Fungi form a separate group of eukaryotic organisms that differ from other groups, such as the plants and animals, in several major respects. Fungal cells are encased within a rigid cell wall, mostly composed of chitin, glucan, chitosan, mannan, and glycoproteins in various combinations. These features contrast with the animals, which have no cell walls, and the plants, which have cellulose as the major cell wall component. As in other eukaryotic organisms, fungal cells have a true nucleus with a surrounding membrane, and cell division is accompanied by meiosis or mitosis.

Fungi are heterotrophic (lacking in chlorophyll), and therefore require preformed organic carbon compounds for their nutrition. Fungi live embedded in a food source or medium, and obtain their nourishment by secreting enzymes into the external substrate and by absorbing the released nutrients through their cell wall. Fungi are found throughout nature, performing an essential service in returning to the soil nutrients removed by plants.

Fungi can be multicellular or unicellular. In multicellular organisms, the basic structural unit is a chain of multinucleate, tubular, filament-like cells (termed a hypha). In most multicellular fungi the vegetative stage consists of a mass of branching hyphae, termed a mycelium or thallus. Each individual hypha has a rigid cell wall and increases in length as a result of apical growth with mitotic cell division. In the more primitive fungi, the hyphae remain aseptate (without cross walls). In the more advanced groups, however, the hyphae are divided into compartments or cells by the development of more or less frequent cross walls, termed septa. Such hyphae are referred to as being septate. Fungi that exist in the form of microscopic multicellular mycelium are commonly called molds.

Many fungi that exist in the form of independent single cells propagate by budding out similar cells from their surface. The bud may become detached from the parent cell, or it may remain attached and itself produce another bud. In this way, a chain of cells may be produced. Fungi that do not produce hyphae but just consist of a loose arrangement of budding cells are called yeasts. Under certain conditions, continued elongation of the parent cell before it buds results in a chain of elongated cells, termed a pseudohypha. Unlike a true hypha, the connection between adjacent pseudohyphal cells shows a marked constriction. Yeasts are neither a natural nor a formal taxonomic group, but are a growth form shown in a wide range of unrelated fungi. Many medically important fungi change their growth form as part of the process of tissue invasion. These so-called dimorphic pathogens usually change from a multicellular mold form in the natural environment to a budding, single-celled yeast form in tissue under the influence of temperature as they exhibit thermal dimorphism. Histoplasma capsulatum, Blastomyces dermatitis, Paracoccidioides brasiliensis, and Sporothrix schenckii are the best-known examples of this dimorphic change, but many other fungal pathogens show subtle morphological differences between forms found in tissue and in culture.
Fungi reproduce by means of microscopic propagules called spores or conidia. The term conidium (pl. conidia) is used to describe propagules that result from an asexual process (involving mitosis only). Except for the occasional mutation, asexual conidia are identical to the parent. They are generally short-lived propagules that are produced in enormous numbers to ensure dispersal to new habitats. Many fungi are also capable of sexual reproduction (involving meiosis, preceded by fusion of the nuclei of two cells). Some species are self-fertile (homothallic) and able to form sexual structures between different cells within an individual thallus. Most, however, are heterothallic and do not form their sexual structures unless two compatible isolates come into contact. Once two compatible haploid nuclei have fused, meiosis can occur, and this leads to the production of the sexual spores. In some species the haploid sexual spores are borne singly on specialized generative cells and the whole structure is microscopic in size. In other cases, however, the spores are produced in millions in macroscopic “fruiting bodies” such as mushrooms. Sexual reproduction and its accompanying structures form one scheme for classification of the fungi.

NOMENCLATURE OF FUNGI
The scientific names of fungi are subject to the International Code of Nomenclature for algae, fungi, and plants (ICN) (http://www.iapt-taxon.org), formerly the International Code of Botanical Nomenclature (ICBN), a convention that dates from the time when biologists regarded these organisms as “lower plants.” The rules of the ICN must be followed when proposing the name for a new fungal species; otherwise, the name being proposed can be rejected as invalid (3). The main requirements for valid publication are that the name must be in Latin binomial form, and a living culture of the specimen on which the author based his or her original description of the species must be preserved. The previous requirement for a descriptive paragraph in Latin has been removed.

Names of fungi may have to be changed for a number of reasons. Many common and widely distributed species of fungi have been described as new many times and thus have come to have more than one name. In general, the correct name for any species is the earliest name published in line with the requirements of the code of nomenclature. The later names are termed synonyms. To avoid confusion, however, the ICN permits certain exceptions. The most significant of these is when an earlier generic name has been overlooked, a later name in common use, and a reversion to the earlier name would cause problems (3).

Another reason for changing the name of a fungus is when new research necessitates the transfer of a species from one genus to another or establishes it as the type of a new genus. Such changes are quite in order, but with the provision that the specific epithet should remain unchanged, except for inflection according to the rules of Latin grammar. However often a species is transferred to a new genus, the correct species epithet is always the first one that was applied to that particular organism. As an example, when *Phialophora parasitica* was moved to a new genus, it became *Phaeoacremonium parasiticum*.

If there is one complication of fungal nomenclature that is confusing to many microbiologists, it is the fact that a large number of fungi appear to bear more than one name. This is an apparent departure from the basic principle of biological classification, in which an organism can only have one correct name. As described in the previous section of this chapter, many fungi have an asexual stage (or anamorph) characterized by the production of asexual conidia, and a sexual stage (or teleomorph) characterized by sexual spores (e.g., ascospores, basidiospores). Many fungi propagate asexually and the teleomorph is unknown or only rarely encountered. Because of this, mycologists have often given separate names to the asexual and sexual stages. Often, this is because the anamorph and teleomorph were described and named at different times without the connection between them being recognized. In 2011, the code of nomenclature was modified to apply a policy where a given fungus will have only one name (3). As of 1 January 2013, the system of permitting separate anamorph and teleomorph names ended; it is no longer necessary to provide different names for different morphologies of the same fungus. All legitimate names proposed for a species can serve as the correct name for that species. The name(s) to be widely used will be decided by a Nomenclature Committee for Fungi (3). Various proposals have been made to suggest the name to be retained, and these names should be formalized by 2016. At this time, it is permissible to refer to a fungus by its asexual designation if this is the stage that is usually obtained in culture. For example, *Blastomyces dermatitidis* is the anamorph of the ascomycete *Ajlilomyces dermatitidis*. The anamorph is the stage that is ordinarily encountered in culture, and only under certain special conditions is the sexual stage formed.

TAXONOMY AND CLASSIFICATION OF THE FUNGI
The kingdom Fungi is one of the six kingdoms of life (1, 4). It is organized in a hierarchical manner, each rank being named with and recognizable by a particular ending: phylum, -mycota; subphylum, -mycotina; class, -mycetes; order, -ales; family: aceae (5). Each family is composed of a number of genera, and these are divided into species. The kingdom Fungi is currently divided into seven phyla, which include the Ascomycota and Basidiomycota (6). The phylum Zygomycota is no longer accepted due to its polyphyletic nature (6). Pending resolution of their relationships, the organisms that have traditionally been placed in the Zygomycota are at this time divided among the phylum Glomeromycota and four subphyla incertae sedis. The subphylum Mucoromycotina has been proposed to accommodate the Mucorales, while the subphylum Entomophthoromycotina has been created for the Entomophthorales (6).

In addition to the true fungi, there are a number of human and animal fungus-like microbes, such as *Lagenidium* spp., *Psithian insidiosum*, and *Rhinosporidium seeberi*, that are now studied by mycologists (see chapter 127). These organisms, while not fungi sensu stricto, are “para-fungi” or “pseudofungi,” protists sharing fungus-like morphological features with the true fungi. *Lagenidium* spp. and *P. insidiosum* are presently classified in the kingdom Straminipila (Stramenopila), phylum Oomycota. *R. seeberi* was placed by Adl et al. (7) in the supergroup Ophisthokonta, division Holozoa. Furthermore, molecular studies have established that several organisms, long considered as protists, belong to the kingdom Fungi. These include *Pneumocystis*, now placed in the Ascomycota, and the microsporidians.

Historically, the classification of fungi has largely been based on their morphology, rather than on the physiologi-

These groups are described in the following sections. A simplified key to their identification is provided in Table 2.

Kingdom Fungi

Subphyla Mucoromycotina and Entomophthoromycotina (Formerly Phylum Zygomycota)

The traditional Zygomycota have been divided among the phylum Glomeromycota and four subphyla pending resolution of further taxonomic questions (6). In these groups of lower fungi, the thallus is paucisepaete and consists of wide, hyaline (colorless) branched hyphal elements. The asexual spores (termed sporangiospores) are nonmotile and are often produced inside a closed sac, termed a sporangium, the wall of which ruptures to release them, although in some genera the spores are formed around a vesicle at the tip of the sporangiophore. Sexual reproduction leads to the formation of a single large zygospor with a thickened wall. Most of the medically important species are heterothallic and do not form their sexual structures unless two compatible isolates come into contact.

The subphylum Mucoromycotina contains the order Mucorales, which is the most clinically important, and includes the genera Lichtheimia (formerly Abisia), Macror, Rhizomycotina, and Rhizopus. The subphylum Entomophthoromycotina contains one order of medical importance, the Entomophthorales. The Entomophthorales includes the genera Basidiobolus and Conidiobolus, agents of subcutaneous infections.

Phylum Basidiomycota

Most members of this group of higher fungi have a septate, filamentous thallus, but some are typical yeasts. Sexual reproduction leads to the formation of haploid basidiospores on the outside of a generative cell, termed a basidium. Fifteen classes are recognized, but only a few members of this large phylum are of medical importance. The most prominent are the basidiomycetous yeasts with anamorphic stages belonging to the genera Cryptococcus, Malasseza, and Trichosporon. The genus Cryptococcus, which contains more than 30 species, has teleomorphs that have been assigned to the genera Filobasidium and Filobasidiella.

In culture, filamentous basidiomycetes often produce fast-growing, nonsporulating (sterile) white colonies with clamp connections. These are hyphal outgrowths which, at cell division, make a connection between the two cells forming a bypass around the septum to allow the migration of a nucleus. The basidia are often produced in macroscopic structures, termed basidiomata or basidiocarps, and the basidiospores are often forcibly discharged. Asexual reproduction is variable; some species produce spores like those of the Ascomycota (see below), but many others are not known to produce spores at all. Most filamentous basidiomycetes are wood-rotting fungi or obligate plant pathogens. The most frequently reported clinically important filamentous basidiomycete is *Schizopyllum commune*.

**Phylum Ascomycota**

This large phylum contains almost 50% of all named fungal species, and accounts for around 80% of fungi of medical importance (2). Sexual reproduction leads to the development of haploid spores, termed ascospores, which are produced in a sac-like structure termed an ascus. The Ascomycota show a gradual transition from primitive forms that produce single ascus to species that produce large structures, termed asci, or ascomata, containing numerous ascis. Variations in ascus structure are of major importance in the classification of these fungi. Asexual reproduction consists of the production of conidia from a generative or conidiogenous cell. In some species the conidiogenous cell cannot be distinguished from the rest of the mycelium. In others, a special structure is produced that bears one or more conidiogenous cells.

The phylum Ascomycota includes four classes of medical importance: the *Pneumocystidomycetes, Saccharomycetes, Eurotiomycetes, and Sordariomycetes*. The class Pneumocystidomycetes contains the genus *Pneumocystis*, formerly classified as a member of the kingdom Protozoa but now reassigned to the fungi on the basis of small-subunit rDNA and other gene sequence comparisons (13). The class Saccharomycetes contains the ascomycetous yeasts, while the Eurotiomycetes and the Sordariomycetes contain the filamentous ascomycetes.

The order Saccharomyceae, which belongs to the class Saccharomycetes, is characterized by vegetative yeast cells that proliferate by budding or fission. These fungi do not produce ascocarps, the ascus being formed by direct transformation of a budding vegetative cell, by "mother-bud" conjugation, or by conjugation between two independent single cells. Many members of the order have an anamorphic stage belonging to the genus *Candida*. This genus, which consists of around 200 anamorphic species, has teleomorphs in more than 10 different genera, including *Clavispora*, *Debaryomyces*, *Issatchenkia*, *Kluyveromyces*, and *Pichia* (14). Many of these will be renamed as the "one fungus, one name" concept is applied.

In the class Eurotiomycetes, sexual reproduction leads to the formation of ascomata containing ascii with ascospores. This class has seven orders that include species pathogenic to humans. Among the more important are the *Onygenales*, which contains the teleomorphs of the dermatophytes and a number of dimorphic systemic pathogens (including *Histoplasma capsulatum* and *Blastomyces dermatitidis*) and the *Eurotiales*, which includes the teleomorphs of the anamorphic genera *Aspergillus* and *Penicillium*. In the class Sordariomycetes, the order Sordariales contains many of the teleomorphs of the anamorphic genus *Fusarium*. In addition, the teleomorphs of numerous melanized fungi of medical importance belong to a number of orders in the classes Eurotiomycetes or Sordariomycetes. These include the *Chaetothyriales*, *Microascales*, *Hypocreales*, and *Ophiostomatales*.

Although most of the septate molds that are isolated in clinical laboratories belong to one of the classes described above, it is unusual to encounter their sexual reproductive structures in routine cultures. The few species that do produce ascocarps in culture are included in the anamorphic abundance include *Pseudallescheria boydii* (anamorph: *Scedosporium boydii*) and *Emberuclia nidulans* (anamorph: *Aspergillus nidulans*). For the most part, however, routine identification of these molds is based on the form and arrangement of the assexual spore-bearing structures and the manner in which the spores are produced (see below).

**Kingdom Protozoa**

Microsporidia, some of which are obligate parasites of humans, have long been classified with the protozoa. However,
phylogenetic analysis has indicated that these organisms belong among the fungi (15), and the phylum Microsporidia within the kingdom Fungi has been created to accommodate them (6). However, parasitologists have been reluctant to part with this group, while mycologists have been just as reluctant to accept it. At this time, these organisms have been classified as true fungi (see chapter 128).

**Kingdom Straminipila (formerly Chromista)**

Members of the order Pythiales mostly occur in the soil or on plants. Two genera cause infection in mammalian hosts: Lagenum spp. and Pythium insidiosum (see chapter 127). Members of the Straminipila have been long regarded as fungi because they develop sparsely septate mycelial structures similar to those in filamentous fungi. However, these slime-fungus-like microbes are located basal to plants and are closely related to some algal groups; for this reason, they are now placed in the kingdom Straminipila, phylum Oomycota (16).

**Identification of Yeasts**

Yeasts are neither a natural nor a formal taxonomic group, but are a growth form found in a wide range of unrelated ascomycetous and basidiomycetous fungi. Their identification relies on a combination of morphological, physiological, and biochemical characteristics. Useful morphological characteristics include the color of the colonies; the size and shape of the cells; the presence of a capsule around the cells; the production of hyphae, pseudohyphae, or arthroconidia; and the production of chlamydospores. Useful biochemical tests include the assimilation and fermentation of sugars and the assimilation of nitrate. Most yeasts of medical importance can be identified using one of the commercial tests systems that are based on sugar assimilation of isolates. However, it is important to remember that microscopic examination of cultures on cornmeal agar is essential to avoid confusion between organisms with identical biochemical profiles (see chapter 115).

The so-called black yeasts are not a formal taxonomic group, but the description is applied to a wide range of unrelated ascomycetous and basidiomycetous fungi that are able to produce melanized budding cells at some stage in their life cycle (17). Because most of these fungi are also able to produce true mycelium, their routine identification is largely based on the morphological characteristics of the asexual spore-bearing structures and the manner in which the spores are produced.

**Classification and Identification of Anamorphic Molds**

Most of the septate molds that are isolated in clinical laboratories do not produce their sexual reproductive structures in routine cultures, and their identification is based on the manner in which the asexual spores are produced. Two artificial form classes of anamorphic or "mitosporic" molds are informally recognized, based on the mode of conidium formation. The Hyphomycetes produce their conidia directly on the hyphae or on specialized conidiophores, while the Coelomycetes have more elaborate reproductive structures termed conidiomata. Although these form classes are no longer formally recognized, they continue to offer a useful framework for identification based on morphology.

**Form Class Coelomycetes**

Three artificial orders are recognized: the Sphaeropsidales, Melanconiales, and Pycnothrytales. In the Sphaeropsidales, the conidia are produced in conidiomata that are either spherical with an apical opening and with conidiogenous cells lining the inner cavity wall (termed pycnidia), or are open and cup-shaped, in which case the conidiogenous cells cover the conidiomatal surface (termed acervuli). A few members of this form class are common pathogens of humans. One of the more frequently encountered species is Neoscytalidium dimidiatum, a plant pathogen that can also cause infections of the skin and nails. Until recently, this species was known by the synanamorph name Scyalidium dimidiatum.

**Form Class Hyphomycetes**

The Hyphomycetes contains a large number of septate anamorphic molds of medical importance, including the genera Aspergillus, Blastomyces, Cladosporium, Fusarium, Histoplasma, Microsporum, Penicillium, Phialophora, Scedosporium, and Trichophyton. In addition, numerous Hyphomycetes have been reported as occasional opportunistic pathogens of humans. For this reason, it is important for clinical microbiologists to be able to recognize and correctly identify this group of fungi.

As mentioned earlier, the process of conidiogenesis is of major importance in the identification of these molds. Two basic methods of conidiogenesis can be distinguished: thallic conidiogenesis, in which an existing hyphal cell is converted into one or more conidia; and blastic conidiogenesis, in which conidia are produced as a result of some form of budding process (for a detailed discussion of this topic, see reference 17).

**Thallic Conidiogenesis**

In this form of conidiogenesis, the conidia are produced from an existing hyphal cell. Arthroconidia, which are derived from the fragmentation of an existing hypha, represent the simplest form of thallic conidiogenesis and have evolved in many different groups of fungi. The first step in the examination of cultures of these molds should be to ascertain whether another spore form is present. If so, identification should be based upon that form. The few molds of medical importance that produce arthroconidia as their sole means of conidiogenesis include Coccioidioides species.

Aleurioconidia are formed from the side or tip of an existing hypha and, during the initial stage before a septum is laid down, can resemble short hyphal branches. This form of thallic conidiogenesis is characteristic of the dermatophytes (Epidemophyton, Microsporum, and Trichophyton spp.), as well as a number of dimorphic systemic pathogens, including Blastomyces dermatitidis, Histoplasma capsulatum, and Paracoccidioides brasiliensis.

**Blastic Conidiogenesis**

Many fungi have evolved some form of repeated budding that allows them to produce large numbers of asexual spores from a single conidiogenous cell. There are two basic forms of blastic conidiogenesis: holoblastic development, in which all layers of the wall of the conidiogenous cell swell out to form the conidium; and enteroblastic development, in which the conidium is produced from within the conidiogenous cell, the outer layers of the cell wall breaking open and an inner layer extending through the opening to become the new spore wall. These two forms of blastic conidiogenesis can be further subdivided according to the details of spore development. Almost all molds that produce holoblastic conidia have melanized cell walls and thus are similar in colonial appearance. The
morphological characteristics of their conidia and the manner in which the spores are produced serve as the main distinguishing features. Holoblastic conidia range in size from minute unicellular to large thick-walled multicelled conidia. In some species, the first-formed conidium buds to produce a second, and the second produces a third, and so on until a chain of conidia is produced with the youngest at its tip (acropetal). As each spore can produce more than one bud, a branching chain becomes possible (e.g., Cladosporium species). In another group, the conidiogenous cell that produced the first spore then grows past it to produce a second. If this process is repeated, it will result in an elongated conidiogenous cell with numerous lateral single spores along its sides. This is termed sympodial development and is typical of species of Bipolaris and Exserohilum.

In molds that produce enterothelial conidia, the wall of the conidium is derived from the inner layer of the wall of the conidiogenous cell. This permits a succession of conidia to be produced from the same point. There are two main forms of enteroblastic conidiogenesis: phialidic, in which the specialized conidiogenous cell from which the conidia are produced is termed a phialide, and anellidic, in which the conidiogenous cell is termed an anellide.

In phialidic conidiogenesis, the first blown-out cell breaks open at its tip and remains as a collarette, from the inside of which conidia are produced in succession. In some species, the collarette is distinct (e.g., Phialophora species), but in others it is almost invisible at the tip of the phialide. In some phialidic molds, such as species of Fusarium and Acremonium, the conidia are not firmly attached to each other and often move aside to accumulate in a wet mass around the phialide. In other phialidic molds, such as species of Aspergillus and Penicillium, continuous replenishment of the inner wall of the tip of the phialide results in the formation of an unbranched chain of connected conidia, with the youngest at the base (basipetal). Anellides, like phialides, are conidiogenous cells that produce conidia at their tips in unbranched chains (e.g., Scopulariopsis species) or in wet masses (e.g., Scedosporium species). In anellidic conidiogenesis the first blown-out cell becomes a conidium, and subsequent conidia are formed by blowing out through the scar of the previous one. Unlike phialides, anellides increase in length each time a new spore is produced. An old anellide that has produced many conidia will have a number of apical scars or anellations at its tip.

IDENTIFICATION OF MOLDS

Most molds can be identified after growth in culture, but the criteria for recognition often differ from the fundamental characteristics that are used as a basis for classification. Macroscopic characteristics, such as colonial form, surface color, pigmentation, and growth rate, are often helpful in mold identification. Although the culture medium, incubation temperature, age of the culture, and amount of inoculum can influence colonial appearance and growth rate, these characteristics remain sufficiently constant to be useful in the process of identification. Molds that fail to sporulate in culture may be impossible to speculate using morphology, and it is therefore important to select culture conditions that favor sporulation. Although molds often grow best on rich media, such as Sabouraud’s dextrose agar, overproduction of mycelium often results in loss of sporulation. In such cases, subculture to a low-nutrient medium may help to stimulate sporulation.

POLYPHASIC IDENTIFICATION

A frequent problem with the traditional morphological approach to fungal identification is that nonsporulating organisms cannot be identified or given a taxonomic placement. With comparative DNA sequence analysis, most such isolates can now be identified and classified by applying PSR concepts. Interpretive criteria for identification of fungi using DNA sequencing have been published (18).

Many clinical laboratories today employ DNA sequencing as part of their routine protocol for fungal identification. In circumstances where morphology-based identification is not helpful, an isolate may be a candidate for DNA-based identification. This approach may be useful when an isolate displays atypical morphology, fails to sporulate, requires lengthy incubation or incubation on specialized media in order to sporulate, or if the phenotypic results are nonspecific or confusing. Precise identification of particular isolates may also be necessary as part of outbreak investigations or during other studies of the epidemiologic significance of particular groups of organisms. In these cases, DNA sequencing may be required. A polyphasic approach to fungal identification that combines both morphological and genotypic approaches may be the most useful, practical, and cost-effective way forward for fungal identification at this time (19).

COMMON MYCOLOGICAL TERMS

Acrevulus (plural, acervuli): an open or cup-shaped structure on which conidia are formed.

Acropetal: pertaining to a chain of conidia in which new spores are formed at the tip of the chain.

Aleuroconidium (plural, aleuroconidia): a thallic conidium that is formed from the end of an undifferentiated hypha or from a short side branch.

Aleurospore: see Aleuroconidium.

Anamorph: the asexual form of a fungus.

Anellide: a specialized conidiogenous cell from which a succession of spores is produced and which has a column of apical scars at its tip.

Anelloconidium (plural, annelloconidia): a blastic conidium that is formed from an anellide.

Anellospore: see Anelloconidium.

Apophys: the enlargement of a sporangium just below the columella.

Appressoriorum (plural, appressoria): a swelling on a germ tube or hypha, typical of Colletotrichum spp.

Arthroconidium (plural, arthroconidia): a thallic conidium produced as the result of fragmentation of an existing hypha into separate cells.

Arthrospore: see Arthroconidium.

Ascom): a structure that contains asci.

Ascomata (plural, ascomata): see Ascocarp.

Ascospore: a haploid spore produced within an ascus following meiosis.

Ascus (plural, asci): a thin-walled sac containing ascospores, characteristic of the Ascomycota.

Aseptate: without cross walls or septa.

Ballistoconidium: a conidium that is forcibly discharged.
113. Taxonomy and Classification of Fungi

Ballistospore: see Ballistoconidium.
Basidiocarp: a structure that produces basidia.
Basidioma (plural, basidiomata): see Basidiocarp.
Basidiospore: a haploid spore produced on a basidium following meiosis.
Basidium: a cell upon which basidiospores are produced, characteristic of the Basidiomycota.
Basipetal: a chain of conidia in which new spores are formed at the base of the chain.
Blastic: one of the two basic forms of conidiogenesis in which enlargement of the conidial initial occurs before a delimiting septum is laid down.
Blastocladium (plural, blastocladia): a Blastocladiomycota. (a term used to describe colonies).

