydrate antigen in throat swabs by agglutination methods or immunoassays (enzyme, liposome, or optical), also referred to as “rapid antigen assays,” have become commercially available during the past 2 decades. A list of FDA-cleared tests is accessible via the Internet (http://www.accessdata.fda.gov/scripts/cdrh/devicesatfda/index.cfm?Search_Term=866.3740). Although these tests provide rapid results and allow early treatment decisions, the throat culture remains the gold standard. Sensitivities of rapid antigen tests range from 70% to 96% and have never equaled that of culture (63, 64). Negative rapid antigen test results should therefore be confirmed by culture in children and adolescents when typical clinical signs are present (65). In adults, the confirmation of negative rapid antigen test results has not been regarded as necessary for many years, but the most recent Infectious Diseases Society of America (IDSA) guidelines challenge this concept (66). The specificity, however, is generally high, even though false-positive antigen results are seen from patients previously diagnosed and/or treated for *S. pyogenes* (67). Moreover, the low positive predictive value of rapid group A antigen tests in the adult population frequently results in prescribing unnecessary antimicrobial therapy (68).

**Antigen Detection of *S. agalactiae* in Urogenital Tract Samples**

Several different commercially available antigen detection tests have been developed for the identification of *S. agalactiae* in samples from the urogenital tract. Independent from the technique involved (latex agglutination, enzyme immunoassay, or optical immunoassay), without a prior cultural enrichment step, all of the currently available tests lack sufficient sensitivities to detect bacterial colonization with *S. agalactiae* (69). They are not recommended for screening of pregnant women by the CDC (35).

**Antigen Detection of *S. pneumoniae* in Urine Samples**

An immunochromatographic membrane test relying on the detection of the cell wall-associated polysaccharide that is common to all *S. pneumoniae* serotypes (C-polysaccharide antigen) (Binax NOW; Binax Inc., Portland, ME) has proven helpful for the identification of *S. pneumoniae* infections in adult patients, especially in patients that already received antibiotic treatment. In contrast to conventional diagnostic methods, reported sensitivities of antigen detection in urine samples range between 50 and 80%, and specificities are higher than 90% (70, 71). Following pneumococcal infection, the test can remain positive for about 1 to 6 months (72). Due to the fact that the test is also positive in *S. pneumoniae* carriage without infection, as is often observed among infants (73), it is of limited value in pediatric patients. The test should not be used in children below the age of 6 (73), and comprehensive studies on schoolchildren with lower colonization rates have not been performed. It can currently be recommended only in adults as an addition to conventional diagnostic culture techniques for *S. pneumoniae* (74) and is probably most helpful in patients who received antimicrobial treatment before cultures were obtained.

**Streptococcal Antigen Detection in CSF**

Commercially available antigen detection tests for the diagnosis of pathogenic microorganisms in cerebrospinal fluid (CSF) samples include reagents for the detection of *S. agalactiae* and *S. pneumoniae*. These tests have also been used on positive blood culture specimens. The tests are not recommended for routine use, as the results should not be used to change decisions about empiric therapy based on clinical and laboratory criteria (75). It has also been shown that the sensitivity of direct antigen detection in CSF is low (<30%) and offers no advantage over a conventional Cytospin Gram stain (76). However, very promising results have been published for the use of the *S. pneumoniae* urinary antigen test on CSF samples (77), an application for which the test received FDA clearance.

**Nucleic Acid Detection Techniques**

*S. pyogenes* A rapid method for the detection of *S. pyogenes* in pharyngeal specimens is based on a single-stranded chemiluminescent nucleic acid probe assay to identify specific rRNA sequences (Group A Streptococcus Direct Test [GP-ST]; Gen-Probe, Inc., San Diego, CA). This test performed well in comparative studies with the culture technique. Sensitivity and specificity for the probe test ranged from 89% to 95% and from 98% to 100%, respectively, in contrast to the results of the culture technique with a sensitivity of 98% to 99% (67, 78). These data suggest that the probe test may be suitable as a primary test or as a backup test for negative antigen tests, particularly for batch screening of throat cultures. Recently, a commercial PCR for the direct detection of *S. pyogenes* using the Illumigene system (Meridian Bioscience Inc., Cincinnati, OH) received FDA clearance. A multicenter evaluation study revealed an excellent sensitivity (99%) and specificity (99.6%) for this test (79).

*S. agalactiae* Several nucleic acid-based methods for the detection of *S. agalactiae* colonization in pregnant women have been developed and evaluated (80–82). Currently, 6 nucleic acid amplification tests (NAATs) received FDA clearance, of which 3 are performed following cultural enrichment while the 3 other tests are designed to be used directly on clinical samples. Molecular platforms used in these assays include the BD max system (Becton, Dickinson), the Smartcycler and Xpert technology (Cepheid, Sunnyvale, CA), and the Illumigene system (Meridian Bioscience). A current list of the approved tests can be accessed at the following website: http://www.fda.gov/medicaldevices/productsandmedicalprocedures/in vitrodiagnostics/ucm330711.htm. While the costs are exceedingly higher than for selective culture, these tests were designed to provide results within a short time, in order to be able to assess vaginal and/or rectal colonization status at the time of delivery. Although PCR tests performed at the time of delivery provide rapid results, this is often not sufficient to allow effective administration of peripartum antibiotics, since many women deliver within a few hours after hospital admission. Therefore, the CDC does not recommend performing routine screening by NAATs at
delivery. The most recent CDC recommendations for antenatal S. agalactiae screening include detection by NAAT, but only after prior cultural enrichment in selective broth (35). Enrichment procedures considerably increase the sensitivity of NAAT to detect S. agalactiae colonization.

**S. pneumoniae**

Several different laboratory-developed NAATs have been developed for the identification of S. pneumoniae from culture isolates. Tests are based on the detection of the genes for autolysin lytA, the pneumococcal surface antigen psaA, and the pneumolysin gene ply. Comparison of the ability to distinguish difficult-to-identify S. pneumoniae strains and closely related atypical streptococci revealed that the lytA-based PCR was the most specific method (83, 84). While results based on the detection of psaA are also acceptable, the different pneumolysin-targeted methods appear to be relatively nonspecific. So far, none of these assays are commercially available, and they have to be established as laboratory-developed tests. A quantitative real-time PCR based on the detection of the lytA gene directly from nasopharyngeal swabs has recently been published (85). The study showed promising results for the identification of patients presenting with pneumococcal pneumonia. Nucleic acid probes for the confirmation of cultured isolates as S. pneumoniae are commercially available (AccuProbe; GenProbe, San Diego, CA) (86). Detection relies on hybridization of a specific probe to 16S rRNA sequences, but the test fails to distinguish S. pseudopneumoniae from S. pneumoniae. These tests are not routinely performed for standard identification procedures but can aid in the identification of atypical S. pneumoniae isolates with unusual patterns of bile solubility and optochin susceptibility.

**ISOLATION PROCEDURES**

**General Procedures**

Streptococci are usually grown on blood agar medium because the assessment of the hemolytic reaction is important for identification. Growth of streptococci is often enhanced in the presence of an exogenous catalase source. Streptococcal species with low or absent hydrogen peroxide production, such as S. agalactiae, can be grown on other commonly used nonselective media without blood.

Agar media selective for Gram-positive bacteria (e.g., phenylethyl alcohol-containing agar or Columbia agar with colistin and nalidixic acid) support the growth of streptococci. The optimal incubation temperature range for most streptococcal species lies between 35°C and 37°C. Supplemental carbon dioxide (5% CO₂) or anaerobic conditions enhance the growth of many streptococcal species since streptococci are facultative anaerobes. Although some streptococci grow well in ambient air, incubation in 5% CO₂ is recommended for the culture of S. pneumoniae and other streptococcal species of the viridans group.

**Special Procedures for Streptococcus pyogenes Throat Cultures**

A properly performed and interpreted throat culture on a 5% sheep agar with Trypticase soy base incubated in air remains the gold standard for the diagnosis of S. pyogenes acute pharyngitis (87). The isolation of only a few colonies of S. pyogenes does not allow the differentiation between a carrier and an acutely infected individual and may reflect inadequate specimen collection (88). Lack of hemolysis, overgrowth and production of toxic bacterial metabolites by the normal upper respiratory tract microbiota, or depletion of substrates often leads to false-negative results or delays caused by labor-intensive resolution steps. In order to enhance S. pyogenes isolation, numerous studies analyzed incubation conditions in anaerobic or CO₂-enriched atmosphere as well as different media selective for beta-hemolytic streptococci (89–91). Due to cost restraints and an uncertain benefit, these additional efforts are not generally recommended for S. pyogenes but may increase the yield of other beta-hemolytic streptococci. After 18 to 24 h of incubation, culture plates should be examined for growth of beta-hemolytic colonies. Negative cultures should be reexamined after an additional 24-h incubation period. Presumptive identification of S. pyogenes can be achieved by susceptibility to bacitracin or testing for PYR activity. Other beta-hemolytic streptococci are occasionally positive in one of these tests but not in both. Definitive diagnosis includes the demonstration of the Lancefield group A antigen by immunossay. Although other species may rarely possess the group A antigen (Table 1), they lack PYR activity (1).

**Special Procedures for Streptococcus agalactiae Screening**

Early-onset neonatal group B streptococcal (S. agalactiae) infections can be prevented by administration of antibiotic prophylaxis during delivery (92). An essential requirement for efficient prophylaxis is the reliable detection of colonization with S. agalactiae before delivery. Screening should be performed between weeks 35 and 37 of pregnancy. A lower vaginal and rectal swab (i.e., inserted through the anal sphincter) should be obtained with either one swab or two different swabs and placed in an appropriate transport medium (Amies or Stuart’s with or without charcoal; see chapter 18). While culture counts decline to some extent, the viability of S. agalactiae is preserved in transport medium kept at room temperature or 4°C for up to 4 days. To reduce costs, vaginal and rectal swabs can be placed in a single transport medium tube and cultured together. Swabs should be cultured in selective broth medium for 18 to 24 hours at 35 to 37°C in ambient air or 3% CO₂ and subsequently plated on tryptic soy agar (TSA) blood agar plates or S. agalactiae selective agar medium. Selective broth medium is commercially available (Trans-Vag broth supplemented with 5% sheep blood from Thermo Fisher Scientific Remel Products, Lenexa, KS; or LIM broth from BD BBL, Franklin Lakes, NJ). Selective broth can also be prepared by supplementation of Todd-Hewitt Broth with nalidixic acid (15 μg/ml) and colistin (10 μg/ml) or supplementation of THB with nalidixic acid (15 μg/ml) and gentamicin (8 μg/ml). TSA blood agar plates should be checked for typical colonies (narrow zone of beta-hemolysis) of S. agalactiae after 24 and 48 h of incubation at 35 to 37°C. Identification of S. agalactiae is then achieved by standard techniques as described below. Selective media relying on the detection of the orange S. agalactiae pigment (Granada medium, StrepC Carrot broth from Hardy Diagnostics, Santa Maria, CA; or GBS broth from Northeast Laboratory Services, Winslow, ME) are highly specific and sensitive (93, 94). Subculture of enrichment broth on Granada medium enhances sensitivity and obviates the need for further identification steps due to excellent specificity, but nonhemolytic strains cannot be detected with pigment-dependent selective medium. NAAT-based detection of S. agalactiae following overnight enrichment broth increases sensitivity and reduces detection time in comparison to conventional selective culture (95). It is recommended as an alternative screening method by the most recent CDC guidelines (35). For the identification
of questionable cultured strains as S. agalactiae, a 16S RNA-based nucleic acid detection test (AccuProbe; GenProbe, San Diego, CA) or matrix-assisted laser desorption ionization—time of flight mass spectrometry (MALDI-TOF MS) can be helpful.

IDENTIFICATION

Description of Colonies

Colonies of streptococci usually appear gray or almost white with moist or glistening features. Dry colonies are rarely encountered. Colony size varies between the different beta-hemolytic species and helps to distinguish groups of streptococci. Beta-hemolytic streptococci of the pyogenic group (S. pyogenes, S. agalactiae, and S. dysgalactiae subsp. equisimilis) form colonies of >0.5 mm after 24 h of incubation, in contrast to beta-hemolytic strains of the S. anginosus group (formerly called the “S. milleri” group), which present with pinpoint colonies of ≤0.5 mm after the same incubation time (Fig. 1). Members of the S. anginosus group emit a distinct odor resembling butterscotch or caramel, presumably due to the production of diacetyl by the species belonging to this group. Among the beta-hemolytic species of the pyogenic group, S. agalactiae produces the largest colonies with a relatively small zone of hemolysis. Nonhemolytic S. agalactiae strains do occur and resemble enterococci.

Within the group of alpha-hemolytic streptococci, S. pneumoniae has a colony morphology that helps to distinguish pneumococcal isolates from other streptococci of the viridans group. Due to the production of capsular polysaccharide, colonies glisten and appear moist. Colonies may be large and mucoid if large amounts of capsular polysaccharide are made, a feature often encountered in serotype 3.
strains. This phenotype is usually typical for *S. pneumoniae* but can also occasionally be observed in *S. pyogenes*. Another characteristic feature of *S. pneumoniae* is the central navel-like depression of the colonies that is caused by the pneumococcal autolysin. Other viridans group streptococci lack this feature and have a dome-like appearance; however, up to 20% of *S. pneumoniae* strains display a phenotype that is indistinguishable from that of viridans group streptococci (96). Nonhemolytic gray colonies are typical for species of the *S. bovis* and *S. salivarius* groups. Typical streptococcal colony morphologies are presented in Fig. 1.

### Identification of Beta-Hemolytic Streptococci by Lancefield Antigen Immunnoassays

Commercially available Lancefield antigen grouping sera are primarily used for the differentiation of beta-hemolytic streptococci. Products for rapid antigen extraction and subsequent agglutination can be obtained from many different suppliers. The presence of the Lancefield group B antigen in beta-hemolytic isolates from human clinical specimens correlates with the species *S. agalactiae*, but cross-reactivity of the group B antigen with the newly described species *S. pseudoporporicus* has been reported (58). Similarly, the detection of the Lancefield group F antigen in small-colony-forming streptococci from human clinical material allows a fairly reliable identification of a strain as a member of the *S. anginosus* group. The presence of Lancefield group A, C, or G antigens necessitates further testing (Table 1). Beta-hemolytic streptococcal strains not reacting with any of the Lancefield antisera are rare and should be further identified by phenotypic tests or nucleic acid detection techniques.

### Identification of Beta-Hemolytic Streptococci with Phenotypic Tests and MALDI-TOF MS

A number of streptococcal identification products incorporating batteries of physiologic tests are commercially available (see chapters 4 and 19). In general, these products perform well with commonly isolated pathogenic streptococci but may lack accuracy for identifying streptococci of the viridans group. The MALDI-TOF (Bruker, Daltonics, Billerica, MA)-based bacterial identification also has limitations concerning several streptococcal species. While among beta-hemolytic streptococci, identification of *S. pyogenes* and *S. agalactiae* corresponds well to conventional tests, the correct identification of *S. dysgalactiae* to the species level cannot be achieved for the majority of isolates (97). Further problems include the misidentification of *S. mitis* or *S. oralis* as *S. pneumoniae* and continuing difficulties in the correct species identification of viridans group streptococci. For the bulk of pathogenic streptococci isolated in clinical laboratories (e.g., *S. pyogenes*, *S. agalactiae*, and *S. pneumoniae*), serologic or presumptive physiologic tests (as described below) still offer an acceptable alternative to commercially available identification systems.

### PYR Test

The presence of the enzyme pyrrolidonyl aminopeptidase is often tested to distinguish *S. pyogenes* from other beta-hemolytic streptococci. Hydrolysis of *L*-pyrrolidonyl-betanaphthylamide by the enzyme to β-naphthylamide produces a red color with the addition of cinnamaldehyde reagent (see chapter 19). The beta-hemolytic streptococcal species *S. iniae*, *S. porcinus*, and *S. pseudoporporicus* can be PYR positive but are only rarely identified in human clinical specimens. PYR spot tests are commercially available. It is important to distinguish *Streptococcus* from *Enterococcus* prior to PYR testing, and strains of other related genera may be PYR positive (including the genera *Achromobacter*, *Aerococcus*, *Enterococcus*, *Gemella*, and *Lactococcus*). However, PYR-positive beta-hemolytic enterococcal isolates typically present with a different colonial morphology (smaller zone of hemolysis and bigger colony size) and, when combined with other phenotypic characteristics (see chapter 23), may be distinguished from streptococci. To avoid false-positive reactions caused by other PYR-positive bacterial species (for example, *staphylococci*), the test should be performed only on pure cultures.

### Bacitracin Susceptibility

With rare exceptions, *S. pyogenes* displays bacitracin susceptibility, in contrast to other human beta-hemolytic streptococci. Together with Lancefield antigen determination, it can be used for the identification of *S. pyogenes*, since beta-hemolytic strains of other streptococcal species that may contain the group A antigen are bacitracin resistant. The test can also be used to distinguish *S. pyogenes* from other PYR-positive beta-hemolytic streptococci (*S. iniae* and *S. porcinus*). A bacitracin disk (0.04 U) is applied to a sheep blood agar (SBA) plate that has been heavily inoculated for 4 colonies of a pure culture of the strain to be tested. It is important to perform the test from a subculture on SBA, since placement of bacitracin disks on primary plates is not sensitive enough. After overnight incubation at 35°C in 5% CO2, any zone of inhibition around the disk is interpreted as indicating susceptibility. Importantly, bacitracin-resistant *S. pyogenes* isolates have been reported and clusters of bacitracin-resistant strains were observed in several European countries (98–100).

### VP Test

The Voges-Proskauer (VP) test detects the formation of acetoin from glucose fermentation. It is performed on streptococci as a modification of the classical VP reaction that is used for the differentiation of enteric bacteria. Small-colony-forming beta-hemolytic streptococci of the *S. anginosus* group that are VP positive may be distinguished from large-colony-forming beta-hemolytic streptococci harboring identical Lancefield antigens (A, C, or G). Streptococci of the *S. mitis* group are VP negative. For the modified VP reaction as described by Facklam and Washington in the 5th edition of this Manual (160), the culture growth of an entire agar plate is used to inoculate 2 ml of VP broth and incubated at 35°C for 6 h. Following the addition of 5% α-naphthol and 40% KOH, the tube is shaken vigorously for a few seconds and incubated at room temperature for 30 min. A positive test yields a pink-red color that results from the reaction of diacetyl with guanidine.

### BGUR Test

Detection of β-glucuronidase (BGUR) activity distinguishes *S. dysgalactiae* subsp. *equisimilis* strains containing Lancefield group antigen C or G from BGUR-negative, small-colony-forming streptococci of the *S. anginosus* group with the same Lancefield group antigens. Rapid methods for the BGUR test are commercially available. Alternatively, a rapid fluorogenic assay with methylumbelliferyl-β-D-glucuronide (MUG)-containing MacConkey agar, often used for *Escherichia coli*, has been described (101).

### CAMP Test

The CAMP factor reaction was first described in 1944 by Christie, Atkins, and Munch-Petersen and refers to the synergistic lysis of erythrocytes by the beta-hemolysin of
**FIGURE 2** CAMP factor test. Arrowhead-shaped zone of hemolysis in the zone of the *S. aureus* beta-hemolysin. (A) Clinical isolate of a weakly beta-hemolytic *S. agalactiae* strain. (B) Beta-hemolytic *S. agalactiae* strain O90R. (C) Nonhemolytic *S. agalactiae* strain R268. doi:10.1128/9781555817381.ch22.f2

**Staphylococcus aureus** and the extracellular CAMP factor of *S. agalactiae*. The gene (*cfr*) and its expression can be demonstrated in the vast majority (>98%) of *S. agalactiae* isolates, but CAMP-negative mutants do occur. The strain to be tested and a Staphylococcus aureus strain (ATCC 25923) are streaked onto a sheep blood agar plate at a 90° angle. Plates are incubated in ambient air overnight at 36 ± 1°C. A positive reaction can be detected by the presence of a triangular zone of enhanced beta-hemolysis in the diffusion zone of the beta-hemolysin of *S. aureus* and the CAMP factor (Fig. 2). CAMP factor-positive strains can also be detected by a method using β-lysine-containing disks (Remel Inc., Lenexa, KS) or by a rapid CAMP factor spot method (102). Despite the fact that close homologs of the CAMP factor gene are present in many *S. pyogenes* strains, most beta-hemolytic streptococci other than *S. agalactiae* are negative in the above-described CAMP factor test, except for the rare human isolates of *S. mitis*, *S. porcinus*, and *S. pseudoporcinus*. Several Gram-positive rods including corynebacteria and *Listeria monocytogenes* strains may also be CAMP factor positive.

**Hippurate Hydrolysis Test**

The ability to hydrolyze hippurate is an alternative test for the presumptive identification of *S. agalactiae*. A rapid version of the test, as it is used for campylobacters, can be performed by incubating a turbid suspension of bacterial cells in 0.5 ml of 1% aqueous sodium hippurate for 2 h at 35°C. Glycine formed as an end product of hippurate hydrolysis is detected by adding ninhydrin reagent and observing the development of a deep purple color, signifying a positive test (103). Streptococci other than *S. agalactiae* may also be hippurate hydrolysis positive, especially viridans group streptococci.

**Identification of *S. pneumoniae* and Viridans Group Streptococci**

The correct species identification of viridans group streptococci other than *S. pneumoniae* is challenging. Recent taxonomic changes and identification of novel streptococcal species have further complicated matters. The number of recognized species in this group is now greater than 30. The viridans group includes alpha-hemolytic, nonhemolytic (*S. salivarius* group and *S. bovis* group), and beta-hemolytic (*S. anginosus* group) streptococcal strains. All of the viridans group streptococci are leucine aminopeptidase positive and pyrrolidonaryl arylamidase negative. Conventional microbiologic tests are limited with respect to species identification but are helpful in placing isolates into the correct streptococcal groups (Table 2). Brighton et al. described an identification scheme based on phenotypic tests that allowed the differentiation and correct species identification of the majority of viridans group species (104). The scheme requires the evaluation of enzymatic reactions performed by in-house fluorogenic tests that are not commercially available. Importantly, most clinical laboratories must strive for group, instead of species, classifications with current phenotypic test panels.

The API tests (bioMérieux, Marcy l’Etoile, France) offer species identification of viridans group streptococci. While many species from this group are identified with acceptable accuracy, several species have not been included in the database. Comparisons of molecular species identification by DNA reassociation studies with the results of the API Rapid ID 32 Strep system showed that more than 85% of 156 strains from streptococcal species included in the database were correctly identified (105). However, for species not included in the database, more than 50% were incorrectly identified by the test (105). Evaluation studies performed under routine clinical conditions appear to yield less favorable results (106). Evaluations of the Vitek 2 (bioMérieux) automated phenotypic identification system showed that streptococcal group assignment for 75% of isolates were concordant with 16S rRNA gene sequencing data (107). In another study, correct identification at the species level was accomplished for only 55% of the tested isolates (108). Similarly, some publications on MALDI-TOF MS technology report major problems with the correct species identification of streptococci from the viridans group and a frequent misidentification of *S. pneumoniae* (97, 109). However, very recent publications indicate that a different system (Vitek MS; bioMérieux) has solved this problem for *S. pneumoniae* (110, 111). Novel commercial identification systems for streptococci include the FDA-cleared Verigene Gram-positive blood culture (BC-GP) nucleic acid test (Nanosphere, Inc., Northbrook, IL) and the FilmArray platform (FA; BioFire, Salt Lake City, UT) for the identification of bacterial pathogens directly from blood culture bottles (112, 113). While very promising results are published for major bacterial pathogens, including *S. pyogenes* and *S. agalactiae*, a reliable species identification for *S. pneumoniae* and streptococci from the viridans group is currently not possible with these tests. In conclusion, phenotypic and automated species identification of viridans group streptococci remains challenging, and acceptable results can currently be achieved only at the group level.
Molecular methods may offer alternative approaches to conventional phenotypic identification schemes. The most common molecular identification method, 16S rRNA gene sequencing, does not yield reliable species identification for several species including *S. mitis*, *S. oralis*, and *S. pneumoniae*. The 16S rRNA gene sequences are more than 99% identical. Sequence determination of the manganese-dependent superoxide dismutase gene sodA appears to be more reliable. In contrast to 16S rRNA sequencing, it allows the differentiation of *S. mitis*, *S. oralis*, and *S. pneumoniae* and the correct identification of streptococcal species from the viridans group.

Descriptions of the species belonging to the viridans group streptococci are given below, and physiological traits of the groups are shown in Table 2.

*S. mitis* Group
The large number of different streptococcal species belonging to the *S. mitis* group has been mentioned earlier. This group of predominantly alpha-hemolytic streptococci includes several species of known clinical significance together with others for which few or no clinical data have been collected. Among the phenotypic characteristics of the species in this group, extracellular polysaccharide production is negative for *S. mitis* strains but is a variable characteristic of *S. oralis* isolates. This feature correlates with the smooth colony surface of many *S. oralis* strains and the rough and dry appearance of *S. mitis* colonies.

*S. anginosus* Group
The small-colony-forming species *S. anginosus*, *S. constellatus*, and *S. intermedius* belong to the *S. anginosus* group. Strains of the *S. anginosus* group may be non-, alpha-, or beta-hemolytic on blood agar plates with some variations between the species. While *S. constellatus* is frequently beta-hemolytic, most isolates of *S. intermedius* are nonhemolytic. For many strains, growth is enhanced in the presence of CO2 with some strains requiring anaerobic conditions. *S. anginosus* and *S. constellatus* strains may possess Lancefield group antigen A, C, F, or G. Most *S. constellatus* or *S. intermedius* strains react with antisera against Lancefield group F antigen or are nongroupable.

The species *S. constellatus* has been further subdivided into two subspecies, *S. constellatus* subsp. *constellatus* and *S. constellatus* subsp. *pharyngis* (115). *S. constellatus* subsp. *constellatus* is phenotypically different from *S. constellatus* subsp. *pharyngis*, which usually possesses the Lancefield group antigen C, is beta-hemolytic, and has been associated with pharyngitis. Detailed phenotypic characteristics of the *S. anginosus* group are shown in Table 3 (1, 116, 117).

*S. mutans* Group
The *S. mutans* group includes *S. mutans*, *S. sobrinus*, *S. ratti*, *S. ratti*, *S. downei*, *S. ferri*, *S. hyovaginalis*, *S. devriesi*, and *S. macciae*. *S. mutans* and *S. sobrinus* are frequently found in human hosts, while the other species are only rarely encountered in humans or represent animal pathogens. The species of the *S. mutans* group are characterized by the production of extracellular polysaccharides from sucrose, which can be tested by culturing the bacteria on sucrose-containing agar and by the ability to produce acid from a relatively wide range of carbohydrates. *S. mutans* strains may present with an atypical morphology for streptococci, forming short rods on solid medium or in broth culture under acidic conditions. On blood agar, colonies are often hard and adherent and usually alpha-hemolytic. Under anaerobic growth conditions, some strains are beta-hemolytic. *S. sobrinus* strains are mostly nonhemolytic or occasionally alpha-hemolytic. On sucrose-containing agar, species from this group form colonies that are rough (frosted-glass appearance), heaped, and surrounded by liquid-containing glucan.

*S. salivarius* Group
Streptococcal species in the *S. salivarius* group are *S. salivarius*, *S. vestibularis*, and *S. thermophilus*. *S. salivarius* strains are usually non- or alpha-hemolytic on blood agar. On sucrose-containing agar, strains form large mucoid or hard colonies due to the production of extracellular polysaccharides. A high proportion of *S. salivarius* strains react with the Lancefield group K antiserum. Species in this group may also react with the streptococcal group D antiserum. It is unclear if these strains truly possess the group D antigen or yield a nonspecific cross-reaction. *S. vestibularis* is alpha-hemolytic, and the failure of this species to produce extracellular polysaccharides on sucrose-containing agar is helpful in distinguishing *S. vestibularis* from *S. salivarius* strains. *S. thermophilus* is found in dairy products but has not been isolated from clinical specimens.

*S. bovis* Group
The species belonging to the *S. bovis* group (*S. equinus*, *S. gallolyticus*, *S. infantarius*, and *S. alactolyticus*) are nonentero-

1The *S. mitis* group comprises the species *S. mitis*, *S. sanguinis*, *S. paraanginosus*, *S. gordonii*, *S. cristatus*, *S. oralis*, *S. infantis*, *S. porinis*, *S. australis*, *S. suis*, *S. orisvani*, *S. oligoferramentans*, and *S. massiliensis*. *S. sanguinis* is isolated from *S. paranginosus*, *S. gordonii*, and *S. cristatus* are arginine hydrolysis positive; other species from the *S. mitis* group are arginine hydrolysis negative.

2The *S. anginosus* group comprises *S. constellatus* and *S. intermedius*, and the following species rarely isolated from humans: *S. ratti*, *S. downei*, and *S. equus*.

3The *S. salivarius* group contains *S. salivarius*, *S. vestibularis*, and *S. thermophilus*. *S. salivarius* is variable, *S. vestibularis* is positive, and *S. thermophilus* is negative for urea hydrolysis.

4The *S. bovis* group now includes *S. equinus*, *S. gallolyticus*, *S. infantarius*, and *S. alactolyticus*. *S. gallolyticus* is positive for the acidification of mannitol, and the other species from the *S. bovis* group are negative.

*aSymbols and abbreviations: +, positive; −, negative; v, variable; data from Summanen et al. (116), Facklam (1), and Whiteley (117).

*bThe species S. constellatus subsp. pharyngis is β-d-fucosidase, β-d-acetylglucosaminidase, β-d-acetylgalactosaminidase, and β-d-glucosidase positive, in contrast to S. constellatus subsp. constellatus.

*cVoges-Proskauer test (formation of acetoin from glucose fermentation).

coccal group D streptococci that are PYR negative. Most strains grow on bile esculin agar and are unable to grow in 6.5% NaCl. On blood agar, strains are either nonhemolytic or alpha-hemolytic. Strains of the S. bovis group share phenotypic characteristics with S. mutans strains, such as production of glucan, fermentation of mannitol, and growth on bile esculin agar. However, the S. bovis group does not ferment sorbitol. S. galactolysus subsp. galactolysus and S. infantarius subsp. coli typically ferment starch or glycogen and give a Lancefield group D reaction, in contrast to S. galactolyticus subsp. pasteurianus. A detailed phenotypic characterization and emended description of the different subspecies has recently been published (53). For the identification of species in this group, testing of β-glucuronidase, α- and β-galactosidase, β-mannosidase, acid production from starch, glycogen, inulin, and mannitol is helpful. As described, strains formerly known as S. bovis currently belong to several species of the S. bovis group.

Physiologic Tests

Optochin Test

Most S. pneumoniae isolates are optochin susceptible. Before application of the optochin disk, several colonies of a pure culture are streaked on a sheep blood agar plate. Optochin testing should be performed on plates that are incubated at 35 to 36°C overnight in 5% CO₂ because up to 8% of strains do not grow under ambient conditions. S. pneumoniae isolates show zones of inhibition of ≥14 mm with a 6-mm disk (containing 5 µg of optochin) and zones of inhibition of ≥16 mm with a 10-mm disk. Incubation in 5% CO₂ yielded increased specificity (6, 96). Optochin-resistant S. pneumoniae strains have been reported as well as optochin-susceptible S. mitis isolates (especially when tested under ambient conditions). Since optochin testing may miss between 4% and 11% of bile-soluble S. pneumoniae isolates (6, 96), strains displaying a smaller zone of inhibition (9 to 13 mm for the 6-mm disk) should be subjected to additional testing (e.g., bile solubility or genetic testing) to confirm species identification.

Application of an optochin disk onto the primary culture medium may facilitate a rapid presumptive identification but may miss pneumococcal isolates in a mixed culture. The optochin susceptibility test should be repeated with a pure culture in cases of mixed cultures, or additional tests should be performed (e.g., bile solubility).

Bile Solubility Test

The bile solubility test can be performed either in a test tube or by direct application of the reagent to an agar plate. For the test tube method, a saline suspension of a pure culture is adjusted to a McFarland standard of 0.5 to 1.0, and 0.5 ml of the suspension is added to a small tube. The bacterial suspension is mixed with 0.5 ml of 10% sodium deoxycholate (bile) and incubated at 35°C. A control containing 0.5 ml of bacterial suspension with 0.5 ml of saline...
should be prepared for each strain tested. A positive result is characterized by clearing of the bile suspension within 3 h; clearing can start as early as 5 to 15 min after inoculation and allows the identification of a strain as *S. pneumoniae*. For the plate method, 1 drop of 10% sodium deoxycholate is placed directly on a colony of the strain in question, and the plate is incubated at 35°C for 15 to 30 min in ambient air. It is important to keep the plates in a horizontal position in order to prevent the reagent from washing away the colony. Colonies of *S. pneumoniae* disappear or demonstrate a flattened colony morphology, while other viridans group streptococci appear unchanged. In contrast to optochin susceptibility testing, bile solubility testing demonstrated excellent sensitivity and specificity in a recent comprehensive evaluation (96).

**Bile Esculin Test**

For the bile esculin test, bile esculin medium (available from commercial sources) in either plates or slants should be inoculated with one to three colonies of the organism to be tested and incubated at 35°C in ambient air for up to 48 h. Optimal results can be achieved by using medium supplemented with 4% oxgall (the equivalent of 40% bile) (Remel, Lenexa, KS) and a standardized inoculum of 10⁶ CFU (118). A definitive blackening of plated medium or blackening of at least one-half of an agar slant is considered a positive result, indicative of species belonging to the *S. bovis* group or enterococci. Occasional other viridans group streptococci are positive with this test or display weakly positive reactions that are difficult to interpret. Isolates from patients with serious infections (e.g., endocarditis) should be more completely characterized.

**Arginine Hydrolysis**

Arginine hydrolysis is a key reaction for the identification of viridans group streptococci. Discrepancies can occur among test methods (119). Two commonly used methods are detailed here. Moeller's decarboxylase broth containing arginine (Becton Dickinson, Franklin Lakes, NJ, and other sources) should be inoculated with the test organism, overlaid with mineral oil, and incubated at 35 to 37°C for up to 7 days. Degradation of arginine results in elevated pH, indicated by development of a purple color. Negative results are indicated by a yellow color, which is due to acid accumulation from metabolism of glucose only. For the microtiter plate method (104), 3 drops of the arginine-containing reagent are inoculated with 1 drop of an overnight Todd-Hewitt broth culture and incubated for 24 h at 37°C anaerobically. Production of ammonia is detected by the appearance of an orange color following addition of 1 drop of Nessler's reagent.

**Urea Hydrolysis**

Christensen's urea agar (Becton Dickinson and other sources) is inoculated and incubated aerobically at 35°C for up to 7 days. Development of a pink color indicates a positive reaction. An alternative format is to dispense Christensen's medium without agar into a microtiter tray well and, after inoculation, overlay it with mineral oil prior to incubation.

**VP Test**

The VP test can be performed as described above for the identification of beta-hemolytic streptococci. A standard method for performing the VP test, requiring extended incubation, is described in chapter 19.

**Esculin Hydrolysis**

Esculin agar slants (Becton Dickinson and other sources) are inoculated and incubated for up to 1 week. A positive reaction appears as a blackening of the medium; no change in color indicates a negative esculin hydrolysis test result.

**Hyaluronidase Production**

Hyaluronidase activity can be detected on brain heart infusion agar plates supplemented with 2 mg/liter of sodium hyaluronate (Sigma-Aldrich, St. Louis, MO). The strains to be tested are inoculated by stabbing into the agar, and plates are incubated anaerobically at 37°C overnight. After the plate is flooded with 2 M acetic acid, hyaluronidase activity is indicated by the appearance of a clear zone around the stab. A quantitative method for determining hyaluronidase activity can be performed in microtiter trays (120).

**Production of Extracellular Polysaccharide**

Strains may be isolated as single colonies on sucrose-containing agar. The two most commonly used media are (i) mitis-salivarius agar containing 0.001% (wt/vol) potassium tellurite (Becton Dickinson) and (ii) trypone-yeast-cystine-citrate-agar (Lab M, Bury, United Kingdom). Incubation may require up to 5 days at 37°C under anaerobic incubation conditions.

**Typing Systems**

In the majority of cases, typing of streptococci has no immediate clinical or therapeutic consequences. It is most often performed by reference laboratories for the purposes of epidemiologic studies and the evaluation of vaccine efficacy. Although classical antibody-dependent typing systems for capsular serotypes and surface proteins have been used for years, molecular methods are increasingly applied, since they do not require special techniques or the maintenance of rarely used reagents such as a large antibody panel. Another advantage is the independence of DNA sequences from culture conditions and gene expression. For the differentiation of distinct clones, pulsed-field gel electrophoresis (PFGE) and multilocus sequence typing (MLST) systems have been established for many streptococcal species (121).

*S. pneumoniae* comprises more than 90 antigenically distinct capsular serotypes that can be detected by the Neufeld test (Quellung reaction), which is still regarded as the gold standard for epidemiologic studies. Pure cultures of pneumococci are grown on a freshly prepared 5% sheep blood agar plate or a 10% horse blood agar plate at 35°C to 37°C and 5% CO₂ for 18 to 24 h. A small amount of bacterial growth (less than a 10-μl loopful) is resuspended in a droplet of phosphate-buffered or physiological saline (McFarland standard of 0.5). A few microliters of the saline suspension are mixed with an equal amount of specific pneumococcal rabbit antisera on a glass slide. The specimen is subsequently evaluated for capsular swelling (a clear area surrounding the bacterial cells) by phase-contrast microscopy (oil immersion; magnification, ×1,000) (122). Following the same principle, commercially available kits (Pneumotest Statens Serum Institut, Copenhagen, Denmark) allow rapid testing of *S. pneumoniae* serotypes with pooled antisera by a checkerboard method. A rapid antigen detection test using pooled antisera coupled to latex beads (Statens Serum Institut) has been developed (123). Due to strain discrepancies, confirmation by the Neufeld Quellung reaction is recommended. In addition, PCR methods for pneumococcal serotype determination have been developed during the last years (124–126). For the distinction of single clones, PFGE (127) or
MLST typing schemes (128) have been used in pneumococcal investigations.

Ten different antibody-defined capsular polysaccharides have been described for *S. agalactiae* (Ia, Ib, and II to IX). The percentage of nontypeable strains can be minimized by optimization of capsular expression (129). In addition to antibody detection of capsular serotypes, PCR- and DNA sequencing-based techniques allow the detection of capsular serotypes (130, 131). Individual clones of *S. agalactiae* have been detected either by MLST (132) or by PFGE (133).

Conventional typing of *S. pyogenes* is based upon the antigenic specificity of the surface-expressed T and M proteins (134). The trypsin-resistant T protein is part of the pilus structures (135). The T type can be identified by agglutination with commercially available serologic assays utilizing approximately 20 accepted anti-T sera. M proteins are major antiphagocytic virulence factors of *S. pyogenes* (136). N-terminal sequence variation in genes encoding these highly protective antigens is the basis of the *S. pyogenes* precipitation typing system. At present, 83 M serotypes are unequivocally validated and internationally recognized to be serologically unique and are designated M1 to M93 in the Lancefield classification (137). M serotypes that are not included are from non-*S. pyogenes* organisms or correspond to an existing M serotype.

A molecular typing system is based on the nucleotide sequences encoding the amino termini of M proteins. The *emm* gene sequences encode M proteins and have been correlated with Lancefield M serotypes. This methodology allows assignment to a validated M protein gene sequence (*emm*1 through *emm*124) and the identification of new *emm* sequence types and has evolved into the gold standard of *S. pyogenes* typing (137). A large database of approximately 350 *emm* gene sequences from strains originally used for Lancefield serotyping and including *emm* sequences from beta-hemolytic streptococci of groups C, G, and L is maintained at the CDC (http://www.cdc.gov/ncidod/biotech/strep/streptblast.htm). An MLST scheme is also available for *S. pyogenes*. Population genetic studies demonstrated stable associations between *emm* type and MLST among isolates obtained decades apart and/or from different continents (138).

In outbreak situations that include *S. pyogenes*, restriction enzyme-mediated digestion of *emm* amplicons is a valuable tool for rapid identification of isolates containing similar *emm* genes (139). For clusters of isolates sharing the same *emm* type, PFGE profiles may be helpful for distinguishing similar strains (140).

**SEROLOGIC TESTS**

Determination of streptococcal antibodies is indicated for the diagnosis of poststreptococcal disease, such as acute rheumatic fever or glomerulonephritis (141). A 4-fold rise in antibody titer is regarded as definitive proof of an antecedent streptococcal infection. Multiple variables, including site of infection, time since the onset of infection, age, background prevalence of streptococcal infections (142), antimicrobial therapy, and other comorbidities, influence antibody levels. The most widely used antibodies are anti-streptolysin O (anti-ASO) and anti-DNase B.

Antibodies against ASO reach a maximum at 3 to 6 weeks after infection. While ASO responses following streptococcal upper respiratory tract infections are usually elevated, pyoderma caused by *S. pyogenes* does not elicit a strong ASO response. *Streptococcus dysgalactiae* subsp. *equisimilis* can also produce streptolysin O, and thus elevated ASO titers are not specific for *S. pyogenes* infections. Among the four streptococcal DNases produced, the host response is most consistent against DNase B. Anti-DNase B titers may not reach maximum titers for 6 to 8 weeks but remain elevated longer than ASO titers and are more reliable than ASO for the confirmation of a preceding streptococcal skin infection. Moreover, since only 80 to 85% of patients with rheumatic fever have elevated ASO titers, additional anti-DNase B titers may be helpful.

Due to frequent exposure to *S. pyogenes*, ASO and anti-DNase B titers are higher in children in the United States from 2 to 12 years of age. Geometric mean values are 89 Todd Units for ASO and 112 Units for anti-DNase B, while the upper limits of normal values are 240 Todd Units (ASO) and 640 Units (anti-DNase B) (143). Prompt antibody therapy of streptococcal infections can reduce the titer but does not abolish antibody production. Streptococcal carriers do not experience a rise in streptococcal antibody titers.

The hemagglutination-based Streptozyme test (Carter-Wallace, Inc., Cranbury, NJ) was developed to detect antibodies against multiple extracellular streptococcal products. However, variabilities in test standardization and inconsistent specificities have been reported (144). Antibody detection against other *S. pyogenes* proteins (hyluronidase, streptokinase, and NAD glycohydrolase [NADase]) are technically difficult to perform and not commercially available.

**ANTIMICROBIAL SUSCEPTIBILITIES**

**Beta-Hemolytic Streptococci**

Penicillin remains the drug of choice for the empirical treatment of streptococcal infections due to *S. pyogenes*, because in contrast to *S. pneumoniae* and other alpha-hemolytic streptococci, *S. pyogenes* remains uniformly susceptible to penicillin. Reports about reduced penicillin susceptibility in strains of *S. pyogenes* have not been confirmed by reference laboratories. This is, however, no longer true for *S. agalactiae*. The emergence of diminished susceptibility to penicillin G caused by a mutation of the penicillin binding proteins (PBPs) *Pbp2x* in isolated strains in Asia and the United States has been reported (145, 146). Due to suspected or confirmed penicillin allergies in more than 10% of patients, macrolides are often given as an alternative treatment. Macrolide resistance rates among isolates of *S. pyogenes* and *S. agalactiae* have been increasing in North America as well as in Europe (147). Resistance rates correlate with the use of macrolides in clinical practice, and geographic differences in resistance rates are often due to differences in macrolide use. In the United States, macrolide resistance among *S. agalactiae* strains rose from 12 to 38% from 1990 to 2006 (148, 149) but has substantially declined to about 5% in one recent investigation (150). While isolates with a reduced susceptibility to glycopeptides have not been found in *S. pyogenes*, a very recent publication reports two independent *S. agalactiae* isolates from invasive infections, harboring vanG resistance genes (151). Due to the uniform susceptibility of *S. pyogenes* to penicillin, resistance testing for penicillin- or other β-lactams approved for treatment of *S. pyogenes* and *S. agalactiae* is not necessary for clinical purposes. So far, the rare isolates of *S. agalactiae* with reduced susceptibility to penicillin have not resulted in a change of this recommendation, which may of course change if increasing numbers of such strains are encountered. Susceptibility testing for macrolides should be performed using erythromycin, since resistance and susceptibility of azithromycin, clarithro-
mycin, and dirithromycin can be predicted by testing erythromycin. As specified in the CDC guidelines (35), S. agalactiae isolates from pregnant women with severe penicillin allergy should be tested for erythromycin and clindamycin resistance. Testing should include constitutive as well as inducible clindamycin resistance, preferentially with the double-disk diffusion method (D-zone test). In accordance with changes in the most recent CLSI recommendations, however, only results for clindamycin should be reported.

**S. pneumoniae and Viridans Group Streptococci**

In view of the development of penicillin resistance in *S. pneumoniae* and other alpha-hemolytic streptococci, penicillin can no longer be recommended as the empirical treatment of choice in many countries. Penicillin is considered a preferred antimicrobial agent only for *S. pneumoniae* and other alpha-hemolytic streptococci with demonstrated susceptibilities to penicillin. Penicillin resistance in *S. pneumoniae* is caused by altered PBPs. Approximately 25% of *S. pneumoniae* isolates from the United States were not fully susceptible to penicillin in 2007 (http://www.cdc.gov/abcs/reports-findings/surv-reports.html). But the changes of *S. pneumoniae* breakpoints in nonmeningal isolates (≥2 µg/ml, susceptible [S]; 4 to 8 µg/ml, intermediate [I]; ≥8 µg/ml, resistant [R]) for penicillin in CLSI definitions caused this value to drop to less than 10% (152). Currently, 5.9% of strains are reported as penicillin resistant (http://www.cdc.gov/abcs/reports-findings/survreports/spneu12.pdf). Susceptibility to penicillin can be determined by a disk diffusion test with 1 µg of oxacillin. According to the current CLSI guidelines, all isolates with oxacillin zone sizes ≤19 mm indicate a reduced penicillin susceptibility, MIC determinations for penicillin should be performed. For susceptibility testing of all other β-lactams in *S. pneumoniae*, MIC determinations are recommended. *S. pneumoniae* infections should be treated according to current guidelines (153). Depending on the clinical situation, treatment options include penicillin, extended-spectrum cephalosporins, macrolides, fluoroquinolones, and vancomycin. In addition, more than one-third of blood culture isolates of the viridans group streptococci collected in the late 1990s in the United States were not susceptible to penicillin (154). Elevated percentages of penicillin-resistant strains can be found among *S. mitis* and *S. salivarius* isolates. *S. pneumoniae* was uniformly susceptible to macrolides until the late 1980s in the United States, but macrolide resistance rates as high as 29% for *S. pneumoniae* strains have been reported in more-recent investigations (41, 155).

The increased use of fluoroquinolones to treat *S. pneumoniae* infections has been accompanied by a rise in fluoroquinolone-resistant *S. pneumoniae* strains. Resistance occurs in a stepwise fashion and is due to mutations in DNA topoisomerase IV (ParC) and/or a subunit of DNA gyrase (GyrA). While the overall prevalence of fluoroquinolone resistance remains below 1% according to the most recent Active Bacterial Core Surveillance (ABCS) data (http://www.cdc.gov/abcs/reports-findings/survreports/spneu12.pdf), the increase in resistant strains during recent years emphasizes the need for close monitoring. Clinical failures of levofloxacin therapy due to resistance have been reported (156). Vancomycin-resistant *S. pneumoniae* isolates have not been described. However, the isolation of a vancomycin-resistant *S. bovis* isolate has been reported (157).

### TAXONOMY

The genus *Enterococcus* includes microorganisms that have a historical connection with the genus *Streptococcus*, and their initial documentation is related to the “streptococci of fecal origin” or “enterococci” (see reference 1 for a brief historical overview). They were initially considered a distinct category within the genus *Streptococcus*, distinguished by their higher resistance to chemical and physical agents and accommodating most of the serological group D streptococci. After the introduction of molecular methods for studying these microorganisms, however, the enterococci have undergone considerable changes in taxonomy, which started with the splitting of the genus *Streptococcus* and the recognition of *Enterococcus* as a separate genus in 1984 (2). *Streptococcus faecalis* and *Streptococcus faecium* were the first species to be transferred to the new genus as *Enterococcus faecalis* (the type species) and *Enterococcus faecium*, respectively. Subsequently, other earlier streptococcal species and subspecies were transferred and received new denominations as members of the genus *Enterococcus* (3). The continuous use of molecular approaches has allowed major developments in the classification of the enterococci, resulting in the recognition of 49 entero-coccal species as of April 2014 (for further details, see references 1 and 4, as well as the List of Prokaryotic Names with Standing in Nomenclature [http://www.bacterio.net]).

The enterococci belong to the low DNA guanine-plus-cytosine (G+C <50 mol%) content branch of the phylum *Firmicutes*. Phylogenetic analyses based on the comparison of the 16S rRNA gene sequences have revealed that the members of the genus *Enterococcus* are more closely related to those included in the genera *Vagococcus* and *Tetragenococcus* than they are to *Streptococcus* and *Lactococcus*, genera to which they have been phenotypically associated (1, 4, 5). Such observations culminated in the recent proposal to allocate the genus *Enterococcus* to a newly designated family (Enterococcaceae fam. nov.) together with the genera *Melissococcus*, *Tetragenococcus*, and *Vagococcus* (4, 6, 7).

Current criteria for inclusion in the genus *Enterococcus* and for the description of new entero-coccal species encompass a polyphasic approach resulting from a combination of different molecular techniques (frequently involving DNA-DNA reassociation experiments, 16S rRNA gene sequencing, and whole-cell protein [WCP] profiling analysis) and phenotypic tests. Partial or nearly entire sequencing of the 16S rRNA gene is a practical and powerful tool in aiding the identification of entero-coccal species, and it has been performed for all recognized species of *Enterococcus*. Figure 1 shows the phylogenetic relationships among the species of *Enterococcus* based on the analysis of 16S rRNA gene sequences, which are available from the GenBank database. Several other molecular methods, mostly nucleic acid-based assays, have been used as additional tools to assess the phylogenetic relationships among entero-coccal species and to formulate the description of new species, but their use is still limited (for further details, see references 1 and 4 and “Identification” below).