Cleistothecium (plural, cleistothecia): a form of closed ascocarp with no predefined opening, which splits open to release the ascospores.
Coelomycete: an artificial taxonomic grouping referring to anamorphic molds that form conidia within a specialized multihyphal structure, such as an acervulus or pycnidium.
Collarette: a cup-shaped structure at the tip of a conidiogenous cell.
Conidiophore: a specialized hypha or cell on which, or as part of which, conidia are produced.
Conidiogenous cell: any cell that produces or becomes a conidium.
Conidioma (plural, conidiomata): a conidium-bearing structure.
Conidiophores: a specialized hypha or cell on which, or as part of which, conidia are produced.
Conidium (plural, conidia): an asexual spore.
Cruciate: cross-shaped (a term used to describe spores).

Cylindrical: having a cylindrical shape (a term used to describe spores).
Dematiaceous: darkly pigmented.
Denticulate: having a convoluted surface (a term used to describe spores).
Cuneiform: thinner at one end than at the other (a term used to describe spores).
Denticle: a small tooth-like projection on which a spore is borne.
Distoseptate: or pertaining to spores in which the individual cells are each surrounded by a sac-like wall distinct from the outer wall.
Echinulate: of or pertaining to spores with small, pointed spines.
Endoconidium (plural, endoconidia): a conidium formed inside a hypha.
Euseptate: of or pertaining to spores in which the outer and inner walls of the septum are continuous.
Floccose: having a cotton-like texture (a term used to describe colonies).
Fusiform: having a spindle-like shape (a term used to describe spores).
Geniculate: of or pertaining to an irregular conidiogenous cell formed by some holoblastic molds.
Glabrous: having a wax-like texture (a term used to describe colonies).
Gymnothecium (plural, gymnothecia): an ascocarp in which the asci are distributed within a loose network of hyphae.
Heterothallic: self-sterile; sexual reproduction of a heterothallic fungus cannot take place unless two compatible mating strains are present.
Hüll: a slightly prominent scar at the base of a conidium.
Holoblastic: a form of conidiogenesis in which both the inner and outer walls of the conidiogenous cell swell out to form the conidium.
Homothallic: self-compatible; sexual reproduction of a homothallic fungus can take place within an individual strain.
Hülle cell: a large, thick-walled, sterile cell found in some Aspergillus spp.
Hyaline: colorless, transparent, translucent.
Hypha (plural, hyphae): one of the individual filaments that make up the mycelium of a fungus.
Hyphomycete: an artificial taxonomic grouping referring to anamorphic molds that form conidia directly on the hyphae or on specialized conidiophores.
Macroconidium (plural, macroconidia): the larger of two different sizes of conidia produced by a fungus in the same manner.
Meristematic: perpetual increase in biomass in all directions with concordant septum formation.
Mesorhizomycota (plural, mesorhizomycota): a cylindrical outgrowth from the end of a sporangiophore in which a chain-like series of sporangiospores is produced, characteristic of Syncephalastrum spp.
Metula (plural, metulae): a conidiophore branch that bears phialides, characteristic of Aspergillus and Penicillium spp.
Microconidium (plural, microconidia): the smaller of two different sizes of conidia produced by a fungus in the same manner.
Mitosporic: an anamorphic fungus.
Mold: a filamentous fungus.
Moniliaceous: hyaline or lightly colored.
Murriform cell: a thick-walled, darkly pigmented cell found in tissues affected by chromoblastomycosis.
Mycelium: a mass of branching filaments that make up the vegetative growth of a fungus.
Oligokaryotic cell: a cell with several nuclei.
Oospore: a sexual spore produced in the Oomycota.
Ostiole: the opening through which spores are released from an ascocarp or pycnidium.
Pauciseptate: having few septa.
Perithecium (plural, perithecia): a flask-shaped ascomarp with an apical opening (ostiole) through which the ascospores are released.
Phialide: a specialized conidiogenous cell from which a succession of spores is produced.
Pleomorphic: term used to describe a fungus that has more than one anamorph.
Pleomorph: of or pertaining to a nonsporing strain of a fungus.
Pseudohypha (plural, pseudohyphae): a chain of yeast cells that have arisen as a result of budding and that have elongated without becoming detached from each other, forming a hypha-like filament.
Punctate: marked with small spots (a term used to describe colonies).
Pycnidiospora: a conidium formed within a pycnidium.
Pycnidium (plural, pycnidia): a flask-shaped structure with an apical opening (ostiole) inside which conidia are produced.
Pyroid: a short branching hypha that resembles a root.
Sclerotoid: see Muriform cell.
Sclerotium (plural, sclerotia): a firm mass of hyphae, normally having no spores in or on it.
Septate: having cross walls or septa.
Septum (plural, septa): a cross wall in a fungal hypha normally having no spores in or on it.
Sessile: not having a stem.
Sporangiole: a sporangium that contains a small number of assexual spores, characteristic of the Mucorales.
Sporangiophore: a specialized hypha upon which a sporangium develops. Sporangiospore: an asexual spore produced in a sporangium, characteristic of the Glomeromycota.
Sporangium (plural, sporangia): a closed sac-like structure containing assexual spores, characteristic of the Glomeromycota. This term has also been used for members of kingdom Straminipila to denote the segmented hyphal structures (and not spores). Sporogenous cell: the cell from which spores are produced.
Sporangiole: a specialized conidiogenous structure which conidia are borne on a compact mass of short conidiophores.
Stroma (plural, stromata): a solid mass of hyphae, sometimes bearing spores on short conidiophores, or having ascocarps or pycnidia embedded in it.
Symphylal: developing a single conidium at successive sites along a lengthening conidiogenous cell.
Synnema (plural, synnemata): a compact group of erect and sometimes fused conidiophores bearing conidia at the tip, along the upper portion of the sides, or both.
Teleomorph: the sexual form of a fungus.

Thallic: one of the two basic forms of conidiogenesis in which enlargement of the conidial initial occurs after a delimiting septum has been laid down.
Thallus: the vegetative growth of a fungus.
Vesicle: the swollen tip of the conidiophore in Aspergillus spp., or the swollen part of a sporogenous cell in other fungi.
Villose: covered with long hairs (a term used to describe spores).
Yeast: a unicellular, budding fungus.
Zoosporophore: a motile asexual spore.
Zygospore: a thick-walled sexual spore produced in the Glomeromycota.

The findings and conclusions in this chapter are those of the authors and do not necessarily represent the views of the CDC. The use of product names in this manuscript does not imply their endorsement by the U.S. Department of Health and Human Services.

REFERENCES

Successful laboratory diagnosis of fungal infections requires attentiveness on the part of physicians and nurses, proper collection and transport of appropriate specimens, and comprehensive procedures in the laboratory. This chapter offers guidelines for specimen collection and transport, specimen handling, specimen pretreatment and processing in the laboratory, medium selection, and incubation of cultures.

**SPECIMEN COLLECTION AND TRANSPORT**

As in bacteriology, the goals of a good mycology laboratory are to accurately isolate and identify fungi suspected of causing infection. It is our responsibility to provide the guidelines for proper specimen selection, collection, and transport to the laboratory. Table 1 is a listing of the types of specimens most commonly submitted for fungal culture (1–3) (see also Fig. 1). Once collected properly, all specimens should be transported in leak-proof sterile containers and processed as soon as possible. Anaerobic transport media or anaerobic containers should never be used for fungi. Fungi are quite resilient, but because some fungi can be affected by temperatures above 37°C and below 10°C, transport at room temperature is recommended. Dermatophytes are particularly sensitive to cold temperatures. With the exception of skin, hair, and nails, specimens that contain the normal bacterial biota should be transported as rapidly as possible because bacterial overgrowth can inhibit slower-growing fungi as well as reduce fungal viability. If such specimens cannot be transported to the laboratory within 2 h, they should be stored at 4°C.

As with other infectious diseases, the best specimen for determining the causative agent comes from the active infective site (e.g., cerebrospinal fluid [CSF] for meningitis). For a number of fungal diseases, however, peripheral specimens as well as specimens from the active infective site may also be useful. Table 2 is a listing of the clinical sites associated with recovery of different pathogenic fungi. Laboratories should not hesitate to suggest that peripheral specimens be taken when specific fungal diseases are suspected. Prostate fluid, for example, is an excellent high-yield specimen when endemic mycoses are suspected, but it is a specimen not often submitted to clinical laboratories (4–8).

Fortunately, many of the specimen collection and transport guidelines for mycology are similar to those used in bacteriology. In those occasions where they differ, it is critical to convey that information to physicians and nurses. One such difference is in specimen volume. The volume of material required for fungal cultures usually exceeds that used in bacteriology because several types of specimens (body fluids, respiratory secretions, etc.) need to be concentrated or pretreated prior to plating to maximize recovery of fungi. In general, except for a few specific sites noted in Table 1, specimens submitted on swabs are not optimal for recovering fungi, and this practice should be discouraged.

Mycology laboratories should be encouraged to offer physicians different types of fungal cultures. The choice of media used for primary isolation as well as the length and temperature of incubation can vary with the culture request. In my laboratory, fungal culture choices include a dermatophyte culture for hair, skin, and nail specimens; a rule-out Candida culture for vaginal, urine, skin, and throat specimens; a fungal blood culture (lysis-centrifugation culture); and a complete fungal culture. By choosing the culture type, physicians can signal the laboratory when they suspect a specific pathogen, which can often reduce the time that cultures need to be kept in the laboratory.

**SPECIMEN HANDLING, PRETREATMENT, AND SAFETY**

If specimens that are unacceptable for any reason are received in the lab, they should be rejected and appropriate physicians should be notified. Poor-quality specimens can result in incorrect information, including false-negative results. As required by the Joint Commission (formerly called JCAHO), a requisition must accompany each specimen and must include the following: patient name, age, sex, and location or address, physician name, specific culture site, date and time of specimen collection, name of person who collected the specimen, clinical diagnosis, and any special culture request. In addition, each specimen must have a firmly attached label indicating the patient name, location, physician, and date and time of collection (9).

Pretreatment of several specimen types is necessary to maximize the recovery of fungi (2, 3). While this takes additional time and effort, it allows the lab to make the most out of every specimen submitted, particularly for those that are difficult to obtain from patients. Pretreatment procedures are listed in Table 3 and include centrifugation of urine and sterile body fluids, mincing of nail and tissue.

specimens, lysis and centrifugation of blood or bone marrow received in Isolator tubes (Wampole Laboratories, Cranbury, NJ), and lysis by mucolytic agents, followed by centrifugation, for respiratory secretions. Such procedures release fungi enclosed within cells, concentrate fungal material in the specimen, and help to reduce or eliminate bacteria present in contaminated specimens because of the action of mucolytic agents, such as N-acetyl-L-cysteine, 5% oxalic acid, or dithiothreitol (Sputolysin).

All work in mycology should be carried out in a certified type 2 laminar-airflow biosafety cabinet whenever possible. There are different biosafety regulations in Europe and other countries, and for this reason, practices may differ. Biosafety level 2 procedures are recommended for personnel working with clinical specimens that may contain dimorphic fungi as well as other potential pathogenic fungi. Gloves should be worn for processing specimens and cultures. A number of techniques are available for examining clinical specimens microscopically, and these are discussed in chapter 116 in this Manual.

**SPECIMEN PROCESSING AND CULTURE GUIDELINES**

**Abscess (Drainage, Exudate, Pus, and Wound Material)**

Abscess specimens should be collected from the active peripheral edge of open abscesses or aspirated from closed abscesses by use of a syringe. Abscess, pus, or drainage material should be examined for grains or granules by use of a dissecting microscope. The presence of grains or granules is indicative of a mycetoma. If none are present, the material can be inoculated directly onto media. If the specimen is thick, it should be pretreated similarly to a sputum specimen. If present, grains and granules should be teased out of the specimen and washed in sterile distilled water, sterile saline, or either solution plus antibiotics. The color of the granules should be noted and recorded. A portion should be crushed between two glass slides and examined microscopically for the presence of hyphae. Both true fungal hyphae and bacteria (branching Gram-positive rods) can be observed with

</table>
grains. If branching Gram-positive rods are seen, a modified acid-fast stain should be performed to look for *Nocardia*. Another portion of the grains and granules should be crushed by using sterile technique (sterile glass rod or mortar and pestle) and then inoculated directly onto media (10).

**Blood**

Fungemia is a major cause of morbidity and mortality in hospitalized patients, with *Candida* species being the major cause (11, 12). Early detection of organisms in the bloodstream is incredibly important because it is an indicator of disseminated disease. As in bacteriology, the volume of blood, the blood-to-blood ratio, and the number of blood cultures are all critical factors, with the volume of blood being the most important variable. For adults, 20 to 30 ml per culture, divided between two bottles, is recommended for the highest recovery rate (13-15) and the shortest time to detection (16). Studies recommend a 5- to 10-fold dilution of blood in broth, and dilutions of <1:5 may result in reduced recovery of organisms (11, 17). For infants and children, total blood volumes based on the weight of the patient are presently recommended (17-19). Unlike bacteremia, fungemia is almost always continuous in patients with infectious endocarditis, so the timing of obtaining a blood culture for fungi is not critical (13). Both iodine tincture and chlorhexidine are effective for skin decontamination prior to obtaining the blood culture (20). In a review of 270 cases of fungal endocarditis in the world literature, the organisms responsible were *Candida albicans* (24%), *non-C. albicans Candida* spp. (28%), *Aspergillus* spp. (24%), *Histoplasma* spp. (6%), and other yeasts and molds (17%) (21). In Europe, if blood cultures are negative in patients with suspected *Candida* endocarditis, then a laboratory diagnosis can often be achieved by *Candida* serology testing.

There are presently a wide variety of manual, biphasic, automated, and continuous monitoring systems for blood cultures, but no single commercial system or culture medium can detect all potential blood pathogens. If manual blood cultures are used, a biphase system is best for fungi (SeptiChek; Becton Dickinson Diagnostic Systems, Sparks, MD), and the agar slant should be rewashed with the broth-blood mixture each time the bottles are examined. Many automated and continuous monitoring systems are available, and several have medium modifications to enhance fungal growth. These include the Bactec (BD Diagnostics, Sparks, MD), BacT/Alert 3D (bioMérieux, Durham, NC), and VersaTrek (Trek Diagnostic Systems, Cleveland, OH) blood culture systems. Use of these mycosis bottles ensures the highest sensitivity for detecting fungemia (22). Studies evaluating all of these systems have shown that they can recover all pathogenic yeast species except for *Malassezia* spp. Even without specific fungal media, automated and continuous monitoring systems are able to recover *Candida*, *Cryptococcus*, *Rhodotorula*, and *Trichosporon* spp., with sensitivities equal to or higher than those of manual or lysis-centrifugation methods (13, 16, 23, 24–30). Automated systems with routine bacteriology media are not, however, satisfactory for molds and *Nocardia* spp. (30).

Lysis-centrifugation performed either manually (13) or by using the commercially available Isolator collection system is a more sensitive method for recovery of molds and dimorphic fungi such as *Histoplasma capsulatum* (30–32). Several studies, however, have argued against the routine use of lysis-centrifugation for all fungal blood cultures because of high contamination rates, high false-positivity rates, and equivalent or shorter times to detection of yeasts than those with automated systems (24, 25, 33). If molds are suspected, either a special fungal medium for an automated system, such as Bactec Myco/F lytic medium or BacT/Alert MB, or a lysis-centrifugation system should be considered (34). Blood placed in either adult or pediatric Isolator tubes should be kept at room temperature until it is processed, ideally within 16 h of collection. Sediment from lysis-centrifugation should be streaked onto a variety of enriched media not containing cycloheximide and onto a chocolate agar plate (35). The only yeast species requiring special

<sup>a</sup>N-Acetyl-l-cysteine, 5% oxalic acid, or dithiothreitol (Sputolysin).
processing are the Malassezia species, which require lipids for growth. This can be achieved by overlaying solid media with a thin layer of olive oil or by adding a paper disk saturated with olive oil to a subculture plate or plates containing sediment from a lysis-centrifugation tube (10, 17, 36). Specialized media such as modified Dixon's, Leeming's, and Ushijima's media can also be used to isolate Malassezia species, if available.

Bone Marrow
Bone marrow is most useful for the diagnosis of disseminated candidiasis, cryptococcosis, and histoplasmosis. Approximately 0.5 ml (pediatrics) to 3 ml (adults) should be collected aseptically in a heparinized syringe or pediatric Isolator tube. Because lysis-centrifugation enhances the recovery of H. capsulatum and other molds, the use of Isolator tubes is the method of choice for these organisms. Clotted bone marrow is an unacceptable specimen. With the exception of H. capsulatum, fungi are rarely seen in bone marrow aspirates from immunocompetent hosts. For immunocompromised patients, however, bone marrow is an excellent specimen, and Aspergillus spp., Candida spp., Cryptococcus spp., H. capsulatum, and Talaromyces marneffei can all be observed (37). While it is quite clear that microscopic examination of Giemsa-stained bone marrow can be diagnostic, recent data show that compared with other, less-invasive methods, such as blood cultures, bone marrow aspirate cultures are of limited value and should be performed only selectively (38). Bone marrow should not be placed into blood culture bottles because with many continuously monitoring systems, the specimen will quickly register a false-positive result due to CO2 from massive numbers of white blood cells.

Catheter Tips (Intravenous)
If performed simultaneously with blood cultures, quantitative bacterial and fungal cultures have been advocated to demonstrate catheter tip colonization. Acceptable specimens are intravenous or intra-arterial catheter tips, with the distal 3 to 5 cm of the line tip being submitted to the laboratory for culture. Specimens should be placed in a sterile container and transported and stored at room temperature. The semiquantitative method of Maki et al. (39) is the most common method used in clinical laboratories, where the catheter tip is rolled across the surface of an agar plate four times and cultures yielding ≥15 CFU are considered positive. The semiquantitative method distinguishes infection (≥15 colonies) from contamination and is considered a more specific method for diagnosing catheter-related sepsis compared to culturing the catheter tip in broth.

Cutaneous Specimens (Hair, Skin, and Nails)
Hair
The hair root is the most important part to culture for detection of fungi, so plucking or pulling rather than cutting hair is recommended. The area should be cleaned with 70% alcohol and allowed to dry. Infected hairs can appear dull, broken, and faded. Hairs that fluoresce under Wood's light should also be selected for culture. Hair should be submitted in a sterile container or clean, dry paper envelope. Hair can also be collected by using a soft-bristle toothbrush and rubbing in a circular motion over margins or patches of alopecia (hair loss) (40).

Skin
The area should be cleaned with 70% alcohol and allowed to dry. The skin should then be scraped with the dull edge of a scalpel or glass slide or vigorously brushed in a circular motion with a soft-bristle toothbrush (40). Only the leading edge of a skin lesion should be sampled, because the centers of lesions are frequently nonviable. Skin can be submitted in a sterile container or clean, dry paper envelope or on a toothbrush.

Nails
Nails should be cleaned with 70% alcohol and then clipped or scraped with a scalpel. If material is present under the leading edge of the nail, it should also be scraped and submitted in a sterile container or paper envelope designed specifically for this purpose. Prior to being plated, nail pieces should be pulverized or minced into tiny pieces by use of a scalpel.

All cutaneous specimens should be inoculated into the agar medium by gently pressing them onto the agar with a sterile swab or scalpel. Distribute the pieces evenly over the agar surface; do not streak the plate with a sterile loop. If a toothbrush is used to collect skin and/or hair specimens, the brush should be pressed gently onto the surface of the agar in four or five places on the plate, leaving an imprint. If organisms are present, growth will occur within the bristle imprint. By nature, cutaneous specimens are usually contaminated with bacteria. For this reason, a plate of inhibitory medium with chloramphenicol and cycloheximide, such as Mycosel, should be used for dermatophytes. Because Trichosporon spp., the cause of white piedra, in addition to Scopulariopsis and Fusarium species, are sensitive to both chloramphenicol and cycloheximide, a noninhibitory medium such as Sabouraud dextrose agar should be inoculated, and then olive oil or a paper disk saturated with olive oil should be placed on the first quadrant of the plate. Malassezia furfur grows best at ≥ 35°C but can grow at 30°C. Cutaneous specimens should never be refrigerated because dermatophytes are sensitive to low temperatures.

Eye Specimens (Corneal Scrapings and Vitreous Humor)
Several types of eye infections require that corneal scrapings and/or vitreous humor be obtained by an ophthalmologist. These include mycotic or fungal keratitis, fungal endophthalmitis, and extension oculomycosis. Mycotic or fungal keratitis is an infection of the cornea. The most common causes are Acremonium spp., Aspergillus spp., C. albicans, Candida parapsilosis, Candida tropicalis, Curvularia spp., and Fusarium spp. (41, 42). Fungal endophthalmitis is a late-stage result of hematogenous dissemination of a systemic fungal infection. It can involve many areas of the eye and surrounding tissues. The most common causes are Aspergillus spp., Blastomyces dermatitidis, Candida spp., C. neoformans, Coccioidoides spp., H. capsulatum, Paracoccidioides brasilienis, and Sporothrix schenckii (41, 42). Extension oculomycosis is a result of rhinoencephalomucormycosis, and like fungal endophthalmitis, it may involve many areas of the eye and surrounding tissues. The diagnosis of these infections requires attempting to demonstrate the organism on a microscopic exam plus positive culture. Corneal scrapings are taken by physicians, and media are inoculated directly by use of a heat-sterilized platinum spatula (43). Very little material is usually obtained because of the risks of corneal thinning or perforation. Physicians should be instructed to
first inoculate the specimen directly onto a noninhibitory medium, such as Sabouraud dextrose agar, and then to place some material on a sterile glass slide (in the center) for staining. The scraping should be placed in two or three places on the plate, using an X- or C-shaped motion (3). The inoculated plate should be kept at room temperature and transported immediately to the laboratory. Vitreous, or vitreous humor, is the clear, gelatinous material that fills the space between the lens of the eye and the retina. When taken by physicians, vitreous is often diluted with irrigation fluid. For this reason, it should be concentrated by centrifugation, and the sediment should be used to inoculate media and to make smears. Specimens should be placed onto Sabouraud dextrose agar, inhibitory mold agar, and/or brain heart infusion (BHI) agar with 10% sheep blood and incubated at 30°C. Media containing cycloheximide should be avoided (41, 42, 44).

Medical Devices
A wide variety of medical devices (contact lenses, stents, wound-healing dressings, contraceptives, surgical implants, replacement joints, etc.) may be submitted for fungal culture. Most are collected surgically and should be submitted in a sterile container and transported and stored at room temperature. Each should be examined for vegetative growth and biofilms, and if these are present, they should be scraped from the device by use of a sterile scalpel for direct inoculation of agar media and broth (3). Specimens should be placed onto Sabouraud dextrose agar, inhibitory mold agar, and/or BHI agar with 10% sheep blood and incubated at 30°C. Media containing cycloheximide should be avoided. If biofilm or vegetative growth areas are not obvious, portions of the device should be placed in a broth medium such as BHI broth and incubated at 30°C.

Prostate Fluid
Prostate fluid consists of secretions of the testes, seminal vesicles, prostate, and bulbourethral glands. After the bladder is emptied, the prostate gland is massaged to yield pure prostatic fluid. The prostate is frequently seeded when organisms are present in the bloodstream. A key clinical sign in males with endemic mycoses is the complaint of a history of chronic urinary tract infections but negative urine cultures. Prostatic fluid for such patients is frequently positive when cultured for fungi. The secretions should also be examined microscopically. After the prostate fluid is obtained, the next urine specimen should also be obtained and submitted for culture because this urine has a high yield (4–8).

Lower Respiratory Tract Specimens (Sputum, Bronchial Aspirate, and Bronchoalveolar Lavage Fluid)
After a patient’s teeth have been brushed, sputum should be collected as a first morning specimen. Neither saliva nor 24-h sputum specimens are acceptable for fungal culture. Viscous lower respiratory tract specimens should be pretreated before being processed. Lysis with mucolytic agents, such as N-acetyl-L-cysteine, 3% oxalic acid, or dithiothreitol (Spartocyn), followed by centrifugation at 2,000 × g for 10 min and then plating of the sediment, greatly increases the yield and improves the recovery of many fungi. Sodium hydroxide, which is used to concentrate specimens for detection of mycobacteria, should not be used because it inhibits the growth of many fungi. Unfortunately, centrifugation also increases the number of bacteria in the sediment, and for this reason, media containing antimicrobial agents, with and without cycloheximide, should be used. As in bacteriology, lower respiratory tract specimens should be examined for the presence of blood, pus, or necrotic portions; these have the highest yields (45, 46). Because Candida spp. are the most common yeasts isolated from respiratory specimens of patients with cystic fibrosis, use of a chromogenic medium that is selective and differential for Candida is recommended (47). Scedosporium is now the second most common mold associated with cystic fibrosis, and use of a Scedosporium-selective medium containing the antifungal agents dichloran and benomyl has been proposed to improve isolation of this mold in this patient population (48).

Upper Respiratory Tract Specimens (Oral and Oropharyngeal Specimens)
The mucosal surface of gums, oral lesions, and oropharyngeal specimens submitted for fungal culture are usually screened for candidiasis. When thrush is suspected, lesions should be scraped gently with moist swabs and submitted for microscopy and a rule-out yeast culture. Antibacterial media or chromogenic agars for Candida spp. should be inoculated. While culture is not required to make the diagnosis of candidiasis, it can be useful if microscopy is not available in an outpatient setting or if species other than C. albicans are suspected. On rare occasions, oral lesions can be seen with histoplasmosis or paracoccidioidomycosis, but they do not resemble those seen with Candida spp. If these are suspected, a full fungal culture and microscopic smear should be performed. The use of nasal swabs should be discouraged because contamination from environmental spores in the nasal cavity makes interpretation of culture results difficult. Nasal tissue or sinus washings are better specimens and should be plated on a variety of media containing antibiotics, but not cycloheximide, since significant pathogens recovered from these sites (Aspergillus spp.) are sensitive to cycloheximide (49).