### DESCRIPTION OF THE GENUS

The members of the genus *Enterococcus* are Gram-positive, catalase-negative cocci that occur singly or are arranged in pairs or as short chains. Cells are sometimes coccoid or bacillary when Gram stains are prepared from growth on solid medium but tend to be ovoid and in chains when grown in liquid medium, such as thioglycolate broth. After growth on blood agar medium for 24 h, colonies are usually between 1 and 2 mm in diameter, although some variants may appear smaller. Some (about one-third) of the *E. faecalis* isolates may be beta-hemolytic on agar containing rabbit, horse, or human blood but nonhemolytic on agar containing sheep blood. Some isolates of *E. faecalis* and *Enterococcus durans* may be beta-hemolytic regardless of the type of blood used. All other species are usually alpha-hemolytic or nonhemolytic. Enterococci are facultative anaerobes with a homofermentative metabolism that results in the production of L-(+)-lactic acid as the major end product of glucose fermentation. Because of their ability to ferment a wide range of carbohydrates to lactic acid, the enterococci are referred to as typical lactic acid bacteria (LAB). Gas is not produced. These microorganisms are usually able to grow at temperatures ranging from 10 to 45°C with optimum growth at 35 to 37°C. The majority of the species grow in broth containing 6.5% NaCl, and they hydrolyze esculin in the presence of bile salts (bile-esculin [BE] test). They also hydrolyze leucine-β-naphthylamide by producing leucine aminopeptidase (LAPase). Apart from *Enterococcus cocorum*, *Enterococcus columbiae*, *Enterococcus pullus*, *Enterococcus saccharolyticus*, and some isolates of the more recently described species *Enterococcus caniintestini*, *Enterococcus devriesei*, *Enterococcus

FIGURE 1 Phylogenetic tree based on comparative analysis of the 16S rRNA gene sequences showing the relationship among the type strains of the species included in the genus Enterococcus. Vagococcus fluvialis was used as an outgroup, and bootstrap values at the nodes were displayed as percentages. Black dots indicate the species that have been isolated from human sources.

doi:10.1128/9781555817381.ch23.f1

moraviensis, and Enterococcus termitis, most enterococci hydrolyze 1-pyrrolidonyl-β-naphthylamide (PYR) by producing pyrrolidonyl arylamidase (pyrrolidone [PYRase]). Results for both LAP and PYR testing, especially for some of the more recently described species, may vary according to the methodology, including the test format and media used to grow the bacterial cells. A few species are motile (Enterococcus casseliflavus and Enterococcus gallinarum), and some are pigmented (E. casseliflavus, Enterococcus gilvus, Enterococcus mundtii, E. gallinarum, E. mundtii, Enterococcus plantarum, Enterococcus ruminantium, and Enterococcus urticae) (1, 4, 5, 8). Methods used for detection of enterococcal motility have to be selected carefully, as differences in motility due to the composition of the medium have been demonstrated (9). Enterococci are not able to synthesize porphyrins and therefore do not produce cytochrome enzymes (4, 8). However, cytochrome activity is sometimes expressed when strains of E. faecalis are grown on blood-containing medium, and a weak effervescence is observed in the catalase test. Positive catalase testing has also been reported for strains of Enterococcus haemoperoxidus (10), Enterococcus silesiacus (11), and E. plantarum (12) when cultivated on blood-containing agar media. Most enterococcal strains produce a cell wall–associated glycerol teichoic acid that is identified as Lancefield’s serological group D antigen. The DNA G+C contents range from 32 to 45 mol%. The genome sizes are in the range of approximately 2.3 to 5.4 Mb (13, 14, 15). Genome sequencing of E. faecalis V583 (16), the first vancomycin-resistant clinical isolate in the United States, has opened many lines of investigation to improve our understanding about the genus Enterococcus. A variety of Enterococcus genomes are at different stages of analysis, and some have been completely sequenced, according to information available at specialized sites and databases, such as the NCBI (http://0-www.ncbi.nlm.nih.gov.elis.tmu.edu.tw/genome/?term=enterococcus), the Broad Institute (https://olivebroadinstitute.org/projects/enterogenome), and the American Society for Microbiology (http://genomema.asm.org/).

The other genera of catalase-negative Gram-positive cocci and the characteristics that distinguish them from the enterococci are discussed in chapters 22 and 24. No phenotypic criteria are available for clearly distinguishing the genus Enterococcus unequivocally from other genera, since there are no particular characteristics that are common to all enterococci. However, certain characteristics are usually found in the majority of the strains belonging to the
most frequently isolated enterococcal species. Presumptive identification of a Gram-positive, catalase-negative coccus as an Enterococcus can be accomplished by demonstrating that the strain is positive for the BE, PYR, and LAP tests and grows in the presence of 6.5% NaCl and at 45°C. Because strains of Lactococcus, Leuconostoc, Pedicoccus, and Vagococcus with phenotypic similarities have been isolated from human infections (17, 18), the presumptive identification of enterococci based on the BE reaction and growth in 6.5% NaCl broth can be erroneous. Demonstrating the presence of group D antigen by a serological reaction may be helpful in the identification, although this antigen is detected in only about 80% of the enterococcal strains. On the other hand, pediococci and leuconostocs (17), as well as some vagococcal strains (18), can also react with anti-group D serum. Taking into account that certain characteristics traditionally considered to be typical for the genus do not apply to some atypical strains and to several of the more recently described species, the above-mentioned criteria may exclude several isolates or species. The use of molecular identification methods, such as a PCR-based test having the tuf gene as a genus-specific target, may be helpful in circumventing these difficulties by correctly identifying both typical and unusual Enterococcus isolates at the genus level (19).

**Epidemiology and Transmission**

Several intrinsic characteristics of the enterococci allow them to grow and survive under harsh conditions and persist almost everywhere, colonizing several ecological niches. These microorganisms are widespread in nature and can be found in soil, plants, water, food, and animals, including mammals, birds, insects, and reptiles (4, 5, 20). In humans, they are predominantly inhabitants of the gastrointestinal tract and are less commonly found in other sites, such as the genitourinary tract, the oral cavity, and skin, especially in the perineal area. The prevalence of the different enterococcal species appears to vary according to the host and is also influenced by age, diet, and other factors that may be related to changes in physiologic conditions, such as underlying diseases and prior antimicrobial therapy. Enterococci are considered among the most abundant Gram-positive cocci colonizing the intestine, with E. faecalis being one of the most common bacterial species recovered from this site (5, 20, 21). Other species, such as E. faecium, E. casseliflavus, E. durans, and E. gallinarum, are also found in variable proportions in the gastrointestinal tract of humans. Since the enterococci are opportunistic pathogens, the incidence of each species found in human infections probably reflects the distribution of the different species of Enterococcus in the human gastrointestinal tract. This site is believed to represent an important reservoir for strains associated with disease; from this location, they may migrate to cause infections and can also disseminate to other hosts and to the environment (22, 23, 24). On the other hand, the occurrence of high numbers of enterococci in the feces and their ability to resist different chemical and physical conditions and to survive in the environment imply that the enterococci can be used as indicators of fecal contamination and of the hygienic quality of food, milk, and drinking water (25, 26). The occurrence of enterococci as members of the intestinal microbiota of humans (20) and the relationship between the presence of enterococci in foods and human safety (25) have been extensively reviewed.

**Clinical Significance**

The enterococci are commensal microorganisms that act as opportunistic agents causing a variety of infections in humans. Many of these infections have been suggested to arise from translocation of the enterococcal cells from their major site of colonization in the gastrointestinal tract. They most commonly infect the urinary tract, bloodstream, endocardium, burn and surgical site wounds, abdomen, biliary tract, and catheters and other implanted medical devices (24, 27, 28, 29, 30). The ubiquitous presence of enterococci, however, requires caution in establishing the clinical significance of a particular isolate. Unnecessary work and potentially misleading laboratory reports should be avoided whenever possible, especially with respect to in vitro susceptibility testing decisions (see “Antimicrobial Susceptibilities” below). Over the last decades, they have emerged from being considered virtually harmless bacteria to medically important multiple-antibiotic-resistant health care-associated pathogens that contribute significantly to patient morbidity and mortality as well as health care costs. Changes in the dynamics of the commensal host-bacterial relationship, such as those promoted by the use of broad-spectrum antibiotics, host injury, or diminished host immunity, could allow these bacteria to gain access to extraintestinal host sites and cause infection. Therefore, elderly patients with serious underlying diseases and other severely ill immunocompromised patients who have been hospitalized for prolonged periods, have been treated with invasive devices, and/or have received broad-spectrum antimicrobial therapy are at higher risk to acquire enterococcal infections (22, 24, 27, 28, 29).

The pathogenesis of enterococcal infections is still poorly understood. Although the debate continues over whether serious enterococcal infections arise from one’s own indigenous microbiota or from exogenously acquired strains, epidemiological studies show the existence of clonal relationships among outbreak isolates and support the notion that a subset of virulent lineages with greater propensity to cause disease exist and are often responsible for infections of epidemic proportions (24, 31, 32, 33, 34, 35). Several potential virulence factors that may play a role in the pathogenesis of enterococcal infections have been identified in enterococcal isolates, including the surface adhesin Esp (Enterococcal surface protein) and aggregation substance (AS), secreted toxin cytolysin/hemolysin, secreted proteases gelatinase and serine protease, MSCRAMM Ace (Adhesin to collagen of E. faecalis), E. faecalis antigen A (EfaA), enterococcal capsule, cell wall polysaccharides, and extracellular superoxide (24, 31, 36, 37). Nevertheless, none has been established as making a major contribution to enterococcal virulence in humans. One mechanism by which the enterococci can deviate from their commensal behavior is through the acquisition of new traits that allow the bacterium to overcome host defenses and colonize new niches, as suggested by the identification of the E. faecalis pathogenicity island (PAI), which highlights genetic differences between infection-derived and commensal strains (31, 38, 39). In this context, acquired antimicrobial resistance is considered one of the many traits that virulent enterococci possess, in contrast to commensal isolates, and allow members of this genus to survive for extended periods of time in the host or environment, leading to their persistence and role as prominent health care-associated pathogens (24, 31, 36, 38). In addition, enterococci can transfer resistance determinants to other bacteria, for example, staphylococci, which further increases the clinical importance of the enterococci. The
ability to form biofilms has recently been listed among the most prominent virulence properties of these microorganisms, allowing colonization of inert and biological surfaces while protecting against antimicrobial substances and mediating adhesion and invasion of host cells (27, 30, 40, 41, 42). Biofilm formation may be of particular importance in the development of endocarditis and endodontic and urinary infections, as well as implant and other medical-device-associated infections.

The variety of infections associated with the enterococci have been thoroughly reviewed and summarized (28, 29). Although the spectrum of infections has remained relatively unchanged since the extensive review by Murray (29), trends toward an increasing prevalence of these organisms as health care-associated pathogens have been frequently observed. Enterococci have become the second or third leading cause of nosocomial urinary tract infections (UTIs), wound infections (mostly surgical site wounds, decubitus ulcers, and burn wounds), and bacteremia in the United States (28, 29, 43, 44, 45, 46). UTIs are the most common of the enterococcal infections: enterococci have been implicated in approximately 10% of all UTIs and in up to approximately 16% of health care-associated UTIs. Enterococcal bacteremia is frequently associated with metastatic abscesses in multiple organs and high mortality rates. Enterococci have also been considered an important cause of infective endocarditis and are estimated to account for about 20% of the cases of native valve bacterial endocarditis and for about 6 to 7% of prosthetic valve endocarditis cases. Endocarditis remains one of the most difficult enterococcal infections to treat because of limitations on bactericidal antimicrobial therapy for enterococcal infections, especially when caused by vancomycin-resistant enterococci (VRE). Intra-abdominal and pelvic infections are also commonly associated with enterococci. However, cultures from patients with peritonitis, intra-abdominal or pelvic abscesses, biliary tract infections, surgical site infections, and endomyometritis are frequently polymicrobial, and the role of enterococci in these settings remains controversial. The significance of isolates from some of these sites should then be carefully evaluated before clinical decisions are made. There is also a growing concern regarding the role of the enterococci in endodontic and implanted and medical device-associated infections (27, 41). Infections of the respiratory tract or the central nervous system, as well as otitis, sinusitis, septic arthritis, and endophthalmitis, may occur but are rare.

The ratios of isolation of the different enterococcal species can vary according to each setting and can be affected by a number of aspects, including the increasing dissemination of outbreak-related strains such as vancomycin-resistant E. faecium. E. faecalis and E. faecium are usually the most frequent enterococcal species isolated from human clinical specimens. Historically, E. faecalis represented about 80 to 90% of the clinically significant enterococcal isolates, while E. faecium was found in 5 to 10% of enterococcal infections (47, 48, 49). However, a trend for a progressive decline in the ratio of E. faecalis to E. faecium is notable, particularly among isolates from bloodstream infections (24, 33, 44, 45, 46, 50, 51). The other enterococcal species are identified less frequently, even though clusters of infections associated with E. casseliflavus (52), E. gallinarum (53, 54, 55), and E. raffinosus (56, 57) have been reported. Several other enterococcal species, including E. avium, E. cacaoe, E. caninestiniti, E. coccum, E. dispers, E. durans, E. gilvus, “E. hawaiensis,” E. hirae, E. italicus, E. malodoratus, E. mundii, E. paliens, E. pseudoeae, and E. thailandicus, have also been isolated from human sources.

Although the enterococci can cause human infections in the community and in the hospital, these microorganisms began to be recognized with increasing frequency as common causes of health care-associated infections (HAIs) in the late 1970s, paralleling the increasing resistance to most currently used antimicrobial agents. A major impact on the incidence and epidemiology of enterococcal infections was noted after the first reports on the occurrence and epidemic increase of VRE in hospitals in the United States. From 1989 to 1999, the percentage of VRE isolates reported by U.S. hospitals increased from 0.3% to over 25% of all isolates (43). Since then, the enterococci have been usually listed as the second or third most frequent health care-associated pathogen isolated from intensive care unit (ICU) patients in the United States, depending on the type of infection (45, 46, 58). In the 2009-2010 report from the National Healthcare Safety Network (NHSN) at the Centers for Disease Control and Prevention (CDC), the enterococci were listed as the second most common antimicrobial-resistant pathogen associated with HAIs, accounting for about 14% of the total cases of infection (46). In this report, 9.5% of E. faecalis and 82.6% of E. faecium isolates recovered from the bloodstream infections were found to be resistant to vancomycin (46). The occurrence and spread of VRE have now reached a more global dimension. According to the 2011-2012 surveillance report from the European Centre for Disease Prevention and Control (ECDC), the prevalence of health care-associated VRE ranges from 3.6% to 31% in several European countries (51).

The occurrence of VRE has also been reported from several other parts of the world, including South America, Asia, and Australia, illustrating the pandemic spread of health care-associated VRE (24, 34).

Hospitalized patients with gastrointestinal carriage of VRE appear to be the major reservoir of the organism, and once colonized, the patients remain so for weeks or months. Thus, as colonized patients leave the hospital, the possibility that transmission might occur in the community cannot be discounted. VRE can be disseminated by direct patient-to-patient contact or indirectly via transient carriage on health care personnel hands, contaminated medical instruments, such as glucose meters, blood pressure cuffs, electronic thermometers, electrocardiogram (ECG) monitors and wires, and environmental surfaces, such as patient gowns and linens, beds, bedside rails, overbed tables, floors, toilets, door knobs, and wash basins (22, 59). Besides surviving for long periods on environmental surfaces, these microorganisms are tolerant to heat, chlorine, and some alcohol preparations, enhancing the possibilities for transmission.

As a response to the rising rates of VRE colonization and infection in U.S. hospitals, the CDC’s Hospital Infection Control Practices Advisory Committee (HICPAC) established guidelines with recommendations for preventing the spread of VRE (60). These include prudent vancomycin use and implementation of surveillance procedures for early detection of VRE, as well as infection control procedures to limit cross-contamination, such as isolation precautions, hand washing, and education about transmission of VRE.

Although only a small percentage of colonized patients develop serious systemic enterococcal infections, intestinal colonization with VRE has been clearly associated with subsequent VRE infections. However, in certain specific clinical situations (i.e., for liver transplant recipients, patients on chronic hemodialysis, and patients with hematological malignancies), VRE-colonized patients appear to be at increased risk for developing serious enterococcal infections (22, 24, 27). This underscores the importance of active
surveillance in high-risk patient groups to prevent transmission and outbreaks.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

The standard methods for collecting blood, urine, wound secretions, and other secretions or swab specimens suspected of harboring enterococci are adequate (see chapter 18). No special methods or procedures are usually necessary for transporting and storage of clinical specimens containing enterococci because these microorganisms are easily recovered and are relatively resistant to environmental changes and adverse conditions. Transport can be performed on almost any transport medium or on swabs that are kept dry. Like most clinical samples, the material should be cultured as soon as possible. In a recent study, VRE strains were shown to survive for 14 days in Amies medium when stored at 4°C or room temperature (61).

Enterococcal strains can be stored indefinitely when lyophilized. In our experience, cultures frozen at −70°C or less can be stored for several years as heavy cell suspensions made directly in defibrinated sheep or rabbit blood or in a skim milk (10%) solution containing glycerol (10%). These are the preferable methods for preservation of enterococcal strains. They can also be preserved for many years at −20°C in other cryopreservative media commonly used for maintenance of bacteria. Most strains of enterococci can survive for several months at 4°C on agar slants prepared with ordinary agar bases, such as brain heart infusion (BHI) agar and Trypticase soy agar. Certain of the less well known species, however, are not as resistant to adverse conditions and may not survive long if more-adequate preservation procedures are not used.

DIRECT EXAMINATION

Microscopy

The direct microscopic examination of Gram-stained smears of normally sterile clinical specimens, such as blood, may be useful for the diagnosis of enterococcal infections. Direct examination of certain nonsterile specimens may also be informative but should not be overemphasized. In any case, only a presumptive report of the “presence of Gram-positive-cocci” should be made, as microscopy by itself cannot differentiate the enterococci from most of the other Gram positive-cocci. Culture and appropriate identification techniques should be performed for confirmation.

Nucleic Acid Detection

As the occurrence of VRE continues to represent an important problem worldwide, hospitals are encouraged to implement surveillance programs for VRE detection. In an attempt to overcome the inherent limitations of the culture-based methods of detection (discussed in “Isolation Procedures” below), PCR-based methods have been evaluated for direct detection of these microorganisms in clinical and surveillance specimens. Three major systems are commercially available. They are the LightCycler VRE assay (Roche Molecular Diagnostics, Indianapolis, IN), the GenOhm VanR assay (Becton-Dickinson Microbiology Systems, Cockeysville, MD), and the Cepheid Xpert vanA/vanB assay (Cepheid, Sunnyvale, CA) (62–73). The GenOhm VanR and the Xpert vanA/vanB assays have been approved by the U.S. Food and Drug Administration (FDA), while the LightCycler VRE assay has not been licensed for use in diagnostic procedures in the United States yet. An updated version of the GenOhm VanR assay has also been evaluated, and improved specificity was reported (71). Recently, the Cepheid Xpert vanA assay for identification of VRE (vanA only) was evaluated, and excellent results were reported (74). Nearly all of these studies have reported improved detection of VRE in rectal swabs and fecal specimens over that obtained with conventional culture techniques. It is important to note that these systems use proprietary sequences for detection of the van genes and sensitivities may vary. Specificity is also a potential problem unless PCR controls for genus and/or species identification are included, because van genes, especially vanB, may be found in bacteria other than enterococci (64, 67, 74, 75). The type of sample tested may influence the outcome of testing for VRE. Improved specificities were reported in some studies to be achieved by testing perianal swabs in place of rectal swabs or stool specimens (68, 71). Also, some investigators have used the vanA/vanB assays to test selective enrichment broths (62, 69) or colonies taken from selective agar plates (66). It may be advisable, if time is not a concern, to detect only vanA/vanB from an enrichment broth like the Enterococcus broth (EB), which turns black if enterococci are present.

Assays for detection and identification of enterococci directly in blood samples have been reported. A laboratory-developed real-time PCR assay for quantitative detection of E. faecalis DNA in blood samples without prior cultivation has been proposed for the diagnosis of bacteremia (76). The LightCycler SeptiFast Test (Roche Molecular Systems) is a commercially available multiplex real-time PCR assay for the rapid detection and identification of major pathogens involved in nosocomial bacteremia, including E. faecalis and E. faecium, directly from whole blood (65). As the technology evolves, these molecular methods may become widely available for the rapid and precise detection of enterococci directly in clinical samples. However, further evaluation is needed to determine the real impact of their use on laboratory diagnosis of invasive enterococcal infections and on patient management.

ISOLATION PROCEDURES

The source of clinical specimens to be tested for the presence of enterococci influences the type of medium needed for primary isolation. Clinical specimens from normally sterile body sites can be plated directly onto a nonselective medium such as Trypticase soy agar, brain heart infusion agar, or other blood agar base containing 5% sheep, horse, or rabbit blood. In general, strains of the most clinically relevant species grow well at 35 to 37°C and do not require an atmosphere containing increased levels of CO₂, although some strains grow better in this atmosphere. Samples for blood culture can be inoculated into conventional blood culture systems. For clinical specimens obtained from nonsterile sites, especially those heavily contaminated with Gram-negative bacteria, use of selective media is a good option for primary isolation. In these cases, and particularly when enterococci may be present in low numbers, consideration must also be given to whether or not an enrichment broth should be employed. The use of a broth enrichment step in the primary isolation delays the identification but increases the recovery rates of enterococci. Many different media have been devised for selective isolation of enterococci. Most of them contain bile salts, sodium azide, and/or antibiotics as selective components and esculin or tetrazolium as indicator substances. Not all enterococcal species
grow on these selective media, although most E. faecalis and E. faecium isolates should do so. The diversity of media used for the isolation of enterococci from various sources has been reviewed (27).

The increasing incidence of vancomycin resistance among the enterococci has raised the importance of selective isolation of VRE. Early identification of infection or colonization by VRE is recommended to prevent the spread of these microorganisms (60, 77). Current recommendations for hospital infection control may include VRE fecal surveillance cultures, but the optimal methods for these cultures are still unclear. Different selective agar and/or broth medium formulations and several procedures have been employed for the isolation of VRE from sources containing a normal microflora, such as stool samples and rectal or perianal swab specimens. Most of them are variations of selective media, differing with regard to the antimicrobial agents or the antimicrobial concentrations used. Although no consensus for a VRE isolation protocol has been established, the use of a selective-enrichment broth seems to be a highly effective procedure to enhance the recovery of VRE. For this purpose, BHI broth has been used with vancomycin concentrations varying from 3 μg/ml (67, 78) and 6 μg/ml (79) to 30 μg/ml (80). Bile esculin azide (BEA) broth has been supplemented with vancomycin at concentrations of 4 μg/ml (69), 6 μg/ ml (68), 8 μg/ml (63, 66), and 15 μg/ml (81). Enterococcosel broth (EB; a BEA medium supplied by Becton Dickinson Microbiology Systems) has also been used in a number of studies as the base medium supplemented with concentrations of vancomycin varying from 4 μg/ml (72), 6 μg/ml (68, 82–84), and 8 μg/ml (62) to 64 μg/ml (85). One advantage that the bile-esculin-based broth media (BEA and EB) have over BHI-based media is that those media containing esculin turn black as the enterococci grow, and if the esculin-containing medium does not turn black, it can be assumed that no enterococci are present. Several studies report improved recovery of VRE from selective-enrichment broth over that obtained with direct plating (78, 80, 81, 83). Among the different concentrations of vancomycin used, 6 μg/ml is the most commonly used. In some of the protocols, various concentrations of other antimicrobial agents, such as aztreonam, meropenem, and clindamycin, have been used in the enrichment broth (67, 69, 85). In a recent work, a 30-μg vancomycin disk was simply added to BHI broth (73). Overall, there are no studies reporting extensive comparison of recovery rates of VRE from different selective-enrichment broths.

Media containing chromogenic substrates have also been proposed for the isolation and presumptive identification of enterococci. Table 1 contains a list of various chromogenic media that are commercially available, as well as the concentration of vancomycin in each, the distributors, and references reporting the results of studies performed with each of these media. Some of these media have not yet been fully evaluated. CHROMagar orientation and CPS ID3 were promoted as isolation and identification media for enterococci from urine (86, 87, 88). Additionally, some chromogenic media that are selective for VRE have the advantage over the bile esculin-based selective media in that the colors of the colonies can help in the presumptive identification of VRE species (87, 89, 90). In some surveillance studies, selective enrichment was used prior to inoculation of the chromogenic agar (67, 78, 81), while in others the perianal, rectal, or stool samples were directly inoculated onto the surface of the agar. In some circumstances, it may be necessary to recover VRE from environmental surfaces for epidemiological studies. Isolation of the organisms from these surfaces can be accomplished by swabbing the surfaces with premoistened swabs and placing them either into a selective-enrichment broth or onto selective agar plates.

Culture-based screening methods for VRE may be especially demanding, can take several days to complete, and have variable degrees of sensitivity, all of which can impact the timely implementation of infection control procedures. Therefore, some microbiology laboratories have considered the introduction of molecular techniques to detect VRE to facilitate the rapid and accurate identification of these organisms and to improve sensitivity for detecting this pathogen in comparison with culture. However, many of the current approaches still require bacterial growth in culture prior to detection, requiring 24 h or more to complete. Consequently, the application of methods for a more rapid detection of VRE directly from clinical samples is still an area of significant interest (see “Direct Examination” above).

Furthermore, because a laboratory report of VRE can initiate a cascade of infection control events that are time-consuming and costly, laboratories must be certain of the epidemiological importance of any suspected VRE isolate. The transferable and high-level vancomycin resistance, especially that encoded by the vanA or the vanB genes, most frequently associated with *E. faecalis* and *E. faecium* isolates, is the major focus of infection control efforts (see “Antimicrobial Susceptibilities” below). In contrast, the intrinsic low-level vanC resistance, which is not associated with wide dissemination of resistant strains, is less likely to be important for infection control surveillance efforts. While the isolation of VRE from clinical and surveillance specimens is important, the need for establishing protocols to rapidly determine the likely underlying mechanism of resistance (see “Antimicrobial Susceptibilities” below) is equally important.