Sterile Body Fluids (CSF and Pericardial, Peritoneal, and Synovial Fluids)
With the exception of CSF, sterile body fluids are often placed in sterile Vacutainer tubes with heparin to prevent blood clotting. Lysis-centrifugation Isolator tubes can also be used for this purpose. With specimen volumes of ≥2 ml, these tubes plus CSF lumbar puncture tubes should be centrifuged at 2,000 × g for 10 min, and the sediment should be used to inoculate media. The supernatant fluid can be used for serologic tests (44). With specimen volumes of ≤2 ml, the sediment should be plated directly, using as much fluid on each plate as possible. Use of a Cytospin centrifuge to prepare microscopic smears is recommended (50, 51). Because sterile fluids are so rarely culture positive for fungi, many laboratories inoculate medium slants with screw-cap lids rather than plates to avoid questions concerning possible contamination. In some countries, a purity plate is placed in the biosafety cabinet when sterile body fluids or tissues are being processed. Growth on the purity plate would signal a contamination event during processing.

Stool
Submission of stool specimens for routine fungal culture should be discouraged. Many Candida spp. are part of the normal stool biota, and anything that disrupts the normal gastrointestinal tract biota, such as diet or use of antibiotics, can yield a predominance of yeast when stool is cultured. Neither colonization with yeast nor a predominance of yeast indicates invasive disease with Candida. If invasive disease
Tissue
With one exception (H. capsulatum), fungi present in tissue are best recovered when the tissue is minced, not ground. For the mucoraceous molds, in particular, mincing is critical for the recovery of organisms. Tissues should be minced by use of a scalpel, and the pieces of tissue should be pressed into the agar so they are partially embedded (54; see Fig. 2). Two to four pieces should be placed onto each piece of medium being inoculated. Further streaking of the plate with sterile loops should not be done. When the medium is inoculated this way, fungi grow out directly from the piece of tissue. Laboratories often question whether growth on agar plates is contamination. When growth comes directly from the tissue piece, it is unquestionably significant growth. A portion of the specimen can be ground for microscopic examination/smears.

When H. capsulatum is suspected, the tissue should be ground or homogenized. Because this pathogen is intracellular, organisms need to be released from the cells to be available to grow on media. If needed, a small amount of sterile broth or distilled water can be added to smooth the process of grinding. Subcutaneous tissue should be examined for the presence of granules (as described above, for abscesses). Homogenate or tissue pieces should be inoculated onto enriched media containing antibacterial agents, and for systemic mycoses, enriched media containing both blood and antibacterial agents are best.

Urine
Clean-catch, suprapubic, or catheterized urine specimens should all be obtained as first morning specimens. Large volumes (10 to 50 ml) give the best results and should be centrifuged for maximum recovery, particularly for agents of deep mycoses. Urine should be centrifuged at 2,000 x g for 10 min. The sediment should be used for microscopic smears and inoculation of media. Quantification of organisms, as performed in bacteriology, is not useful (36). Twenty-four-hour urine specimens are not acceptable.

Vaginal Specimens
Vaginal specimens submitted for fungal culture are frequently screened just for vaginal candidiasis. For this reason, having a rule-out Candida culture as a culture choice is helpful for clinicians and laboratory. Candida spp. are part of the normal vaginal biota, and their presence alone is not significant. Appropriate clinical symptoms plus a positive microscopic exam or culture are sufficient to diagnose vaginal candidiasis. Culture is not required to confirm vaginal candidiasis, but microscopic exams are not available in all settings, while culture is available. Antimicrobial media or chromogenic agar for Candida spp. should be inoculated. On rare occasions, vaginal lesions can be seen with histoplasmosis or paracoccidioidomycosis. These lesions do not resemble those seen with Candida spp. If these are suspected, a full fungal culture and microscopic smear should be performed.

SELECTION AND INCUBATION OF MEDIA
Table 4 is a listing of various media used for the recovery of fungi from clinical specimens, including primary media, selective and/or differential media, and specialized media. Optimal recovery of fungal pathogens depends upon a number of factors, including the choice of an appropriate specimen(s), collection and transport of a quality specimen, appropriate pretreatment of specimens, the media chosen for inoculation and incubation, a proper incubation temperature, and sufficient time of incubation. A wide variety of media are available for primary isolation, and in many laboratories, the choice is based on personal experience and the technologist's preferences. As with bacteria, a battery of several media needs to be used because no single fungal medium is sufficient for detection of all of the clinically important fungi. Several factors should be considered in selecting a battery of several media, as follows.

• Choices of media should be driven by the type of specimen being processed (1–3). Media that inhibit bacterial growth but allow for the growth of fungi should be used for nonsterile specimens that may contain large numbers of bacteria (BHI or Sabhi medium plus antibiotics or inhibitory mold agar). The eukaryotic protein synthesis inhibitor cycloheximide should be used in one medium choice, with or without antibiotics. The battery for sterile body sites should include one or two media lacking antibiotics plus one medium with antibiotics.

• Cycloheximide is a component in several primary media and suppresses saprophytic fungi, but it is known to inhibit the growth of some Aspergillus spp., some Candida spp., Cryptococcus spp., Nattrassia mangiferae, Pseudallescheria boydii, Talaromyces marneffei, most members of the Mucorales, Neoscytalidium dimidiatum, Scopulariopsis, Trichosporon asahii, and many saprophytic or opportunistic fungi. While cycloheximide prevents fast-growing contaminants from overgrowing slow-growing pathogens such as H. capsulatum, it should not be included in all medium choices.

• Traditionally, Sabouraud dextrose agar without antibiotics (SDA) has been used as a primary medium choice. Inhibitory mold agar is a better choice because of its ability to inhibit bacterial growth more effectively than SDA (55).

• Chloramphenicol, with or without other antibiotics, is included in several primary media to suppress the growth of bacteria. While these are excellent medium choices for processing of specimens that contain the bacterial

Abbreviations: BHI, brain heart infusion agar; SDA, Sabouraud dextrose agar; Sabhi, Sabouraud dextrose and brain heart infusion agar.

Biota, they prevent the growth of *Nocardia* and aerobic actinomycetes. Mycology laboratories that are responsible for culturing these organisms must include other media for these pathogens, such as Sabouraud agar.

- Dimorphic fungi that grow endemically grow best on an enriched medium (BHI or Sabhi medium) with antibiotics and 5 to 10% sheep blood. The sheep blood promotes the growth of dimorphic fungi but inhibits sporulation. Molds recovered on this enriched medium should be subcultured immediately to blood-free enriched medium to promote conidiation and for DNA probe testing.
- Laboratories expecting to frequently isolate and identify *Cryptococcus* spp. should consider esculin-based medium with chloramphenicol and gentamicin for use as a primary medium with CSF, pleural fluid, bone marrow, tissue, and deep respiratory specimens. The dark brown-black pigment produced by *Cryptococcus* spp. on EMB can be used as a presumptive identification (56).

Exceptions to using a battery of media would be for fungal cultures that screen for a specific pathogen, such as a rule-out *Candida* culture, where a chromogenic medium that is selective and differential for yeast can be used, or a rule-out dermatophyte culture, where a single Mycosel or Mycobiotic plate can be used (57). In attempting to isolate *Malassezia* spp., Sabouraud agar with antibiotics should be supplemented with sterile olive oil by adding 0.5 ml of oil to the surface of the plate after inoculation or by dropping...
an olive-oil-saturated paper disk on the first half of the plate. Alternatively, specialized media, such as modified Dixon’s, Leeming’s, and Ushijima’s media, can also be used, if available.

The container used for fungal media is often debated because of safety issues related to fungi that grow endemically (58). Agar plates are considered more dangerous, are easily contaminated, and dehydrate the fastest, but they offer the largest surface area to work from, and colonies are easier to reach on plates. Plates can be sealed individually or placed in plastic bags to avoid environmental contamination and to provide a layer of safety beyond the use of a laminar-airflow biosafety cabinet. Screw-cap flat-sided bottles and agar slants in tubes both reduce contamination and are safer to use, but both have the disadvantage of a narrow opening through which to access colonies. Most clinical laboratories use plated media, but some compromise by using flat-sided bottles or tubes with those specimen types that laboratories use plated media, but some compromise by using flat-sided bottles or tubes with those specimen types that are rarely culture positive, such as CSF or other sterile fluids.

Inoculated media for fungal culture should be incubated aerobically at 30°C, but if a 30°C incubator is not available, then 25°C can be used. S. schenckii, a rare exception, grows faster at 27 to 28°C, but it still grows well at 30°C. The length of incubation depends on the type of fungal culture requested. Cultures that screen for Candida spp. need to be incubated for no longer than 72 h, cultures that screen for dermatophytes need to be incubated for only 8 days, and cultures screening for all pathogens, including fungi that grow endemically, should routinely be held for 4 weeks. A single study suggests that 3 weeks of incubation may be sufficient (59). Culture media should be examined every 2 to 3 days for the first 2 weeks and weekly thereafter.

REFERENCES

A variety of stains, media, and reagents are available to the mycology laboratory for the detection, isolation, characterization, and identification of yeasts and moulds. Familiarity with the composition and characteristics of these materials is critical to the diagnostic approach when processing specimens from patients with suspected mycotic diseases.

The direct microscopic examination of properly stained clinical material is rapid and cost-effective and may denote the presumptive identification of the etiologic agent (1–3). Results of direct examination can also guide the laboratory in the selection of media that best support fungal growth in vitro (1). Stained preparations made from fungal cultures are essential for definitive identification. It is important to note that when processing patient specimens, universal precautions should be observed and work should be performed in a biosafety hood.

Many media are available for the primary inoculation and cultivation of fungi from clinical specimens. No one specific medium or combination of media is adequate for all specimens. Media should be carefully selected based on specimen type and suspected fungal agents (2–6). If the specimen is from a nonsterile site, it is important to include media that contain inhibitory substances such as chloramphenicol, gentamicin, and/or cycloheximide. Chloramphenicol or gentamicin inhibits most bacterial contaminants, while cycloheximide inhibits most saprobic moulds. Remember that cycloheximide may also inhibit some important opportunistic fungi such as Fusarium, Scopulariopsis, Pseudallescheria, Trichosporon, some Aspergillus species, Talaromyces (Penicillium) marneffei, mucoraceous fungi, some dematiaceous fungi, and yeasts such as Cryptococcus species and some Candida species. Therefore, it is necessary to select media both with and without inhibitory agents for the primary inoculation of the specimen. The Clinical and Laboratory Standards Institute (CLSI) Standard M54-A (7) is an excellent source for determining the selection and use of fungal media.

Media can be dispensed into containers such as 25- by 150-mm screw cap tubes or 100-mm-diameter petri dishes. Tubed media (slants/deeps) offer maximum safety and resistance to dehydration and contamination but have a small surface area for inoculation. Petri plates, in contrast to agar tubes, offer the advantage of a large surface area for isolation and dilution of inhibitory substances in the specimens, but they must be poured thick, with at least 25 ml of medium, in order to resist dehydration during extended incubation periods. Because plates are vented, they are more likely to become contaminated during incubation. Plates may be placed in gas-permeable bags or sealed with gas-permeable tape (Shrink Seals; Scientific Device Laboratory, Des Plaines, IL) to offset this disadvantage. The gas-permeable tape also secures the lid of plated media, preventing the accidental removal of the lid outside the biosafety cabinet.

Another format, in which media are poured into a flat-bottom flask (Bactiflask [Remel, Thermo Scientific, Waltham, MA]; Mycoflask [BD Diagnostic Systems, Sparks, MD]), provides the combination of an increase in surface area of plated media and the safety of tubed media. Flasked media may be particularly useful when culturing dimorphic pathogens.

Once inoculated, the cultures are incubated at 25 to 30°C. Fungal cultures should be incubated for 4 to 6 weeks before being regarded as negative; however, many cultures can be read as early as 24 h after inoculation. For example, most yeasts are detected within 5 or fewer days, dermatophytes are detected within 1 week, and dematiaceous and dimorphic fungi may require 2 to 4 weeks. Therefore, to account for differences in growth rates, fungal cultures should be examined at regular intervals (e.g., daily during the first week, three times the second week, twice at 3 weeks, and once at 4 weeks) rather than being evaluated once at the end of 4 weeks. While growth may be observed within the first few weeks of incubation, continue to incubate the original plate after subculture to allow for the emergence of slower-growing pathogenic organisms. Manipulation of cultures must be performed inside a certified biological safety cabinet to prevent contamination of the plate and exposure of personnel to potentially hazardous fungi.

Each new lot of medium, whether purchased or prepared in-house, must be subjected to a quality-control protocol that verifies appearance, pH, and performance (7, 8). Both positive and negative control strains need to be included in quality-assurance testing protocols (7, 8). Media for primary isolation should be tested for optimal growth of several fungal pathogens. Selective media should be tested with strains known to be sensitive and resistant to the inhibitory...
agent in the media, while differential media should be evaluated with fungi that produce both positive and negative reactions. Many media are also commercially available as prepared plates or tubes. Although manufacturers perform quality-control testing, clinical laboratories still need to ensure that media meet performance standards. Some widely used commercially prepared media are exempt from routine quality-assurance testing. These media include cornmeal agar, inhibitory mould agar, inhibitory mould agar with gentamicin, soy peptone agar with cycloheximide/chloramphenicol without pH indicators, potato dextrose agar, brain heart infusion agar with 5% sheep blood containing chloramphenicol/gentamicin, Sabouraud’s dextrose agar, and Sabouraud’s dextrose agar with chloramphenicol/gentamicin (7, 8). Nonexempt media that require specific quality-assurance testing include cornmeal agar with Tween, brain heart infusion agar with 5% sheep blood and cycloheximide/chloramphenicol, bismuth sulphite-glucose-glycine-yeast (BIGGY) agar, birdseed agar, brain heart infusion with 5% sheep blood and penicillin/streptomycin, dermatophyte test medium, and potato flakes agar with or without cycloheximide/chloramphenicol (7, 8).

Unless stated otherwise, the reagents and media listed in this chapter should be prepared by dissolving the components in the stated liquid with a magnetic stirring bar. The standard sterilization technique of autoclaving at 121°C at 15 lb/in² for 15 min should be used when needed. However, certain solutions, such as those containing antibiotics or carbohydrates, cannot be autoclaved because they will be denatured. These solutions are sterilized by filtration through a 0.22-μm-pore-size filter; Candida chromogenic agars can be heated in a microwave.

Storage of prepared reagents in sterile, airtight, screw-cap containers is recommended. Some reagents require storage in dark containers, and some need to be stored refrigerated (2 to 8°C) instead of at room temperature. Special storage instructions are given when appropriate. Standard safety precautions should be taken when preparing the reagents. Follow the safety guidelines for the chemicals being used, in addition to the laboratory safety protocols.

The stains, media, and reagents listed in this chapter include those commonly used and a few specialized items. For more specific information not included here, refer to the literature cited in the chapter.

REAGENTS

■ N-Acetyl-l-cysteine (NALC) (0.5%) NALC (Alpha Tec Systems, Inc.) is a mucolytic agent used for digestion of sputum specimens submitted for detection of Pneumocystis jirovecii cysts and/or trophozoites by microscopic examination. This compound can also be used for preparing samples for microscopic examination for a wide range of fungi. Sodium citrate (0.1 M) is included in the mixture to exert a stabilizing effect on the acetyl-l-cysteine. Formulations containing NaOH should be avoided due to adverse effects on fungal organisms.

■ Dithiothreitol (Sputolysin), 0.0065 M Dithiothreitol is a mucolytic agent that can be purchased commercially and has been used to prepare sputum specimens for detection of P. jirovecii. Equal volumes of sputum and dithiothreitol are mixed and incubated at 35°C. The mixture is periodically mixed vigorously until nearly liquefied (complete liquefaction disperses the cells of P. jirovecii, making microscopic detection difficult). As with NALC, dithiothreitol can be useful for preparing samples for microscopic examination of a wide range of fungi. Formulations containing NaOH should be avoided due to adverse effects on fungal organisms.

■ Potassium hydroxide (KOH) Wet mounts prepared in 10% KOH are used to distinguish fungi in thick mucoid specimens or in specimens that contain keratinous material such as skin, hair, and nails. The proteinaceous components of the host cells are partially digested, leaving the fungal cell wall intact and more apparent. An aliquot of specimen is added to a drop of 10% or 20% KOH, which can be preserved with 0.1% thimerosal (Sigma Chemical Co.). The slide is held at room temperature for 5 to 30 min after the addition of KOH, depending on the specimen type, to allow digestion to occur. Digestive capabilities can be enhanced with gentle heating or the addition of 40% dimethyl sulfoxide.

■ Potassium hydroxide (10%) with lactophenol cotton blue (LPCB) The wet mount with KOH and LPCB is used for the same purpose as the KOH preparation but incorporates LPCB dye (see below). LPCB enhances the visibility of fungi because aniline blue stains the outer cell wall of fungi, and lactic acid serves as an additional clearing agent. The phenol component in LPCB acts as a fungicide.

■ Sodium hydroxide (10 or 25% with added glycerin) Solutions of sodium hydroxide may be used as alternatives to potassium hydroxide for the direct microscopic examination of hair, skin, and nails for dermatophyte-mediated infections. Visualization of fungal elements may be enhanced by the addition of glucan-binding fluorescent brighteners such as calcofluor white or Congo red, both of which bind to chitin, a major component of the fungal cell wall.

STAINS

■ Alcian blue stain Alcian blue and the more commonly used mucicarmine stain (see below) are mucopolysaccharide stains. These are useful for visualizing the polysaccharide capsule produced by Cryptococcus species in histological sections of tissue.

Basic procedure

Deparaffinized sections are stained in Alcian blue (1 g in 100 ml of acetic acid, 3% solution) for 30 min, washed in running tap water, and then rinsed in distilled water. The sections are counterstained in nuclear fast red (0.1 g in 100 ml of aluminium sulfate, 5% solution). After dehydration through 95% and absolute alcohol, the sections are cleared with xylene and mounted in Permount (Fisher Scientific). Capsular polysaccharides stain blue against a pink background.

■ Ascospore stain Ascymycetous fungi may produce ascospores when grown on media that promote their formation. Visualization of
ascospores can be accomplished with a differential staining procedure consisting of malachite green and safranin. Ascospores stain green, while the vegetative portion of the fungus stains red. The Kinyoun acid-fast stain (see chapter 19) may also be used for visualizing ascospores, as these structures tend to be acid-fast.

**Basic procedure**

A thin smear of growth is applied to a glass slide and heat fixed. The slide is flooded with malachite green (5 g in 100 ml of distilled water) for 3 min, washed with tap water, decolorized with 95% ethyl alcohol for 30 s, and counterstained with aqueous safranin (5%) for 30 s. The slide is washed with tap water, allowed to dry air, and examined at ×400 to ×1,000 magnification.

- **Calcofluor white**

Calcofluor white and related compounds such as Uvitex 2B and Blankophor are nonspecific, nonimmunological fluorochromes that bind to β,1,3 and β,1,4 polysaccharides, specifically cellulose and chitin of fungal cell walls. Like the auramine-rhodamine stain, calcofluor white has become commonplace in microbiology laboratories because of the rapidity with which specimens can be observed. The fluorochrome can be mixed with KOH to clear the specimen for easier observation of fungal elements, including *P. jirovecii*. Fungal elements appear bluish white against a dark background when excited with UV or blue-violet radiation. Optimal fluorescence occurs with UV excitation. A barrier filter such as 510, 520, or 530 should be used for eye protection. Organisms impart a green fluorescence (1). Typical *P. jirovecii* cysts are generally 5 to 8 μm in diameter, round, and uniform in size, and they exhibit a characteristic peripheral cyst wall staining with an intense “double-parenthesis-like” structure (9, 10). Yeast cells are differentiated from *P. jirovecii* by budding and intense staining. Care must be used in interpreting the calcofluor white staining results because nonspecific reactions may be observed. Cotton fibers fluoresce strongly and must be differentiated from fungal hyphae. Additionally, tissues such as brain biopsy specimens from patients with tumors may fluoresce and resemble hyphae suggestive of *Aspergillus* or other moulds with branching hyphae.

**Basic procedure**

Calcofluor white may be purchased from multiple mycological media and chemical suppliers either as premixed or powdered form (see list of suppliers at the end of the chapter). KOH (10%) is mixed in equal proportion with calcofluor white solution (0.1 g of calcofluor white M2R and 0.05 g of Evans blue in 100 ml of water). The specimen is covered with this mixture and a coverslip is applied. Allow the slide to sit for 5 to 10 minutes prior to viewing to permit the tissue to clear and the stain to interact with the fungal elements. Some nail and tissue preparations may require a longer incubation time (up to 30 minutes) for clearing to occur. Alternatively, the slides may be gently warmed on a slide warmer to speed up the clearing process. For optimal results, the slide should be viewed as soon as the tissue has cleared. The preparation is examined using a fluorescent microscope containing appropriate excitation and barrier filters at ×100 to ×400 magnification. Darkly pigmented fungi may stain poorly with calcofluor white due to the pigmentation, which may mask the fluorescence.

- **Colloidal carbon wet mounts (India ink, nigrosin)**

Colloidal carbon wet mounts are used for visualization of encapsulated microorganisms, especially Cryptococcus species. The polysaccharide capsule of organisms is refractory to the particles of ink, and capsules appear as clear halos around the organism. Artifacts such as erythrocytes, leukocytes, and t alc particles from gloves or bubbles following a myelogram may displace the colloidal suspension and mimic yeast (false positive). These artifacts make it necessary to perform a careful examination of the wet mount for properties consistent with the organisms (e.g., rounded forms with buds of various sizes and double-contoured cell walls). Interpretation can also be hindered if the emulsion with the colloidal suspension is too thick, blocking transmission of light.

**Basic procedure**

Mix equal parts of the patient’s cerebrospinal fluid with either commercial India ink or nigrosin on a slide. Add a coverslip and examine at ×100 to ×1,000 magnification. Care must be taken not to contaminate India ink supplied in larger volumes. Limited volume or individual-use dispensers can be purchased through many of the media and reagent distributors.

- **Fontana-Masson stain**

The Fontana-Masson stain was originally developed for demonstrating melanin granules in mammalian tissue. It has a mycological application in detecting dematiaceous (melanin-containing) fungi, and to a lesser extent *Cryptococcus neoformans* / *gattii*, in histological sections. Fungal elements appear brown to brownish black against a reddish background.

**Basic procedure**

A silver solution is prepared by adding concentrated ammonium hydroxide to 10% silver nitrate until the precipitated form disappears. Deparfaffinized sections of tissue are hydrated and placed in heated silver solution for 30 to 60 min. The slides are then rinsed in distilled water and toned in gold chloride (0.2 g in 100 distilled water) for 10 min followed by fixation in 5% sodium thiosulfate for 5 min. The sections are dehydrated through increasing concentrations of alcohol, cleared in xylene, and mounted with a coverslip.

- **Giemsa stain**

The Giemsa stain is used for the detection of intracellular yeast forms of *Histoplasma capsulatum* in bone marrow and buffy coat specimens. The fungus is usually seen as small oval yeast cells, is often contained within macrophages, stains blue, and has a hyaline halo that represents poorly staining cell wall. The stain can also be used to visualize the trophozoite of *P. jirovecii*.

**Basic procedure**

A thin smear is prepared on a glass slide and placed in 100% methanol for 1 min. The slide is drained and then flooded with freshly prepared Giemsa stain (stock Giemsa stain diluted 1:10 with phosphate-buffered water). After 5
min, the slide is rinsed with distilled water and air dried. Examine at ×100 to ×400 magnification.

**Lactophenol cotton blue**

Lactophenol cotton blue is a basic mounting medium for fungi that consists of phenol, lactic acid, glycerol, and aniline (cotton) blue dye. The solution may be filtered to remove precipitated dye and stored at room temperature. It is commonly used for the microscopic examination of fungal cultures by tease or tape preparation. The addition of 10% polyvinyl alcohol (LPCB-PVA) makes an excellent permanent stain or fixative for mounting slide culture preparations.

**Basic procedure**

Concentrated phenol (20% [vol/vol]) is added to a mixture of lactic acid (40%), water (20%), followed by the addition of aniline blue (0.05%). The solution may be filter-sterilized to remove precipitated dye. A drop is added to a glass slide, and a tease or tape mount is prepared. Add a coverslip and examine at ×100 to ×400 magnification.

**Methenamine silver stain**

Methenamine silver stains are perhaps the most useful stains for visualizing fungi in tissue. Fungal structures are sharply delineated in black against a pale green or yellow background. They are specialized stains that are more often performed in the histology laboratory than in the microbiology laboratory. Grocott’s modification of the Gomori methenamine silver stain is commonly used for the histopathological examination of deparaffinized tissues for fungi. A variation that can be used by counterstaining with the hematoxylin and eosin (H&E) stain displays the silver-stained fungal structures within host tissue reaction.

**Basic procedure**

Stock methenamine silver nitrate solution is prepared by adding 3% methenamine (3 g in 100 ml of distilled water) to 5% silver nitrate (5 g in 100 ml of distilled water) until a white precipitate forms that clears upon shaking. This solution is then diluted 1:2 with distilled water to which 5 ml of 5% photographic-grade borax is added. Prepared slides are oxidized in a solution of chromic acid (5 g in 100 ml of distilled water), neutralized in sodium bisulfite (1 g in 100 ml of distilled water), placed in the diluted methenamine silver nitrate solution, and heated in an oven to 58 to 60°C until the material turns yellowish brown. After being rinsed vigorously in distilled water, the slides are toned in gold chloride (0.1 g in 100 ml of distilled water). Unreduced silver is removed by placing the slides in a sodium thiosulfate solution (2 g in 100 ml of distilled water) and counterstained in 0.03% light green. Rinse, blot dry, and examine at ×100 to ×400 magnification.

**Mucicarmine stain**

The mucicarmine stain is useful for differentiating C. neoformans/gattii from other fungi of similar size and shape when found in samples of tissue. The mucopolysaccharide in the capsular material of the fungus stains deep rose to red, whereas the other tissue elements stain yellow. Blastomyces dermatitidis and Rhinosporidium seeberi may also react positively with this stain but are differentiated by the size of the yeast and the intensity of the staining reaction of the mucopolysaccharide capsule of Cryptococcus.

**Basic procedure**

Fixed tissue sections on glass slides are stained first with Weigert’s iron hematoxylin and then placed in a solution of mucicarmine (1 g of carmine combined with 0.5 g of anhydrous aluminum chloride in 2 ml of distilled water and then diluted in 100 ml of 50% ethanol) for 30 to 60 min. The slides are rinsed in distilled water and then counterstained in metanil yellow (0.25 g in 100 ml of distilled water). Rinse, blot dry, and examine at ×100 to ×400 magnification.

**Periodic acid-Schiff (PAS) stain**

The periodic acid-Schiff (PAS) stain is used to detect fungi in clinical specimens, especially yeast cells and hyphae in tissues. Fungi stain a bright pink against a light blue background if picric acid is used as the counterstain, or against a green background if light green is used. The procedure is a multistep method combining hydrolysis and staining. The periodic acid step hydrolyzes the cell wall aldehydes, which are then able to combine with the modified Schiff reagent, coloring the cell wall carbohydrates a bright pink-magenta. The PAS stain is an excellent general stain, because most fungi in clinical material take up the stain. However, the PAS staining procedure is rather involved, requiring several different reagents and time-consuming steps, and it has been replaced in many laboratories by the calcofluor white staining procedure. The PAS stain cannot be used with undigested respiratory secretions, since mucin also stains bright pink-magenta.

**Basic procedure**

The prepared slide is fixed in formalin-alcohol for 1 min and is then air dried. The slide is then immersed in 5% periodic acid for 5 min, followed by 2 min in basic fuchsin (0.1 g of dye in 5 ml of 95% alcohol-95 ml of H₂O). The slide is rinsed in water and immersed in zinc or sodium hydrosulphite solution for 10 min (1 g of zinc or sodium hydrosulphite in 0.5 g of tartaric acid and 100 ml of H₂O). Rinse in water and counterstain with saturated aqueous picric acid in 20% acetic acid for 2 min or with light green stain (1 g of dye in 0.25 ml of acetic acid and 100 ml of 80% alcohol) for 5 s. Rinse, blot dry, and examine at ×100 to ×400 magnification.

**Toluidine blue O**

Toluidine blue O is used primarily for the rapid detection of P. jirovecii from lung biopsy specimen imprints and bronchovascular lavage (BAL) specimens. Toluidine blue O stains the cysts of P. jirovecii reddish brown or purple against a light blue background. The cysts are often clumped and may be punched in, appearing crescent shaped. Trophozoites are not discernible. Although the silver stain, monoclonal antibody, and calcofluor white stains are also used, the toluidine blue O stain is easy and rapid and yields reliable results with appropriate specimens (e.g., BAL specimens).

**Basic procedure**

After the slide is air dried, place it in the sulfation reagent (45 ml of glacial acetic acid mixed with 15 ml of concentrated sulfuric acid) for 10 min. Rinse in cold water for 5
min, drain, and place in toluidine blue O (0.3 g of dye in 60 ml of H₂O) for 3 min. Rinse in 95% ethanol, followed by absolute ethanol and then xylene. Examine at ×100 to ×1,000 magnification.

MEDIA

■ Agar slide culture plate

Microscopic morphology of a fungal isolate is best observed using the slide culture method, where an approximately 15-by 15-mm square block of medium is placed on a sterile microscope slide. The desired fungal organism is inoculated on each edge of the block, covered with a sterile 22- by 22-mm coverslip, and incubated in an individual humidified chamber. When sufficient sporulation is present, the coverslip is removed and placed growth-side down on a microscope slide containing a drop of lactophenol cotton blue. Fungal morphology is visualized microscopically at ×200 and ×400 magnification. Commercial sources are available with preformed slide culture setups. Agar and incubation temperature should be selected based on the optimum conditions to induce sporulation for the fungal organism used.

■ Acetate ascospore agar

Acetate ascospore agar is used for the cultivation of ascosporogenous yeasts such as Saccharomyces cerevisiae. A potassium acetate formulation has been shown to be a better sporulation medium than the previously used formulation with sodium acetate. Ascospores produced on this medium are visible microscopically after staining with Kinyoun carbol-fuchsin acid-fast stain.

■ Antifungal susceptibility testing media

Recent advances in methods for antifungal susceptibility testing have resulted in several media that are now used for this type of testing (see chapter 131). The broth dilution method for yeasts and filamentous fungi described in the Clinical and Laboratory Standards Institute M38-A2 and M27-A3 documents (12, 13) uses RPMI 1640 synthetic medium without sodium bicarbonate and supplemented with L-glutamine. The medium is buffered to pH 7.0 with 0.165 M morpholinepropanesulfonic acid (MOPS). Although this medium supports the growth of most fungi, it is not optimal for Cryptococcus species (14), nor does it accurately discriminate amphotericin B-resistant Candida spp. (15).

The Antifungal Susceptibility Testing Subcommittee of the European Committee on Antibiocic Susceptibility Testing (AFST-EUCAST) has described a proposed standard broth microdilution that is based on the M27-A3 broth microdilution reference procedure. Both procedures utilize RPMI 1640 as the primary assay medium, but that used in the EUCAST procedure differs from the CLSI procedure by the incorporation of 2% glucose (16, 17).

■ Birdseed agar

Birdseed agar is a selective and differential medium used for the isolation of Cryptococcus species, especially C. neoformsans and C. gattii, which are unique in that they produce the enzyme phenol oxidase. The breakdown of the substrate (Guizotia abyssinica seeds or niger seed) produces melanin, which is absorbed into the yeast wall and imparts a tan to brown pigmentation to the colonies. Colonies of other yeasts are beige or cream in color. Chloramphenicol is the selective agent that inhibits bacteria and some fungi. Creatinine enhances melanization of some strains of C. neoformans.

■ Bismuth sulfite-glucose-glycine yeast (BiGGY) agar

Bismuth sulfite-glucose-glycine yeast agar is a selective and differential medium used for the isolation and differentiation of Candida spp. Peptone, glucose, and yeast extract are the nutritive bases. Candida species reduce the bismuth sulfite to bismuth sulfide, which results in pigmentation of the yeast colony and, with some species, the surrounding medium. Candida albicans appears as brown to black colonies with no pigment diffusion and no sheen, whereas Candida tropicalis appears as dark brown colonies with black centers, black pigment diffusion, and sheen. Specific colonial morphologies and growth patterns of the different Candida species are also detected. The bismuth sulfite also acts as an inhibitor of bacterial growth, making the medium selective.

■ Blood-glucose-cysteine agar

A fungal isolate believed to be a thermally dimorphic pathogen can be identified by converting the mould phase to the yeast phase at 37°C. Blood-glucose-cysteine agar medium is used to promote the mould-to-yeast conversion of Histoplasma capsulatum, Blastomyces dermatitidis, Paracoccidioides brasiliensis, and Sporothrix schenckii. The medium contains tryptose blood agar base, L-cysteine, and defibrinated sheep blood. Penicillin is added to inhibit bacterial contamination.

■ Brain heart infusion agar (fungal formulation)

Brain heart infusion (BHI) agar with sheep blood is a medium used for the cultivation and isolation of all fungi including fastidious dimorphic fungi. The nutritive base is BHI agar with 10% sheep blood for added enrichment. The antibiotics chloramphenicol and gentamicin are added to make the medium selective by inhibiting bacteria. This medium does not inhibit saprophytic fungi. When attempting to isolate more fastidious moulds, a medium containing cycloheximide should be included to inhibit overgrowth by the saprophytic fungi.

■ Bromcresol purple-milk solids-glucose medium

Bromcresol purple-milk solids-glucose (Dermatophyte Milk Agar; Hardy Diagnostics) is a differential medium used for the identification of Trichophyton species. The medium’s differential capacity is based on the type of growth (profuse versus restricted as compared to growth on standard nutrient media) and change in the pH indicator due to the production of alkaline by-products.

■ Canavanine-glycine-bromthymol blue agar

Canavanine-glycine-bromthymol blue agar is a differential medium for distinguishing C. neoformans from C. gattii. The medium contains glycine, thiamine, l-canavanine sulfate, and bromthymol blue. A colony of Cryptococcus is streaked onto the surface of the agar and incubated at 30°C for 1 to 5 days. C. gattii (serotypes B and C) turns the medium cobalt blue, whereas C. neoformans var. grubii (serotype A)

*Species identified as provided by the manufacturer. Species that are presumptively identified require further testing for final identification.

and C. neoformans var. neoformans (serotype D) leave the medium greenish yellow.

### Candida chromogenic media

The introduction of chromogenic media has facilitated the direct and rapid identification of yeasts and is particularly useful for detecting and separating mixed cultures. These media contain chromogenic substrates that are hydrolyzed by species-specific enzymes (e.g., β-N-acetylhexosaminidase) and, depending on the medium, a second enzyme, β-glucosidase or phosphatase, resulting in identification of yeasts to the species level based on colonial features and color development (18–20). Commercially available chromogenic media are summarized in Table 1.

A brief description of selected chromogenic agar products that are approved by the U.S. Food and Drug Administration (FDA) for use in U.S. laboratories is provided as an overview of how different yeasts react with chromogenic substrates and the resultant characteristic colony color.

### CHROMagar (BBL; BD Diagnostic Systems)

CHROMagar is a differential and selective medium used for the isolation and differentiation of clinically important yeasts. The nutritive base is peptone and glucose. Chloramphenicol makes the medium selective by inhibiting bacteria. The medium is available with and without fluconazole, the former providing the additional selection of fluconazole-resistant yeasts such as Candida krusei. A proprietary chromogenic mixture allows the differentiation of many yeast species. For example, C. albicans forms yellow-green to blue-green colonies. Colonial morphology as well as distinctive color patterns have been shown to make the presumptive identification of yeast species very reliable (19, 20). The medium has been shown to be more selective than Sabouraud agar and helpful in identifying mixed cultures of yeasts, and it may enhance the rapid assimilation of trehalose by Candida glabrata (20). The colonies on the medium should be evaluated at 48 h. Although C. neoformans and Geotrichum species can grow on this medium, definitive identification requires subculture to a nonselective medium followed by utilization of the appropriate biochemical and morphological characterization tools.

### chromID Candida agar (CAN2) (bioMérieux)

Colonies of C. albicans produce a blue color following the hydrolysis of a hexosaminidase chromogenic substrate in the presence of an inducer of the enzyme (bioMérieux patent). The hydrolysis of a second substrate (pink color) differentiates mixed cultures and indicates the need for identification of other species of yeast (bioMérieux patent).

### Christensen’s urea agar

The ability to hydrolyze urea is an important phenotypic characteristic for the presumptive identification of Cryptococcus, Trichosporon, and Rhodotorula spp. Urea hydrolysis also facilitates separation of certain dermatophytes, in particular T. mentagrophytes and T. rubrum. The medium contains 2% urea with phenol red serving as the indicator.

### Cornmeal agar with 1% dextrose

Cornmeal agar with 1% dextrose is used for the cultivation of fungi and the differentiation of Trichophyton mentagrophytes from Trichophyton rubrum on the basis of pigment production. The replacement of Tween (polysorbate) 80 with dextrose promotes the growth and production of a red pigment by T. rubrum.

### Cornmeal agar with Tween 80

Cornmeal agar with Tween (polysorbate) 80 is used for the cultivation and differentiation of Candida species on the basis of morphological characteristics. Tween 80, a surfactant, is specifically incorporated in lieu of dextrose for the demonstration of pseudohyphae, chlamydospore, and arthrospore formation. Chlamydospore production is best ob-
tained if the yeast inoculum is placed under a coverslip or following subsurface inoculation creating a microaerophilic environment. The basic nutrients for yeast growth are provided by cornmeal infusion.

■ Czapek-Dox agar
Czapek-Dox agar is a medium used for the differentiation of *Aspergillus* spp. (1, 3, 5). Sucrose is the sole carbon source, with sodium nitrate serving as the sole nitrogen source. Any bacteria or fungi that can utilize sodium nitrate as a nitrogen source can grow on this medium.

■ Dermatophyte test medium (DTM)
Dermatophyte test medium is used as a screening medium for the recovery, selection, and differentiation of dermatophytes (*Microsporum*, *Trichophyton*, and *Epidermophyton*) from keratinous specimens (hair, skin, and nails). Nitrogenous and carbonaceous compounds are provided by soy peptone. Cycloheximide inhibits saprophytic moulds, chloramphenicol inhibits many Gram-positive bacteria, and gentamicin inhibits Gram-negative bacteria. The morphology and microscopic characteristics are easily identified with this medium. Pigmentation cannot be discerned because of the presence of phenol red indicator. The medium is yellow and turns red with growth of dermatophytes. *Aspergillus* species and other saprophytic fungi can grow and produce pigment on this medium, which accounts for its recommended use BD as a screening medium only.

■ Inhibitory mould agar
Inhibitory mould agar is a selective and enriched medium that is used for the general cultivation of cycloheximide-sensitive fungi (e.g., *Cryptococcus* and mucoraceous fungi) from contaminated specimens. Casein and animal tissue provide growth nutrients. Yeast extract serves as a source of vitamins. Chloramphenicol inhibits many Gram-positive and Gram-negative bacteria. Gentamicin is another additive that inhibits some Gram-negative bacteria. This is an excellent media for use in the primary cultivation of fungi and has been demonstrated to be more sensitive than the standard Sabouraud dextrose agar (21).

■ Lactrimel agar (Borelli’s medium)
Lactrimel agar (Borelli’s medium) is composed of whole-wheat flour, skim milk, and honey, which favors the sporulation of most dermatophytes and the pigment production of *Trichophyton* species. The medium may also be used for the morphological examination of dematiaceous fungi.

■ Leeming and Notman medium
Leeming and Notman medium is used for the isolation and growth of lipodependent *Malassezia* species. The key components of the medium include ox bile, glycerol monostearate, glycerol, Tween 80, and cows’ milk (whole fat) (22). The medium may serve as an alternative to Sabouraud glucose agar, since not all species can grow on this medium (e.g., *M. globosa*, *M. restricta*, and *M. obtusa* require more complex media for their isolation).

■ Littman oxgall agar
Littman oxgall agar is a selective general-purpose medium used for the isolation of fungi from contaminated specimens. Crystal violet and streptomycin are the selective agents and inhibit bacteria. Oxgall restricts the spreading of fungal colonies. The isolation characteristics of this medium are similar to those of Sabouraud dextrose agar with chloramphenicol and inhibitory mould agar in that it allows the growth of fungi that are sensitive to cycloheximide.

■ Malt extract (2%) agar
This medium is used for the cultivation of yeasts and moulds. A variety of formulations have been described, but they typically include malt extract with agar and are supplemented with peptone, glucose, maltose, and dextrin and/or glycerol. Malt agar is particularly useful for stimulating the production of macroconidia in *Microsporum canis*.

■ Mycobiotic or Mycosel agar
Mycobiotic (Remel) and Mycosel (BD Diagnostic Systems) are trade names for a selective medium principally formulated for the isolation of dermatophytes but also used for the isolation of other pathogenic fungi from specimens contaminated with saprophytic fungi and bacteria. The medium consists primarily of peptones from a pancreatic digest of soybean meal and dextrose. The selective agents are cycloheximide and chloramphenicol. Cycloheximide inhibits the faster-growing saprophytic fungi but is also inhibitory to some clinically relevant species. These inhibited fungi include some *Candida* and *Aspergillus* species, mucoraceous fungi, and *C. neoformans*. Chloramphenicol inhibits Gram-negative and Gram-positive organisms.

■ Niger seed agar
See Birdseed agar.

■ Potato dextrose agar (PDA)
Potato dextrose agar is a medium used to stimulate conidium production by fungi. The medium also stimulates pigment production in some dermatophytes. This medium is most commonly used with the slide culture technique to view morphological characteristics. Infusions from potatoes and dextrose provide nutrient factors for excellent growth. The incorporation of tartaric acid in the medium lowers the pH, thereby inhibiting bacterial growth.

■ Potato flake agar
Potato flake agar is a medium useful in the stimulation of conidia by fungi. Its advantages over potato dextrose agar may be preparation and stability. Potato flakes and dextrose provide the nutrient factors that allow excellent growth. The pH is adjusted to 5.6 to enhance growth of fungi and to inhibit bacterial growth. The medium may be made selective by the addition of cycloheximide and chloramphenicol.

■ Sabouraud brain heart infusion (SABHI) agar
Sabouraud brain heart infusion agar is a general-purpose medium used for the isolation and cultivation of all fungi. The medium is a combination of brain heart infusion agar and Sabouraud dextrose agar. The combined formulation allows for the recovery of most fungi including the yeast phase of dimorphic fungi. The inclusion of sheep blood provides essential growth factors for the more fastidious fungi and enhances the growth of *H. capsulatum*. Selectivity
is attained by the addition of chloramphenicol, cycloheximide, penicillin, and/or streptomycin.

- **Sabouraud dextrose agar**
  Sabouraud dextrose agar was formulated by Sabouraud for cultivating dermatophytes. The medium consists of pancreatic digest of casein, peptic digest of animal tissue, and dextrose at 4% concentration and buffered to a pH of 5.6. Emmons modified the original formulation by reducing the dextrose concentration to 2% and adjusting the pH nearer to neutrality at 6.9 to 7.0. Antibiotic additives in various combinations include cycloheximide, chloramphenicol, gentamicin, ciprofloxacin, penicillin, and/or streptomycin, which inhibit some fungi and Gram-positive and Gram-negative bacteria to achieve selectivity for this medium. This medium is also available as a broth.

- **Soil extract agar**
  Soil extract agar is a medium composed of garden soil, yeast extract, and glucose. The primary use of this medium is to promote sporulation of some saprobic fungi and for mating strains of *B. dermatitidis* (1).

- **Trichophyton agars 1 to 7**
  Trichophyton agars are a set of seven media that facilitate the identification of Trichophyton species on the basis of their growth factor requirements. The basic ingredients in the media are listed below. Growth in all seven media is then scored on a scale of 1 to 4, and an identification is assigned.

  1. Casamino Acids; vitamin-free
  2. Casamino Acids plus inositol
  3. Casamino Acids plus inositol and thiamine
  4. Casamino Acids plus thiamine
  5. Casamino Acids plus niacin
  6. Ammonium nitrate
  7. Ammonium nitrate plus histidine

- **V8 agar**
  V8 agar is a medium consisting of dehydrated potato flakes and V8 juice (Campbell Soup Co.; Camden, NJ) that induces early sporulation of some environmental fungi. The naturally low pH makes the medium inhibitory to most bacteria.

- **Water (tap) agar**
  This medium is nutritionally deficient (1% water-agar, 1 g of agar, 100 ml of sterile tap water) and promotes the sporulation of dematiaceous fungi, *Apophysomyces* elegans, and *Saksenaea vasiformis* (23). The medium can be supplemented with sterilized carnation leaves for the identification of *Fusarium* spp. (6).

- **Yeast carbon agar**
  Yeast carbon agar is a solid medium recommended for use in qualitative procedures for the classification of yeasts according to their ability to assimilate nitrogenous compounds. The yeast carbon base provides amino acids, vitamins, trace elements, and salts that are necessary to support growth. The ability to assimilate nitrogen is tested by the addition of various nitrogen sources such as potassium nitrate.

General Approaches for Direct Detection and Identification of Fungi*

H. RUTH ASHBEE

The frequency with which invasive fungal disease occurs has increased markedly over the last decade and the ability to detect and identify the causative fungi rapidly is essential to the successful management of these diseases (1). Culturing the fungus has always been important to determine the etiology of the infection; however, other non-culture-based methods may provide more timely results and offer advantages over culture techniques. Non-culture-based methods reviewed in this chapter include direct microscopic examination, antibody and antigen detection, detection of (1, 3)-β-D-glucan and other fungal metabolites, the use of mass spectrometry, and nucleic acid detection. Although these methods are helpful in clinical use, they have not entirely replaced culture methods and should still be used in conjunction with appropriate culture-based methods (reviewed in chapters 114 and 115). Although cultures from invasive infections are positive only infrequently, when a culture is obtained it allows susceptibility testing and epidemiological comparisons not widely available via non-culture-based methods.

DIRECT MICROSCOPIC EXAMINATION

The ability to detect fungi in clinical material depends on several factors, including the quality of the specimen received into the laboratory. If very small samples are received, few fungi may be present, making detection and identification less reliable. Also, if material is not taken from a representative part of the lesion, fungi may not be present in the part sampled. If very small samples are received, generally culture should take precedence over direct microscopy as culture is more sensitive. The exceptions to this would be dermatological samples where microscopy is diagnostic, and also if mucoraceous moulds are suspected, where microscopy may be positive in the absence of a positive culture. If the sample is large enough, both direct microscopy and culture should be performed, because microscopy is better able to differentiate colonization, tissue invasion, and contamination. Conversely, only nonviable organisms may be present in specimens obtained while the patient is receiving antifungal therapy, and microscopy and molecular methods may be the only means for detecting the etiologic agent.

Specimen quantity and quality may be compromised when multiple clinical laboratories process portions of the specimens. Good communication among microbiology services, other pathology services, and the clinician can greatly enhance diagnostic accuracy.

Consideration of the patient’s travel history and residence is also important when attempting to detect and identify fungal causes of disease due to the endemicity of certain diseases (Table 1). Lifelong travel history is important in patients who do not normally reside in areas of endemicity, because certain infections (e.g., paracoccidioidomycosis, histoplasmosis) (2) may reactivate decades later. For example, although reported worldwide, most cases of mycetoma come from tropical and subtropical regions around the Tropic of Cancer (3), and specific travel or residence details may improve diagnostic accuracy.

Examination of clinical material before any processing takes place may be very informative and should always be performed. Areas of caseous necrosis, microabscesses, grains, granules, and nodules should all be noted. Grains and granules may indicate mycetoma, granulomas, and caseous necrosis histoplasmosis, while microabscesses are seen with hepatosplenic or renal candidiasis. Grains and granules should be examined for color, shape, size, and consistency as these may be indicative of the etiological agent. For example, Scedosporium apiospermum, a common cause of eumycetoma, produces yellowish-white soft grains of 1 or 2 mm diameter, while Trematosphaeria grisea produces globose or lobed black grains of 0.5 to 1 mm diameter (3).