**IDENTIFICATION**

**Identification by Conventional Physiological Testing**

Once it is established that an unknown catalase-negative Gram-positive coccus is an *Enterococcus* or closely related genus (see “Description of the Genus” above), the appropriate tests (see reference 17 and chapters 4, 19, and 20) listed in Table 2 can be used to identify the species. The data presented in Table 2 for the phenotypic characteristics are derived from conventional testing (except for β-galactosidase) as performed at the CDC Streptococcus Laboratory (see http://www.cdc.gov/ncidod/biotech/strep/strep-doc/index.htm). Table 2 presents the phenotypic characteristics of isolates most frequently recovered from humans. Isolates from nonhuman sources, even those belonging to well-known species, may have different results for some tests. Species that have not been recovered from humans to date are also included in Table 2, as the possibility exists that they may be isolated from human sources in the future. Two recently described species (*Enterococcus diestrammenae* and *Enterococcus xiangfangensis* (see http://www.bacterio.net for further details)) were not included in Table 2 because their respective type strains were not available for testing by the time this chapter was prepared. Identification of enterococcal species by conventional tests can be time-consuming and may require incubation of the tests for up to 10 days before a definitive identification can be reached. On the other hand, the majority of the isolates recovered from human sources can be identified after 2 days of incubation.

*Enterococcus* species can be initially separated into five physiological groups of species based on acid formation from mannitol and sorbose and hydrolysis of arginine (see Table 2 for details). Group I includes 10 species (Table 2). “*E. hauiensis*” is a denomination that has been proposed for the new species previously provisionally designated as *Enterococcus* sp. nov. CDC PNS-E3 (91). *E. avium* and *E. raffinosus* are possibly the most relevant species in this group, considering their association with human clinical sources.

Group II comprises 9 species. The majority of the isolates recovered from human sources belong to species included in this group. Atypical strains that do not hydrolyze arginine or do not form acid from mannitol have been documented. *Lactococcus* sp. is also listed in this group because the phenotypic characteristics of some strains can lead to their misidentification as *Enterococcus* isolates. If nonmotile variants of *E. casseliflavus* and *E. gallinarum* are encountered, production of acid from methyl-α-D-glucopyranoside can be used to help in the identification of these species.

Group III consists of 7 species. Three of these species (*E. durans*, *E. ratti*, and *E. villorum*) have very similar phenotypic profiles in the tests listed in Table 2. Reactions in litmus milk and hydrolysis of hippurate may also be used to help differentiate the species in addition to those reactions listed in Table 2. In litmus milk *E. durans* forms acid and clot, *E. villorum* forms acid but no clot, and *E. ratti* does not form acid or clot. *E. durans* hydrolyzes hippurate, while *E. villorum* does not. *E. ratti* is variable in the hippurate hydrolysis test. Uncommon manniitol-negative variant strains of *E. faecalis* and *E. faecium* resemble species in this group. However, *E. faecalis* strains are positive in the pyruvate test but not for acid formation from arabinose, raffinose, or sucrose, and *E. faecium* variant strains form acid from arabinose.

Group IV includes 8 species. *E. cassaceae* and *E. cecorum* are the only species in this group that have been isolated from human sources to date.

Group V comprises 13 species. They correspond to isolates from a variety of environmental and animal sources. Only *E. italicus* has already been recovered from human sources (91, 92). Variant strains of *E. casseliflavus*, *E. gallinarum*, and *E. faecalis* that fail to hydrolyze arginine resemble the microorganisms included in this group. However, these variant strains have characteristics similar to the strains that hydrolyze arginine and can be differentiated by these same phenotypic tests. *Vagococcus fluvialis* is listed here because the phenotypic characteristics of this species are very similar to those of the genus *Enterococcus* and some strains may be identified as *enterococci* (18).

**Identification by Commercial Systems**

Several miniaturized, manual, semiautomated, and automated systems are commercially available and represent alternatives to conventional testing for the phenotypic identification of enterococcal species in routine diagnostic laboratories. Since their introduction, these systems have been updated to improve their performance characteristics and expand their identification capabilities, as investigator have become more aware of inaccuracies (19, 57, 93, 94). In general, these systems are reliable for the identification of the most common species: *E. faecalis*, and to a lesser extent, *E. faecium*. Precise identification of other species, the microorganisms included in this group. However, these improvements have been observed with updated formats and databases. Commercial systems available for the identification of enterococcal species include the API 20S and the API Rapid ID32 STREP systems (bioMérieux, Durham, NC), the Crystal Gram-Positive and the Crystal Rapid Gram-Positive identification systems (Becton Dickinson Microbiology Systems, Sparks, MD), and the commercial

*Names in boldface represent species that have been isolated from human sources.*

*Abbreviations and symbols: MAN, mannitol; SOR, sorbitol; ARG, arginine; ARA, arabinine; SBL, sorbitol; RAF, raffinose; TEL, O-2%, tellurite; MOT, motility; PIG, pigments; SUC, sucrose; PYU, pyruvate; MGP, methylpyruvate-naphthyl-β-D-galactopyranoside; TRE, trehalose; XYL, xylose; GAL, 2-naphthyl-β-D-galactopyranoside; *, 90% or more of the strains are positive; −, 90% or more of the strains are negative; V, variable (11 to 89% of the strains are positive).*

*Phenotypic characteristics based on data from type strains.*

*Occasional exceptions occur (<3% of strains show atypical reactions).*

*Late positive (3 days of incubation or longer).*

*Weak reaction.*
Identification of enterococcal species, sometimes including *E. faecalis* and *E. faecium*, have been reported (19, 95). Strict adherence to the instructions provided by the manufacturer, including the base of the medium used to grow strains for testing, is of paramount importance. Our own unpublished experimental results indicate that differences in growth conditions can lead to variation in the results of some tests, interfering with the accuracy of the identification. Identification of an unusual enterococcal species by a commercial system should be confirmed by a reference method before being reported.

**Identification by MALDI-TOF MS**

Currently, bacterial identification using matrix-assisted laser desorption ionization–time of flight mass spectrometry (MALDI-TOF MS) is being considered a revolutionary tool for bacterial identification in the clinical microbiology laboratory (96, 97). Compared with other methods, this technology can readily and conveniently identify a wide range of microorganisms, including enterococcal species (98–102). Two major MALDI-TOF MS platforms are available at this time: the Microflex LT Biotyper (Bruker Daltonics, Bremen, Germany) and the Vitek MS system (bioMérieux, Marcy l’Etoile, France). Results of a comparative evaluation of these platforms indicated that they both were able to identify correctly all the enterococcal isolates tested (98). However, only *E. faecalis*, *E. faecium*, *E. casseliflavus*, and *E. gallinarum* were identified in this study. At this point, an extensive evaluation of either system including the different enterococcal species is still not available. Although the numbers of studies and species tested are still limited, the results indicate that the method constitutes an important tool to rapidly identify the major enterococcal species recovered from human sources and certainly deserves to be further evaluated for the identification of the diversity of the diverse members of the genus *Enterococcus*, including isolates with a variety of biochemical profiles and obtained from different sources. In addition, MALDI-TOF MS has also been applied directly to positive blood cultures without the need for additional culturing (103, 104).

**Identification by Molecular Methods**

Molecular methods, such as DNA-DNA hybridization and sequencing of the 16S rRNA genes, have been primarily used for taxonomic purposes in reference or research laboratories. In the past decades, however, the application of molecular techniques for the rapid identification of *Enterococcus* species has also been expanded dramatically for use in clinical microbiology laboratories.

A variety of molecular procedures have been proposed for the identification of enterococcal species as previously reviewed and summarized (1, 105). Many of these molecular procedures have been performed in only a few laboratories and have not been evaluated for all the species of *Enterococcus*. Most of them are potentially applicable to all enterococcal species, and others are species specific. Several of these methods deserve consideration for expanded testing and future improvements, as they represent promising adjunct tools for a more rapid and precise identification of enterococcal species.

Among the molecular techniques proposed to identify the different enterococcal species, sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) analysis of whole-cell protein (WCP) profiles and sequencing of the 16S rRNA genes have been more extensively evaluated in reference laboratories. SDS-PAGE analysis of WCP profiles was shown to be a reliable tool for the differentiation and identification of typical and atypical *Enterococcus* strains, since WCP profiles are species specific (1, 12, 91, 106, 107). After the introduction of DNA-based methods, however, the use of this molecular phenotypic approach has decreased and is now basically limited to taxonomic studies.

Table 2, which describes the phenotypic characteristics of the *Enterococcus* species discussed in this chapter, is based on correlations between the WCP profiles and the phenotypic tests, in conjunction with DNA-DNA reassociation experiments and 16S rRNA gene sequencing. Sequencing of the 16S rRNA gene is currently the most frequently used among the nucleic acid-based methods for identification of enterococcal species. It has been performed for all species of enterococci, and the sequences are available for comparison purposes via public databases of nucleotide accessions, such as GenBank. Comparisons can be made by using one of the several sequence-comparing software packages, many of which are available for public access. Figure 1 depicts a dendrogram generated by comparison of 16S rRNA gene sequences of the type strains of the species included in the genus *Enterococcus*. Nevertheless, clear-cut differentiation is not always obtained for all enterococcal species, since some of them differ by only 2 or 3 bases over the approximately 1,500-base span of the 16S rRNA gene. Therefore, this procedure should not be used alone, but together with phenotypic characterization and other alternative molecular methods, it can be an important tool to establish enterococcal species identity. Several other housekeeping genes have been investigated as alternative tools to develop sequencing-based methods to identify enterococci, either alone or in association. They include the gene sequences encoding the ATP synthase β subunit (*atpD*), the phenylalanyl-tRNA synthase (*phbS*), the RNA polymerase α subunit (*rpoA*), the RNA polymerase β subunit (*rpoB*), the manganese-dependent superoxide dismutase (*sodA*), and the elongation factor Tu (*tufA*) (108–113). Their use has been restricted to taxonomic purposes mostly, and none has been applied to all the enterococcal species described to date.

PCR-based techniques have also been a focus of major interest for rapid and accurate enterococcal identification. Tests based on the amplification of the gene encoding the β-ala β-ala ligase (dil) (19, 98, 114) or the *sodA* gene (19) have already been designed for several enterococcal species and constitute convenient alternative approaches for rapid routine identification. PCR methods to identify all the enterococcal species, however, are not available yet.

The use of molecular methods for the rapid identification of enterococci directly from positive blood culture bottles has also been investigated. Fluorescence in situ hybridization (FISH) techniques have been developed and evaluated for the identification of enterococci from positive blood culture bottles (115–117). One of these assays, the *E. faecalis/Other Enterococcus species* (EF/OE) PNA FISH (AdvPanDx, Woburn, MA) is a peptide nucleic acid (PNA) FISH test that is FDA cleared. Recent multicenter studies have indicated that the EF/OE PNA FISH procedure can offer a time to reliable results of 1.5 h, thus further reducing the reporting turnaround time when compared to the original 2.5-h assay procedure (117). Other commercially available diagnostic systems based on nucleic acid technologies that have been
cleared by the FDA include the Verigene Gram-positive blood culture (BC-GP) nucleic acid test (Nanosphere, Inc., Northbrook, IL) (118, 119) and the FilmArray Blood Culture ID Panel (Biofire Diagnostics, Inc., Salt Lake City, UT) (120). These multiplex tests are capable of detecting most leading causes of Gram-positive bacterial bloodstream infections, including enterococci, as well as the genetic markers of vancomycin resistance vanA and vanB. These assays have been considered relatively easy to implement, leading to earlier identification of invasive infections caused by Enterococcus species than that obtained with conventional microbiological methods. As recently reported, these technologies can also have a significant impact on the clinical and economical outcome of patients with enterococcal bacteremia by decreasing the time to antimicrobial therapy, the hospital length of stay, and health care costs (121).

**Typing Systems**

The increasing documentation of Enterococcus as a leading nosocomial pathogen frequently resistant to several antimicrobial agents, as well as the evidence supporting the concept of exogenous acquisition of enterococcal infections, has generated demand for strain typing and epidemiological studies. Classic phenotypic methods used to investigate the diversity among isolates of a given enterococcal species have frequently failed to adequately discriminate among strains, and they have limited value in epidemiological studies. However, phenotypic information in association with molecular data can constitute valuable information (1, 105).

The introduction of molecular techniques has substantially improved the ability to discriminate enterococcal isolates and has provided critical insights into the epidemiology of the enterococci. By using molecular typing approaches, it was possible to demonstrate the exogenous acquisition of enterococcal strains by direct and indirect contact among patients, breaking the traditional conception that enterococcal infections were endogenous in nature. Intrahospital transmission and interhospital spread have been extensively documented for antimicrobial-resistant enterococci, especially VRE (1, 24, 28, 122, 123). In addition to epidemiological investigations, some of the molecular typing techniques are now used to trace the dissemination of enterococci in different environments and hosts and the evolution of multidrug-resistant strains, greatly expanding our understanding of enterococcal epidemiology, population structure, antimicrobial resistance, and virulence. Emergence and global dispersion of certain epidemic enterococcal clonal complexes have been identified (32–35, 39, 124).

Several molecular methods have been proposed to type enterococcal isolates, as previously reviewed (1, 105). In addition to differences in complexity and costs, these methods vary in their reproducibility and discriminatory power. Overall, there is not a single definitive typing technique for enterococci, so a strong match among the results of different typing techniques, particularly those based on different genomic polymorphisms, should be used as indicative of high relatedness. Among these techniques, analysis of chromosomal DNA restriction profiles by pulsed-field gel electrophoresis (PFGE) has been extensively evaluated for epidemiological characterization of enterococcal outbreaks, showing improved discrimination and allowing the identification of clonal complexes that predominate among multidrug-resistant enterococci, mainly isolates with high-level resistance (HLR) to aminoglycosides and VRE (1, 48, 122, 125). Smal is the restriction enzyme most frequently used to digest enterococcal DNA, although the usefulness of others, such as Apal and Sfil, has also been reported (1). PFGE is possibly the typing method most commonly used in clinical microbiology settings, and it is considered by many investigators to be the gold standard for the epidemiological analysis of enterococcal outbreaks. Several protocols for performing PFGE typing of enterococcal strains have been published. However, the development of standardized protocols for execution, interpretation, and nomenclature, as a result of collaborative studies, is still needed in order to allow for interlaboratory data exchange and comparisons. On the other hand, although PFGE is quite discriminatory, epidemiological interpretation of PFGE profiles is not always clear-cut. The occurrence of genetic events can be associated with substantial changes in the PFGE profiles, leading to problems in clonality assessment (126). Due to the possibility of such inconsistencies in DNA banding patterns of enterococci, PFGE is recommended mostly for the purpose of evaluating the genetic relatedness and tracing transmission of strains that are associated in time and location, as its usefulness for long-term epidemiological studies may be limited. The use of PFGE in conjunction with at least one additional typing technique, such as an independent PFGE analysis using different restriction enzymes, is highly recommended to help in clarifying epidemiological interpretation.

General principles proposed for the interpretation of molecular typing data based on fragment differences are usually applied to interpret PFGE profiles obtained for enterococcal strains (1, 127). Well-characterized control strains should be evaluated along with unknown isolates. For that purpose, two reference strains, *E. faecalis* OGI1RF (ATCC 47077) and *E. faecium* GE1 (ATCC 51558), have been proposed (127).

Two other robust molecular techniques are multilocus sequence typing (MLST) and multilocus variable-number tandem repeat analysis (MLVA). These techniques circumvent the difficulties in data exchange between different laboratories by generating information that is suitable for the development of Web-based databases. MLST is based on identifying alleles after sequencing of internal fragments of a number of selected housekeeping genes, resulting in a numeric allelic profile. Each profile is assigned a sequence type (ST). Internet sites with the possibility for data exchange (www.mlst.net and www.pubMLST.org), which contain MLST schemes for *E. faecium* (128) and *E. faecalis* (129), have been developed. Application of MLST has revealed the occurrence of host-specific genogroups of *E. faecium* and allowed the recognition of a hospital-adapted *E. faecium* polyclonal subpopulation (particularly MLST sequence type 17 [ST17], ST18, ST78, and ST192) that predominates in several geographic areas and is associated with the increased frequency of isolation of *E. faecium* worldwide (24, 32, 33, 39, 123, 124, 130). This hospital-adapted lineage was initially named “C1 lineage” and later renamed “clonal complex-17” (CC17), and it is classified as an example of the so-called high-risk enterococcal complexes (HREC). Recent comparisons of available genome sequences support the concept of a hospital-associated clade that is genetically distinct from most commensal isolates (34, 313).

Two major clonal complexes (named CC2 and CC9) have also been identified among hospital-derived *E. faecalis* isolates (35, 39, 122, 129) by using MLST.

Two simultaneously published studies described the development of MLVA typing schemes for *E. faecalis* (132) and *E. faecium* (133). MLVA is based on variation in variable-number tandem repeats (VNTR) loci dispersed over the enterococcal genome. For each VNTR locus, the number of repeats is determined by PCR using primers based
on the conserved flanking regions of the tandem repeats. PCR products are separated on agarose gels, and the band size determines the number of repeats. These numbers together result in an MLVA profile, and each profile is assigned an MLVA type (MT). Comparative studies indicate that both techniques can achieve high degrees of discrimination between isolates and have discriminatory power (134) comparable to that of PFGE-based typing (122, 129, 133). In contrast to the overt advantages (being reproducible, portable, highly discriminatory, and unambiguous), MLST is time-consuming, expensive, and still limited to laboratories that have facilities for both PCR and sequencing, while MLVA requires PCR and basic electrophoresis facilities.

More recently, whole-genome sequencing (WGS) using next-generation sequencing (NGS) has emerged as a cost-effective and convenient approach for several microbiological applications, including typing of bacterial isolates (135, 136). The use of this technology is still limited, but the advantages of using it for genotyping enterococcal isolates and the consequent impact on our understanding of the epidemiology of enterococcal infections have already been reported (136, 137).

**SEROLOGIC TESTS**

Serologic tests for detecting antibody responses to different enterococcal antigens have been proposed (138, 139). However, their usefulness in the clinical laboratory setting for the diagnosis of enterococcal infections has not been demonstrated.

**ANTIMICROBIAL SUSCEPTIBILITIES**

Resistance to several commonly used antimicrobial agents is a remarkable characteristic of most enterococcal species. Moreover, most of this information is based on studies with *E. faecalis* and *E. faecium*, the two species that are frequently associated with human infections. Antimicrobial resistance can be classified as either intrinsic or acquired. Intrinsic resistance is related to inherent or natural chromosomally encoded characteristics present in all or most of the enterococci. Furthermore, certain specific mechanisms of intrinsic resistance to some antimicrobial agents are typically associated with a particular enterococcal species or groups of species. In contrast, the occurrence of acquired resistance is more variable, resulting from either mutations in existing DNA or acquisition of new genetic determinants carried in plasmids or transposons (24, 29, 36, 140, 141, 142). Enterococcal intrinsic resistance involves several antimicrobial agents, particularly two major groups: the aminoglycosides and the β-lactams. Because of the poor activity of several antimicrobial agents against enterococci due to intrinsic resistance, the recommended therapy for serious infections (i.e., endocarditis, meningitis, and other systemic infections), especially in immunocompromised patients, includes a combination of a cell wall-active agent, such as a β-lactam (usually penicillin or ampicillin) or vancomycin, and an aminoglycoside (usually gentamicin or streptomycin). These combinations overcome the intrinsic resistance exhibited by the enterococci, and a synergistic bactericidal effect is generally achieved since the intracellular penetration of the aminoglycoside is facilitated by the cell wall-active agent.

In addition to the intrinsic resistance traits, enterococci have acquired different genetic determinants that confer resistance to several classes of antimicrobial agents, including chloramphenicol, tetracyclines, macrolides, lincom-

occur rarely among enterococci. Furthermore, the isolation of vancomycin-dependent (154) and vancomycin-heteroresistant (155) enterococcal strains from clinically significant infections, although sporadically reported, may also represent additional serious threats for the treatment and control of enterococcal infections.

While in vitro methods for detecting vancomycin resistance are discussed in detail in references 1 and 145 as well as in chapters 71 and 73, some aspects regarding vanC-containing species (e.g., E. gallinarum and E. casseliflavus) need to be emphasized. Resistance associated with vanC genotypes is not usually detected by disk diffusion, but VanC strains frequently grow on vancomycin agar screen tests. Because of the low clinical significance of the VanC resistance, the implications of susceptibility testing for patient management may be unclear. However, the need to differentiate VanA or VanB strains, as well as strains displaying the other less commonly found types of acquired vancomycin resistance, from VanC strains is quite evident for therapeutic, infection control, and surveillance reasons. Because growth on vancomycin screening agar fails to help with this important distinction, species identification is necessary. For practical purposes, growth on the vancomycin screening agar test by E. faecalis or E. faecium is likely due to the presence of vanA or vanB. Although rare, the occurrence of the other kinds of vancomycin resistance may also be considered. Additionally, simultaneous occurrence of the vanA gene has been increasingly reported in vanC-carrying species E. casseliflavus and especially E. gallinarum, so that identification of a species that usually harbors only VanC resistance does not completely rule out moderate to high levels of vancomycin resistance (28, 49, 55). In this regard, determining vancomycin MICs is useful, as VanC resistance frequently results in MICs of <32 μg/ml, whereas VanA and VanB usually result in MICs of >32 μg/ml. In such cases, determination of the genetic elements associated with vancomycin resistance has important epidemiological and infection control implications. Also, resistance to other agents such as ampicillin and aminoglycosides is uncommon among VanC isolates. Moreover, the unexpected finding of simultaneous occurrence of the vanA and vanC1 genes in an E. faecalis isolate from ewe bulk tank milk was recently reported (156), illustrating the increasing complexity for precise determination of glycopeptide resistance and its association with the different enterococcal species. Because of limited alternatives, chloramphenicol, erythromycin, tetracycline (or doxycycline or minocycline), and rifampin may be tested for VRE. Selective testing of quinupristin-dalfopristin, linezolid, and daptomycin, based on the site of infection, is recommended when reporting vancomycin-resistant E. faecium isolates (144, 145).

Molecular methods (see chapter 77) have been used to detect specific antimicrobial resistance genes and have substantially contributed to the understanding of the spread of acquired resistance among enterococci, especially resistance to vancomycin. However, because of their high specificity, molecular methods do not detect antimicrobial resistance due to mechanisms not targeted by the testing, including emerging resistance mechanisms.

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

The diversity and species specificity of acquired antimicrobial resistance traits among enterococcal isolates created an additional need for accurate identification at the species level and for in vitro evaluation of susceptibility to antimicrobial agents. The significance of a particular enterococcal isolate is a major factor in determining when antimicrobial testing should be done. Once the need to test a particular isolate has been established, selection of the appropriate antimicrobial agents for testing must be considered on the basis of the site of infection. Testing of antimicrobial agents to which enterococci are intrinsically resistant is contraindicated. The drugs that should not be reported include aminoglycosides at standard concentrations, cephalosporins, clindamycin, and trimethoprim-sulfamethoxazole. They may appear active for enterococci in vitro but are not effective clinically, and as such they should not be reported as drugs to which enterococci are susceptible. Updated guidelines (145) for the selection of antimicrobial agents should be followed for routine testing and reporting. The in vitro methods for detecting antimicrobial resistance in enterococcal isolates were reviewed and summarized in reference 1 and are also discussed in chapters 71 and 73.

As already mentioned, testing for high-level aminoglycoside resistance as a predictor of synergy should be done with any enterococcal isolate implicated in infections for which combination therapy is indicated, e.g., from systemic infections. Enterococci are also frequently encountered in polymicrobial infections associated with the gastrointestinal tract or superficial wounds of hospitalized patients. Their pathogenic significance in such settings is uncertain, but susceptibility testing is warranted when predominant or heavy growth is observed. Testing of E. faecalis isolates from lower urinary tract infections is optional, as these infections usually respond to therapy with ampicillin or nitrofurantoin. However, many hospital infection control programs require routine testing as part of surveillance programs for VRE. For those instances when testing a urinary tract isolate is appropriate, ciprofloxacin, fosfomycin, levofloxacin, norfloxacin, and tetracycline could be selected, in addition to nitrofurantoin and ampicillin (28, 36, 142, 143, 145). In cases of treatment failure, testing is always warranted.

The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the CDC. The use of product names in the manuscript does not imply their endorsement by the U.S. Department of Health and Human Services.

Aerococcus, Abiotrophia, and Other Aerobic Catalase-Negative, Gram-Positive Cocci

JENS JØRGEN CHRISTENSEN AND KATHRYN L. RUOFF

TAXONOMY
The catalase-negative, Gram-positive cocci included in this chapter form a taxonomically diverse group of bacteria that are isolated infrequently as opportunistic agents of infection. Most of these organisms resemble other more well-known clinical isolates (i.e., streptococci and enterococci) and consequently may be mistaken for members of those genera. Although probably misidentified or overlooked in clinical cultures in the past, these organisms may represent emerging pathogens in immunocompromised patient populations. Table 1 lists the organisms included here along with some of their basic characteristics. The bacteria discussed in this chapter are members of the phylum Firmicutes (low-G+C, Gram-positive bacteria). Helcococcus is the only genus in the class "Clostridia," while the remaining genera are classified in the class "Bacilli" (1). The reader is referred to chapter 21 for information on Rothia mucilaginosa, another infrequently isolated Gram-positive coccus that may be catalase negative.

The genus Lactococcus is composed of organisms formerly classified as Lancefield group N streptococci (2). The species Lactococcus lactis and Lactococcus garvieae have been documented in human infections. Motile Lactococcus-like organisms with Lancefield’s group N antigen (a teichoic acid antigen) are classified in the genus Vagococcus (3, 4). The vagococci also resemble the enterococci, and Facklam and Elliott (5) reported that Vagococcus flavialis (the principal species described in human clinical specimens to date) isolates examined at the Centers for Disease Control and Prevention gave positive reactions in a commercially available nucleic acid probe test for enterococci.