Microscopic examination of specimens can be carried out using unfixed specimens or fixed, stained specimens. Obviously, the use of unfixed specimens has the advantages of being quick and relatively simple to carry out, while the use of fixed, stained specimens may highlight features specific to certain fungi and the host response in tissue; however, the latter takes longer to process and thus may delay reporting. Generally, if fixed, stained specimens are being examined, a general stain such as hematoxylin and eosin (H&E) is used for screening. If fungi are suspected after examination of H&E, then stains which are specific for fungal structures (e.g., Gomori methenamine silver [GMS]) can be used, and finally, more specialized stains such as mucicarmine or Fontana-Masson will demonstrate characteristic structures in fungi of interest. A range of

### TABLE 1 Characteristic fungal morphology seen by direct examination of clinical specimens

<table>
<thead>
<tr>
<th>Fungal morphology observed</th>
<th>Organism(s)</th>
<th>Diameter range (µm)</th>
<th>Characteristic features</th>
<th>Geographic distribution</th>
</tr>
</thead>
<tbody>
<tr>
<td>Yeast forms</td>
<td>Histoplasma capsulatum</td>
<td>2–5</td>
<td>Small; oval to round budding cells; often found clustered within histiocytes; difficult to detect when present in small numbers; often intracellular (Fig. 23)</td>
<td>Worldwide, eastern half of the United States (localized in Ohio and Mississippi River valleys) and throughout Mexico, Central and South America</td>
</tr>
<tr>
<td>Sporothrix species</td>
<td>2–6</td>
<td>Small; oval to round to cigar shaped; single or multiple buds present; uncommonly seen in clinical specimens (Fig. 21)</td>
<td>1. Worldwide, eastern half of the United States (localized in Ohio and Mississippi River valleys) and throughout Mexico, Central and South America; 2. Tropical areas of Africa (Gabon, Uganda, Kenya)</td>
<td></td>
</tr>
<tr>
<td>Cryptococcus species</td>
<td>4–10</td>
<td>Cells vary in size; usually spherical but may be football shaped; buds usually single and &quot;pinched off&quot;; capsule may or may not be evident; rarely, pseudohyphal forms with or without capsule may be seen (Fig. 7, 15, and 16)</td>
<td>Cryptococcus neoformans: Worldwide, especially Europe, Africa, Australia; Cryptococcus gattii: tropical and subtropical areas, including Australia, America, South Africa, Central America</td>
<td></td>
</tr>
<tr>
<td>Blastomyces dermatitidis</td>
<td>8–15</td>
<td>Cells usually large and spherical, double refractile; buds usually single, but several may remain attached to parent cells; buds connected by broad base (Fig. 22)</td>
<td>Southeast and south-central United States, Great Lakes region, near St. Lawrence River</td>
<td></td>
</tr>
<tr>
<td>Paracoccidioides brasiliensis</td>
<td>5–60</td>
<td>Cell usually large and surrounded by smaller buds around periphery (mariner's wheel appearance); smaller cells (2–5 µm) that resemble H. capsulatum may be present; buds have &quot;pinched off&quot; appearance (Fig. 25)</td>
<td>South and Central America</td>
<td></td>
</tr>
<tr>
<td>Yeast forms (fission)</td>
<td>Talaromyces (previously Penicillium) marneffei</td>
<td>3</td>
<td>Fission yeast, not budding, elongated, curved with septa visible (Fig. 26)</td>
<td>Southeast Asia and China</td>
</tr>
<tr>
<td>Cysts and trophozoites</td>
<td>Pneumocystis jirovecii</td>
<td>1–4</td>
<td>Trophozoites: small pleomorphic forms</td>
<td>Worldwide</td>
</tr>
<tr>
<td></td>
<td>4–5</td>
<td>Cysts: round to cup shaped with as many as 8 intracystic bodies (Fig. 18)</td>
<td>Worldwide</td>
<td></td>
</tr>
<tr>
<td>Spherules</td>
<td>Coccioides immitis, Coccioides posadaii</td>
<td>10–200</td>
<td>Spherules vary in size; some contain endospores, others are empty and collapsed; hyphae may be seen in cavitary lesions (Fig. 24)</td>
<td>Southwestern United States, Mexico, Central and South America (C. posadaii organisms are non-Californian strains)</td>
</tr>
<tr>
<td>Yeast forms and pseudothalli or true hyphae</td>
<td>Candida spp.</td>
<td>3–4 (yeast forms); 5–10 (pseudothalli)</td>
<td>Cells usually exhibit single budding (Fig. 4, 6); pseudohyphal, when present, are constricted at ends and remain attached like links of sausage (Fig. 4, 5); true hyphae, when present, have parallel walls and are septate</td>
<td>Worldwide</td>
</tr>
<tr>
<td>Yeast forms and pseudothalli</td>
<td>Malassezia species</td>
<td>3–8 (yeast forms); 5–10 (pseudothalli)</td>
<td>Short, curved hyphal elements may be present with round, oval or elongated yeast cells that are round at one end and flattened at point of condensation (Fig. 8)</td>
<td>Worldwide</td>
</tr>
<tr>
<td>Wide pauciseptate hyphae</td>
<td>Mucoraceous moulds</td>
<td>10–30</td>
<td>Hyphae are large, ribbonlike, often fructified or twisted. Occasional septa may be present, branching usually at right angles (Fig. 3, 11, and 12). The Splendore-Hoeppli phenomenon on H&amp;E sections may be seen with Basidiobolus and Conidiobolus species.</td>
<td>Entomophthorales: worldwide Basidiobolus ranarum: tropical areas of Asia, Africa, South America (mostly Brazil), Mexico, Australia (children) Conidiobolus coronatus and C. incongruus: tropical and subtropical regions of Africa and Southeast Asia (adults)</td>
</tr>
<tr>
<td>Hyaline (colorless) septate hyphae</td>
<td>Dermatophytes (skin and nails)</td>
<td>3–15</td>
<td>Hyaline septate hyphae commonly seen; chains of arthroconidia may be present (Fig. 19)</td>

| Dematiaceous (darkly pigmented) septate hyphae | Dematiaceous fungi | 1.5–6 | Dematiaceous polymorphous hyphae, budding cells with single septa and chains of swollen rounded cells may be present. Occasionally, aggregates may be present when infection is caused by Phialophora or Exophiala species (Fig. 2) | Hortaea werneckii: subtropical coastal locations |
|                                               |                    |      |                                                                                  | Piedra hortae: tropical climates of Central and South America, Southeast Asia, and the South Pacific Islands |
|                                               |                    |      |                                                                                  | Rhinocladiella mackenziei: Middle East |
|                                               |                    |      |                                                                                  | Cladophialophora bantiana found in Asia |

| Sclerotic bodies (muriform cells) | Cladophialophora carrionii, Fonsecaea compacta, Fonsecaea pedrosii, Phialophora verrucosa, Rhinocladiella aquaspersa | 5–20 | Brown, round to pleomorphic, thick-walled cells with transverse septa. Commonly, cells contain two fission plates that form tetrads of cells. Occasionally, branched septate hyphae may be found in addition to sclerotic bodies (Fig. 20). | Occurs worldwide, although most reported cases are from tropical and subtropical regions of the Americas and Africa |

| Granules (white grain eumycetomas) | Acremonium and related spp. (Sarocladium kilense, Acremonium recifei) | 200–300 | White, soft granule; cementlike matrix absent | Asia, North, South and Central America, Oceania, Europe |
|                                    | Aspergillus nidulans | 65–160 | White, soft granule; cementlike matrix absent | Africa |
|                                    | Fusarium spp. (F. moniliforme, F. oxysporum species complex, F. solani species complex) | 80–200 | White-yellowish color of the grains, edges are entire or lobed; surrounded by an eosinophilic homogeneous material. Hyphae comprising the granules are not embedded in cement. | Europe, South America, Caribbean, Africa, Asia |
|                                    | Neotestudina rosatii | 500–1,000 | Round, oval or lobed white grains; compact with cement in the center | West Africa |
|                                    | Pseudallescheria boydii | 1,000–2,000 | White-yellow, soft granules composed of hyphae and swollen cells at periphery in cement-like matrix (Fig. 17) | Worldwide, most common in North America |

</table>
2), and the role of histopathological diagnosis has recently been comprehensively reviewed (4). Staining methodology is reviewed in Chapter 115.

The Gram stain may be useful in diagnosis, primarily because it is commonly used in most laboratories (hence, laboratory staff are familiar with it) and it may enable differentiation of yeasts from moulds in the initial sample. Although Gram reactions can vary, yeast cells and pseudohyphae generally stain Gram positive and hyphae (septate and aseptate) stain Gram negative. The size and shape of budding yeastlike cells can indicate a presumptive genus identification. Cryptococcus yeast cells are generally round and display an amorphous orange-staining material, presumably the capsule.

Familiarity with the appearance of certain fungi in tissue may be helpful when performing direct examination. Aspergillus hyphae tend to be of a consistent diameter (4 to 6 \( \mu \text{m} \)) and commonly demonstrate 45° branching, with 90° branching less common. Fusarium and Scedosporium species look very similar to Aspergillus species in tissue (5). Sporulation in tissue is rare, but it can be distinctive with certain fungi. For example, aleurioconidia can be indicative of Aspergillus terreus. Fusarium may produce a combination of hyphae and yeastlike structures, and Scedosporium may produce ovoid, pigmented annelloconidia (4). When fungal stains show both unicellular forms and filaments that appear to be hyphae or pseudohyphae, infection with Fusarium, Paecilomyces, or Acremonium species should be considered, although filamentous yeast should also be included in the differential diagnosis (6). Mucoraceous moulds have aseptate or sparsely septate hyphae with wide-angle branching. The hyphae often appear twisted and flattened due to the lack of hyphal support because of the absence of septa (7).

The Splendore-Hoeppli phenomenon on H&E sections may be seen with blastomycosis and sporotrichosis as well as with infections caused by Basidiobolus and Conidiobolus species. This phenomenon is the deposition of amorphous, eosinophilic material in tissue that occurs as a result of the antigen-antibody reaction. Dematiaceous moulds may display multiple forms, such as septate hyphae with parallel walls, rounded forms arranged in chains, or muroform (sclerotic) bodies. The diagnosis of phaeohyphomycosis can be made if pigmented hyphae are observed. Sometimes pigmentation can be observed by using a traditional KOH preparation; however, care should be taken if these are stained with calcofluor white, because this is not taken up well by melanized hyphae. Some structures can provide definitive diagnosis of the etiologic agent (e.g., spherules of Coccioides spp.). Specimens obtained from patients treated with antifungal drugs may demonstrate atypical structures, such as variations of hyphal size within the same hyphae, lack of septation within the hyphae, or bulb forms within the hyphae or at the hyphal tips.

Many artifacts can be mistaken for fungal structures when performing direct microscopy. Lymphocytes in cerebrospinal fluid (CSF) may be mistaken for Cryptococcus species; fibers and debris may be mistaken for hyphae, because they can fluoresce with calcofluor white; and fat droplets may be confused with budding yeastlike cells. Experience reading direct microscopy may overcome these problems, and discussions with colleagues may be necessary where doubt persists. Alternatively, use of another method may help differentiate artifacts from genuine findings.

A positive result on direct microscopy should be reported promptly with as much information as necessary to clarify the result. For example, “Yeast cells seen” is more helpfully reported as “Microscopic appearance may represent commensal species (e.g., Malassezia)” in a skin sample if the characteristic broad-based budding associated with this genus is seen. Examples of various characteristic structures seen in direct microscopy of clinical specimens from fungal infections are seen in Fig. 1 to 26.

**ANTIBODY DETECTION**

Antibody detection may be useful in a range of diseases, particularly when they occur in immunocompetent patients, although it may have limited use in immunocompromised patients. Several immunological techniques have been used to detect antibodies during fungal infections, including immunodiffusion (1D), countercurrent immunoelectrophoresis (CIE), enzyme-linked immunosorbent assay (ELISA), complement-fixation tests (CFTs), and most recently, fluorescent-enzyme immunoassay (FEIA).

**Aspergillus Species**

Antibodies to Aspergillus can be detected in most healthy individuals due to exposure to spores in the air (8), but their role in diagnosing aspergillosis in immunocompromised patients is minimal. In contrast, in patients who are non-neutropenic and develop aspergillosis, antibody detection may be helpful. Various techniques have been used, including countercurrent immunoelectrophoresis and FEIA; these tests mainly measure IgG but often use poorly defined antigen preparations, although recombiantant antigens are available from some manufacturers. Antibody detection is helpful in diagnosing allergic bronchopulmonary aspergillosis (ABPA) (9), aspergilloma (10), and chronic cavitary aspergillosis (11). Although background levels of antibody do occur, through careful examination of the performance of tests (e.g., using receiver operator curve analysis), it is possible to define a lower, nonsignificant level and also a level at which antibodies become indicative of disease (12).

An EIA is available commercially for the measurement of Aspergillus IgG (Platelia BioRad; Bio-Rad, Hercules, CA), which is CE-marked but not U.S. Food and Drug Administration (FDA) approved. The kit defines antibody levels of <5 U/ml as negative, ≥10 U/ml as positive, and levels in between as intermediate. However, from the data presented by the manufacturer on evaluation of the performance of the kit in patients with cystic fibrosis, it is not clear how the diagnosis of ABPA was made and thus how reliable the figures are for sensitivity and specificity.

** Blastomycosis Species**

Blastomycosis yeasts produce two antigens, A antigen and WI-1 antigen, of which only the former is used in commercially available kits. Detection of antibodies to Blastomycosis can be carried out by immunodiffusion, CFT, or ELISA, and there are commercially available assays or reagents in all these formats. Immunodiffusion may be positive in about 40 to 60% of patients, but the CFT is less helpful, with positivity in less than 20% of patients (13). Using an EIA, antibodies were detected in 83% of patients with blastomycosis, but 47% of specimens from patients with histoplasmosis were also positive (14). Therefore, antibody detection is rarely definitive due to its lack of sensitivity and widespread cross-reactivity with other dimorphic fungi (15).

**Candida Species**

Detection of antibodies specific to Candida is problematic as a diagnostic tool, because many people carry Candida as a commensal and thus have low levels of antibodies in the

</table>
absence of disease (16). The main antigen used is mannan, a cell wall component, and various immunoglobulin classes may be detected, including IgG, IgM, and IgA. Many studies have examined the sensitivity and specificity of antibody detection for diagnosis of invasive candidiasis and found disappointingly low figures (17, 18). Sensitivity as low as 62% and specificity as low as 53% have been reported when antibodies alone are used for diagnosis, and thus most experts now recommend they be used in conjunction with Candida mannan antigen detection (18, 19).

**Coccidioides Species**

Antibodies to Coccidioides can be detected by various methods, including ID, CFT, and EIA. Historically, the tube precipitin (20) was also used, which has now been replaced by the ID test using the same antigens. The ID test detects mainly IgM antibodies to a β-glucosidase antigen, which is positive early in disease, while the CFT detects IgG antibodies to a heat-labile chitinase antigen, which is useful in diagnosing acute and chronic disease and can also be used prognostically (21). Early studies indicated that, in primary infection, precipitating antibodies peak by the third week of infection, with approximately 90% of sera positive, but then decline rapidly, with only 10% of sera positive at 5 months. Complement-fixing antibodies are detected in about 50% of sera by 1 month and continue to increase for several months (22).

An EIA is also now available that detects both IgG and IgM and can be used with serum or CSF (Premier Coccidioides EIA; Meridian, Cincinnati, OH). The EIA has higher sensitivity than ID and CFT, but there has been concern about whether the increased sensitivity is associated with decreased specificity (23). One study found no false-positive results (24), while others have found false IgM-positive results in patients (25). This has led to the suggestion that the EIA should be used as a screening tool, with any positive results confirmed by another method (21).

**Cryptococcus Species**

Antibodies to Cryptococcus—including IgG, IgM, and IgA produced against glucuronoxylmannan antigen and also crude antigen preparations—can be detected in patients with cryptococcosis (26). Such antibodies have been suggested to have prognostic value (27) and can be a marker for reactivation of disease in solid-organ transplant recipients (28). However, their utility in diagnosis is limited because the polysaccharide capsular antigen may inhibit the synthesis of antibodies (29).

**Histoplasma capsulatum**

Detection of antibodies is an important component in establishing a diagnosis of histoplasmosis. Antibodies appear approximately 4 to 6 weeks after the primary acute infection and decline over a 2- to 5-year period (30). Two tests have been widely used and evaluated, namely ID and CFT.

The antigens used in the tests are extracted from histoplasmin, which is obtained from the mycelial phase of the fungus. Two antigens detected by the tests are the M antigen, which is a catalase (31), and the H antigen, which is a β-glucosidase (32).

The ID test, which is about 80% sensitive, detects precipitating antibodies to the antigens, resulting in the H and M “bands.” The M band appears first during infection, can indicate either active or previous infection, and persists for several years. In contrast, the H band occurs during active infection, but is found in only a minority of patients, although it may persist for 1 or 2 years. If both bands are detected, this is considered to be diagnostic (33).

The CFT uses histoplasmin and an antigen produced by the yeast phase to detect complement-fixing antibodies, which appear 3 to 6 weeks after infection. Up to 95% of patients with histoplasmosis have a positive reaction in the CFT, although titers may be relatively low (34). Low titers may represent past infection, but titers of 1:32 or greater or a 4-fold rise in titer indicate active disease (30). Antibodies generally appear first to the yeast antigen and later to histoplasmin and decline over several years in the absence of further exposure (33). The CFT is more sensitive than ID but also subject to more cross-reactivity. Patients with aspergillosis, blastomycosis, candidiasis, coccidioidomycosis, paracoccidioidomycosis, tuberculosis, and other bacterial or viral diseases have been found to have positive reactions in the CFT (35). False-negative results can occur due to the presence of rheumatoid factor or cold agglutinins (36).

**ANTIGEN DETECTION**

**Aspergillus Species**

The main antigen used as a diagnostic marker in commercially available kits for invasive aspergillosis (IA) is galactomannan (GM). GM, a carbohydrate molecule with a mannose backbone, is released from the cell wall of Aspergillus hyphae during growth in vitro but is probably not detectable in patients until angioinvasion has occurred (37). GM can be detected in serum, bronchoalveolar lavage (BAL) fluid, and urine in infected patients. The Platelia Aspergillus GM antigen ELISA kit produced by BioRad uses a monoclonal rat antibody (EBA-2) to coat microtiter wells and as act the detector antibody conjugated to peroxidase. The amount of GM in each sample is expressed as a ratio of the sample optical density compared with the cutoff control optical density; GM indices greater than 0.5 are considered positive (Platelia Aspergillus Ag Kit insert). Although the manufacturers currently recommend a cutoff of 0.5 for BAL, many laboratories use a cutoff of 1 due to the improved sensitivity of the kit with BAL. The kit (which is CE-marked and FDA approved) is currently approved for the detection of GM in serum and BAL and has been extensively studied in a range of different patient groups; sensitivities and specificities vary widely depending on the setting in which it is used. Studies in patients with hematological malignancies and patients who have undergone hematopoetic stem cell transplantation (HSCT) have generally resulted in higher sensitivity and specificity than patients with solid organ transplantation. For patients with hematological malignancies, sensitivities of up to 100% have been reported in those with proven or probable IA (38), although other groups have found sensitivity of only 17% in proven IA (39). A recent review that analyzed data from 42 studies found that the sensitivity and specificity results varied from 0 to 100% and 50 to 99%, respectively (40). Unsurprisingly, studies that used a higher cutoff reported higher specificity and lower sensitivity, but this difference was not statistically significant. The frequency of testing will also affect the utility of the test, and twice weekly testing may be optimal (41).

Although GM is a useful marker for IA, there are many causes of false positivity. Piperacillin/tazobactam or amoxicillin with clavulanic acid (42), Plasmalyte (43), and certain foodstuffs, including pasta, vegetables, and milk, are all known to cause false positives. In addition, several other fungal genera are known to be reactive in the kit, including...
Penicillium, Alternaria, Rhodotorula, Paecilomyces, Cryptococcus, Blastomyces, and Histoplasma. Detection of GM may be reduced in patients with chronic granulomatous disease (44) and patients treated with mould-active antifungals (45). As well as being used for diagnosis, GM has been assessed as a prognostic tool. Early studies demonstrated that an increase in the GM index was associated with progression of disease (46) and that patients in whom the GM index remained high had significantly poorer outcomes than those in whom it decreased (47). More recently, it has been shown that the initial level of the GM index in serum and the rate of decay in GM over the first week were predictive of time to mortality. In the first week, if the GM index increased by 1 unit, the risk of time to mortality increased by 25%, whereas a fall of 1 unit decreased the risk by 22% (48).

Although the GM ELISA is the most widely used assay for the diagnosis of IA, a new lateral flow device (LFD) has been developed (Isca Diagnostics, Truro, UK) that uses a monoclonal antibody, JFS, which binds to a protein epitope from an extracellular glycoprotein antigen produced by A. fumigatus (8). It was hypothesized that the problems with cross-reactivity would be reduced by targeting a non-GM antigen. The monoclonal antibody is used for both the capture and detection of the antigen in serum or BAL, visualized using colloidal gold, and seen as a line that appears within 10 to 15 minutes of the sample being added to the LFD. Because the antigen is produced only by growing hyphae, any issue due to contamination of samples with Aspergillus spores should not produce positive results. This makes the test most useful for testing BAL samples, while it is potentially a more useful marker of invasive disease than other tests that may detect inhaled spores.

A recent comparison of the LFD and GM ELISA in patients after allogeneic stem cell transplantation showed that the negative predictive value of the LFD was high (~92%). If only a single positive sample was used to define positivity, the LFD and ELISA had similar performance; however, if two samples were used for positivity, the LFD performed worse than the ELISA, with a positive predictive value (PPV) of 50% and a sensitivity of 20% (compared with the ELISA PPV of 75% and sensitivity of 30%) (49). Another comparison of the LFD and GM ELISA found that the LFD had a higher sensitivity (82%) and a specificity of 98% (50). Although the LFD has been described as a point-of-care test (8), the requirement to boil serum samples in a pH-buffered EDTA solution and centrifuge them during processing still means that testing must be done in a laboratory, although BAL samples may be processed directly. The kit is CE-marked, and FDA approval is currently being sought.

### Blastomyces Species

Diagnosis of blastomycosis is often made by culture, which is ultimately positive in over 80% of patients; however, due to the time taken for the culture to grow, other methods may also be used to give quicker results (51). Currently, only one assay is available to detect Blastomyces antigen; provided by MiraVista Diagnostics (MiraVista Diagnostics, Indianapolis, IN), it uses rabbit antibodies raised against whole cells of B. dermatitidis in the mould phase (52). The assay can be used for most body fluids and has been evaluated mainly in urine, in which sensitivity is higher than for serum (53). The drawback with the assay is the presence of cross-reactivity in a range of other mycoses, including histoplasmosis, paracoccidioidomycosis, infections with Talaromyces marneffei, cryptococcosis, and aspergillosis (http://miravistalabs.com/medical-fungal-infection-testing/antigen-detection/blastomyces-dermatiditis-quantitative-eia-test/). A recent modification of the assay allowed quantification of antigen and increased its sensitivity when used with serum; however, it produced cross-reactivity in 96% of patients with histoplasmosis (54), which is problematic because the endemic areas for histoplasmosis and blastomycosis overlap in the United States. Due to the presence of such high rates of cross-reactivity, the utility of the Blastomyces antigen test is limited.

### Candida Species

Diagnosis of systemic candidiasis can be problematic because many people carry Candida as a commensal, and the presence of Candida colonization is often thought to affect the sensitivity and specificity of current diagnostic tests. Commercially available tests usually detect mannan or mannoproteins and include the Platelia Candida Ag EIA (Bio-Rad) and the CandTec latex agglutination test (Ramco Laboratories, Stafford, TX). Candida mannan is rapidly cleared from the circulation and hence frequent testing is important. A recent meta-analysis has examined the issues of sensitivity, specificity, and the effect of colonization on these parameters, mainly in studies that examined both mannan antigen and antimanman antibody detection (19). One issue with the meta-analysis is the heterogeneity of the studies included, which is reflected in the wide ranges for the results reported. For mannan antigen detection alone, sensitivity ranged from 31 to 100%, with a median of 62% reported for the results. For antimanman antibodies, the figures were...

44 to 100%, but when the two approaches were combined, the median sensitivity was 86%. Sensitivity varied for different species of Candida, with the best results for C. albicans, followed by C. glabrata and C. tropicalis. Of note, the meta-analysis examined the effect of colonization of patients with Candida in four studies and found that neither colonization nor superficial candidiasis was associated with detection of mannan or antimannan antibodies (19). This led the authors to recommend that both mannan and antimannan antibodies should be used for the diagnosis of invasive candi-

Coccidioides Species
Diagnosis of coccidioidomycosis can be achieved using a range of methods, including antibody or antigen detection, or by culture. While culture remains the gold standard, the risks inherent to laboratory personnel dealing with cultures means that use of other methods is to be encouraged. The most fully validated test available for detection of Coccidioides antigen is an EIA provided by MiraVista Laboratories (http://miravistalabs.com/medical-fungal-infection-testing/antigen-detection/coccidioides-quantitative-eia-test/). The MiraVista test uses antibodies against Coccidioides GM and is suitable for use with urine, serum, plasma, BAL, CSF, and various other body fluids in patients with severe forms of disease (35). Treatment of serum and urine with EDTA to remove immune complexes improves the positivity in serum from 28 to 73%, but positivity in urine is only 50% (56). However, as with several other antigen detection assays for the endemic fungi, cross-reactions are common in patients with histoplasmosis or blastomycosis (56).

Cryptococcus Species
Detection of cryptococcal polysaccharide antigen in body fluids is an integral part of the diagnostic process for cryptococcal disease. The antigen detected is glucuronoxylmannan, which is the main component of the capsule and differs structurally among different serotypes. Classically, species of Cryptococcus were divided into five serotypes, A, B, C, D, and AD, but recent molecular studies have defined nine types and ongoing work may define further types. Serotype A contains molecular types VNI, VNII, and VNB and is designated C. neoformans var. grubii. Serotype D contains molecular type VNIIV and, with serotype AD hybrids (VNIII), comprises C. neoformans var. neoformans. Serotypes B and C are C. gattii and comprise molecular types VGI, VGII, and VGIV (259).

Commercially available kits for detection of cryptococcal antigen, which have both FDA approval and CE marking for serum and CSF, include enzyme immunoassays (Meridian and IMMMy [Immunno-Mycologies, Norman, OK]) and latex agglutination assays (BioRad, IMMMy, and Meridian). The sensitivity and specificity for the EIA and LA tests are high for both serum and CSF, in which the assay results may be caused by low antigen titers (72) or high results may be caused by low antigen titers (72) or high titers (73). False positives due to high antigen titers are collectively known as the prozone effect; for this reason, it is good practice to test specimens undiluted and at a 1:10 dilution. Modifications of the tests have generally overcome these problems (73, 74).

Histoplasma capsulatum
Histoplasmosis may be diagnosed using different methods, but as with other slow-growing fungi, diagnosis by culture may take several weeks to become positive (30). Other modalities for diagnosis include histopathology, antigen detection, antibody detection, and PCR. There is currently only one commercially available test for Histoplasma antigen (MiraVista Diagnostics), which was originally developed in the mid 1980s as a radioimmunoassay but is now an EIA. The assay uses polyclonal rabbit antiserum raised against a polysaccharide antigen from H. capsulatum found in various body fluids during infection (75). The sensitivity of the assay varies with patient group, and most experience has been in patients with HIV infection and disseminated disease in whom antigen is found in the urine and serum in 95 and 86% of patients, respectively. In other immunocompromised patients, the test is less sensitive, with 82% sensitivity in urine and 60% in serum (76). It is useful only in the early diagnosis of acute histoplasmosis, within 3 weeks of exposure. As well as disseminated histoplasmosis, the antigen test may also be useful in acute pulmonary disease, in which antigenemia and antigenemia were reported in 68 and 65% of patients, respectively (77). The utility of the test in other forms of histoplasmosis is much lower, with sensitivities of 15% or less for mediastinal or chronic pulmonary disease (76). In addition to serum and urine, the assay has also been evaluated in BAL and CSF. A recent study found that antigen could be detected in BAL from 94% of patients with histoplasmosis and in urine and serum samples from 79 and 63%, respectively, of the same patients (78). Although no large studies have assessed the sensitivity of antigen in CSF, it has been reported to have sensitivities ranging from 38% to 67% in small case series (79).

Antigen titers fall with successful treatment (80) and rise with relapses (81), so the test also has prognostic utility. One of the major drawbacks with the antigen test is the frequency of false-positive results. Cross-reactivity in the urine test occurs in patients with blastomycosis, paracoccidioidomycosis, and Talaromyces marneffei infection. Rabbit antihistoplasmine globulin can cause false positives in serum, rheumatoid factor, and treatment with rabbit antihistoplasmine globulin (30).

Although the antigen test from MiraVista is the most widely used and studied, other groups have also developed assays (82, 83). Cloud et al. (83) used commercially available polyclonal antibodies and found good correlations with both positive and negative samples compared with the MiraVista test, but again, the problem of cross-reactivity remained with Blastomyces, Coccidioides, and Paracoccidioides. Although monoclonal antibodies have been produced, overcoming the problem of specificity, they lack sensitivity and thus have not been further developed (84). An assay for
diagnosis and that the combined approach was better than use of either technique alone.

Histoplasma capsulatum
urinary Histoplasma antigen has been developed by the Centers for Disease Control and Prevention and evaluated specifically for resource-limited settings; it demonstrated a sensitivity of 81% and specificity of 95% during evaluations (85).

The problems of cross-reactivity have led some workers to suggest that the detection of the urinary antigen should not be used as the sole method on which to base a diagnosis of histoplasmosis but that it should be used in conjunction with other methods (30).

(1, 3)-\( \beta \)-D-GLUCAN DETECTION

\( (1,3)-\beta \)-D-Glucan is a polysaccharide present in the cell wall of many fungi, including Aspergillus, Candida, and Fusarium; however, Cryptococcus, Blastomyces, and the mucormaceous moulds have very little or none. It is found in the blood of patients with invasive fungal infections, and its ability to activate factor G of the horseshoe crab coagulation pathway allows it to be measured and quantified. Several assays are commercially available (86), but the most widely available assay, and the only one with FDA approval and CE marking, is Fungitell, produced by Associates of Cape Cod (Associates of Cape Cod, Inc., Falmouth, MA) (87), which uses the coagulation cascade derived from the Limulus horseshoe crab as the detector method.

Early studies of the assay initially used a cutoff of 60 pg/ml (87). However, in a large multicenter study, the sensitivity and specificity were found to be 69.9 and 87.1%, respectively, at 60 pg/ml and 64.4 and 92.4%, respectively, at 80 pg/ml (88); the manufacturers now recommend interpreting <60 pg/ml as negative and ≥80 pg/ml as positive, with an indeterminate region in between (http://www.acciusa.com).

Clinical use of the assay has highlighted several important features. In one study, levels of \( \beta \)-d-glucan varied markedly between and within patients; optimal sensitivity, specificity, and accuracy occurred when two sequential samples had levels of ≥80 pg/ml, and successful clinical outcome did not always result in falls in \( \beta \)-d-glucan levels (89). A large retrospective study of 80 patients with proven and 36 patients with probable invasive fungal disease found that systemic antifungal therapy did not affect the sensitivity of the test. The test was more sensitive in IA than in invasive candidiasis; however, in patients with either hematological malignancy or stem cell transplantation, sensitivity was reduced (90). Optimal sensitivity occurs when patients are tested twice weekly (91). False-positive \( \beta \)-d-glucan results may be due to several factors, such as administration of intravenous immunoglobulins or albumin (90), hemodialysis using cellulose membranes (90), the use of glucan-containing gauzes or swabs (92), bacteremia (93), mucositis or graft-versus-host disease, and the use of various antibiotics (94).

One recent meta-analysis (95) included various \( \beta \)-glucan assays (including Fungitell, Glucatell [Associates of Cape Cod, Inc.], Fungitec [Seikagaku Corp, Tokyo, Japan], and Wako BG [Wako Pure Chemicals Co, Osaka, Japan]) and documented a pooled sensitivity of 79.1% and a pooled specificity of 87.7% for the \( \beta \)-d-glucan assays for 365 patients with proven invasive fungal disease; however, the ranges in the individual studies were very wide (sensitivity, 50 to 100%; specificity, 45 to 100%). Interestingly, they found no difference in sensitivity between patients with candidiasis or aspergillosis, in contrast with some single-center studies (90). The authors concluded that the assay has good diagnostic accuracy but that the optimal sampling regimen, criteria to define positive results, and optimal cutoff all required further evaluation, as well as careful consideration of causes of false positivity during routine clinical use.

Recently, \( \beta \)-d-glucan proved useful in diagnosing and monitoring an outbreak of fungal meningitis caused by Exserohilum rostratum (96).

\( \beta \)-D-Glucan has also been used as a diagnostic marker for Pneumocystis jirovecii in both HIV-positive and HIV-negative patients (97, 98). Sensitivity and specificity in this setting were generally high, with sensitivities of 96.4 to 100% and specificities of 87.8 to 100%, although studies have used widely differing cutoff values to define positives: 23.2 pg/ml (99) and 100 pg/ml (98). Despite successful treatment in HIV patients, the \( \beta \)-d-glucan levels did not decrease and thus the assay could not be used prognostically (99). Two recent meta-analyses have evaluated the test for diagnosis of P. jiroveci pneumonia (PCP) and confirmed that it performs better for this indication than for diagnosis of other invasive fungal infections. The diagnostic odds ratio in one analysis for PCP was 102.3, compared with 25.7 for other invasive fungal disease (100). Although the presence of \( \beta \)-d-glucan in patients may indicate the presence of either PCP or another invasive fungal disease, a recent meta-analysis concluded that, because of the risk of false positives in certain patient groups due to their exposure to various procedures and medications, a negative \( \beta \)-d-glucan result might be more helpful in excluding these diagnoses, and a positive result should be treated cautiously (101).

FUNGAL-SPECIFIC METABOLITE DETECTION

Many fungal metabolites, as well as fungal antigens, have been evaluated for their utility in detecting fungi in clinical specimens. Metabolites that have been assessed include \( \alpha \)-arabinotol (102), \( \beta \)-mannotol (103), the ratio of \( \alpha \)-arabinotol to \( \alpha \)-arabinotol (104), glotoxin (105), and 2-pentylfuran (106). The ratio of \( \alpha \)-arabinotol to \( \alpha \)-arabinotol in serum has recently been shown to be useful in detecting candidemia in the context of hematological neutropenic patients (18), while 2-pentylfuran has shown promise in diagnosing IA in a breath test (107). The ability to detect these metabolites using mass spectrometry may enable larger studies of their clinical utility (108), but to date, none of these tests is available commercially.

MASS SPECTROMETRY

Matrix-assisted laser desorption ionization-time of flight (MALDI-TOF) mass spectrometry is increasingly used for the identification of both yeast and mould cultures after recovery on solid media (109, 110). However, the requirement to grow the organisms on solid media introduces a delay, and the ability to identify fungi directly in the original clinical sample is desirable. The presence of proteins and hemoglobin in blood cultures can interfere with the spectra produced and confuse the identification obtained (111). Several groups have developed methods for direct detection, but with varying success rates (112, 113), and several of the studies used simulated blood cultures (114, 115), which obviously differ significantly from those obtained in clinical practice. Recently, a large two-center study with 346 positive yeast blood cultures found that direct MALDI-TOF identification yielded correct identifications of 95.9% of C. albicans and 86.5% of non-C. albicans species compared with conventional culture-based methods (116). This suggests that direct detection and identification of many Candida species following incubation of blood cultures is already feasible and may become the standard procedure relatively
soon, although large-scale clinical evaluations in different patient groups are still required to confirm this.

NUCLEIC ACID DETECTION

Nucleic acid detection for diagnosis of fungal infection and identification of the etiological agent has been actively pursued since the early 1990s. Use of this modality directly on clinical samples offers numerous theoretical advantages, including the ability to detect organisms that are present in small numbers or that cannot be cultured, the potential for automation, removal of the risks associated with culturing Category 3/Biosafety Level 3 fungi, decreased time for identification of the agent, and the potential to detect antifungal resistance in primary clinical samples (117). Moreover, nucleic acid detection offers the potential to identify pathogens in biopsy samples that have been formalin-fixed and even wax-embedded. However, although there are many published methods (118–120), there is little consensus about the optimal methods for specimen processing, extraction of DNA, target design, and quality control. While many laboratories use “in-house” PCR methods, often with favorable results, these methods may be problematic when transferred between laboratories.

One of the diseases for which molecular detection has been very actively researched is IA. However, several issues are as yet unresolved, such as the correct specimen, the optimal sample volume and frequency of sampling, the best method for DNA extraction, the best target, and what constitutes a “positive” result (121). Sensitivity and specificity vary considerably; for aspergillosis, figures of 88 and 75%, respectively (122), and for candidiasis, 95 and 92%, respectively, have been reported (123). Use of whole blood, rRNA, or P450 multiplex targets and an in vitro PCR detection limit of ≤10 CFU/ml were all associated with improved assay performance for candidiasis (123).

The European Aspergillus PCR Initiative (EAPCRI)/ISHAM (International Society for Human and Animal Mycology) working group has attempted to address some of these areas and to define a set of standard recommendations for diagnostic PCR for IA rather than a standard PCR assay. By performing various multicenter, multinational studies to evaluate each of the variables, they have suggested standardized conditions that should be used for PCR diagnosis of aspergillosis (124). These include using serum as the sample, using sample volumes of ≥0.5 ml, using an elution volume of <100 μl, and including various internal controls for each assay.

Some commercially available PCR assays are on the market, including Septifast by Roche (Roche Diagnostics, Indianapolis, IN), which is able to detect several species of Candida and A. fumigatus, and the MycAssay by Myconostica (Myconostica, Cambridge, UK) for diagnosis of IA. Septifast and MycAssay Aspergillus are CE-marked. Septifast has limited sensitivity and specificity and does not look promising for fungal infections. The MycAssay Aspergillus has also been evaluated in several studies in patients in intensive care units (ICUs) (127, 128) and in high-risk hematology patients (129). The assay can be used with serum as a screening test or with BAL as a diagnostic test (http://www.myconostica.co.uk/aspergillus). In the setting of hematopoietic patients, the sensitivity ranged from 50 to 80% and the specificity from 90.5 to 100%, and the authors concluded that its performance was similar to the GM assay (129). In the ICU setting, the sensitivity was higher (86.7 to 100%), and specificities of 87.6 to 92.9% (127) were reported, with increased sensitivity when multiple samples were examined (128). The MycAssay for Pneumocystis has also been reported to have a sensitivity and specificity of 100% in BAL in a recent comparative study (130).

The detection of other fungal infections by nucleic acid detection is still largely research-based, although some studies have been promising. A new test, the T2Candida test, has also shown promise in detecting Candida in whole blood and is currently undergoing evaluation in a clinical trial (131). Although detection of invasive fungal infection remains a significant challenge, the use of nucleic acid-based detection does have potential, and further evaluation in large, clearly defined populations is required.

116. Direct Detection and Identification of Fungi ■ 1983

Yeast taxonomy is continually evolving, and yeasts are currently being placed into taxonomic categories using DNA sequencing and phylogenetic analysis (see chapter 113). Taxonomic analysis has recently delineated "cryptic species" or "species complexes," groups of organisms that are phenotypically and morphologically indistinguishable but can be separated based on DNA sequencing analysis at particular target sequences. In some cases, each member of a species complex has been given a separate species name, such as Candida metapsilosis, Candida orthopsilosis, and Candida parapsilosis. In other cases, the species have not been formally separated. Kurtzman and Robnett (1) and Fell (2) have provided guidance on the phylogenetic relationships among ascomycetous and basidiomycetous yeast, respectively, but there are still no formal rules for the degree of DNA sequence concordance necessary for two isolates to be considered identical or different species.

A major recent taxonomic development that will affect the clinical community is the end of "one fungus–two names," the practice of assigning separate names to the anamorph (asexual) and teleomorph (sexual) names of an organism. The use of DNA-based methods for identifying organisms rather than the demonstration of sexual structures has brought an end to this practice. Although the International Botanical Congress, the nomenclature authority for fungi, has not yet defined formal nomenclature rules, it appears that the correct name for a given organism will be the earliest name published according to the rules of legitimacy, and organisms previously designated with two names should have the earliest name considered legitimate and valid (3). Input from the clinical community will be required to determine the name to be retained (discussed in more detail in reference 4).

The laboratorian should be familiar with both anamorph and teleomorph names for organisms. Historically, the teleomorph name has been used for an organism when appropriate sexual structures (e.g., asci, ascospores) are present. The teleomorph name is also given preference in some DNA sequence databases. The anamorph name is used when a sexual stage cannot be demonstrated or does not occur. Generally, the anamorphic state is the one recovered in the clinical laboratory. Lists of valid anamorph and teleomorph names can be found at www.mycobank.org. Recent taxonomy changes have also been reviewed (5).

Ascomycetous Yeasts

Genus Blastoschizomyces

Blastoschizomyces capitatus is a taxon derived from the combination of the obsolete taxa Blastoschizomyces pseudotrichosporon and Trichosporon capitatum (6). A synonymous name is Saprobacte capitata. The teleomorph is Magnusomyces capitatus (7). Older names for this fungus are Geotrichum capitatum, Trichosporon capitatum (anamorph), and Dipodascus capitatus (teleomorph).

Genus Candida

The heterogeneous genus Candida currently belongs to the order Saccharomycetales within the ascomycetes. The genus contains approximately 200 species, but phylogenetic advances will certainly result in the remaking of this genus. Due to the uncertainty surrounding its taxonomy, this manual uses anamorph names for members of this genus, with teleomorph names displayed in parentheses, as appropriate.

Candida albicans

Candida albicans remains the major pathogen in this group. A number of species have been merged into Candida albicans, including Candida clauseni and Candida langeronii (8). C. africana is a germ-tube positive, chlamydospore-negative yeast closely related to Candida albicans (9), but its precise taxonomic placement remains uncertain. Recent multilocus sequence typing placed C. stellatoidea type I with C. africana in a group of strains highly distinct from most C. albicans (10), but many authors consider C. africana a biovar of
C. albicans. C. stellatoidea type II has been redefined as a sucrose-negative variant of C. albicans (11, 12). Candida dubliniensis has many phenotypic and genotypic similarities to Candida albicans.

Non-C. albicans Species

Most notable in this group is the designation of species complexes. Candida parapsilosis is now considered a species complex made up of three species: C. parapsilosis, C. orthopsilosis, and C. metapsilosis (13). The newly named genus Meyerozyma includes Candida guilliermondii (teleomorph Meyerozyma guilliermondii) and Candida fermentati (teleomorph Meyerozyma caribbica) (14, 15). The Candida glabrata species complex includes C. glabrata and the closely related but phenotypically indistinguishable Candida bracarensis (16) and C. nivariensis (17). The Candida rugosa species complex includes the species C. rugosa, C. pseudorugosa, C. pararugosa, and C. neoergasa. C. pseudorugosa could be differentiated from C. rugosa by utilization of xylose, glycerol, and sorbitol, and the additional utilization of ribitol differentiated C. neoergasa (18). Other species that are frequently reported using their teleomorph names (in parentheses) include Candida efferi (Trichosporon escheri), Candida famata (Debaryomyces hansenii), Candida guilliermondii var. membranifaciens (Kodamaea ohmeri), Candida kefyr (Kluvyeromyces marxianus), Candida krusei (Pichia kudriavzevii), Candida lipolytica (Yarrowia lipolytica), Candida lusitaniae (Claviscopora lusitaniae), Candida pelliculosa (Wickerhamomyces anomalous), and Candida utilis (Lindnera jadinii). Candida norvegensis and C. zeylanoides have no known teleomorph. These nomenclature changes resulted from a variety of taxonomic reassignments. For example, in the genus Pichia, the number of species was reduced from more than 100 to about 20 (19).

Minor species known from single case reports include the species Candida aaseri and C. pseudoaaseri, which are close genetic relatives (20). Candida subhashii is genetically most closely related to the C. parapsilosis species complex, C. tropicalis, C. albicans, and C. dubliniensis (21). Candida aeriis was originally misidentified as Candida haemulonii and shares a phylogenetic relationship with this species (22).

■ Genus Saccharomyces

Although the wine-making industry has spent considerable effort investigating the taxonomy of the genusSaccharomyces, the single medically relevant species is Saccharomyces cerevisiae. The former species S. boulardii has been placed into synonymy with S. cerevisiae.

Basidiomycetous Yeasts

■ Genus Cryptococcus

A number of phylogenetic studies have resulted in the designation of Cryptococcus neoforms and C. gattii as separate species (23). Five serotypes have been recognized within these two species. Serotype A was proposed by some as C. neoforms var. grubii, and by others as the distinct species C. grubii. Its species status is still unresolved. Serotype D was recognized as C. neoforms var. neoforms. The A/D serotype was recognized as an intervarietal grubii/neoforms hybrid. Serotypes B and C were recognized as the distinct species C. gattii. Serotypes A and D were found to produce the teleomorphic state Filobasidella neoforms, and serotypes B and C produce the teleomorph originally named Filobasidella bacillifera.

Several non-C. neoforms species have been described as agents of human infection, including C. adeliensis, C. albicans, C. curvatus, C. flavescens, and C. laurentii. C. uniguttulatus is sometimes described using its teleomorph Filobasidium uniguttulatum.

■ Genus Malassezia

Fourteen Malassezia species have been isolated from human and animal skin. The species most commonly seen in the clinical laboratory include M. furfur, M. globosa, and M. pachydermatis (24). Malassezia species have a basidiomycetous affiliation within the sub-phylum Ustilaginomycotina (2, 24). Species may be distinguished using a variety of methods, but DNA sequencing remains the most reliable.

■ Genus Pseudozyma

At least 20 Pseudozyma species are recognized, most of which are environmental organisms. This genus is classified in the family Ustilaginaceae, and its name is a close relative of Ustilago maydis and other smut fungi. The major human pathogens are Pseudozyma aphidis, P. antarctica, P. paramartica, and P. thailandica.

■ Genus Rhodotorula

Although more than 60 species of Rhodotorula are listed in the Mycobank database, the major clinically relevant species are Rhodotorula mucilaginosa, R. minutus, and R. glutinis.

■ Genus Sporobolomyces

Sporobolomyces are basidiomycetous yeasts that are environmental organisms. Three species have been isolated from human infection: S. roseus, S. holstii, and S. salmonicolor, the latter two species having the teleomorphs Sporidiobolus johnsonii (homothallic) and Sporidiobolus salmonicolor (heterothallic), respectively.

■ Genus Trichosporon

Although 37 valid species are listed in the Mycobank database at this writing, most systemic human infections are caused by one of a smaller number of species: T. asahii, T. asteroides, T. cutaneum, T. dermatis, T. inquin, T. jirovecii, T. loubieri, T. mucoides, T. mycotoridianus, and T. ovoides (25). The name T. beigelii is an invalid name and is no longer used.

DESCRIPTION OF THE AGENTS

Yeasts are unicellular, eukaryotic, budding cells, generally round to oval, or, less often, elongate or irregular in shape. They multiply principally by the production of blastoconidia (buds), such that a typical medically important yeast is composed of a progenitor cell with one or more attached progeny. When blastoconidia are produced one from the other in a linear fashion without separating, a structure termed a pseudohypha is formed. Under certain circumstances such as growth under reduced oxygen tension, some yeasts may produce true septate hyphae.

Cultures of yeasts are moist, creamy, or glabrous to membranous in texture. Several produce a capsule that makes the colony mucoid. With rare exceptions, aerial hyphae are not produced. Colonies may be hyaline, brighty colored,
or darkly pigmented due to the presence of melanins. The latter group, referred to as phaseoid fungi and belonging to the class Eurotiales, is discussed in chapter 124; also, dimorphic fungal pathogens possessing a yeast phase in tissue are discussed in separate chapters.

Yeasts are generally identified by observing the macroscopic and microscopic features mentioned above. In the routine laboratory, biochemical tests in the forms of manual kits or automated instruments are used to obtain a species identification. However, for some organisms, this phenotypic identification may be of low certainty. These isolates may represent separate species not defined by the phenotypic database used by the test instrument. Furthermore, biochemical and morphologic tests can be used successfully to place an unknown organism within a species complex but may not be able to identify the particular species within that complex to which the isolate belongs. Molecular methods (DNA- or MALDI-matrix assisted laser desorption ionization-based) are usually required for this purpose (discussed below).

Ascomycetous Yeasts

- **Genus Blastochizomyces**
  Macroscopically, colonies are glabrous with radiating edges, white to cream-colored, and shiny. Microscopically, isolates produce true hyphae, pseudohyphae, and annelloconidia resembling arthroconidia (Fig. 1f). Based on morphological features alone, B. capsatus can be difficult to separate from *Trichosporon* spp. and physiological tests are needed. B. capsatus is nonfermentative and can be separated from *Trichosporon* spp. by growth on Sabouraud glucose agar at 45°C, on cycloheximide-containing agar at room temperature, and failure to hydrolyze urea.

- **Magnusiomyces capitatus**, the teleomorph of Blastochizomyces capsatus, is heterothallic, and asci are round to ellipsoidal, containing hyaline ellipsoidal ascospores. Only glucose, galactose, glycerol, D, L-lactate, and succinate assimilation tests are positive; hyphae, arthroconidia, and clavate conidia with truncate bases may be seen. The organism grows at 37°C.

- **Genus Candida and Its Telemorphs**
  Blastocandia of Candida spp. vary in shape, from round to oval to elongate. Occasional initial isolates, especially from patients receiving antimicrobial agents, may be highly pleomorphic. Asexual reproduction is by multilateral budding, and true mycelium may be present. Several species of Candida, most notably *C. albicans*, are diploid (26).

  Appearance of pseudohyphae and attachment of blastoconidia are important characteristics to observe when identifying Candida spp. (Fig. 1). They illustrate these morphologic features and other characteristics of the most common clinical species. Observation of germ tubes and chlamydoconidia is also helpful in identifying *C. albicans*. Growth on fungal media can be detected as early as 24 hours; however, colonies usually are visible in 48 to 72 hours as white to cream colored or tan. They are creamy in texture and may become more membranous and convoluted with age. Occasionally, initially isolates of *C. albicans* glucose agar are wrinkled or rugose but revert to smooth colonies on subculture. In our experience, many isolates of *C. albicans* produce “colonies with feet” (i.e., colonies with short marginal extensions) on blood agar, while most other yeasts do not, with the exception that this might be observed in 25% of isolates of *C. tropicalis* and *C. krusei* (27). These colonies should not be used to perform germ tube tests because hyphal/pseudohyphal cells will be present in the inoculum.

Colonies of *C. krusei* tend to spread radially on Sabouraud dextrose agar and blood agar, which can be a useful clue to the identification of the organism. Most Candida spp. grow well aerobically at 25 to 30°C, and many grow at 37°C or above. A reddish colony variant of *C. glabrata*, which would otherwise have been confused with *Rhodotorula*, has been described (28). Bile-dependent strains of *C. glabrata* have also been isolated from urine (29). These isolates either do not grow on routine media or appear as pinpoint colonies on MacConkey agar containing bile. *Candida nivariensis* can be distinguished from the closely related *C. glabrata* by its inability to assimilate trehalose. Although *C. nivariensis* was originally considered less susceptible to azoles and flucytosine compared with *C. glabrata*, this difference has been questioned (30, 31). *Candida bracarensis* also resembles *C. glabrata*, but it produces a different color on CHROMagar and can ferment trehalose (16, 17).