The genera Abiotrophia and Granulicatella accommodate organisms previously known as nutritionally variant or satellite streptococci (6, 7). These bacteria were originally thought to be nutritional mutants of viridans streptococcal strains, most notably of the species Streptococcus mitis. Bouvet and colleagues (8) suggested that this group of organisms were really members of two novel streptococcal species given the names Streptococcus defectivus and Streptococcus adiacens. A comparative analysis of 16S rRNA gene sequences led Kawamura and cowokers to propose the creation of a new genus, Abiotrophia, containing two species, Abiotrophia defectiva and Abiotrophia adiacens, to accommodate these bacteria (7). A third species from human sources, Abiotrophia elegans, was described in 1998 (9). Kanamoto et al. noted the heterogeneity among Abiotrophia strains and proposed a fourth species, Abiotrophia para-adiacens (10). In 2000, Collins and Lawson proposed a new genus, Granulicatella, with Granulicatella adiacens and Granulicatella elegans representing strains formerly called A. adiacens and A. elegans. A. defectiva remains as the sole Abiotrophia species (6).

Among the intrinsically vancomycin-resistant, catalase-negative, Gram-positive cocci, a number of Leuconostoc species have been noted in human infection (Leuconostoc mesenteroides, Leuconostoc lactis, Leuconostoc pseudomesenteroides, and Leuconostoc citreum [11]). In 1993, the former Leuconostoc paramesenteroides and related species were placed into a novel genus, Weissella (12). Pedicoccus acidilactici and Pedicoccus pentosaceus are the most common clinical isolates of pediococci (13). The vancomycin-susceptible species formerly named Pedicoccus halophilus was reclassified in the genus Tetragnococcus (14). The organism formerly called Enterococcus solitarius has also been transferred to the Tetragnococcus genus as Tetragnococcus solitarius (15). Little is known about the role of the tetragnococci in human infection.

The organism we now know as Gemella morbillorum was described in 1917 by Tunnicliff (16) as an isolate from the blood of patients with measles. G. morbillorum was originally named Diplococcus rubelae and was also called Diplococcus morbillorum, Peptostreptococcus morbillorum, and Streptococcus morbillorum until a proposal to include it in the genus Gemella as G. morbillorum was made in 1988 (17). A second species, Gemella haemolytica, was originally classified as a Neisseria species, due to its Gram-variable or even Gram-negative nature and its cellular morphology (diplococci with flattened adjacent sides). Collins and coworkers described two additional Gemella species isolated from human sources, Gemella bergeriae (originally named Gemella bergeriae [18]) and Gemella sangunis (19). Gemella asaccharolytica was recently described by Ulger-Toprak and colleagues (20). The genus Dolosigranulum shows phenotypic similarities to Gemella, although it is not phylogenetically closely related to Gemella strains (21, 22). Aerococcus urinae, described in 1992, is negative for pyrrolidonyl arylamidase production (PYR) and positive for leucine aminopeptidase production (LAP), showing opposite reactions of Aerococcus viridans in these important identification tests (23). In spite of these phenotypic differences,

^aAbbreviations and symbols: NaCl, growth in 6.5% NaCl; +, ≥90% of strains positive; –, ≤10% of strains positive.
^bSome strains may display vancomycin resistance, and some strains are motile.
^cMost enterococcal strains are capable of growth at 45°C, differentiating them from vagococci, which may be phenotypically similar. Strains of vagococci have been reported as testing positive with a commercially available nucleic acid probe for members of the genus Enterococcus.
^dPhenotypically similar strains of enterococci and lactococci can be differentiated with a commercially available nucleic acid probe for members of the genus Enterococcus.
^eMotile.
^fSome strains display satelliting growth; some strains are urease positive.
^gMembers of this genus display satelliting growth.
^hAlthough H. kunzii shares some phenotypic traits with A. viridans, it is facultative and usually nonhemolytic, in contrast to A. viridans, which prefers an aerobic growth atmosphere and is alpha-hemolytic.
^iTwo additional species of Helcococcus (H. sueciensis and “H. pyogenes”) have been proposed (36–38), both based on the isolation of a single strain. These new species are negative reactions in the PYR test, in contrast to H. kunzii.
^jVancomycin resistant.
^kViridans group streptococci include streptococci of the anginosus, mitis, mutans, salivarius, and bovis species groups. Some strains of Streptococcus pneumoniae (a member of the mitis species group) may produce positive reactions in the PYR test.

molecular taxonomic studies suggest that A. urinae should remain in the Aerococcus genus. Organisms currently included in the A. urinae species are fairly heterogeneous and can probably be subdivided into at least two subspecies (24). Aerococcus christensenii, isolated from the human genitourinary tract, was described by Collins and coworkers in 1999 (25) and was joined by the species Aerococcus sanguinicola (originally named Aerococcus sanguicola [26, 27]) and Aerococcus urinaehominis (28) in 2001.

Globicatella, Faccklamia, Ignavigranum, and Dolosicoccus are related genera that are isolated infrequently from clinical specimens. Globicatella sanguinis, initially named Globicatella sanguis, was described in 1992 (29). Faccklamia currently contains four species isolated from human sources: Faccklamia hominis (30), Faccklamia sourekii (31), Faccklamia ignava (32), and Faccklamia languida (33). The genus Ignavigranum, currently consisting of a single species, Ignavigranum rouffiae, was described by Collins and coworkers (34), along with the genus Dolosicoccus and its single species, Dolosicoccus paucivorans (35).

The genus Helcococcus, originally composed of the single species Helcococcus kunzii (36), came to include a new species isolated from humans, Helcococcus sueciensis, in 2004 (37). A third human species, “Helcococcus pyogenes,” has been proposed, but to date has not received official taxonomic standing (38, 39). Helcococcus ovis, isolated from infections in animals, displays satelliting growth, unlike the human Helcococcus species (40).

DESCRIPTION OF THE GENERA

The organisms included in this chapter form Gram-positive coccoid cells, but G. haemolysans may appear Gram variable or Gram negative due to the ease with which its cells are decolorized. Cell shape and arrangement can be used to divide these organisms into two broad groups: those with a “streptococcal-like” Gram stain (cocccobacilli in pairs and chains) and those with a “staphylococcal-like” Gram stain (more spherical coco in pairs, tetrads, clusters, or irregular groups). Abiotrophia and Granulicatella isolates (formerly the nutritionally variant streptococci) form coccobacilli arranged in pairs and chains, but these organisms may also appear pleomorphic, especially when grown under suboptimal nutritional conditions (41). Dividing these diverse bacteria into two groups based on cellular shape and arrangement serves only as an aid in identification; no relatedness of organisms is implied by this grouping. With the exception of the infrequently isolated vagococci, these bacteria are all nonmotile.

Most of the genera described here are catalase-negative facultative anaerobes, but A. viridans is classified as a microaerophile that grows poorly, if at all, under anaerobic conditions. Some strains of Aerococcus may exhibit weakly positive catalase reactions due to nonhemolytic catalase activity. None of the genera are beta-hemolytic on routinely employed blood agars, but strains of G. haemolysans, G. bengeri, and Gemella sanguinis have been described as beta-hemolytic on agars supplemented with horse blood (18, 19, 42).

EPIDEMIOLOGY AND TRANSMISSION

The organisms discussed in this chapter are opportunistic pathogens. Some of the genera have been characterized as constituents of the normal microbiota of the human oral cavity or upper respiratory tract (Gemella, Abiotrophia, and Granulicatella) and skin (Helcococcus). Lactococci, pediococci, and leuconostocs can be isolated from foods and vegetation (5, 43, 44) and may also be found as part of the normal microbiota of the alimentary tract. Aerococci are environmental isolates that can also be found on human
skin. Although they have been isolated from human clinical cultures, the natural habitats of many of the organisms mentioned here are not well characterized.

The bacteria examined here seem to be of low virulence and are usually pathogenic only in immunocompromised hosts. Infection often occurs in previously damaged tissues (e.g., heart valves) or may be nosocomial and associated with prolonged hospitalization, antibiotic treatment, invasive procedures, and the presence of foreign bodies.

**CLINICAL SIGNIFICANCE**

The bacteria described in this chapter may be present as contaminants in clinical cultures, but they are also isolated infrequently as opportunistic pathogens. Blood, cerebrospinal fluid, urine, and wound specimens are likely to yield significant isolates of these bacteria. Details on reported infections due to each of the genera follow.

**Lactococcus**

Due to their phenotypic similarities with streptococci and enterococci, clinical isolates of lactococci have probably been misidentified in the past, accounting at least in part for the paucity of reports concerning the clinical role of these bacteria. Elliott and coworkers (45) studied the phenotypic characteristics of a number of lactococcal strains isolated from blood, urinary tract infections, and an eye wound culture. Lactococci have been associated with native valve and prosthetic valve endocarditis (46–49), sepsis in an immunosuppressed patient, osteomyelitis, spondylodiscitis (46), peritonitis (50), liver abscess (51, 52), acalculous cholecystitis (53), and prosthetic joint infection (54). L. garvieae is a known pathogen of aquatic cultured fish, and human infections have been linked to consumption of or contact with fish (46, 54).

**Vagococcus**

To date, only a handful of Vagococcus isolates from human sources have been reported in the literature. Teixeira and coworkers (55) described strains isolated from blood, peritoneal fluid, and a wound. Al-Ahmad and colleagues reported isolation of *V. fluvialis* from an infected root canal system (56). Vagococci are motile organisms that, like lactococci, elaborate Lancefield’s group N antigen (5). Difficulties encountered in identifying vagococci may partially account for their infrequent recognition in clinical cultures.

**Abiotrophia and Granulicatella**

Organisms in the genera *Abiotrophia* and *Granulicatella* (formerly known as nutritionally variant streptococci) are normal residents of the oral cavity and are recognized as agents of endocarditis involving both native and prosthetic valves (57–60). These organisms have also been isolated from other types of infections, including ophthalmic infections (61, 62), central nervous system infections (63, 64), peritonitis in patients undergoing continuous ambulatory peritoneal dialysis (65), musculoskeletal infection (66), septic arthritis (67), and a breast implant-associated infection (68).

**Leuconostoc, Pediococcus, and Weisella**

The vancomycin-resistant genera *Leuconostoc* and *Pediococcus* were first recognized in clinical specimens in the mid-1980s. Handwerger and colleagues (69) observed that host defense impairment, invasive procedures breaching the integument, gastrointestinal symptoms, and prior antibiotic treatment were common features among adult patients with *Leuconostoc* infection. They also noted a predisposition to *Leuconostoc* bacteremia among neonates, suggesting that infants may become colonized during delivery by *leuconostocs* inhabiting the maternal genital tract. *Leuconostoc* have been isolated from blood, cerebrospinal fluid, peritoneal dialysate fluid, and wounds. Case reports have implicated *leuconostocs* as agents of infection in osteomyelitis (70), ventriculitis (71), brain abscess (72), postsurgical endophthalmitis (73), and bacteremia in the setting of short gut syndrome. Short gut syndrome favors a microbiota with a high prevalence of *Lactobacillus* and *Leuconostoc* bacteria (74). Several reports have related *Leuconostoc* bacteremic episodes to the presence of short gut syndrome, central venous catheters, and disrupted bowel mucosa (75).

*Pediococcus* strains have been isolated from bacteremia and cases of sepsis and hepatic abscess in compromised patients (13, 76–79). Barros and coworkers (13) noted that *P. acidilactici* was isolated from clinical specimens more frequently than *P. pentosaceus* and was also more commonly isolated from cases of bacteremia. Barton and coworkers noted the role of *Pediococcus* in bacteremia in infants with gastrointestinal malformations requiring surgical correction (76).

*Weisella confusa*, formerly classified as *Lactobacillus confusus*, has been reported infrequently as an agent of bacteremia and endocarditis (80, 81).

**Gemella**

*G. haemolysans* has been isolated from cases of endocarditis (82), meningitis (83), brain abscess (84), a total knee arthroplasty (85), and ocular infection (86–88). *G. morbillorum* has been implicated in cases of endocarditis (89, 90), empyema and lung abscess (91), septic shock (92), brain abscess (93), osteomyelitis (94), septic arthritis (95), and peritonitis (96). Information on the clinical significance of the other Gemella species continues to accumulate. *G. bergeri* and *G. sanguinis* have been isolated from blood cultures, and they may also be causative agents of endocarditis (18, 19, 97). A strain of *G. sanguinis* was isolated from an infected prosthetic hip joint (98), and *G. asaccharolytica* has been isolated from wound cultures (20).

**Dolosigranulum**

*Dolosigranulum*, a genus phenotypically similar, but not closely related, to *Gemella* (21), has been documented in blood, eye, and respiratory specimens (22). The single species of the genus, *Dolosigranulum pigrum*, has been associated with nosocomial pneumonia and sepsis (99), synovitis (100), acute cholecystitis accompanied by acute pancreatitis (101), and biomaterial-associated arthritis (102).

**Aerococcus**

*A. viridans* has been noted as a contaminant in clinical cultures and infrequently as a clinically significant isolate from cases of endocarditis and bacteremia and a case of spondylodiscitis (103–105). Four additional Aerococcus species isolated from humans have been described since the early 1990s. *A. torvalae* (23, 106) has been implicated as a urinary tract pathogen in patients predisposed to infection (107–109) and as an agent of endocarditis (110, 111), lymphanitis (112), and peritonitis (113). *A. sanguinicola* has been isolated from blood and urine specimens (26, 27) and cases of urosepsis and endocarditis (114). Little is currently known about the clinical significance of *A. christensenii* (isolated from vaginal specimens [25]) and *A. urinaehominis* (isolated from urine [28]).
**Globicatella**

*G. sanguinis*, isolated from human clinical specimens, has been implicated in cases of bacteremia, urinary tract infection, and meningitis (29, 115, 116). A second species in the genus, *Globicatella sulfidifaciens*, has been isolated from purulent infections in domestic mammals (117).

**Facklamia**

The *Facklamia* genus is closely related to, but phenotypically and phylogenetically distinct from, *Globicatella* (30). Strains of the four *Facklamia* species isolated from humans have been recovered from blood, wound, and genitalurnary sites (30–33) and a case of chorioamnionitis (118).

**Ignavigranum**

A limited number of isolates of *I. ruoffiae*, the sole species of *Ignavigranum*, have been described to date. Sites of isolation include a wound and an ear abscess (34).

**Dolosicoccus**

The single species of the genus *Dolosicoccus*, *D. paucivorans*, has been isolated from blood cultures (35, 119).

**Helcococcus**

*H. kunzii* can be isolated from intact skin of the lower extremities (120) as well as from mixed cultures of wounds, notably foot infections (36, 121). In such scenarios the clinical significance of this organism is difficult to interpret, since it may be present merely as a colonizer of the wound site. The ability of *H. kunzii* to function as an opportunistic is, however, suggested by its isolation as the sole or predominant organism from an infected sebaceous cyst (122), a breast abscess (123), a postauricular foot abscess (124), an infected prosthetic joint (125), and cases of bacteremia and empyema in intravenous drug users (126). Two additional species isolated from humans, *H. succinsis* and *H. pyogenes*, are based on single isolates from a wound and a prosthetic joint infection, respectively (37–39).

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

No special requirements for collection and transport of specimens for isolation of the organisms discussed in this chapter have been described. Routine procedures for collection, transport, and storage of specimens for aerobic culture allow for the isolation of these bacteria, since the majority are facultative anaerobes or microaerophiles. These organisms should also be recovered from specimens that have been collected and transported under anaerobic conditions (see chapter 18).

**DIRECT EXAMINATION**

The organisms described in this chapter can be visualized in direct Gram stains of clinical material but have no outstanding morphological characteristics that distinguish them from commonly isolated Gram-positive cocci (streptococci and staphylococci). Although *Abiotrophia* and *Granulicatella* strains may appear pleomorphic in direct Gram stains, they form Gram-positive cocci in pairs and chains when grown on nutritionally adequate media. Direct detection of these genera by antigenic methods has not been described, but some authors have employed amplification of 16S rRNA genes for direct detection in clinical specimens (59).

**ISOLATION PROCEDURES**

Generally, there are no special requirements for isolation of the group of bacteria discussed here; general recommendations for the culture of blood, body fluids, and other specimens should be followed (see chapter 18). These organisms are likely to be isolated on rich, nonselective media (e.g., blood or chocolate agar and thioglycolate broth) since they are nutritionally fastidious. If selective isolation of the vancomycin-resistant genera *Leuconostoc* and *Pedococcus* is desired, Thayer-Martin medium may be used to inhibit normal microflora or other contaminating microorganisms (127). Some of the genera (e.g., *Helcococcus*) grow slowly, forming tiny colonies that may not be visible unless extended incubation (48 to 72 h) is employed. The recovery of many of the genera included in this chapter may be enhanced by CO₂ enrichment of the incubation atmosphere.

Members of the genera *Abiotrophia* and *Granulicatella* usually grow on chocolate agar, on brucella agar with 5% horse blood, and in thioglycolate broth, but not on Trypticase soy agar with 5% sheep blood. These organisms can be cultured on nonsupportive media that have been appropriately supplemented (see “Procedures for Phenotypic Differentiation, *Abiotrophia* and *Granulicatella*” below).

**IDENTIFICATION**

**Procedures for Phenotypic Differentiation**

While molecular characterization may be required for accurate species-level identification of the aerobic catalase-negative, Gram-positive cocci encountered infrequently in clinical laboratories, phenotypic methods can be helpful in characterization of these bacteria to the genus level. Gram stain morphology has been employed as a major decision point in the identification protocols in Fig. 1 and 2 and Table 1, with two general categories: morphology resembling that of streptococci, meaning cocci or coccobacilli in pairs and chains, versus staphylococcoc morphology, consisting of coccolid cells arranged in pairs, clusters, tetrads, or irregular groups. Broth-grown cells (thioglycolate broth is suitable) should be used for making accurate morphological determinations. Note that *Gemella* and *Facklamia* strains may display either type of cellular morphology, depending on the species. Figures 1 and 2 display phenotypic tests used to differentiate the genera of bacteria discussed in this chapter. Descriptions of tests for catalase, PYR, LAP, β-glucuronidase, and hippurate hydrolysis, as well as bile esculin agar and *Lactobacillus* MRS (DeMan, Rogosa, Sharpe) broth media, can be found in chapter 19 and reference 5. Additional phenotypic tests are described below in the discussion of identification criteria for each genus.

**Lactococcus** and **Vagococcus**

The members of the genera *Lactococcus* and *Vagococcus* are usually PYR and LAP positive, grow in the presence of 6.5% NaCl, and can be confused with enterococci or streptococci. For the salt tolerance test, heart infusion broth supplemented with 6.0% NaCl (producing a final NaCl concentration of 6.5%), with or without the acid-base indicator brom cresol purple, is inoculated with two or three colonies and incubated at 35°C for up to 72 h. Turbidity with or without a color change from purple to yellow indicates growth (3, 128). Facklam and colleagues (3, 128) recommended growth temperature tests for distinguishing lactococci from streptococci and enterococci. Consult Fig. 1 for growth temperature characteristics of each of the genera. For growth temperature tests, broths (heart infusion broth containing 1% glucose...
Identification of catalase-negative, Gram-positive cocci that grow aerobically with cells arranged in pairs or chains. Abbreviations: 6.5% NaCl, growth in broth containing 6.5% NaCl; bile esculin, hydrolysis of esculin in the presence of 40% bile; motility, motility in motility test medium; 45°C, growth at 45°C; 10°C, growth at 10°C; probe, reaction with commercially available nucleic acid probe for the genus *Enterococcus*; HIP, hydrolysis of hippurate; satellitism, satelliting growth behavior; ARG, arginine hydrolysis activity; BGUR, β-glucuronidase activity.

doi:10.1128/9781555817381.ch24.f1

and bromcresol purple indicator) are inoculated with a single colony or drop of broth culture of the test strain and incubated at 35°C for up to 7 days. A water bath is recommended for incubation of cultures at 45°C. Turbidity with or without a change in the broth's indicator to yellow indicates a positive test. The motile vagococci can be distinguished from lactococci with modified motility test medium, stab-inoculated and incubated at 30°C for up to 48 h, according to the method of Facklam and Elliott (5). Further information on the phenotypic traits of *Lactococcus* and *Vagococcus* isolates may be found in references 2, 45, 55, and 129.

**Abiotrophia** and **Granulicatella**

A test for satelliting behavior is important for identification of these two genera. The strain to be examined is streaked for confluent growth on a medium that does not support growth or supports only weak growth (e.g., sheep blood agar). A single cross streak of *Staphylococcus aureus* (ATCC 25923 or another suitable strain) is applied to the inoculated area. After incubation at 35°C in an atmosphere containing elevated CO₂, strains of *Abiotrophia* or *Granulicatella* grow only in the vicinity of the staphylococcal growth. Some strains of *Ignavigranum* may also show satelliting behavior (34). Alternatively, media can be supplemented with pyridoxal. An aqueous stock solution of filter-sterilized 0.01% pyridoxal hydrochloride (which can be stored frozen) should be added to media to achieve a final concentration of 0.001%. Pyridoxal disks (Remel, Lenexa, KS) may also be used in the satelliting test.

Detailed phenotypic information for the PYR- and LAP-positive *Abiotrophia* and *Granulicatella* species can be found in references 6, 41, 130, and 131. Davis and Peel (132) reported that the API 20 Strept system (bioMérieux, Durham, NC) was superior to the Rapid ID32 Strept system (bioMérieux) for identification of these organisms.

**Leuconostoc, Pediococcus, and Weissella**

Members of the PYR-negative, vancomycin-resistant genera *Leuconostoc, Pediococcus,* and *Weissella* produce small, alpha-
hemolytic or nonhemolytic colonies on blood agar. Vancomycin resistance can be tested by streaking several colonies over half of a Trypticase soy agar with 5% sheep blood plate. After placing a 30-μg vancomycin disk in the center of the inoculated area, the plate is incubated overnight in a CO₂-enriched atmosphere at 35°C. Any zone of inhibition indicates susceptibility, while resistant strains exhibit no inhibition zone (5, 128). In addition to differing cellular morphologies (Table 1), these vancomycin-resistant genera, along with vancomycin-resistant strains of lactobacilli that form short coccoid cells, can be differentiated by tests for gas production from glucose and arginine hydrolysis. Leuconostocs produce gas and are always arginine negative. Lactobacilli are variable in both tests, but a positive arginine test for a gas-producing strain would rule out identity of the organism as a leuconostoc. Pediococci are gas production negative and show variable reactions in the arginine test, although P. acidilactici and P. pentosaceus, the two species commonly found in clinical material, are arginine positive. Weissella strains may be misidentified as leuconostocs or lactobacilli. These organisms produce gas from glucose. The few clinical isolates reported in the literature have been described as positive for hydrolysis of arginine (12, 81). MRS broth (BD Diagnostic Systems, Franklin Lakes, NJ; Hardy Diagnostics, Santa Maria, CA; see chapter 19), sealed with melted petrolatum and incubated for up to 7 days at 35°C, is used to test for gas production, indicated by displacement of the petrolatum plug (5, 128). The arginine hydrolysis test can be performed with Moeller decarboxylase broth containing arginine (5). Lancefield group D antigen can be detected in pediococci (128). References 5, 11, 13, 128, and 131 should be consulted for further information on identification of Leuconostoc and Pediococcus to the species level.

**Gemella**

On sheep blood agar media, members of the Gemella genus (usually PYR positive) form small colonies that are similar in appearance to those of viridans group streptococci. Slow growth of some Gemella strains may lead to confusion of these organisms with *Abiotrophia* or *Granulicatella* (formerly called nutritionally variant streptococci). A test for satelliting behavior should separate these two groups of bacteria (128), but Leung and coworkers (98) reported on a single *G. sanguinis* strain that exhibited "pseudosatelliting" behavior (satelliting growth after 24 h, but widespread growth after 48 h of incubation). Cells of *G. haemolysans* are easily decolorized and resemble those of neisserias, since they occur in pairs with the adjacent sides flattened. *G. haemolysans* prefers an aerobic growth atmosphere. The esculin hydrolysis test for differentiation of *G. haemolysans* and *R. mucilaginosus* in Fig. 2 is performed with esculin agar slants (heart infusion agar containing 0.1% esculin and 0.5% ferric citrate) that are inoculated and incubated at 35°C for up to 7 days. Partial or complete blackening of the agar indicates a positive reaction (5). *G. morbillorum* cells are Gram positive and arranged in pairs and short chains; individual cells in a given pair may be of unequal sizes. Only a small number of strains of *G. bergeri* and *G. sanguinis* have been reported on to date. Information on phenotypic characteristics of
these Gemella species can be found in references 18 and 19. The recently described G. asaccharolytica is PYR negative, unlike other Gemella species (20).

**Aerococcus**
The PYR-positive, LAP-negative member of the genus, *A. viridans*, is characterized by displaying weak or no growth when incubated in an anaerobic atmosphere (134). This trait can be tested by incubating duplicate blood agar plate cultures of the organism in question in anaerobic and aerobic atmospheres and comparing growth after 24 to 48 h. *A. viridans* forms alpha-hemolytic colonies that could be confused with those of either viridans group streptococci or enterococci. *A. sanguinicola* is positive in the PYR and LAP tests, while *A. urinaehominis* is negative in both. The PYR-negative, LAP-positive species, *A. urinae* and *A. christensenii*, are differentiated by production of β-glucuronidase (*A. christensenii* is negative and *A. urinae* is positive). *A. urinae* forms small (0.5 mm in diameter after 24 h of incubation), alpha-hemolytic, convex, shiny, transparent colonies on blood agar media. Additional information on the identifying characteristics of *A. urinae* can be found in reference 107, and a second biotype (esculin hydrolysis positive) of this species is described in reference 24. Additional information on phenotypic traits of the species *A. christensenii*, *A. sanguinicola*, and *A. urinaehominis* can be found in Table 1, Fig. 2, and references 25–28.

**Dolosigranulum**
*D. pigrun*, the sole species of Dolosigranulum described to date, displays positive PYR and LAP reactions and was initially described as phenotypically similar, though not closely related, to members of the genus Gemella (21). *D. pigrun* is distinguished from Gemella spp. by its abilities to hydrolyze arginine and to grow in the presence of 6.5% NaCl.

**Globicatella**
*G. vaginalis* and Related Genera (*Facklamia*, *Dolosicoccus*, and *Ignavigranum*)
*Globicatella* and the related genera *Facklamia*, *Dolosicoccus*, and *Ignavigranum* are all, with the exception of the species *G. sulfidiferus*, PYR positive. *Facklamia* and *Ignavigranum* are also LAP positive and salt tolerant. *Globicatella* is LAP negative and salt tolerant, while *Dolosicoccus* is LAP negative and salt intolerant. *Dolosicoccus* strains are also hippurate hydrolysis negative, which further distinguishes them from strains of *Facklamia* and *Globicatella* (hippurate hydrolysis positive). Strains of *F. hominis* and *Ignavigranum* may produce urease. *Ignavigranum* strains may exhibit satelliting behavior. Further details of phenotypic traits of these organisms can be found in references 30–35 and 135.

**Helcococcus**
Colonial morphology (tiny, gray, usually slightly alpha-hemolytic colonies), good growth under anaerobic conditions, and stimulation of growth by addition of 1% horse serum or 0.1% Tween 80 to the medium differentiate *H. kunzii* from aerococci (36). Isolates of *H. kunzii* are PYR positive, and most produce an API 20 Strep profile of 4100413. Additional Helcococcus species isolated from humans (H. succinics and the proposed "H. pyogenes") are negative in the PYR test. Detailed phenotypic data on these organisms can be found in references 36–39.

**Commerically Available Kits and Automated Methods Based on Phenotypic Traits**
There have been no comprehensive evaluations of the ability of commercially available products to identify the diverse and infrequently isolated bacteria described in this chapter. Phenotypic variation among isolates classified in the same species, the relative metabolic inactivity of some organisms, and a relatively small number of strains available for inclusion in databases have challenged the capabilities of these products for accurate identification. Manual methods for performance of some of the basic differentiation tests (e.g., PYR and LAP) are available (e.g., BactiCard Strep; Remel). Commercially available identification kits or systems offering a more comprehensive array of phenotypic tests are improving in their ability to identify many of the organisms discussed in this chapter (26, 135–139). These products include manual methods, e.g., API 20 Strep and RapID Strep (Remel), and automated systems, e.g., VITEK 2 (bio-Mérieux), MicroScan (Siemens Healthcare Diagnostics, Inc., Deerfield, IL), and Phoenix (BD Diagnostics, Sparks, MD). In the absence of an accurate genus- or species-level identification, these systems will at least provide additional phenotypic information that can be used to augment results of the basic tests mentioned above.

**Molecular Methods**

**Sequence-Based Techniques**
16S rRNA gene sequencing-based identifications have proven to be more accurate than phenotypic methods for identifying many of the infrequently isolated aerobic catalase-negative, Gram-positive cocci (136, 138). Bosshard and colleagues (136) analyzed 171 clinical strains of the genera Streptococcus, Enterococcus, Abiotrophia, Aerococcus, Granulicatella, and Gemella and observed that more species- or genus-level identifications were achieved based on 16S rRNA gene sequence analysis than based on a commercially available phenotypic method (API 20 Strep), and identifications based on phenotypic traits often disagreed with those determined by 16S rRNA gene sequencing. Woo and coworkers (138) examined strains of Abiotrophia, Granulicatella, Gemella, and Helcococcus in their evaluation of a commercially available 16S rRNA gene sequence-based identification system that analyzes a 527-bp fragment of the 16S rRNA gene (MicroSeq 500; Life Technologies, Foster City, CA). They noted disagreement in identifications obtained with commercially available phenotypic test systems (API 20 Strep and VITEK) and MicroSeq 500 compared with conventional sequencing of the entire 16S rRNA gene. The authors stressed the importance of adequate databases for accurate rRNA gene sequence-based identification.

Different regions of the 16S rRNA gene have been used for identification. The first 500 bp is the most applied target for identification. The entire 16S rRNA gene (1.5 kb) has also been sequenced when making more detailed descriptions of taxa or strains (139). 16S rRNA gene sequencing is an effective method for identifying the genera included in this chapter, many of which are difficult to identify with conventional phenotypic methods (139, 140). Accumulating data on the clinical significance of species makes it possible to link an accurate species identification to clinically relevant information (139). Other reports on identification of strains of the genera Aerococcus, Granulicatella, and Globicatella support the benefits of using 16S rRNA gene sequencing for these genera (41, 114, 141–143).

Broad-range amplification of the 16S rRNA gene directly from clinical samples has made it possible to detect taxa described in this chapter from various clinical samples giving no growth by culture (for instance, *G. elegans* and *A. urinae* from cardiac valvular tissue [144, 145]). The sensitivity of
direct 16S rRNA gene sequencing on valve material is reported to be between 72 and 93% when looking at definite infective endocarditis cases. A major challenge for this methodology is the difficulty in analyzing sequence data when multiple bacterial species are present in the same specimen. Kunmedal and coworkers used a set of group-specific, broad-range primers targeting the 16S rRNA gene followed by DNA sequencing and 454 analysis (iSentio AS, Paradis, Norway) and identified Gemella species from abscess material also containing bacterial DNA from other taxa (146). When examining clinical samples, cross-reactivity with human DNA is a major pitfall that can result in mixed electropherograms complicating subsequent sequence analysis and species identification. Kunmedal and colleagues employed the principle of dual-priming oligonucleotides to circumvent cross-reactivity even in specimens with a high ratio of human to bacterial DNA (147).

Alternative sequencing targets for identification of the organisms discussed in this chapter have also been explored. PCR amplification of a 740-bp rpoB gene fragment followed by sequence analysis was shown to be a suitable molecular technique for the species identification of Streptococcus, Enterococcus, Gemella, Abiotrophia, and Granulicatella isolates by Drancourt and colleagues (148). Hung et al. determined the groESL sequences of three species of nutritionally variant streptococci and three Gemella species and developed a multiplex PCR enabling identification of strains of Abiotrophia, Granulicatella, and Gemella at the genus level. To a large extent, intraspecies sequences were well circumscribed, though higher intraspecies heterogeneity was observed in G. haemolysans, with the six isolates examined being separated into two subgroups (149).

Tung and coworkers (150) evaluated the feasibility of sequence analysis of the ribosomal 16S-23S intergenic spacer region (ITS) for identification of 24 species of Streptococcus, 1 species of Abiotrophia, 18 species of Enterococcus, and 3 species of Granulicatella. The correct species identification rate by ITS sequence analysis was 98.2%. However, all of the genera except Streptococcus produced more than one PCR amplicon, necessitating agarose gel separation and in some cases cloning to purify the amplicons before sequencing. Tung and colleagues (151) further developed an array-based identification setup based on PCR amplification of the ITS regions and found it to be a useful and reliable alternative to phenotypic identification methods. The approach of having a single molecular platform for strains resembling nonhemolytic streptococci, enterococci, and the taxa considered in this chapter based on ITS analysis has also been examined by Nielsen and colleagues (152). Clinical strains of the genera Aerococcus (n = 37), Abiotrophia (n = 2), Granulicatella (n = 9), Gemella (n = 22), and Leuconostoc (n = 5) were examined. All 75 clinical strains, irrespective of obtained maximum score value, were allocated to the expected species except for 2 strains of Gemella.

MALDI-TOF MS Techniques
Matrix-assisted laser desorption ionization–time-of-flight mass spectrometry (MALDI-TOF MS) (see chapter 4) for analysis of bacterial proteins is a promising technique for identification of the bacteria mentioned in this chapter. The MALDI Biotyper (Bruker Daltonics, Billerica, MA) and the VITEK MS (bioMérieux) are two commercially available identification systems employing this technology. Christensen and coworkers (153) examined 51 culture collection strains and 90 well-characterized strains with the Bruker Biotyper system. A mass spectrum profile (MSP) based on 24 separate determinations was created for each strain and stored in a separate library that could be combined with the standard database (Biotyper version 2.0.43.1), which did not include all the taxa examined. The following genera were represented: Aerococcus (n = 42), Granulicatella (n = 30), Abiotrophia (n = 11), Gemella (n = 3), Lactococcus (n = 9), Globicatella (n = 7), Leuconostoc (n = 9), Rothia (n = 9), Facklamia (n = 7), Vagococcus (n = 2), Helcococcus (n = 4), Alloioococcus (n = 2), Pediococcus (n = 3), Ignavigranum (n = 1), Dolosicoccus (n = 1), and Dolosigranulum (n = 1). The protocol for creating one’s own MSPs in a separate library, though somewhat labor-intensive, makes it possible to extend the database. After extension of the database, all challenge strains were correctly identified to the species level except for a few difficult-to-identify Gemella strains. The obtained mean score values illustrated diversity within the different species and also an effect on mean score values of different conditions for creating MSPs. The MSP dendrograms for Aerococcus, Gemella, Granulicatella, and Abiotrophia convincingly delineated the included species. Thus, for routine use, MALDI-TOF MS was shown to be robust. In a study by Rychert et al., 1,146 strains of Gram-positive cocci were examined with the VITEK MS system (154). Fifteen of these strains belonged to taxa described in this chapter: A. defectiva (n = 2), A. viridans (n = 6), G. haemolysans (n = 3), G. adiacens (n = 1), L. garvieae (n = 1), L. lactis (n = 1), and L. mesenteroides (n = 1). All strains were correctly identified except the L. mesenteroides strain, which gave no identification. Other studies have corroborated the usefulness of MALDI-TOF MS for identification of aerobic cocci (155) and Lactococcus (156, 157) and Leuconostoc (157) species and have investigated using this technique for identification of Weisella and Pediococcus strains (158).

**TYPOGRAPHY TESTS**
Little information exists on typing methods for the genera of infrequently isolated Gram-positive cocci included in this chapter. Typing is not routinely used for characterizing these organisms.

**SEROLOGIC TESTS**
Serologic response to the organisms described in this chapter has not been extensively investigated. No clinically useful tests have been described.

**ANTIMICROBIAL SUSCEPTIBILITIES**
Antimicrobial susceptibility studies on the organisms mentioned in this chapter have generally employed dilution testing methods. Little or no data exist on the utility of disk diffusion or the correlation of Etest results with those of broth or agar dilution methods. Standardized dilution methods and interpretive criteria for observed MICs have been described for only four of the genera (Abiotrophia, Granulicatella, Leuconostoc, Aerococcus) [Reference 159 and chapter 74]. The lack of standardized methods and interpretive criteria and the relatively small collections of isolates for some of the genera discussed in this chapter make it difficult to accurately assess antimicrobial susceptibility patterns. With the exception of Leuconostoc, Pediococcus, and Weisella, all of the genera display susceptibility to vancomycin. While many of the genera are susceptible to β-lactams and other antimicrobials, observed strain variations suggest that MICs of antimicrobials used for treatment
should be determined for individual isolates. When susceptibility testing is requested for isolates for which no guidelines exist, dilution methods may be used to generate MICs that can be reported without interpretation. Since many of the bacteria discussed here are fairly fastidious, investigators have often employed blood-supplemented Mueller-Hinton media and, if necessary for good growth, incubation in a CO₂-enriched atmosphere for susceptibility testing. Pyridoxal hydrochloride (final concentration of 0.001%) should also be added to blood-supplemented media for testing strains of Abiotrophia and Granulicatella (159). Details of published susceptibility testing studies for each of the genera appear below.

Information on the in vitro antimicrobial susceptibility of L. lactis and L. garvieae strains isolated from humans suggests that L. garvieae isolates are less susceptible to penicillin and cephalothin than are strains of L. lactis. The uniform resistance of L. garvieae suggests that L. lactis appear below.

Table 1 and Fig. 1 and 2 facilitate presumptive identification of the vancomycin-resistant genera Leuconostoc and Pediococcus are penicillin susceptible when MICs are interpreted using criteria adapted from those for Enterococcus spp. (159, 160). They are usually susceptible to chloramphenicol, tetracyclines, and aminoglycosides. Carbapenem and cephalosporin resistance has been noted in some strains of Leuconostoc (159). Huang and colleagues (161) noted MIC ranges of 0.5 to 8 μg/ml for linezolid and 0.06 to 2 μg/ml for daptomycin in 68 strains of Leuconostoc tested and ranges of 1 to 4 μg/ml for linezolid and 0.06 to 0.5 μg/ml for daptomycin in 13 Pediococcus isolates. Iwen and colleagues reported on the successful treatment of a case of P. acidilactici endocarditis with daptomycin (162).

Abiotrophia and Granulicatella isolates display a range of penicillin MICs, with authors reporting reduced penicillin susceptibility in 33 to 65% of isolates (163–165). Susceptibility to aminoglycosides is also variable, but no cases of high-level resistance have been reported. A synergistic effect between β-lactam agents and aminoglycosides has been demonstrated for isolates of Abiotrophia, and combination therapy with penicillin and gentamicin is the currently recommended treatment for endocarditis caused by Abiotrophia and Granulicatella. High relapse rates have been reported, even with appropriate therapy (163). Tuohy and colleagues (165) examined a collection of 27 G. adiacens and 12 A. defectiva strains, noting susceptibility of all isolates to clindamycin, rifampin, levofloxacin, ofloxacin, and quinupristin-dalfopristin. These authors noted that susceptibilities of G. adiacens and A. defectiva, respectively, to other agents tested were as follows: penicillin, 55 and 8%; amoxicillin, 81 and 92%; ceftriaxone, 63 and 83%; and meropenem, 96 and 100% (165). Zheng and coworkers reported high rates of β-lactam and macrolide resistance in a collection of pediatric Abiotrophia and Granulicatella isolates (166). A daptomycin MIC range of ≤0.125 to 2 μg/ml was observed for 10 strains of this group of bacteria (167).

A. viridans and G. haemolyans appear to be susceptible to penicillin and display a low level of resistance to aminoglycosides (168, 169). Resistance to tetracycline and macrolides has been described in Gemella isolates (170), as well as a synergistic effect for penicillin and gentamicin (169). Piper and colleagues (167) noted daptomycin MICs of ≤0.125 μg/ml for four strains of G. morbillorum. Bui-Hoi and colleagues (168) noted that while A. viridans seems to be naturally susceptible to macrolides, tetracyclines, and chloramphenicol, resistance to these agents has been observed. A. urinae has been described as susceptible to penicillin, amoxicillin, pipercillin, cefepime, rifampin, and nitrofurantoin but resistant to sulfonamides and netilmicin (107, 171, 172). Humphries and coworkers (173) noted that A. urinae’s resistance to trimethoprim-sulfamethoxazole is test medium dependent. Strains of this organism are susceptible to trimethoprim-sulfamethoxazole when tested on lysed horse blood-containing media that display low levels of thymidine (173). A. sanguinicola isolates display susceptibility to penicillin, amoxicillin, cefotaxime, cefuroxime, erythromycin, chloramphenicol, quinupristin-dalfopristin, rifampin, linezolid, and tetracycline (26).

Clinical isolates of D. pignum studied by LaClaire and Facklam (22) were all susceptible to penicillin, amoxicillin, cefotaxime, cefuroxime, clindamycin, levofloxacin, meropenem, quinupristin-dalfopristin, rifampin, and tetracycline. Variable susceptibility to erythromycin was noted, and 1 of the 27 strains examined was resistant to trimethoprim-sulfamethoxazole. The small number of Helcococcus isolates examined displayed susceptibility to penicillin and clindamycin, and most strains were resistant to erythromycin (122, 123). Woo and coworkers described an H. kunzi strain with ermA-mediated erythromycin and clindamycin resistance (126). Strains of Facklamia exhibit variable MICs for a variety of antibiotics (174). A study of 27 strains of Globicatella sanguinis reported susceptibility of all isolates to amoxicillin but varying levels of resistance to other antimicrobials tested (175).

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

Efforts to identify the Gram-positive cocci included in this chapter should be made only when isolates are considered to be clinically significant (i.e., isolated repeatedly, in pure culture, or from normally sterile sites), since these organisms may also appear in clinical cultures as contaminants or constituents of the normal microbiota. Communication with clinicians should guide the microbiology laboratory in evaluating the significance of these infrequently isolated organisms. The phenotypic tests mentioned in Table 1 and Fig. 1 and 2 facilitate presumptive identification of the infrequently isolated catalase-negative, Gram-positive cocci. More extensive phenotypic testing using commercially available identification systems and molecular methods should be employed for definitive identification. Currently there are susceptibility testing guidelines for only four of the genera mentioned in this chapter. The MICs generated with dilution methods can be reported without interpretation when susceptibility testing is requested for significant isolates for which no guidelines exist.

Abiotrophia, Granulicatella, and Gemella species are well-documented agents of endocarditis. The satellitizing behavior of Abiotrophia and Granulicatella and the positive PYR reactions of all three genera are useful for distinguishing them from viridans group streptococci. CLSI guidelines (159)
should be employed for susceptibility testing and interpretation of results for Abiotrophia and Granulicatella. The vancomycin-resistant genera Leuconostoc, Pediococcus, and Weissella are infrequent microorganisms isolated from these broth cultures, but they have been described as agents of bacteremia and central nervous system infection in compromised hosts. Phenotypic testing for vancomycin resistance (see “Identification” above) is important for identifying these genera and also helps guide antimicrobial therapy. Guidelines for antimicrobial susceptibility testing and interpretation of results are available for Leuconostoc and Pediococcus (159). Among the aerobic cocci, A. urinae is a well-documented urinary tract pathogen and should be reported when isolated in significant amounts as the predominant organism in urine cultures. Phenotypic tests mentioned in this chapter presumptively identify A. urinae, which has been described as susceptible to β-lactam agents and nitrofurantoin (107, 171, 172).

BACTERIOLOGY

General Approaches to the Identification of Aerobic Gram-Positive Rods

KATHRYN A. BERNARD

The purpose of this algorithm for the identification of aerobic Gram-positive rods is to assist the reader in finding the appropriate chapter in this Manual for further information. The algorithm emphasizes that the Gram stain (performed on 24- to 48-h-old colonies from rich media) and macroscopic morphologies are initial key features for the differentiation of aerobic Gram-positive rods. All strains of aerobic Gram-positive rods (except the non-rapidly growing mycobacteria) are initially grown on blood agar plates.

Gram-positive organisms demonstrating “regular” rods are those with cells whose longitudinal edges are usually not curved but are parallel. If spore formation is not observed initially, it can be tested for on a nutritionally depleted medium. Catalase activity should be tested with colonies grown on media lacking heme groups. Type of metabolism, initial (i.e., within 48 h), and so these organisms are prone to being misidentified. For yellow-orange-pigmented colonies are usually composed of irregular rods. Some genera that stain partially acid-fast (e.g., Gordonia and Rhodococcus) may also show a yellow-orange pigment (see chapter 29). Rods exhibiting vegetative substrate filaments may show branched-type hyphae, which either form spores or reproduce by fragmentation. Vegetative substrate filaments might not be present initially (i.e., within 48 h), and so these organisms are prone to being misidentified. For yellow-orange-pigmented genera (e.g., Microbacterium, Curtobacterium, and Leifsonia; see chapter 28), as well as for those rods exhibiting vegetative substrate filaments, chemotaxonomic or molecular genetic methods may be required for definitive identification to the genus level; partially acid-fast bacteria may be identified to the genus level by genetic means.

Genera that contain strictly anaerobic Gram-positive rods may also contain species, or strains within a species, that grow reasonably well aerotolerantly or aerobically. This is particularly true for the genera Actinomyces and Actinoba-

**Bacillus and Other Aerobic Endospore-Forming Bacteria**

CHRISTINE Y. TURENNE, JAMES W. SNYDER, AND DAVID C. ALEXANDER

---

**TAXONOMY**

Historically, most aerobic endospore-forming bacteria were classified as species of *Bacillus*. However, the application of phylogenetic methods to prokaryotic systematics has triggered a taxonomic transformation. This includes the valid publication of a new class, Bacilli, within the phylum Firmicutes. *Bacillus*, as defined by 16S rRNA gene sequence analyses, comprises two orders, *Bacillales* and *Lactobacillales*. Currently, the aerobic endospore-forming bacteria are distributed among >60 genera and seven families within the order *Bacillales*.

Minimal standards for describing new taxa of aerobic endospore-forming bacteria have been published (1). These standards acknowledge the role of genetic features but highlight the importance of detailed phenotypic characterization. For any new taxon, it is recommended that descriptions are based on at least five strains and ideally 10 or more. Unfortunately, many new species, and some genera of aerobic endospore-forming bacteria, are represented only by single isolates. The absence of multiple specimens precludes any assessment of intragenus or intraspecies variability.

For the clinical microbiologist, the reallocation of taxa and proliferation of new species are of limited practical concern. The vast majority of aerobic endospore-forming bacteria are nonpathogenic, environmental organisms. The medically important and commonly encountered genera, primarily *Bacillus*, *Lysinibacillus*, *Paenibacillus*, and *Brevibacillus*, are found within the two largest families, *Bacillaceae* and *Paenibacillaceae*. The families *Alicyclobacillaceae*, *Planobacillaceae*, and *Sporolactobacillaceae* are not known to contain clinically relevant species, and *Pasteuria*, the only genus in the family *Pasteuriaceae*, comprises obligate bacterial parasites of invertebrates that have never been grown in axenic culture. In contrast to other *Bacillales*, organisms in the family *Thermoactinomycetaceae* appear filamentous and produce mycelia, aerial hyphae, and sporophores. Although some are true aerobic endospore-forming bacteria, for the purposes of this Manual, the *Thermoactinomycetaceae* are grouped with the aerobic actinomycetes (see chapter 29).

**DESCRIPTION OF THE GENERA**

*Bacillus* is the type genus of the *Bacillaceae*. The typical *Bacillus* isolate is a rod-shaped, endospore-forming organism that is aerobic, mesophilic, catalase positive, and motile by means of peritrichous flagella. Young cultures usually stain Gram positive, whereas older cultures are more likely to be Gram variable or Gram negative. However, the genus is phenotypically diverse such that some species are asporogenous, facultatively anaerobic or strictly anaerobic, and thermophilic or psychrophilic.

Many *Bacillus* species have been renamed and reallocated to new monophyletic and phenotypically coherent taxa, which is consistent with a recent proposal that the designation *Bacillus* be reserved exclusively for organisms belonging to the *Bacillus subtilis* and *Bacillus cereus* clades (2). Even so, the genus *Bacillus* remains polyphyletic, phenotypically diverse, and large. Frequently encountered species include *B. subtilis* (the type species), *B. licheniformis*, *B. megaterium*, *B. pumilus*, and the *B. cereus* group. Also called *B. cereus sensu lato*, this clade includes *B. cereus* (sensu stricto), *B. anthracis*, and *B. thuringiensis* as well as the less common but phylogenetically related *B. mycoides*, *B. pseudomyces*, *B. weihenstephanensis*, *B. cytotoxicus* (143), and *B. toyoensis*.

Other clinically important genera of aerobic endospore-forming organisms are phenotypically similar to the *Bacillus*, but some differences do exist. *Geobacillus* species are obligately thermophilic and *Geobacillus stearothermophilus* (formerly *Bacillus stearothermophilus*) is commonly employed as a biological indicator for laboratory quality control activities (e.g., for monitoring autoclave efficacy and the sporicial activity of disinfectants). *Lysinibacillus* species are distinguished by the composition of the cell wall peptidoglycan, which is rich in lysine and aspartic acid. *Lysinibacillus sphaericus* (formerly *Bacillus sphaericus*) occasionally causes opportunistic infections in human hosts but is best known for its insecticidal toxin, which has been commercialized for use in mosquito control programs (3, 4).

*Paenibacillus* and *Brevibacillus* cultures may stain Gram positive but are more likely to be Gram negative or Gram variable, and sporangia usually have a swollen appearance. *Paenibacillus* is the type genus of the family *Paenibacillaceae* and includes species originally defined by 16S rRNA gene sequencing as *Bacillus “rRNA group 3”* (5). The majority of species are of environmental origin. These include nitrogen-fixing organisms associated with plant roots and insect pathogens used for biocontrol applications. *Paenibacillus* species have been isolated from a variety of clinical sources, including blood, cerebrospinal fluid (CSF), wounds, and urine (6–8).

---

*This chapter contains information presented by Niull A. Logun, Alex R. Hoffmaster, Sean V. Shadomy, and Kendra E. Stauffer in chapter 24 of the 10th edition of this Manual.*

doi:10.1128/9781555817381.ch26
Brevibacillus, also in the family Paenibacillaceae, includes species originally defined by 16S rRNA gene sequencing as Bacillus "rRNA group 4" (9). Brevibacillus brevis (the type species), Brevibacillus agri, Brevibacillus centrosorus, and Brevibacillus parabrevis have been isolated from clinical sources (10, 11). Brevibacillus laterosorus is primarily an insect pathogen (12), but human infection has been reported (13).