Distinguishing *C. albicans* from *C. dubliniensis* can be important, especially if the patient has been exposed to fluconazole (32–34). Several single tests have been suggested to help differentiate these two species from each other. These include: growth at 45°C (positive for *C. albicans*), reduction of 2,3,5-triphenyltetrazolium chloride (positive for *C. dubliniensis*), production of a dark green color on CHROMagar (C. dubliniensis), production of β-glucosidase (C. albicans), rough colony formation on bird seed (thistle seed, niger seed) agar (C. dubliniensis), and abundant chlamydoconidia on Staib agar (C. dubliniensis) (34, 35). These tests are generally not rapid and are not definitive at separating these species (e.g., some isolates of *C. albicans* do not grow at 45°C). Other differential agar media have been suggested (34). An agglutination test has been developed that distinguishes between these two species. The Bichro-Dubli test (Fumouze Diagnostics, France) identified eight isolates of *C. dubliniensis* among 229 isolates recorded as *C. albicans* on the basis of their CHROMagar color (36). Molecular testing is required to obtain a definitive identification (34).

There is evidence that *C. africana* (C. albicans var. africana) is often misidentified as *C. albicans* on the Vitek 2 ID-YST system (37). This species is germ-tube positive but chlamydoconidegative, slower to grow than *C. albicans*, and unable to assimilate N-acetyl glucosamine, trehalose, and lactate (9).

*Candida famata* (teleomorph Debaromyces Hansenii) may be grayish-white to yellowish in culture, soft, shiny or dull, smooth or wrinkled. Budding yeasts and, rarely, pseudohyphae may be seen. Conjugation between mother cell and bud occurs, and asc containing one to four round or oval warty ascospores are formed. Fermentation reactions are variable; urease is negative, nitrate is negative, inositol is negative, and the maximum growth temperature is 35°C. However, growth at 37°C is not a reliable characteristic to distinguish the closely related *D. hansenii* from *D. fabryi*, while riboflavin production is more specific to *D. fabryi* and *D. subglobosus* (teleomorph of Candida famata var. flaveri) (38). *C. famata* is often misidentified as *Candida guilliermondii* (teleomorph Meyerozyma guilliermondii), but these species can be distinguished by the assimilation of DL-lactate and lack of pseudohyphal formation in *C. famata* and the reverse for *C. guilliermondii*, although the production of pseudohyphae may not occur in all *C. guilliermondii* strains (39).

*Candida lipolytica* (teleomorph Yarrowia lipolytica) is infrequently isolated, although it appears to be an emerging pathogen. It is urease positive, and isolates vary in their susceptibility to amphotericin B, fluconazole, itraconazole, and caspofungin. *C. lusitaniae* cells are oval or elongated, multilateral budding occurs on a narrow base, and pseudohyphae are produced. Colonies are white to cream, smooth, shiny or, occasionally, dull. The
FIGURE 1  Morphological features of some yeast and yeast-like organisms on cornmeal agar at 24 to 48 hours and ambient temperature. (a) *Candida krusei*: extremely elongated, rarely branched pseudohyphae; few blastoconidia. (b) *Candida tropicalis*: blastoconidia formed at septa and between septa. doi:10.1128/9781555817381.ch117.f1
organism is heterothallic, and conjugation of opposite mating types produces ascii that quickly disintegrate, releasing one or two smooth clavate ascospores. Growth occurs at 42°C. Fermentation reactions are variable, but C. lusitaniae grow on a variety of sugars, including sucrose, but not on mannitol or inositol. Nitrate and urease are negative.

Individual species of Candida with teleomorphs in Pichia, Kodamaea, Meyerozyma, and Wickerhamomyces (formerly Pichia species) are either homothallic or heterothallic. Candida pelliculosa (teleomorph W. anomalus) is heterothallic, but the sporogenous diploid form occurs naturally and is the one usually recovered from clinical specimens. These diploid cells convert to form asci, which disintegrate to reveal one to four hat- or Saturn-shaped ascospores (Fig. 2a). Variations in colony morphology may cause confusion with Cryptococcus and Candida spp. Texture may be smooth, wrinkled, and color may be white, cream, or tan. Microscopically, multilateral budding cells are observed; yeasts and pseudohyphae may be seen. Carbohydrate assimilation and fermentation studies or molecular analysis are needed to identify the individual species, although urease is negative, nitrate is positive, inositol is negative, and growth at 37°C can be variable.

Genus Saccharomyces
Saccharomyces cerevisiae is the most common species of this genus recovered in the clinical laboratory. Multilateral budding yeast cells are round to oval, and short rudimentary (occasionally well-developed) pseudohyphae may be formed. Ascospore production can be enhanced easily by growing the yeast on Fowell’s acetate agar (see chapter 115) for two to five days at room temperature. Ascii contain one to four round, smooth ascospores (Fig. 2c). Other physiologic properties are listed in Table 1. Assimilation of raffinose by S. cerevisiae is noteworthy. Very few yeasts encountered in the clinical laboratory utilize this carbon source.

Basidiomycetous Yeasts

Genus Cryptococcus

Cryptococcus species are round to somewhat oval yeast-like fungi ranging greatly in size, from 3.5 to 8 μm or more in diameter, with a single bud and a narrow neck between the parent and daughter cell (Fig. 3). Unusually large yeast cells (up to 60 μm) have been observed, and this size appears to be associated with higher incubation temperatures (40). Occasionally, several buds are seen; rarely, pseudohyphae are observed. The cell wall is quite fragile, and it is not unusual to find collapsed or crescent-shaped cells, especially in stained tissue sections. Cells are characterized by the presence of a polysaccharide (galactoolomannan) capsule varying from a wide halo to a nearly undetectable, lighter zone around the cells, depending on...
the strain and the medium used. Colonies typically are mucoid due to the presence of capsular material, become dry and dullyer with age, and exhibit a wide range of color (cream, tan, pink, yellow) that may darken with age. Strains possessing only a slight capsule may appear similar to colonies of Candida.

Standard laboratory tests do not differentiate among the five serotypes of C. neoformans and C. gattii. However, canavanine-glycine-bromthymol blue (CGB) agar has been recommended for separating serotypes A and D from serotypes B and C (41, 42).

All members of the genus produce urease, utilize various carbohydrates, and are nonfermentative aerobes. Separation of species is based on assimilation of various carbohydrates (41), with C. laurentii being one of the slower-growing species. Colonies are cream to beige in color, smooth to deeply folded, and have a brittle texture that is frequently difficult to suspend.

Cryptococcus neoformans is distinguished microscopically from other yeasts by the formation of a prominent monopolar bud scar or collarette resulting from the continued formation of daughter cells at that site (Fig. 2d). These structures are absent from C. glabrata, which could otherwise be confused with Malassezia species due to its small size and typical unipolar budding. Symplodal budding has been observed in cultures of M. sympodialis and M. japonica. The species vary in shape from spherical to oval or elongated, have thick cell walls, and range in length from 1.5 μm to 8 μm. Identification of the individual species is not routinely attempted but can be achieved based on morphology; utilization of certain lipids, including Tween 20, 40, and 80 and cremophor (castor oil); and reactions with esculin and catalase (24, 45) (Table 2). Organisms that are identified as Candida lipolytica (glucose, glycerol, and sorbitol positive) with the API 20C AUX (bioMerieux SA, Marcy l’Etoile, France) may actually be M. pachydermatis (24). In this case, morphology is helpful.

Genus Malassezia

Most species require lipid for growth; only M. pachydermatis can grow independently of lipid supplementation of the media. Van Abbe (43) and Leeming and Notman (44) have designed media optimal for the growth and isolation of all of the Malassezia spp. (see chapter 115 for recipes). These media are not commercially available, and the alternative of overlaying Sabouraud glucose agar with a few drops of sterile olive oil has been used, but some of the more fastidious species do not survive on this medium (24, 45). The inoculated media should be incubated aerobically at 32 to 35°C in a moist atmosphere for up to 2 weeks to permit development of the slower-growing species. Colonies are cream to beige in color, smooth to deeply folded, and have a brittle texture that is frequently difficult to suspend.

Malassezia is distinguished microscopically from other yeasts by the formation of a prominent monopolar bud scar or collarette resulting from the continued formation of daughter cells at that site (Fig. 2d). These structures are absent from C. glabrata, which could otherwise be confused with Malassezia species due to its small size and typical unipolar budding. Symplodal budding has been observed in cultures of M. sympodialis and M. japonica. The species vary in shape from spherical to oval or elongated, have thick cell walls, and range in length from 1.5 μm to 8 μm. Identification of the individual species is not routinely attempted but can be achieved based on morphology; utilization of certain lipids, including Tween 20, 40, and 80 and cremophor (castor oil); and reactions with esculin and catalase (24, 45) (Table 2). Organisms that are identified as Candida lipolytica (glucose, glycerol, and sorbitol positive) with the API 20C AUX (bioMerieux SA, Marcy l’Etoile, France) may actually be M. pachydermatis (24). In this case, morphology is helpful.

Genus Pseudoxysma

Members of the genus Pseudoxysma are basidiomycetous plant pathogens and are usually found in the environment. They

form moist, beige to tan, wrinkled colonies on routine media. 
P. aphidis forms rough green colonies on CHROMagar Candida medium after 48 hours of incubation at 37°C. Growth is inhibited on cycloheximide-containing media. Microscopically, they demonstrate fusiform, spindle-shaped blastoconidia. The germ tube test is negative, and chlamydospores are not formed, although true hyphae may be seen on morphology agars. Isolates hydrolyze urea and assimilate myo-inositol and L-glucuronate (46). Commercial assimilation tests may give inconclusive results due to the absence of this genus from their databases.

**Genus Rhodotorula**

Rhodotorula spp. share many similar physiologic and morphologic properties with Cryptococcus spp. Both are round to oval-shaped, multilateral budding yeasts with capsules, produce urease, and fail to ferment carbohydrates. Rhodotorula spp. differ from cryptococci in their inability to assimilate inositol and their obvious carotenoid pigment. When a capsule is present, it is typically small, unlike C. neoformans. The most common pathogens are R. mucilaginosa and R. glutinis. R. mucilaginosa can be distinguished from R. glutinis by nitrate assimilation, as the former is negative. This is a useful additional test, as occasionally, commercial kits fail by nitrate assimilation, as the former is negative. This is a useful additional test, as occasionally, commercial kits fail to distinguish these species (47).

**Genus Sporobolomyces**

Colonies are soft and shades of salmon pink. Budding oval to ellipsoidal yeasts, pseudohyphae, and ballistoconidia on large sterigmata may be seen. When ballistoconidia are ejected, they can be found on the inside of the lid of the Petri dish. Fermentation is absent and assimilation variable, with sucrose positive, urease positive, nitrate positive, and inositol negative; growth at 37°C is variable.

**Genus Trichosporon**

Trichosporon yeasts grow easily on standard mycological laboratory media, do not ferment carbohydrates, can assimilate various complex sugars, and are urease positive. Colonies form usually within a week on solid media and are cream colored and smooth. They may become dry, moist, shiny, folded, cerebriform, elevated, with or without marginal zones with age. They produce blastoconidia of various shapes, well-developed hyphae, pseudohyphae, and arthroconidia (Fig. 11). T. loubieri also produces one- and two-celled giant cells (48), while T. mycotoxinivorans produces giant cells with as many as eight cells, depending on the growth medium (Hazen, Moore, Padgett, unpublished observation). In cases in which a Trichosporon isolate produces only a few blastoconidia, differentiation from Geotrichum spp. may be difficult. Incubation of malt extract broth at room temperature will encourage blastoconidia production in Trichosporon spp., usually within 48 to 72 hours. These morphological and physiological characteristics have been used to distinguish between the species in the laboratory (25, 49) (Table 3).

### Epidemiology and Transmission

Medically important yeasts are found on humans and warm-blooded animals and in the environments they inhabit (reviewed in reference 26). Some yeasts, such as Candida albicans, Candida glabrata, and most likely Candida dubliniensis, appear to be obligatory saprobes of humans and some warm-blooded animals. Analysis of the oral mycobiome suggests that just three fungi, C. albicans, Cladosporium cladosporioides, and S. cerevisiae, colonize more than 25% of healthy adults (50). Environmental sampling of foods, plants, potable water, and juices (pasteurized and unpasteurized) have revealed an amazing array of yeast species known as opportunistic pathogens. In all cases, the presence of these yeasts could be attributed to direct and indirect warm-blooded animal contamination. For example, Arias et al. (51) noted the presence of C. parapsilosis, C. tropicalis, C. lusitaniae, C. zeylanoides and several other yeast species in single-strength orange juice that had been pasteurized but subsequently contaminated. These observations make clear that immunocompromised patients are repeatedly exposed to potential yeast pathogens other than those residing as part of their normal microbiota, and care should be exercised in preparing foods and in monitoring the level of contamination associated with devices or creams that may be applied to the patient (52, 53). Parenteral nutrition fluids and devices are particularly prone to contamination with yeasts, espe-
cially C. parapsilosis (54). It is also noteworthy that the hospital environment can contribute to the development of colonization with Candida species as well as facilitate replacement of colonizing less virulent species with more virulent species (55).

Person-to-person transmission has a negligible impact on the incidence of disease, except in nosocomial outbreaks in which hands or fomites are often the source. Invasive yeast infections are associated with opportunism; thus, the yeasts causing disease must be present when the conditions are such that disease can be initiated. Several studies have shown that transmission of yeasts through sexual contact (including oral) does occur, but establishment of the transferred organisms in the recipient is affected by a variety of factors, most notably the recipient’s current normal microbiota, immunological status, and antifungal status (56, 57).

■ Genus Blastoschizomyces

This environmental yeast is usually found in climates with hot, dry summers and mild, wet winters. Most infections have been reported from Southern Europe, particularly in Italy, Spain, and France below 44° northern latitude. However, recently, five cases of disseminated infection have been reported from central Switzerland: three from leukemia patients, one renal-pancreas transplant, and one continuous ambulatory dialysis patient (58). The authors propose that this could reflect changes in global temperatures and movement of people from areas of endemicity.

■ Genus Candida

Candida species are ubiquitous yeasts, being found on many plants and as normal flora of the alimentary tract of mammals and mucocutaneous membranes of humans (26). Essentially, all areas of the gastrointestinal (GI) tract of humans can harbor Candida. The most commonly isolated species (50 to 70% of yeast isolates) from the GI tract of humans is C. albicans, followed by C. tropicalis, C. parapsilosis, and C. glabrata.

Candidemia is the third or fourth most common cause of hospital-acquired bloodstream infection in the United States and much of the rest of the developed world and accounts for more than half of all episodes of sepsis in non-neutropenic patients in an intensive care unit (ICU) or surgical ward (59, 60). Most candidemia is caused by one of five species: Candida albicans, C. tropicalis, C. parapsilosis, C. glabrata, or C. krusei, although the proportions of each species vary in different countries and different patient populations around the world. In Latin America, C. albicans (37%), C. parapsilosis (26%), and C. tropicalis (17%) were the leading agents (61). The species distribution in Asian countries, with a high proportion of C. tropicalis, is closer to that of Latin America (62, 63). Very few studies from Africa exist (64). In the United States, the implementation of stringent protocols for the placement of central line catheters has contributed enormously to decreases in the prevalence of candidemia in many institutions (65). However, the proportion of candidemia caused by non-albicans species, particularly C. glabrata, is rising in the United States. The PATH (Prospective Antifungal Therapy) Alliance registry reported results from more than 3,000 patients from 2004 to 2008, showing that the proportion of candidemia caused by non-albicans Candida species (58%) was higher than that caused by C. albicans (42%). C. glabrata candidemia was the highest caused by a non-albicans species, at 26.7% (66).

It is likely that the increase in non-C. albicans infections is linked to changes in the populations at risk.

Pfaller and Diekema (60) demonstrated that older adults were more likely to be infected with C. glabrata than children, and associated risk factors were patient age, severity of underlying disease, use of broad-spectrum antibiotics, central venous catheters, and length of stay in the ICU; with the link to the use of fluconazole only strong in cancer centers. C. parapsilosis has a greater incidence of bloodstream infections in children than in adults (60), but this organism is a known pathogen of the young (52).

C. africana was reported as a new cause of vaginitis in 2009 (37), with isolates identified from Africa, Spain, and Italy. The organism was also associated with an uncomplicated urinary tract infection in the United States (Hazen KC, Byrne T, Regi S, Poultier M, Mathers AJ, 2013, Isolation and description of Candida africana in the United States, Abstr 53rd Intersci Conf Antimicrob Agents Chemother, abstr M-1382 [American Society for Microbiology, Washington, DC]), and its presence in genital specimens from patients in the United Kingdom has also been confirmed (67).

■ Genus Cryptococcus

C. neoformans affects immunocompromised hosts worldwide with var. grubii (serotype A) being the most commonly isolated type, although var. neoformans (serotype D) is more commonly isolated in Europe (23). C. gattii predominantly affects immunocompetent hosts in endemic areas, although approximately 10% of AIDS cases in Botswana and parts of sub-Saharan Africa are infected with this species (68). C. neoformans was first detected in the environment in the late 19th Century, when Sanfelice recovered the yeast from peach juice. Since then, however, C. neoformans var. grubii and C. neoformans var. neoformans have been most frequently associated with pigeon (and other bird) droppings and soils contaminated with these droppings. The yeast usually is not found in fresh droppings but is most evident in bird excreta that have accumulated over long periods of time on window ledges, vacant buildings, and other roosting sites (68).

The environmental habitat of C. gattii was originally identified as being the gum tree, Eucalyptus camaldulensis; however, a number of other trees have been indicated as sources. C. gattii has been reported from subtropical areas and from temperate areas of Europe, Australia, Papua New Guinea, New Zealand, British Columbia, Vancouver Island in Canada, and the Pacific Northwest and Southeast United States (68–70).

CLINICAL SIGNIFICANCE

■ Genus Blastoschizomyces

This organism is recognized as an emerging cause of invasive fungal disease in leukemic patients (58, 71, 72), continuous ambulatory dialysis (58), endocarditis (73), spondylositis, and osteomyelitis (74). It is widely distributed in nature, has been recovered as normal skin flora and from the gastrointestinal tract, and has been associated with onychomycosis (75). Disseminated disease, which is usually diagnosed by blood culture, is often associated with immunosuppressive conditions (76), in particular neutropenia. Mortality from invasive disease is high in neutropenic patients, and survival is associated with neutrophil count recovery.
Genus Candida

Candida spp. can be present in clinical specimens as a result of environmental contamination, colonization, or actual disease processes. An accurate diagnosis requires proper handling of clinical material, ensuring that specimens reach the laboratory in a timely fashion and have been taken and stored in an appropriate manner. Candida spp. that are normal flora can invade tissue and produce life-threatening pathology in patients whose immune defenses have been altered by disease or iatrogenic intervention.

C. albicans is the most common species isolated from nearly all forms of candidiasis (26). Contributing to its high association with disease is its high prevalence in the normal population, as described above. In addition, C. albicans appears to possess a number of virulence determinants that may promote successful parasitism, which includes protease and adhesins, surface integrins, and phenotypic switching (26, 77, 78).

Only C. tropicalis appears more virulent than C. albicans when present in patients with leukemia or lymphoreticular malignant disease (79). Other medically important Candida spp. include C. atemulata, C. ciferri, C. dubliniensis, C. glabrata, C. guillermondii, C. haemulonii, C. kefyr, C. krusei, C. lipolytica, C. lusitaniae, C. noregenensis, C. parapsilosis, C. pulcherrima, C. rugosa, C. utilis, C. viswanathii, and C. zeylanoides (5, 26, 80). This list is not exclusive, as other rare agents will certainly be added in the future. C. lipolytica, C. lusitaniae, and C. krusei have been isolated from cases of fungemia. Fluconazole is one of the primary drugs used to treat candidiasis, but C. krusei is inherently resistant, while isolates of C. glabrata may vary in susceptibility. Two other fluconazole resistant species, C. inopsica and C. noregenensis, are rare agents of candidiasis. C. anseri and C. subshahii have been reported in single case reports as agents of infection. A series of 12 C. auris fungemia cases in India has recently been published (81).

C. glabrata is emerging as a significant pathogen, with a relatively high proportion of strains exhibiting reduced susceptibility to fluconazole. Recently, strains resistant to echinocandin drugs have also been noted (82–84). C. glabrata is regarded as a symbiont of humans and can be isolated routinely from the oral cavity and genitourinary, alimentary, and respiratory tracts of most individuals. As an agent of serious infection, it has been associated with endocarditis (85), meningitis (86), and multifocal, disseminated disease (80, 87). It is recovered often from urine specimens and has been estimated to account for as much as 20% of Candida fungemia cases in India (86). C. glabrata can be associated with underlying conditions such as diabetes, chronic granulomatous disease (103), and chronic granulomatous disease (103). There have been isolated from pigeon droppings (93) and is an emerging opportunistic pathogen that can colonize human skin and has been a cause of fungemia in neonates (98, 99). It has also been associated with catheter-related infections (100–102). Hansenula (Pichia) angusta has been recovered from the mediastinal lymph nodes of a child with chronic granulomatous disease (103). Kodomaea ohmeri has been increasingly reported as an agent of disease in immunocompromised patients (reviewed in 104). There have been a number of reports of human infection caused by Pichia species, several of which have been fully identified only by DNA sequencing, as routine microbiological tests were not conclusive: Hansenula (formerly Pichia) fabianii was recently described as a cause of endocarditis (105) and catheter-related fungemia (106) and P. farinosa, a cause of bloodstream infection in a lymphoma patient (107). Many of these reports describe agents that have since been moved to other genera.

Genus Cryptococcus

Cryptococcus neoformans var. grubii, C. neoformans var. neoformans, and C. gattii are considered the only human pathogens, although C. albidus (108, 109) and a few others, including C. adeliensis and C. zebekistanensis, have, in rare cases, been implicated in disease in severely debilitated individuals.

The clinical presentation in AIDS patients appears to be similar regardless of the species (C. neoformans vs. C. gattii) causing the infection. Initial cryptococcal infection begins by inhalation of the fungus into the lungs, usually followed by hematogenous spread to the brain and meninges. Involvement of the skin, bones, and joints is seen, and C. neoformans is often cultured from the urine of patients with disseminated infection. In nearly 45% of AIDS patients, cryptococcosis was reported as the first AIDS-defining illness. Because none of the presenting signs or symptoms of cryptococcal meningitis (e.g., headache, fever, malaise) are sufficiently characteristic to distinguish it from other infections that occur in patients with AIDS, determining cryptococcal antigen titers and culturing blood and cerebrospinal fluid (CSF) are useful in making a diagnosis (110). In patients without HIV infection, cryptococcosis may occur in association with underlying conditions such as lupus erythematosus, sarcoidosis, leukemia, lymphomas, Cushing’s syndrome, organ transplant, and receipt of tumor necrosis factor (TNF) inhibitors.

Although meningitis is the most common presentation of C. gattii infection in Papua New Guinea and Australia, respiratory disease is the most common presentation in North America (111). Compromised immune status appears to be a significant risk factor for infections with some molecular types of C. gattii (111, 112). In North America, 38%...
Genus Malassezia
These yeasts are isolated from the skin of warm-blooded animals and humans as commensals but can be agents of dermatological diseases. M. sympodialis, M. slooffiae, M. globosa, and M. restricta are the most frequent human colonizers (113–116). The main causative agents of the skin infection pityriasis versicolor are M. globosa, M. sympodialis and, occasionally, M. slooffiae or M. furfur (117–120). Other dermatological diseases, including seborrheic dermatitis and folliculitis, have been associated with Malassezia yeasts, often because there was a clinical response following antifungal therapy with a reduction in yeast numbers. M. restricta, M. globosa, M. furfur, M. sympodialis, and M. obtusa have all been recovered from seborrheic dermatitis patients, and M. restricta and M. globosa have been isolated from folliculitis patients (121). However, because Malassezia may be present on the skin in high numbers and there are no other characteristic features to guide laboratory diagnosis, the exact role of the organisms in these diseases remains unclear. There have been reports of onychomycosis caused by Malassezia species (122–124); however, whether these yeasts are true invaders of nail or secondary colonizers is undecided. In addition, M. furfur and M. pachydermatis have, in rare cases, caused systemic infections, usually of neonates in intensive care units (24, 45).

Genus Pseudozyma
The first description of this genus as a human pathogen came in 2003, when the species Pseudozyma antarctica, P. panantarctica, and P. thailandica were isolated from the blood of three Thai patients (reviewed in reference 125). Two additional cases of fungemia due to P. aphidis were reported from the United States and from India (125). Three new species were recently named as P. alboarmeniaca sp. nov., P. crassa sp. nov., and P. siamensis sp. nov., also isolated from blood of Thai patients (46). Risk factors are similar to those of other less common yeast infections and include neutropenia, cancer chemotherapy, thrombocytopenia, and the presence of indwelling catheters. Although the main manifestation of Pseudozyma infection is fungemia, the organism has also been isolated from brain abscess and pleural fluid associated with pulmonary infection (reviewed in 125).