Additional species of aerobic endospore-forming bacteria may be encountered in the microbiology laboratory. Environmental organisms may act as opportunistic pathogens, but most isolates, especially those obtained from nonsterile sites and wound tracts, are likely to be contaminants of unknown clinical significance.

EPIDEMIOLOGY AND TRANSMISSION

Aerobic endospore-forming bacteria are ubiquitous in nature. They are found in terrestrial and aquatic habitats of all kinds, ranging from acid to alkaline, nonsaline to highly saline, and hot to cold. Because endospores are resistant to heat, desiccation, radiation, and disinfectants, they persist in places where most other organisms cannot. These exotic and extreme environments include air at high altitude, subterranean waters, glacial ice cores, permafrost, and volcanic soils. Dissemination of spores, via wind, dust, and aerosols, contributes to contamination of man-made environments, including hospital operating rooms and industrial clean rooms. Because they contribute to food spoilage and food poisoning, aerobic endospore-forming organisms are unwanted contaminants in food production and preparation environments. However, these bacteria are also essential to the production of certain fermented traditional foods (e.g., natto, cheonggukjang, and gergosh) and the probiotic properties of animal feed and horticultural supplements. Similarly, some of the same species encountered in the clinical laboratory (e.g., B. subtilis, B. megaterium, B. licheniformis) are also employed by industry for the commercial production of enzymes (e.g., amylases, proteases, cellulases), antibiotics (e.g., polymyxins, colistins, garamicidins), and pesticides (e.g., Bt toxins).

The majority of aerobic endospore-forming bacteria are nonpathogenic saprophytes. Although they are commonly encountered in the microbiology laboratory, only a small minority (≤5%) of isolates are clinically relevant, and most of the clinically significant species are best described as opportunistic human pathogens. Transmission is restricted to ingestion, injection, injury, inhalation, or other contact with material that has been contaminated with spores or vegetative cells. Several environmental species (e.g., B. thuringiensis, Paenibacillus larvae, Paenibacillus lentimorbus, Paenibacillus popilliae, and Paetearia sp.) are recognized as professional pathogens of insects and other invertebrates, but only B. anthracis has been described as an obligate pathogen of animals. Infection of wild and domesticated mammals occurs through ingestion of spores from contaminated pastures. B. anthracis spores remain viable for many years and are exceedingly difficult to eradicate. Some authorities contend that, in certain soils, self-maintenance can occur (14) and that it has recently been demonstrated that soil-dwelling amoebae can support the germination and amplification of B. anthracis spores (15). However, the environmental presence of B. anthracis is generally associated with contamination from animal sources, such as anthrax-infected carcasses. Human cases are almost always due to direct contact with infected animals or animal products. Person-to-person spread has been reported but is rare, as are cases of anthrax due to laboratory accidents, biological warfare, and bioterror events.

CLINICAL SIGNIFICANCE

The majority of aerobic endospore-forming species appear to have little or no pathogenic potential and are rarely associated with disease. The principal exceptions to this are species of the B. cereus group, which includes B. anthracis. However, due to the medical and historical importance of anthrax, B. cereus and B. anthracis are discussed separately below.

Aerobic Endospore-Forming Bacteria (Other Than the B. cereus Group and B. anthracis)

Reports of infections due to aerobic endospore-forming bacteria are relatively rare. Cases typically result from contamination of wounds, surgical sites, or medical devices with bacterial spores. Systemic disease most often occurs in patients who are immunocompromised or afflicted with a morbid condition, but some cases do involve immunocompetent individuals. Mixed infections involving multiple aerobic endospore-forming species have also been reported (16). B. subtilis is the type species of the genus Bacillus. Due to taxonomic changes, some clinical isolates originally identified as B. subtilis have been reallocated to other taxa, but cases involving authentic isolates of B. subtilis do occur. Reports include pneumonia, bacteremia, and septicemia in patients with leukemia or other neoplastic diseases, isolations from surgical wound drainage sites, breast prosthesis and ventriculo-atrial shunt infections, endocarditis following drug abuse (17, 18), and meningitis following a head injury (19). B. subtilis has also been implicated as an agent of food-borne illness and isolated in high numbers (10^3 to 10^9 CFU/g) from food. Typical symptoms include vomiting, sometimes accompanied by diarrhea, and reported onset periods have been short (range, 10 min to 14 h; median, 2.5 h) (20). Two cases of severe hepatotoxicity have been attributed to ingestion of B. subtilis-contaminated nutritional supplements (21). A similar case, contamination of an oral probiotic preparation, with an organism ultimately identified as Bacillus clausii, led to a fatal septicemia in an immunocompromised patient. B. clausii was also associated with a case of cholangitis in a renal transplant patient (22).

B. licheniformis is another species commonly associated with clinical illness. Its occasional virulence is attributed, at least in part, to the production of lichenysin, a heat-stable and cytotoxic cyclic lipopeptide. B. licheniformis cases include prosthetic valve endocarditis, pacemaker wire infection (23), ventriculitis following the removal of a meningo-encephalitis, brain abscesses, septicemia following arteriography, bacteremia associated with indwelling central venous catheters, and peritonitis in patients undergoing continuous ambulatory peritoneal dialysis. B. licheniformis contamination of nonsterile cotton wool led to a nosocomial outbreak of bacteremia among patients with blood malignancies (24). Sepsis in immunocompetent patients has also been reported (25). Self-harming behavior was the cause of two unusual cases. In one, B. licheniformis infection followed self-inoculation with drain cleaner (26). In the other, self-inoculation with soil resulted in a polymicrobial infection from which B. licheniformis, B. pumilus, and Paenibacillus polymyxa were isolated (27). B. licheniformis is also an agent of food-borne diarrheal illness, which has led to at least one fatality (28). B. pumilus isolates are known to produce heat-stable, cytotoxic cyclic lipopeptides called pumilacidins. B. pumilus has been implicated in cases of cutaneous, pustule, and rectal
fistula infections, bacteremias in immunosuppressed patients (24), a central venous catheter infection in an immunocompetent child, and sepsis in neonates (29), and at least one fatal ty was reported (30). Toxigenic strains of B. \textit{pumilus} have been isolated from cases of food-borne illness and implicated in a rice-associated food poisoning outbreak (31). \textit{B. megaterium} is occasionally recovered from blood, wounds, and urine. Skin lesions due to \textit{B. megaterium} can resemble cutaneous anthrax, and phenotypically, the organism can mimic \textit{B. anthracis} (32, 33). Organisms identified as \textit{Bacillus circulans} have been isolated from cases of bacteremia in cancer patients, meningitis, CSF shunt infections, endocarditis, wound infections, and peritonitis in a patient undergoing dialysis (34). However, it should be noted that, due to taxonomic changes, some of these isolates might now be classified as species of \textit{Paenibacillus}.

\textit{Paenibacillus alvei} (formerly \textit{Bacillus alvei}) has been isolated from cases of meningitis, a prosthetic hip infection in a patient with sickle cell anemia, wound infections, and in association with \textit{Clostridium perfringens}, a case of gas gangrene. \textit{Paenibacillus macerans} has been isolated from a wound infection following removal of a malignant melanoma, from a brain abscess following penetrating periorbital injury, and from a catheter-associated infection in a leukemic patient, whereas \textit{P. polymyxa} has been isolated from patients with bacteremia (27). \textit{P. popilliae} has been isolated from a case of endocarditis, and \textit{P. larvae} has been reported from infection of a CSF shunt system. \textit{Paenibacillus glucanolyticus} was involved in cardiac device-related endocarditis (35). \textit{Cohnella hongkongensis}, a species historically grouped with \textit{Paenibacillus} (36), was isolated from a case of pseudobacteremia in a boy with neutropenic fever. \textit{Lysinibacillus sphaericus} has been implicated in a fatal lung pseudotumor, bacteremia, and meningitis (3).

Additional clinical cases involve a variety of recently described \textit{Bacillus} and \textit{Paenibacillus} species, many of which were proposed on the basis of single isolates of unknown significance from clinical sources: \textit{B. idriensis} and \textit{B. infantis} from neonatal sepsis (37); \textit{P. konsidinis}, \textit{P. macerans}, \textit{P. simpants}, \textit{P. thiaminolyticus}, and \textit{P. timonensis} from blood cultures (6, 8, 30, 38); \textit{P. provencensis} isolated from CSF (7, 39); \textit{P. turicensis} from a breast (40); \textit{P. pasadenensis} and \textit{P. vulniers} from wounds (41, 42); and \textit{P. trinidadis} from urine (7). Several \textit{Brevibacillus} species have also been recovered from clinical sources, including \textit{B. centrosporus} from bronchoalveolar lavage fluid, \textit{B. parabrevis} from a breast abscess, and both species from human blood (10).

Eye infections due to aerobic endospore-forming bacteria can be quite severe. Many species have been associated with endophthalmitis, including \textit{B. circulans}, \textit{B. licheniformis}, \textit{P. alvei}, and \textit{B. laterosporus} (43). \textit{Bacillus} species, including \textit{B. megaterium}, can cause keratitis. It has also been suggested that \textit{B. oleronius}, a species found in the gut of \textit{Demodex} mites, may act as a copathogen in cases of severe or chronic blepharitis (44).

\textbf{Bacillus cereus Group}

\textit{Bacillus cereus} was initially described in an 1887 survey of environmental bacteria (45). The species name is derived from "cereus," the Latin term for wax, and refers to the wax-like morphology of colonies grown on agar media. \textit{B. cereus} has been isolated from diverse ecological niches and is widely distributed in nature. The original isolate was obtained from the air in a cow shed, and additional strains have been isolated from soil, plant leaves, insects, water, and sewage (46). Psychrotolerant (\textit{B. weihenstephanensis}), thermotolerant (\textit{B. cytotoxicus}), crystal-forming (\textit{B. thuringiensis}), and morphological (\textit{B. mycoides}, \textit{B. pseudomycoides}) variants and a probiotic strain (\textit{B. toyonensis}) have been classified as distinct species. \textit{B. anthracis} also belongs to the \textit{B. cereus} group, but due to the medical and historical importance of anthrax, it will be considered separately.

Clinically, \textit{B. cereus} group organisms are opportunistic pathogens, and cases involving local (e.g., eyes, skin, and wounds) and systemic (e.g., bacteremia, septicemia, meningitis, peritonitis, endocarditis, and respiratory and urinary tract) infections have all been reported (47, 48). Systemic infections are most common in patients who are immunocompromised due to some comorbid condition (e.g., cancer and diabetes). \textit{B. cereus} spores are resistant to many disinfectants, and postoperative and hospital-acquired infections have been traced to contaminated gloves, gowns, linens, dressings, medical devices (e.g., catheters, shunts and implants, bronchoscopy equipment, and ventilators), and even alcohol-based prep pads used for disinfection purposes (49). A recent nosocomial outbreak, involving 171 patients, was attributed to insufficient air filtration, cleaning, and laundry practices, which failed to eliminate spores that had been introduced to the hospital environment by nearby construction work (50). \textit{B. cereus} infections secondary to trauma, including cuts and scrapes, surgery, and burns, occur when, during the initial injury, spores from soil, water, or other sources, are introduced to the wound tract. \textit{B. cereus} contamination of drugs, both legal and illegal, has also been reported (51, 52). Eye injuries and medical procedures (e.g., cataract surgery and intravitreous injections) can result in \textit{B. cereus} endophthalmitis. Without rapid therapeutic intervention, this serious condition can lead to vision loss and even eye evisceration (43, 53). Keratitis has been associated with contact lens wear, and in at least two cases, \textit{B. cereus} was cultured from the eyes as well as the contact lens cases of the infected patients (54, 55).

However, \textit{B. cereus} isolates are most commonly associated with food-borne illness. Between 1998 and 2008, \textit{B. cereus} was suspected or confirmed as the cause in 235 (1.75%) of the 13,405 food-borne outbreaks reported to the Foodborne Diseases Active Surveillance Network (FoodNet) of the Centers for Disease Control and Prevention's Emerging Infections Program (56). However, that statistic likely underrepresents the true burden of \textit{B. cereus} disease because these organisms are not always considered in clinical, epidemiological, and laboratory investigations of food-borne illness. Because they survive normal cooking temperatures and many cleaning procedures, \textit{B. cereus} spores can be widespread in food preparation environments. Food poisoning typically follows the germination of spores and multiplication of toxigenic vegetative cells in improperly stored food. \textit{B. cereus} group organisms cause two distinct food poisoning syndromes. The emetic type is characterized by nausea and vomiting, with symptoms appearing 1 to 5 h after ingestion of the contaminated food. The diarrheal type is characterized by abdominal pain and diarrhea, and onset is later, 8 to 16 h after food consumption (20, 46). \textit{B. cereus} has been isolated from diverse foods, but rice dishes, especially Asian-style fried rice, are frequently implicated in outbreaks of emetic type illness, whereas meat dishes are more often associated with diarrheal type illness (56). \textit{B. cereus} is of increasing concern to the dairy industry. It causes mastitis in goats and dairy cattle, spores persist in barns and processing facilities, and cold-tolerant strains, especially \textit{B. weihenstephanensis}, can survive both pasteurization and refrigeration (57). Outbreaks of food-borne illness have been linked to milk, cheese, pudding, and other dairy products.
Bacteriology

Bacillus anthracis

Robert Koch’s landmark work on anthrax helped establish the germ theory of disease, and an 1877 report on B. anthracis included the first published photomicrographs of any bacteria (59). Anthrax is primarily a disease of wild and domesticated animals that, historically, was a leading cause of mortality among cattle, sheep, goats, and horses. The use of veterinary and human vaccines, improvements in factory hygiene, effective sterilization procedures for imported animal products, and the increased use of synthetic alternatives to animal hides and hair have all contributed to a marked decline in the incidence of disease. Nevertheless, anthrax remains endemic to many countries, particularly those that lack effective vaccination policies. In countries with national vaccination programs, the reduced incidence of anthrax contributes to public ignorance of disease symptoms as well as diminishing veterinary experience. Delays in case recognition can undermine control measures, prolong outbreaks, and lead to the sale and slaughter of affected animals. Because of these challenges, anthrax remains common, especially in agricultural regions of Central and South America, southern and eastern Europe, central and southwestern Asia, sub-Saharan Africa, the United States, and Canada (60).

Animals are usually infected through ingestion of B. anthracis spores from contaminated pastures. Direct animal-to-animal transmission is rare, although scavengers (e.g., vultures and hyenas) can become infected by feeding on anthrax-infected carcasses (61). Human cases usually involve direct contact with infected animals or products from infected animals. Cases resulting from close contact with infected animals or their carcasses are traditionally classified as nonindustrial, whereas those acquired while processing animal products, such as wool, hair, hides, or bones, are classified as industrial. Although anthrax is not a contagious disease, person-to-person transmission has occasionally been reported, including cases of mother-to-child spread from an infected finger, brother-to-brother spread from an abdominal lesion (62), and nosocomial spread from an unifocal infection (63). Regrettably, B. anthracis has been developed, and effectively deployed, for biological warfare and bioterror purposes. Few reports of laboratory-acquired infections exist, but the accidental release of spores from a military production facility has been implicated as the cause of a major 1979 outbreak in the Ural city of Yekaterinburg (formerly Sverdlovsk), Russia, which claimed at least 66 lives (64).

In humans, the major clinical forms of the disease—cutaneous anthrax, gastrointestinal anthrax, inhalational anthrax, and inhalational anthrax—are linked to the route of infection (65). Adult males account for the majority of anthrax cases, but disease may be more severe in pregnant women and children (66, 67). Initial symptoms may be nonspecific and mild (e.g., fatigue, malaise, fever, and/or gastrointestinal symptoms), but following lymphohematogenous dissemination from a primary lesion, fulminant disease can rapidly develop. Symptoms can include dyspnea, cyanosis, severe pyrexia, and disorientation, followed by circulatory failure, shock, coma, and death. The bacteria can multiply rapidly in the blood, and depending on the host, reach terminal levels of 10^7 to 10^9 CFU/ml over the final few hours. Enhanced clinical and laboratory expertise is a critical component of rapid anthrax diagnosis, and due to the biothreat potential of B. anthracis, there is a need for prospective surveillance and response preparedness. Similarly, case investigations should strive to establish the origin of any infection so as to differentiate between naturally occurring events and those of malicious origin.

Cutaneous anthrax accounts for about 99% of naturally acquired human anthrax cases. In the United States, the incidence of anthrax is extremely low, with 0 to 2 cases reported annually for the last 3 decades (68). The global incidence is difficult to determine and varies between countries depending on control strategies and the strength of health systems. Rates are highest in Africa and central and southern Asia (69) and, in some regions, are increasing due to funding cuts (70). Infection typically occurs when spores are inoculated through a break in the skin, although case reports and animal studies suggest that preexisting lesions are not necessary for infection. Rarely, infection has been attributed to insect bites (71, 72). Following an incubation period of usually 2 to 6 days (range, a few hours to 3 weeks), a small papule appears. Over the next 24 h, this progresses to a ring of vesicles, which subsequently ulcerates to form a blackened eschar, the characteristic lesion of cutaneous anthrax. Once formed, the eschar may become thick and surrounded by extensive edema. Fever, pus, and pain at the site are normally absent, and the presence of such symptoms may be indicative of a secondary bacterial infection. Below the availability of antimicrobial therapy, 10 to 20% of untreated cutaneous anthrax cases were fatal. Today, less than 1% of cases are fatal. Fatalities are mainly due to obstruction of the airways by the edema that accompanies lesions that form on the face or neck but can also occur when cutaneous disease progresses to systemic infection. Eschars take several days to evolve, but even with effective antimicrobial therapy, they may take several weeks to resolve.

Gastrointestinal anthrax results from the consumption of anthrax-infected animals, especially meat that is raw or undercooked. Asymptomatic cases can occur, and may not be uncommon, but disease usually presents in one of two forms. The oral, or oropharyngeal, form features lesions on the buccal cavity, tongue, tonsils, or posterior pharyngeal wall. Symptoms include sore throat, dysphagia, and regional lymphadenopathy, followed by severe edema of the neck and chest. The intestinal form can develop anywhere within the gastrointestinal tract, but ulcerations typically appear in the mucosa of the terminal ileum or cecum. Symptoms include nausea, vomiting, anorexia, abdominal pain, fever, mild diarrhea (which can progress to bloody diarrhea), hematemesis, and massive ascites. Owing to the nonspecific nature of the early symptoms, antimicrobial therapy may be initiated late, and mortality rates range widely (73, 74).

Inhalational anthrax is a rare but serious form of the disease. During the 20th century, only 18 cases of naturally acquired inhalational anthrax were recorded in the United States. Of these, 16 (89%) were fatal (75). Figures from the United Kingdom show a similar picture. Previously known as pulmonary anthrax, the preferred designation, “inhalational anthrax,” more accurately reflects the fact that active infection occurs in the lymph nodes rather than the lungs themselves. In late 2001, the malicious dissemination of B. anthracis spores in mailed letters was responsible for an outbreak of 22 cases in the United States. Laboratory-confirmed inhalational anthrax accounted for 11 cases, including all 5 of the deaths attributed to the outbreak (76). All of these patients developed severe illness and were hospitalized, but thanks to early recognition and treatment, the case survival rate was 55% (6/11 patients). Analysis revealed a median incubation period of 4 days (range, 4 to 6 days). Clinical presentation included fever or chills, fatigue or malaise, minimal or nonproductive cough, dyspnea, and nausea or vomiting. Some patients experienced chest pain...
and sweats. All patients had abnormal chest radiographic images, with pleural effusion, infiltrates, or mediastinal widening (77).

Injectional anthrax refers to cases associated with injection drug use (78). Although the route of infection is through the skin, symptoms of injectional anthrax differ from those of cutaneous anthrax. Skin around the injection site may be bruised or discolored, but the characteristic papules and eschars are absent. Cases usually present as severe soft tissue infections with significant edema, and progression to septic shock can be rapid (79). Contaminated heroin has been implicated in cases from Norway, Denmark, France, Germany, and the United Kingdom. In Scotland, a large outbreak (47 confirmed, 35 probable, and 37 possible cases) occurred between December 2009 and December 2010 (80). Genotyping methods have been used to analyze B. anthracis isolates associated with cases of injectional anthrax. The European isolates collected between 2000 and 2012 are highly related, share two distinctive single nucleotide polymorphisms, and likely originate from a single source (81, 82). Genotypically, the drug-associated strain is most similar to the African isolates from Turkey and not B. anthracis strains from opium (i.e., heroin)-producing countries. Drug traffickers are known to use animal skins for smuggling contraband. As such, it has been hypothesized that the heroin associated with the European cases could have become contaminated with B. anthracis spores if transported in skins from an anthrax-infected animal (80).

During the past decade, there have also been several cases of naturally occurring infection. In 2006, a maker of African drums became the first naturally occurring case of inhalational anthrax in the United States since 1976. Infection was traced to imported hides from West Africa which were contaminated with B. anthracis spores. In 2007, two cases of cutaneous anthrax, in a drum maker and a family member, occurred in the United States (83). In 2008, a fatal case of inhalation anthrax occurred in a drum maker in the United Kingdom (84). The handling or playing of goatskin drums contaminated with spores of B. anthracis has been associated with additional cases of cutaneous, inhalational, and gastrointestinal anthrax (83, 85).

In rare instances, cases have occurred for which no source has been found. In 2011, a man acquired inhalational anthrax while traveling through four U.S. states, including midwestern states where B. anthracis is enzootic. Despite thorough sampling and the involvement of a dedicated anthrax investigative team, no exposure source was definitively identified (86). A 2012 case from the United Kingdom involved a member of the armed forces who acquired inhalational anthrax despite being vaccinated. An exhaustive inquiry was conducted, but no exposure history to anthrax was identified (87).

Toxins and Other Virulence Factors of the B. cereus Group

The pathogenicity of B. cereus group organisms (including B. anthracis) is attributed to the production of numerous exotoxins, enterotoxins, hemolysins, and cytolysins. Ongoing studies aim to define roles for individual toxins, including their distribution, structures, mechanisms of action, and specific contribution to B. cereus disease (88–97). Expression of these toxins is controlled by multiple environmental cues, including nutrient status, oxygen concentration (e.g., redox potential), pH, and cell density. The PlcR-PapR quorum-sensing system regulates expression of at least 45 genes, including those that encode Nhe, HBL, and CytK (see below) (98). Remarkably, this "master" virulence regulator is inactive in B. anthracis strains, due to a lineage-specific plcR mutation.

Two toxins, lethal toxin and edema toxin, are associated with the virulence of B. anthracis. Each of these binary toxins contains two components: a protective antigen (PA) plus an enzymatic factor, lethal factor (LF) for lethal toxin and edema factor (EF) for edema toxin. PA facilitates the delivery of the toxin to target cells, where LF or EF then acts to disrupt cell signaling pathways. The pagC, lef, and cya genes that encode PA, LF, and EF, respectively, are found on a virulence plasmid, pXO1. Loss of pXO1 is associated with attenuation of B. anthracis, but even plasmid-cured strains retain some pathogenic potential (88, 89). Conversely, experimental acquisition of pXO1, or natural acquisition of pXO1-like plasmids, can enhance pathogenicity of other B. cereus group organisms.

Multiple toxins contribute to the symptoms of B. cereus food poisoning. Ingestion of a heat-stable toxin, cereulide, triggers the vomiting that is characteristic of emetic food poisoning. Cereulide is produced by the plasmid-borne ces gene cluster (90) and is only found in a subset of B. cereus sensu stricto and B. thuringiensis strains (91). Diarrheal symptoms of B. cereus food poisoning are attributed to multiple toxins, including the nonhemolytic enterotoxin (Nhe), hemolysin BL (HBL), and cytotoxin K (CytK; also known as hemolysin IV) (92). The genes responsible for Nhe production are chromosomally encoded (93) and present in most B. cereus group isolates (91). A plasmid-borne variant has been described for B. weihenstephanensis (94). The HBL toxin is also widely distributed. At least two variants have been described (92), but hbl genes appear to be absent from Bacillus cytotoxicus. CytK was first isolated from an enterotoxigenic strain that is now recognized as the type strain of B. cytotoxicus. Despite the absence of cereulide or HBL production, this strain was responsible for an outbreak that included three fatalities. Two variants of the CytK toxin are now recognized: CytK-1 is produced by B. cytotoxicus, whereas CytK-2 is found in other B. cereus group species and is more prevalent among B. cereus sensu stricto and B. thuringiensis. In vitro, the cytotoxic activity of CytK-1 appears to be greater than that of CytK-2 (95).

Traditionally, B. thuringiensis strains are defined by their production of parasporal crystals comprised of insecticidal proteins. The pesticidal potential of Bt toxin was recognized in the 1920s and first commercialized in the 1930s. To date, more than 200 variants have been isolated. Bt toxins are used extensively for the control of agricultural pests, and targets include moths, butterflies, beetles, flies, and nematode worms. B. thuringiensis spores can be sprayed onto fields and more recently, crops have been genetically engineered to express the cry and cyt toxin genes (99). Remarkably, these applications do not pose a threat to human health. B. thuringiensis can be isolated from agricultural workers exposed to commercial Bt strains, but reports of illness are rare and no deaths have occurred (100).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Bacillus Species Other than B. anthracis

Clinical specimens for the isolation of Bacillus species other than B. anthracis can be handled using the standard methods (see chapter 18 of this Manual and laboratory biosafety references, such as the CDC’s Biosafety in Microbiological and Biomedical Laboratories) (101, 102). If the transportation time will be less than a few hours, most specimens, including
serum, can be shipped at either room temperature or 2°C to 8°C. If transportation will be overnight or longer, specimens such as stool, sputum, pleural fluid, blood, and material on swabs should be sent at 2°C to 8°C, while fresh tissue and serum samples should be shipped frozen. While blood culture contamination from skin flora may occur despite best practices, rates should not exceed 3% (103). If collecting blood for nucleic acid-based testing (e.g., nucleic acid amplification test [NAAT], PCR), collection tubes containing EDTA or citrate as an anticoagulant are preferable to those containing heparin. Formalin-fixed tissues can be sent at room temperature. In cases of suspected endophthalmitis, vitreous aspirate and biopsy tissue are the optimal specimens. These should be processed as quickly as possible, ideally, at the bedside.

Clinical specimens for isolation of *Bacillus* species other than *B. anthracis* can be handled safely on the open bench using standard precautions. Efforts should be made to avoid methods that produce aerosols. Any procedures that have the potential to generate aerosols should be performed in a biological safety cabinet. Biosafety level 2 (BSL-2) practices, containment equipment, and facilities are recommended for all activities involving clinical materials and diagnostic quantities of infectious cultures (101).

The clinically significant isolates reported to date are of species that grow, and often sporulate, on routine laboratory media at 37°C. Maintenance is simple if spores can be obtained, but it is a mistake to assume that a primary culture or subculture on blood agar will automatically yield spores if it is stored on the bench or in the incubator. It is best to grow the organism for a few days on nutrient agar or Trypticase soy agar containing 5-mg/liter manganese sulfate and refrigerate when microscopy shows that most cells have sporulated. For most species, sporulated cultures on slants of this medium, sealed after incubation, can survive in a refrigerator for years. Alternatively, cultures (preferably sporulated) can be frozen or lyophilized.

**B. anthracis**

In many countries, possession of *B. anthracis* is regulated by legislation. The U.S. Department of Health and Human Services/CDC and the U.S. Department of Agriculture/APHIS define *B. anthracis* as a tier I, category A select agent. The Canadian Human Pathogen and Toxins Act ([http://loislaws.justice.gc.ca/eng/acts/H-5.67/FullText.html](http://loislaws.justice.gc.ca/eng/acts/H-5.67/FullText.html)) defines *B. anthracis* and anthrax toxin as schedule 3 and schedule 1 agents, respectively. Human infectious doses have not been established, but using data based largely on nonhuman primate studies, the U.S. Department of Defense estimates that a 50% lethal dose for humans is 8,000 to 10,000 *B. anthracis* spores. When collecting clinical specimens for suspected anthrax, appropriate personal protective equipment should be used, including disposable gloves, disposable apron or overall, and boots which can be disinfected after use. The use of a face shield and/or a respirator should be considered, especially for dusty samples that might contain many spores. Full details of personal protective equipment and of disinfection and decontamination are given in annexes 1 and 3 of the WHO Anthrax in Humans and Animals guidelines (69). It should be noted that waterless rubs containing ethanol are not effective at removing endospores. Hand washing with soap and water or with chlorhexidine gluconate, and the use of hypochlorite-releasing towels, may reduce endospore contamination of the skin. Preexposure vaccination recommendations from the Advisory Committee on Immunization Practices (ACIP) are summarized below (104).

**Bioterrorism-Related Specimens and the LRN**

In 1999, the United States Department of Health and Human Services/CDC, in partnership with the Association of Public Health Laboratories and Federal Bureau of Investigation, established a Laboratory Response Network (LRN) to integrate laboratory responses to public health emergencies, including acts of bioterrorism. The LRN links local laboratories (sentinel level) with state (reference level) and federal (national level) laboratories that provide specialized testing and increased biosafety capacity. In all 50 states, there are reference level laboratories able to rapidly detect and confirm the identity of select agents, including *B. anthracis*. The LRN also provides guidance for testing and transportation of suspicious or challenging specimens. Guidelines for sentinel level laboratories and contact information for state and territorial public health laboratories are available through the CDC ([http://www.bt.cdc.gov/lrn/](http://www.bt.cdc.gov/lrn/)) and American Society for Microbiology ([http://www.asm.org](http://www.asm.org)) websites. For general questions, there is a 24-h hotline number [(800) CDC-INFO/ (800) 232-4636](http://cdcinfo@cdc.gov). LRN consultations may be also requested by calling the CDC Emergency Operations Center [(770) 488-7100](http://www.bt.cdc.gov/lrn/). Although initially limited to the United States, there are now over 150 national and international locations, including laboratories within Canada, Australia, Germany (U.S. military base), Japan (U.S. military base), South Korea (U.S. military base), and the United Kingdom, capable of providing a rapid response to acts of biological terrorism, chemical terrorism, emerging infectious diseases, and other public health threats. Similar programs exist in other countries. In Canada, the National Microbiology Laboratory (NML, Winnipeg, Manitoba, Canada) serves as the federal center and helps coordinate training and testing activities at Canadian LRN (CLRN) sites located in five provinces.

**Specimens from Patients Suspected To Have Anthrax**

The CDC has published guidelines for clinical evaluation of persons with possible anthrax ([http://www.cdc.gov/mmwr/preview/mmwrhtml/mm5043a1.htm](http://www.cdc.gov/mmwr/preview/mmwrhtml/mm5043a1.htm)). In all cases, specimens from potential sources of infection (e.g., animal hides, hair, and carcasses, etc.) should be sought in addition to patient specimens. Due to the hazardous nature of *B. anthracis*, it is recommended that sentinel level laboratories refer testing to a LRN reference level, or higher, laboratory. The preferred diagnostic specimen depends on the form of the disease (69). Whenever possible, patient specimens should be collected prior to the initiation of antimicrobial therapy. If cutaneous anthrax is suspected, the edge of an eschar should be lifted and two specimens of vesicular fluid collected by rotating swabs beneath it. One swab is used for Gram stain and culture and the other for NAAT. Immunohistochemical analyses are rarely performed any more, but if such testing is available, a full-thickness punch biopsy specimen from a papule or vesicle lesion that includes adjacent skin should be taken and fixed in 10% buffered formalin. If vesicle and eschar are present, biopsy specimens should be taken from both (105). Inhalational anthrax will be suspected only if the patient’s history suggests it. Chest radiographs and chest computed tomography scans are recommended. Blood should be collected for culture. Serology is useful for the diagnosis of cases where culture fails owing to previous treatment. Acute-phase serum (obtained within 7 days of onset) and convalescent-phase samples (obtained...
transport of specimens that may contain fluids. Care should be taken to use techniques that avoid spillage. Intestinal anthrax of pigs may be obvious only at necropsy, but *B. anthracis* is usually visible in stained smears made from mesenteric lymph nodes. Because *B. anthracis* competes poorly with putrefactive organisms, it may not be visible in smears prepared from older carcasses (2 to 3 days old). Instead, sections of tissue, or any blood-stained material, should be collected for culture. If the animal has been opened, spleen or lymph node specimens should also be taken. With putrefied and very old carcasses, swabs of the nostrils, nasal turbinates, and eye sockets are likely to yield *B. anthracis*, but the best specimens may be samples of contaminated soil taken from beneath the head and tail.

### B. anthracis Vaccines and Vaccination

Anthrax Vaccine Adsorbed (AVA, also called BioThrax; see [http://www.fda.gov/BiologicsBloodVaccines/Vaccines/ApprovedProducts/ucm061751.htm](http://www.fda.gov/BiologicsBloodVaccines/Vaccines/ApprovedProducts/ucm061751.htm)) is the current human vaccine in the United States. It is a cell-free filtrate (formalin treated) in an aluminum hydroxide-adsorbed gel prepared from a noncapsulated, nonproteolytic derivative of strain V770-NP1-R grown under microaerobic conditions. The FDA has approved a new schedule for preexposure immunization with AVA such that the five-dose primary schedule has been replaced by a three-dose primary schedule (intramuscular injections at 0, 1, and 6 months) with boosters at 12 and 18 months ([http://www.fda.gov/BiologicsBloodVaccines/Vaccines/ApprovedProducts/ucm304758.htm](http://www.fda.gov/BiologicsBloodVaccines/Vaccines/ApprovedProducts/ucm304758.htm)). To maintain immunity, an annual booster injection is recommended. Anthrax Vaccine Precipitated (AVP) is the current human vaccine in the United Kingdom. It is an alum-precipitated cell-free filtrate of the Sterne strain (34F2) cultured under static batch conditions, with activated charcoal, to increase PA production. Both AVA and AVP contain PA as well as trace amounts of LF, EF, and cell wall proteins. In 2010, the updated ACIP recommendations for pre-event vaccination and postexposure prophylaxis were published (104). In addition to previously approved recommendations for occupational and laboratory populations, the updated recommendations included new language to address emergency responders. The ACIP recommends routine preexposure vaccination with AVA for persons engaged in work (i) with high concentrations or pure cultures of *B. anthracis* spores, (ii) with environmental samples associated with anthrax investigations, or (iii) in spore-contaminated areas or other settings with exposure to aerosolized *B. anthracis* spores. Immunization is not routinely recommended for emergency and other responders but may be offered on a voluntary basis as part of a comprehensive occupational health and safety program to persons who perform site investigations, respond to suspicious substance reports (e.g., white powder incidents), or perform other activities that might lead to exposure to aerosolized *B. anthracis* spores. Because workers in the general diagnostic laboratories, using standard BSL-2 practices in the routine processing of clinical or environmental specimens, are not at increased risk for exposure to *B. anthracis* spores, immunization with AVA is not recommended (104). New anthrax vaccines, including second- and third-generation products, as well as several human monoclonal and polyclonal antibody products, are currently in their early development and testing (108).
DIRECT EXAMINATION

Microscopic examination of Gram-stained smears remains a primary tool of the microbiology laboratory (Fig. 1a). Clinically significant aerobic, Gram-positive bacilli include various species of Corynebacterium, Listeria, Lactobacillus, and Nocardia, among others, but Bacillus species are readily distinguished by their microscopic and phenotypic morphology. Aerobic endospore-forming organisms do not always stain Gram positive, but the presence of unstained areas within the cell may be indicative of spores. Phase-contrast microscopy (at a magnification of ×1,000) allows spores to be distinguished from other kinds of inclusions, such as polyhydroxybutyrate (PHB) granules. Spores are larger, more phase bright, and more regular in shape, size, and position. Sporangial appearance is also valuable for species-level identification. Although less convenient, a Gram-stained smear can be stripped of oil with acetone-alcohol, washed, and then stained for spores. Based on the Schaeffer-Fulton endospore stain (109), a heat-fixed smear is flooded with 10% aqueous malachite green for up to 45 min (without heating), then washed and counterstained with 0.5% aqueous safranin for 30 s. When visualized at 1,000× magnification, the cells are pink-red and spores, if present, are green (Fig. 1b).

The polychrome methylene blue (M’Fadyean) staining test allows visualization of the capsule, a characteristic feature of B. anthracis (Fig. 2a). Direct examination of blood smears can reveal capsulated rods or, if blood was collected after treatment was initiated, capsule “ghosts.” Notably, capsule visualization is not recommended in the LRN sentinel level clinical laboratory guidelines, and staining of B. anthracis should only be performed by reference level laboratories. For putrefied specimens, Giemsa stain may be more effective than the M’Fadyean test. The genes required for capsule biosynthesis (capB, -C, -A) are located on the pXO2 virulence plasmid (110). Loss of pXO2 gives rise to noncapsulated B. anthracis strains which are frequently mistaken for B. cereus. Similarly, species other than B. anthracis occasionally acquire genes for capsule biosynthesis, which may confound staining methods as well as NAAT assays that target capBCA (see below).

Molecular and antigen-based methods for direct examination of specimens exist, but most have been developed for the detection of B. cereus or B. anthracis. The symptoms associated with B. cereus food poisoning are attributed to bacterial toxins. The enterotoxin complex responsible for the diarrheal type of B. cereus food poisoning has been increasingly well characterized (92). Tissue culture-based assays have been developed, and two commercial kits are available for the detection of enterotoxin in foods and feces. The Oxoid BCET-RPLA (Oxoid Ltd., Basingstoke, United Kingdom) and TECRA VIA (TECRA Diagnostics, Roseville, New South Wales, Australia) detect different antigens, and there is some controversy about their reliabilities. Biosays using human (HEp-2, HepG2) and mouse (Hepa-1) cell lines, boar spermatozoa, and bacterial cultures have been developed for the nonspecific detection of the B. cereus emetic toxin in food extracts and culture filtrates (111). Specific detection of cereulide requires high-performance liquid chromatography–mass spectrometry methods (112). Toxin profiling can also be performed using real-time PCR assays that target toxin biosynthesis genes (113).

Because of its pathogenicity and biothreat potential, it is critical for laboratory staff to be able to distinguish B. anthracis from morphologically similar bacteria. Whenever large, nonmotile, Gram-positive rods are observed, and especially if large numbers of these bacilli are observed in a patient’s blood at death, then B. anthracis should be suspected. The LRN provides protocols for ruling out B. anthracis and referring out potential isolates. Several methods, including a B. anthracis-specific LRN PCR assay (114) and serology (115), were effectively used during investigation of the 2001 bioterrorism-associated outbreak as well as for confirmation of more recent cases associated with drum making (83, 105).

The most widely used and efficacious detection method in the U.S. public health system is the LRN PCR (114). This test targets several distinct loci on the B. anthracis chromosome and pXO1 and pXO2 virulence plasmids. The use of multiple loci increases specificity and allows for the detection of avirulent or noncapsulated B. anthracis strains (e.g., lacking pXO1 or pXO2), that might otherwise be mistaken for some other organism (e.g., B. cereus). At the
FIGURE 2  Photomicrographs of endospore-forming bacteria viewed by bright-field microscopy (a) and phase-contrast microscopy (b to l). Bars, 2 μm. (a) B. anthracis, M’Fadyean stain showing capsulate rods in guinea pig blood smear; (b) B. cereus, broad cells with ellipsoidal, subterminal spores, not swelling the sporangia; (c) B. thuringiensis, broad cells with ellipsoidal, subterminal spores, not swelling the sporangia, and showing parasporal crystals of insecticidal toxin (arrows); (d) B. megaterium, broad cells with ellipsoidal and spherical, subterminal and terminal spores, not swelling the sporangia, and showing PHB inclusions (arrows); (e) B. subtilis, ellipsoidal, central and subterminal spores, not swelling the sporangia; (f) B. pumilus, slender cells with cylindrical, subterminal spores, not swelling the sporangia; (g) B. circulans, ellipsoidal, subterminal spores, swelling the sporangia; (h) Lysinibacillus sphaericus, spherical, terminal spores, swelling the sporangia; (i) Brevibacillus brevis, ellipsoidal, subterminal spores, one swelling its sporangium slightly; (j) Brevibacillus laterosporus, ellipsoidal, central spores with thickened rims on one side (arrow), swelling the sporangia; (k) Paenibacillus polymyxa, ellipsoidal, paracentral to subterminal spores, swelling the sporangia slightly; (l) Paenibacillus alvei, cells with tapered ends, ellipsoidal, paracentral to subterminal spores, not swelling the sporangium. doi:10.1128/9781555817381.ch26.f2
CDC, a positive PCR result on any clinical specimen from a patient collected from a normally sterile site (such as blood or CSF) or a lesion of other affected tissue (e.g., skin, pulmonary, reticuloendothelial, or gastrointestinal) is regarded as a supportive or presumptive diagnostic test. It is considered sufficient to provide a probable diagnosis but is not confirmatory in itself. The principal reason for such stringent guidelines on the use of NAAT approaches and the value of their results towards providing a confirmatory diagnosis is based on the possibility that environmental contamination of a non-anthrax-related lesion could result in a positive result. This is especially the case with the use of some previously published PCR primers for capsule and chromosomal genes that can produce false positives with reactions to soil microbiota. This is quite similar to the recommendations that are included in the 2008 WHO guidelines (69), in which PCR can be used for identification of an isolate but is not recommended for testing of specimens.

A two-component direct fluorescent-antibody assay was used to identify encapsulated vegetative cells of B. anthracis (116), but NAAT-based detection methods are now preferred.

An antibody specific for one of the B. anthracis S-layer proteins is the basis of RedLine Alert (Tetracore, Inc., Gaithersburg, MD), a rapid test that can provide a result within 15 min. This assay has been approved by the FDA for use on nonhemolytic Bacillus species colonies cultured on sheep blood agar plates. Manufacturer’s data suggest that the test was 98.6% sensitive when tested on 145 B. anthracis isolates and 45 nonhemolytic, non-B. anthracis isolates. However, such identification of B. anthracis is only considered presumptive, and this test should not be used as a stand-alone test.

The Bacillus anthracis immunochromatographic field assay, developed by the U.S. Naval Medical Research Center (Silver Spring, MD), is an immunochromatographic assay for detection of PA in blood samples and tissue exudates. The highly sensitive and specific assay has been used to detect B. anthracis in animals, even several days after death (117).

Numerous reports describe the use of alternative technologies, such as flow cytometry, differential pulse voltammetry, fluorescence resonance energy transfer, surface-enhanced Raman scattering, locked nucleic acid probes, and atomic force microscopy for the detection of B. anthracis (106, 118, 119). Because anthrax toxins are highly expressed during infection, methods for direct detection of PA and LF in specimens (i.e., instead of bacilli) have also been explored. These include immunoassays that target PA (120) as well as bioassays that exploit the metallopeptase activity of LF and the adenyl cyclase activity of EF (121). Direct detection of spores in environmental samples has been achieved using diagnostic electron microscopy (122), whereas a technique developed by the Norwegian Defence Research Establishment uses matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) mass spectrometry (MS) for examination of suspicious powders (123). The MALDI-TOF method can accurately distinguish spores from common non-arthropod materials and differentiate B. anthracis from other Bacillus species. Inactivation of BSL-3 organisms, an essential step prior to performing MALDI-TOF (MS) in a BSL-2 space, has been successful for B. anthracis using trifluoroacetic acid (124) and gamma irradiation (125). A genetically engineered B. anthracis-specific bioluminescent reporter phage was capable of detecting B. anthracis, in clinically relevant concentrations, from simulated blood specimens in as little as 5 h (126) and could also be used for rapid susceptibility testing. These, and other novel approaches, may allow for detection of B. anthracis infection earlier in the course of the disease and thus allow for more successful treatment.

**ISOLATION PROCEDURES**

**Isolation of Aerobic Endospore-Forming Bacteria**

Specimens from patients should be inoculated onto plates of blood agar according to standard methods. Though not commonly used in clinical laboratories, heat treatment (e.g., 70°C for 30 min or 80°C for 10 min) may be used as an enrichment procedure for the isolation of aerobic endospore-forming bacteria. The heat-resistant spores survive temperatures that kill other organisms (e.g., non-spore-forming contaminants), and spores may also be heat shocked into subsequent germination. In general, enrichment procedures are not appropriate for fresh clinical specimens because spores are usually sparse or absent, and heat treatment will kill any vegetative cells. However, for episodes of food poisoning where B. cereus is suspected, nutrient or tryptic soy broth with polymyxin (100,000 U/liter) may be added to a heat-treated stool specimen.

For the majority of aerobic endospore-forming species, selective media are not available. However, such media have been designed for the isolation, identification, and enumeration of B. cereus group organisms. These exploit the phenotypic features of the organism, including the positive egg yolk reaction (i.e., phospholipase C activity) and the negative acid-from-mannitol reaction. Addition of pyruvate and polymyxin can enhance the selectivity of these media. Effective formulations include BCM (Bacillus cereus medium; LabM, Heywood, United Kingdom), PEMBA (polymyxin B, egg yolk, mannitol, bromthymol blue agar; Oxoid), and MEPB (mannitol, egg yolk, polymyxin B agar; Oxoid), which is also called MYP (Difco, BD, Franklin Lakes, NJ). Newer formulations, including Bacillus cereus group plating medium (Biosynth Chemistry and Biology, Staad, Switzerland, also available as Cereus-Ident-Agar from Heipha, Eppelheim, Germany) and Bacillus cereus/Bacillus thuringiensis chromogenic plating medium (R&F Laboratories, Downers Grove, IL), use specific chromogenic substrates, rather than natural egg yolk, to reveal phospholipase C activity. Selective media for B. anthracis include PLET agar (polymyxin-lysozyme EDTA-thallous acetate) and the differential/selective chromogenic medium, R&F Anthracis chromogenic agar (R&F Laboratories). Independent studies indicate that both formulations are effective for isolation of B. anthracis, but PLET agar may be more sensitive and selective.

**Isolation of B. anthracis**

Provided that standard good laboratory practice is observed, isolation and procedures to rule out B. anthracis can be performed safely in the routine clinical microbiology laboratory (e.g., by sentinel level laboratories). In the case of a suspect identification of B. anthracis, the isolate must be referred to an LRN reference center equipped for confirmatory identification of B. anthracis. Due to the infectious nature of this pathogen, all manipulations of specimens should be handled in a BSL-2 facility using BSL-3 precautions (see chapter 14 of this Manual and Biosafety in Microbiological and Biomedical Laboratories) (101). BSL-3 facilities are recommended for laboratory personnel doing routine processing of clinical or environmental specimens, but pre-
exposure vaccination is not (104). When working with pure cultures of *B. anthracis*, the primary hazards to laboratory personnel are direct and indirect contact of broken skin with cultures and contaminated laboratory surfaces, accidental parenteral inoculation, and, rarely, exposure to infectious clinical specimens. Laboratories that frequently centrifuge *B. anthracis* suspensions should use an aerosol-tight rotor that can be repeatedly autoclaved (101). In the United States, occupational exposure or release of the organism outside the primary barriers of the biocontainment area (e.g., on the open bench) requires the completion of APHIS/CDC form 3 ("Information Document for Report of Theft, Loss, or Release of Select Agents and Toxins"; http://www.selectagents.gov/CDForm.html).

Possession of *B. anthracis* requires registration of a laboratory within the United States with either the CDC or APHIS. When *B. anthracis* is identified by a laboratory, the identification of this agent must be reported to the CDC or APHIS immediately and an APHIS/CDC form 4 ("Report of the Identification of a Select Agent or Toxin", http://www.selectagents.gov/CDForm.html) submitted within 7 days. Other authorities should be notified as required by federal, state, or local laws. When *B. anthracis* is isolated in an unregistered laboratory (e.g., diagnostic sentinel level clinical laboratory), the organism must either be destroyed on-site by a recognized sterilization or inactivation process or be transferred to a registered laboratory within 7 days following notification of the isolate having been confirmed as *B. anthracis*. In Canada, all materials containing or suspected to contain anthrax must be referred to a CLRN laboratory for further characterization in order to comply with the Human Pathogens and Toxin Act (http://www.phac-aspc.gc.ca/lab-bio/regul/hpta-lapht-eng.php). Similar protocols exist in other countries.

Tests for the presence of *B. anthracis* may be requested for diverse specimens, such as animal products (e.g., wool, hides, hair, and bone meal) from regions of endemicity, soil or other materials from old burial sites or tannery or laboratory sites due for redevelopment, or other environmental materials associated with outbreaks (e.g., sewage sludge). Detection in such specimens may mean searching for rather few spores of *B. anthracis* among those of many other species, especially other members of the *B. cereus* group. Some environmental specimens may contain substances that inhibit germination and growth of *B. anthracis* (69). At present, there is no enrichment method specific for *B. anthracis*, and culture by the selective agar techniques described above is the best approach.

**IDENTIFICATION**

Species level identification of an aerobic spore-forming organism usually requires examination of microscopic features, colonial morphology, biochemical tests, and increasingly, analysis of nucleic acid or protein profiles. As a first step, it is important to establish that the isolate really is an aerobic endospore-forming organism. *Bacillus* species are typically described as Gram-positive rods, but some are Gram variable, and Gram positivity is readily lost in older cultures. Some species or strains simply appear Gram negative. *Pediococcus*, *Bacillus* and *Brevibacillus* are more likely to stain Gram variable or Gram negative. Phase-contrast microscopy and spore staining can be used to distinguish PHB granules and other storage inclusions from true spores. For some species, the storage granules can actually assist with identification. When grown on carbohydrate-rich media, such as glucose nutrient agar, the large cells of *B. megaterium* may accumulate PHB (Fig. 2d) and appear vacuolated or foamy. However, the microscopic morphology of the sporangia are much more helpful for distinguishing between species (Fig. 2). Spore shapes vary from cylindrical through ellipsoidal to spherical. Occasionally, bean- or kidney-shaped, curved-cylindrical, and pear-shaped spores are also seen. Spores may be positioned terminally, subterminally, or centrally; the sporangia may appear swollen or distended. Despite within-species and within-strain variation, sporangial morphologies can be sufficiently characteristic to allow an experienced worker to make a tentative identification. For example, *B. laterosporus* produces very distinctive ellipsoidal spores that have thickened rims on one side, such that they appear to be laterally displaced in the sporangia (Fig. 2i). Recognition of *B. thuringiensis* is largely dependent on observation of its cuboid or diamond-shaped parasporal crystals in sporulated cultures (Fig. 2c).

In general, morphological features of the vegetative cell tend to be less informative, but they can still assist in species identification. Vegetative cells vary in width from about 0.5 to 1.5 µm and in length from 1.5 to 8 µm. They may occur singly or in chains; usually, cells are round-ended, but some are square or, occasionally, tapered (e.g., *P. alvei*) (Fig. 2i). Many species are motile.

Growth characteristics are often diagnostic. *B. subtilis* and *B. licheniformis* exhibit similar colonial and microscopic morphologies but different growth characteristics, being strictly aerobic and facultatively anaerobic, respectively. *B. megaterium* and *B. cereus* are both large-celled species, but the former is strictly aerobic while the latter is facultatively anaerobic.