Genus Rhodotorula
Rhodotorula spp. are normal inhabitants of moist skin and can be recovered from such environmental sources as shower curtains, bathtub grout, and toothbrushes (126). The species known to have caused human infections are R. mucilaginosa, R. glutinis, and R. minuta (80, 126). In rare instances, Rhodotorula spp. have been reported to cause septicemia (127), meningitis (128), systemic infection (129, 130), peritonitis associated with peritoneal dialysis (131), and sepsis related to complications from indwelling central venous catheters (132).

Genus Saccharomyces
Usually thought to be nonpathogenic, Saccharomyces cerevisiae has been reported to cause thrush, vulvovaginitis, empyema, and fungemia (80, 133). Person-to-person contact and exposure to commercial strains associated with health foods and baking may contribute to the ability of the organisms to colonize and infect human hosts (134).

Genus Sporobolomyces
Sporobolomyces are environmental organisms, some of which have been linked to human diseases, including dermatitis (135), respiratory disease (136, 137), AIDS (138, 139), endophthalmitis (140), and meningitis (141); reviewed in reference 142. Three species have been isolated from human infection: S. roseus, S. holstii, and S. salmonicolor.

Genus Trichosporon
Yeasts of this genus may be isolated from soil, animals, and humans, but most systemic human infections are usually caused by one of six species: T. asahii, T. asteroides, T. cutaneum, T. inkin, T. mucoides, and T. ovoide. T. loubieri is an apparently rare cause of disseminated trichosporonosis (48, 143). T. japonicum has been isolated from the sputum of a neutropenic child (144), and T. mycotoxinivorans (145) has also been associated with disseminated disease (K. C. Hazen et al., unpublished observation). White piedra is a superficial infection characterized by nodules of approximately 0.5 mm attached to the hair shafts on the head, axilla, or genital area. Infections in the genital area are usually due to T. inkin, and rarely encountered infections of hairs on the head are caused by T. ovoide. T. asteroides and T. cutaneum have been associated with superficial skin lesions, and T. asahii and less often, T. mucoides, is the cause of disseminated infection mainly associated with neutropenic patients with hematological malignancy or receiving immunosuppressive therapy (146). Others at risk for trichosporonosis include patients with AIDS, extensive burns, or intravenous catheters or undergoing corticosteroid treatment or heart valve surgery (25, 147, 148). In addition, T. asahii and T. mucoides are thought to be the major causes of summer-type hypersensitivity pneumonitis in Japan, a condition that results from inhalation of arthroconidia present in the homes of the patients (149).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS
No special practices for collection or transport of specimens from patients with suspected yeast infection need to be followed. Chapter 114 describes standard practices for collection, transport, and storage. However, when specimens are collected and sent to the laboratory, consideration should be given to the possibility that a particular fungus is highly infectious (e.g., Coccidioides species) or has unusual growth requirements (e.g., lipids for Malassezia species). Such information regarding the suspected etiologic agent should be provided to the laboratory in a manner that precedes manipulation of the specimen. Transportation of specimens should be accomplished in less than 2 hours. If a delay is anticipated, specimens should be stored at 4°C. Yeasts can withstand normal refrigeration temperatures.

DIRECT EXAMINATION
The appropriate examination of a clinical specimen is essential before proper processing of the material. In addition, it often aids the laboratorian and the physician to obtain a
preliminary identification and in either ruling in or out certain pathogenic yeasts. Some methods are universal to the preliminary observation of fungi in a specimen (e.g., Gram stain, calcofluor, 20% potassium hydroxide [KOH]). If 20% KOH is used in a preparation, neither India ink nor Gram stain may be added. Chapter 115 describes in more detail various stains and examination procedures used in the mycology laboratory.

**Microscopy**

In performing the microscopic examination of a specimen for yeasts, structures may be observed that may aid in identification (Fig. 4): (i) size and shape of the organism, (ii) morphology of the bud attachment site and number of buds, (iii) presence or absence of a capsule, (iv) thickness of the cell wall, (v) presence of pseudohyphae, (vi) presence of arthroconidia. A great deal of information can be gleaned from careful direct microscopic examination of an appropriately prepared and stained specimen.

KOH

Wet mounts prepared in 10 to 30% KOH solution may be used to distinguish fungi in mucoid secretions or in skin, hair, or nail. The KOH digests the proteinaceous material, leaving the fungal elements intact. Gentle warming may speed this process, but care should be taken when using strong concentrations of KOH, because the KOH rapidly crystallizes if overheated or left for prolonged periods before examination. The specimen is prepared by placing an aliquot onto a slide, adding to it a drop of KOH, and placing a coverslip on top. Ensure that enough KOH is present to completely cover the specimen. For skin and nail, the specimen may be gently squashed while removing excess KOH. In these thick materials, this makes visualization of the fungus easier. Hairs should always be viewed without squashing to obtain maximal information about the type of fungal infection. Dimethyl sulfoxide (40% vol/vol in distilled water) may be added to the KOH reagent to facilitate clearing without the need for heating or incubation, but the specimen should be examined quickly. Bubbles can be confused with yeast cells. Budding cells with internal heterogeneous material should be seen in order to enhance confidence that the object is a yeast cell. Round and oval objects lacking buds are common in tissue specimens and could be erroneously identified as yeasts.

The calcofluor stain (Blankophore, Uvitex 2B) fluoresces under filtered UV light to enhance detection of fungus as it binds to chitin in the cell wall, showing as bright green (150). A specimen may be prepared as above; the coverslip is then removed, a drop of calcofluor is added, excess fluid is removed, and the specimen is viewed. Alternatively, a drop of calcofluor can be added at the time of mounting in KOH. However, the stain may fail to penetrate thick nail samples when prepared in this way.

The diagnostic feature of pityriasis versicolor seen by direct microscopic examination of skin scrapings is the presence of short blunt-ended Malassezia hyphae among Malassezia yeasts ("spaghetti and meatballs"). Visualization of Malassezia species can be enhanced by the use of the stain calcofluor white with UV fluorescence.
India Ink

This stain is used to examine specimens of CSF, urine, and other body fluids for the presence of Cryptococcus species. Generally, it is not useful on primary specimens such as sputum or other highly cellular material that do not allow even distribution of the ink. India ink is used to visualize capsules that are transparent by bright field illumination alone, as the ink is excluded from the capsule, showing a clear halo around the yeast. Artifacts such as erythrocytes, lymphocytes, or talc from gloves appear to cause a halo effect; therefore, careful examination for the presence of yeast cells and bud formation is essential. A specimen should be prepared by placing a drop of the centrifuged sediment of a fluid specimen on a slide, adding a drop of Pelikan India ink or nigrosin solution, and placing a coverslip on top. While this method is relatively rapid and is generally satisfactory, a preferred method is to place a coverslip on the specimen and place a drop of ink on the side of the coverslip to allow the ink to diffuse underneath. This provides a gradient of ink which will contain an optimal region to detect a capsule. India ink solution should be replaced regularly as it becomes contaminated, or alternatively, a solution of 10% nigrosin in 10% formalin (using appropriate safety precautions) can be prepared.

Yeast in Tissue Sections

The appearance of fungus in histopathology sections has been reviewed (151). C. neoformans can be distinguished from other nondematous yeasts in fixed tissue by the use of a Fontana-Mason stain, which will detect melanin precursors in the cell wall. Mucicarmine will stain the capsule, which helps to distinguish Cryptococcus spp. from yeasts with similar morphologies. C. neoformans yeast cells in tissue are typically rounder than yeasts of Candida species and tend to vary in size.

Yeasts can be visualized in tissue using Gomori’s silver stain, although they stain blackish and some of the internal detail may be difficult to see. Periodic acid-Schiff (PAS) stain is also useful; fungal material stains reddish.

A variety of methods have been described for the detection and identification of yeast in formalin-fixed tissue blocks using DNA-based technologies (152–154). Although promising, these methods are largely in the experimental stage. The quality and quantity of extracted fungal DNA can be distinguished from other nondematous yeasts in fixed tissue by the use of a Fontana-Mason stain, which will detect melanin precursors in the cell wall. Mucicarmine will stain the capsule, which helps to distinguish Cryptococcus spp. from yeasts with similar morphologies. C. neoformans yeast cells in tissue are typically rounder than yeasts of Candida species and tend to vary in size.

Antigen Detection

Signs and symptoms of invasive yeast infections generally overlap those of bacterial infections, necessitating development of rapid non-culture-based methods for diagnosis. See chapter 116 for a comprehensive review of antigen testing. Non-culture-based tests for discriminating fungal versus bacterial infection and for detection of specific genera have been developed. Of all of these tests, the cryptococcal antigen test has proven the most successful.

The unique composition of the fungal cell wall makes it particularly well suited as a focus for fungal serological tests. Many of the more common pathogenic yeasts contain β-1,3-glucan in the wall. Several commercial kits, the Funigell (Associates of Cape Cod; available in the United States), Fungitek G (Seikagaku Corp.), B-G-Star (Maruhu Nichiru Foods, Inc.), and the Wako test (Wako Pure Chemical Industries), are available for detection of β-1,3-glucan. Repeat testing of patients with negative results is recommended, as single-test positive results provide generally good sensitivities and specificities (155) and repeatedly negative tests have a high negative predictive value. Repeat testing of patients who test positive also improves the specificity of the test (155, 156). A positive test, however, does not provide information about the specific etiology, which is a weakness if tailored antifungal therapy is desired. Cryptococci do not contain β-1,3-glucan, so this test is not positive in patients with cryptococcal infection.

Genus Candida

With the exception of cryptococcal antigen tests for serum and CSF, efforts to develop other genus- or species-specific antigen detection systems have focused primarily on candidemia and disseminated candidiasis. No commercially available tests have been developed for body fluids and tissues other than blood and CSF. Carbohydrate antigens have provided useful targets for several commercial kits for the detection of disseminated candidiasis. Protein antigens have also been investigated. Another antigen, α-arabinitol, has been under investigation for over a decade and has been incorporated into the COBAS FARA II centrifugal autoanalyzer (Roche Diagnostic Systems) (157). While only a limited number of laboratories have evaluated α-arabinitol as a marker for candidiasis, the antigen appears promising. α-Arabinitol levels appear to correlate with therapeutic success (158).

The Platelia Candida Ag test (Bio-Rad) utilizes a monoclonal antibody, EB-CA1, which targets an α-1,2-oligomannoside common among multiple species of Candida. The test has shown reasonable sensitivity and high specificities, although they vary from study to study. Sendid et al. (159) have recommended that both the antigen and the antibody tests (Platelia Candida Ab) be performed to maximize early diagnosis of invasive candidiasis. The specificity of the antigen test can be further enhanced by including a test for a second antigen, β-1,2-oligomannan, which is found in only a limited number of Candida species: C. albicans, C. glabrata, and C. tropicalis (160). C. dubliniensis variably expresses the antigen (161). The Serion ELISA antigen Candida (Institut Virion/Serion GmbH, Würzburg, Germany) is a qualitative and quantitative immunoassay for the detection of Candida antigen in serum or plasma. A corresponding assay, the Serion ELISA classic Candida albicans IgG/IgM/IgA, measures serum antibody directed against C. albicans. These assays were evaluated and compared with the Platelia antigen/antibody assays and β-d-glucan (162). Although the Serion antigen test discriminated between patients with candidiasis and uninfected controls, in this study its discriminatory power was lower than that of the Platelia test. These assays have been available in Europe for some time but are not approved for use in the United States.

The Pastorex Candida (BioRad) and Cand-Tec (Ramco Inc., Stafford, TX) are agglutination tests that detect Candida antigen in human specimens. Their performance has been reviewed recently (163).

Genus Cryptococcus

Detection of cryptococcal antigen (capsular galactosyloligosaccharide) in serum and CSF has been available for over 2 decades and detects both C. neoformans and C. gattii. During this time, commercial tests have evolved to overcome early problems with specificity and sensitivity. The chief problem was false positives due to rheumatoid factor. Once this factor is destroyed, the sensitivity and specificity of the current generation of cryptococcal antigen tests are high. Latex
agglutination-based antigen detection kits include the Cryptococcus Antigen Test (Remel, USA), Cryptococcal Antigen LA System (CALAS; Meridian Bioscience, Inc.), Latex-Cryptococcus Antigen Test (IMMY), Pastorex Crypto Plus (BioRad), the Crypto-LA test (Wampole Laboratories, NJ), and the Eiken Latex test (Eiken, Tokyo, Japan). The PREMIER Cryptococcal Antigen (Meridian) is an enzyme immunoassay (EIA)-based assay, and the newest format is a lateral flow assay (LFA) (IMMY Cryptococcal lateral flow assay, IMMY; ABACUS ALS, Australia). These tests have been recommended as the primary evaluative tool in lieu of an India ink stain for screening CSF in suspected cases of cryptococcal meningitis. This is because the sensitivity of the India ink stain is low.

False-positive tests due to causes other than rheumatoid factor have been observed. These have been associated with trichosporonosis, Capnocytophaga caminorum septicemia, malignancy, Rothia (formerly Stomatococcus) bacteremia, some soaps and disinfectants, and hydroxethyl starch (used in fluid resuscitation) (164–170). Interestingly, the cryptococcal galactoxylomannan contains an epitope that crossreacts with the galactomannan antigen of Aspergillus spp., which is the antigen target of the Platelet Aspergillus assay (171).

Monitoring a decrease in antigen titer as an indicator of effective anticytotoxic therapy has been suggested. However, while the titer may decrease after initiation of therapy in non-HIV patients, it may remain greater than 200 despite microbiological clearance (172). Lu et al. (172) have suggested that a better indicator of successful therapy is the return of CSF glucose, chloride, and leukocyte count to normal limits. Mycologic sterility is also a useful indicator of successful therapy.

**Specific Tests for Invasive Infections Caused by Other Yeasts**

Not surprisingly, little effort has been devoted to develop serologic tests for detection of invasive infections caused by yeasts other than Candida and Cryptococcus species. With the growing awareness of bloodstream infections caused by Trichosporon species, specific serologic tests for their detection may be developed. Before this occurs, a possible strategy is to use the serum cryptococcal antigen test in combination with compatible signs and symptoms and underlying disease to suggest a diagnosis of trichosporonosis.

**Nucleic Acid Detection**

The U.S. Food and Drug Administration has approved several commercially available peptide nucleic acid-fluorescent in situ hybridization (PNA FISH) kits (Advantx, Woburn, MA) for the identification of yeasts directly from positive blood cultures. The probes specifically detect C. albicans, C. glabrata, or C. tropicalis as individual species or detect a yeast species group (e.g., C. albicans and C. parapsilosis fluoresce green with the Yeast Traffic Light PNA FISH kit) in blood cultures by targeting species-specific rRNA sequences. Nucleic acid probes that mimic 26S rRNA are used to hybridize to target rRNA. The probes are also coupled to a fluorophore that is detectable when the probe binds to its target. Several studies have shown that the C. albicans PNA FISH assay is 100% specific (173–175). However, the manufacturer’s package insert notes (and we have observed) that the C. albicans probe can cross-react with C. orthopsilosis. In the most comprehensive study, the test was found to have excellent sensitivity (99%), specificity (100%), positive predictive value (100%), and negative predictive value (99.3%) (175). The test can rapidly (1.5 hours) indicate whether C. albicans is present or not and can thus indicate whether a non-C. albicans yeast is present (173, 174). Other PNA FISH assays are similarly rapid, although recent modifications to the probes and reagents have resulted in a second-generation assay (QuickFISH) that shortens the assay to 30 minutes. The test does not replace subculture because blood cultures may contain mixed species; therefore PNA FISH-positive blood cultures should be subcultured to ensure that no other yeast species is present. C. dubliniensis is not detected with the PNA FISH probe. With this test, laboratories can report whether a positive blood culture with yeast contains C. albicans within a few hours after the culture becomes positive (89).

Most assays for the direct detection of fungal DNA in human body fluids have been directed at diagnosis of invasive candidiasis. White et al. (176) and Lau (177) have reviewed methods for the rapid diagnosis of invasive candidiasis, including PCR-based methods. Avni et al. conducted a meta-analysis of 54 published studies that used whole blood for PCR diagnosis of invasive candidiasis (178) and found that the pooled sensitivity of these assays was 95% and the specificity was 92%. Zhang has recently reviewed molecular approaches for diagnosing fungal infections (179), including candidiasis. He points out that lack of standardization and validation has hindered the acceptance of these tests as diagnostic criteria for fungal infections. Furthermore, clinical outcome and cost-effectiveness data that would be helpful for laboratory decision-making are also largely lacking.

The time required to identify a pathogen could be shortened if more efficient methods of detecting fungal DNA in a specimen were developed. Real-time PCR can detect candidemia much earlier than conventional blood culture, but it does not always detect all cases of systemic infection with all species (180–182). Bennett (183) provides a balanced discussion on the use of this technique, which is likely to be used alongside blood culture protocols while it is developed further.

In Europe, the LightCycler SeptiFast Test M (Roche Diagnostics GmbH) is available to detect five species of Candida and Aspergillus fumigatus DNA in whole blood using broad-range ITS PCR and melting curves. A summary of published studies with the LightCycler SeptiFast Test M is provided in reference 163. Several other commercial tests available in Europe for experimental purposes are described in reference 163. Other assays are described in references 177 and 179. The Lumines xTAG multiplex PCR assay (Lumines Molecular Diagnostics, Ontario, Canada) detects as many as 23 fungi in a single sample. The method uses a microsphere ( bead) suspension array in which the beads each contain an individual probe designed to hybridize to a different amplified fungal DNA sequence. This assay was tested for the detection of Candida species in positive blood culture bottles (184, 185), showing 100% sensitivity and 99% specificity. Microarrays have been tested as diagnostic tools for the detection of invasive fungal infection. Recently, the Prove-it Septis microarray assay (Mobi-diag, Espoo, Finland) was modified to incorporate fungal targets and was found to have a sensitivity of 99% and specificity of 98% in detecting Candida from blood cultures (186). This assay misidentified one C. parapsilosis and C. lusitaniae isolate from 53 isolates of C. albicans, C. glabrata, C. parapsilosis, C. tropicalis, and C. lusitaniae. None of these assays is approved for use in the United States.
The only U.S. FDA-approved DNA probe test is the Affirm VP III Microbial Identification Test (BD), for use in the detection and identification of Candida species, Gardnerella vaginalis, and Trichomonas vaginalis nucleic acid in vaginal fluid specimens from patients with symptoms of vaginitis (187). The Affirm assay was significantly more likely to identify Candida than wet mount of vaginal fluid (11 versus 7%). The T2 Candida panel (T2 Biosystems, Lexington, MA) was recently approved for direct detection of five Candida species in blood samples. T2MR is a magnetic resonance-based system for detection of sepsis agents.

**ISOLATION PROCEDURES**

Processing specimens for fungal recovery is usually performed in conjunction with and as an extension of the processing procedure for recovery of bacteria. The primary difference is the selection of media used for primary plating. The primary processing procedure for recovery of bacteria. The primary processing procedure for recovery of bacteria. The primary processing procedure for recovery of bacteria. The primary processing procedure for recovery of bacteria. The primary processing procedure for recovery of bacteria. The primary processing procedure for recovery of bacteria. The primary processing procedure for recovery of bacteria. The primary processing procedure for recovery of bacteria. The primary processing procedure for recovery of bacteria. The primary processing procedure for recovery of bacteria. The primary processing procedure for recovery of bacteria. The primary processing procedure for recovery of bacteria.

There are, however, yeast infections for which specialized processing steps should be considered. For example, recovery of C. neoformans from blood or bone marrow is enhanced if lysis-centrifugation followed by inoculation onto solid media is used (188). If C. neoformans is suspected from a respiratory specimen, setting up primary media that include a niger seed or related medium will enhance detection.

For some yeasts, a medium supplement may be needed to either enhance or support growth during primary culture. If Malassezia species are suspected, the primary culture plate should be supplemented with an olive oil overlay applied with a swab before inoculation. Malassezia pachydermatis will grow without the overlay, but it is required to grow in the presence of this agent. One processing step that has unproven advantages for isolation of yeasts from sputum specimens is the use of mucolytic agents (N-acetylt-cysteine or Sputolysin).

The appropriate selection of isolation media is essential even though detection of infectious agents using molecular methods is becoming more commonplace in the diagnostic setting. Successful culture is still necessary to perform antifungal susceptibility tests, for preservation in culture collections, and for epidemiological study.

**IDENTIFICATION**

Use of a sound systematic approach to yeast identification is important. With the numerous yeast identification systems available today, most commonly encountered yeast species can be identified easily; however, repeat testing is sometimes necessary, and morphologic characteristics on cornmeal-Tween or similar morphology agars should be mandatory. Isolates that are problematic should be sent for DNA sequence analysis or matrix-assisted laser desorption ionization-time-of-flight mass spectrometry (MALDI-TOF MS) to confirm their identity.

The sections that follow outline the identification tests available, while the previous section on “Description of the Agents” contains the genus-specific detail. This topic has been reviewed (142, 163, 191, 192).

**Macroscopic Characteristics of Yeasts**

Most yeasts grow well (Malassezia species are an exception) on common mycological and bacteriological media. Growth is usually detected in 48 to 72 hours, and subcultures or lab-adapted strains may grow more rapidly. Colonies have a smooth to wrinkled, creamy appearance; some pigment may be observed initially or intensify with age. Heavily encapsulated yeasts give a very moist, mucoid appearance.

The ability of yeasts to grow at 37°C is a very important characteristic. Most pathogenic species grow readily at 25 and 37°C, while saprobes usually fail to grow at the higher temperature. Spiking around the edge of a colony grown in CO₂ is indicative of Candida albicans and has been reported to be more sensitive than germ tube production (193). This feature is the same as the “colonies with feet” described in the Candida section of “Description of the Agents.” Pellicle growth on the surface of liquid media such as Sabouraud glucose broth or malt extract broth has been used in the past to assist with yeast identification. More recent evidence suggests that this characteristic can be variable; however, as an ancillary test, it may be helpful in identifying Candida tropicalis and Candida krusei (194).

**Microscopic Characteristics of Yeasts**

On isolation of a suspected yeast from a clinical specimen, the first examination should be a wet preparation of a colony. This provides an initial clue to the organism’s identity. There are several fungi that produce yeast-like colonies that are not yeasts. Observations should include size and shape

*X Strain variation.
of the yeast, method of bud attachment, and presence or absence of pseudohyphae, true hyphae, or arthroconidia (Table 4). Any round or slightly oval budding yeast with rare or no pseudohyphae seen in this preparation should be examined further for the presence of a capsule.

The same wet preparation used for the initial microscopic examination can be used for an India ink examination for the presence of encapsulated yeasts (Fig. 2) (see previous section). Capsular size cannot be used for identification purposes because this characteristic may be influenced by culture age, media composition, and strain variation. The presence of a capsule does not automatically ensure that the yeast is Cryptococcus neoformans/gattii, as other cryptococci, Rhodotorula spp., and rare Candida spp. will produce capsule-like structures. In practice, any nonpigmented, round, encapsulated yeast recovered from CSF should be considered C. neoformans or C. gattii until proven otherwise.

Purity of Cultures
Before any additional physiologic tests are performed, it is essential to ensure that the culture is pure. A Gram stain of the culture can verify purity, but often, bacterial contamination can be detected during the wet preparation examination. If the culture is mixed with bacteria, the isolate should be inoculated to a blood agar plate or Sabouraud dextrose agar containing antibiotics and individual colonies should be subcultured for purity, or alternatively, treated with hydrochloric acid (Fig. 4). The HCI procedure is performed by inoculating a colony into three tubes of Sabouraud glucose broth (each containing 5 ml). A capillary pipette is used to add 4 drops of 1 N HCl to the first tube, 2 drops to the second tube, and 1 drop to the third tube. After incubation at 25°C for 24 to 48 hours, 0.1 ml of each broth is subcultured onto fresh Sabouraud dextrose agar plates.

More than one yeast species may be recovered from a clinical specimen, especially if the specimen is from a normally nonsterile site (195). In addition, multiple yeast species may be responsible for fungemia episodes. Careful attention to colonial morphology and microscopic characteristics can offer clues to a mixed population. Subculturing individual isolates to additional media can be helpful (195), and the use of a chromogenic medium may delineate the presence of more than one yeast species.

Chromogenic Agars
Presumptive identification of one or two yeast species based on colony characteristics can be obtained with chromogenic agar media (reviewed in references 163 and 192). CHROMagar Candida (CHROMagar France, Paris, France, distributed in the United States by Becton Dickinson/BBL, Sparks, MD) allows differentiation of more than 10 species and is marketed for the presumptive identification of C. albicans, C. tropicalis, and C. krusei. Colony identification is based on the differential release of chromogenic breakdown products from various substrates following exoenzyme activity. It is important to recognize that identifications are presumptive. Evidence suggests that variation in colony appearance occurs among the species (196, 197). The directions of the manufacturer must be strictly followed, as is the case in any rapid test based on exoenzyme activity. Incubation time and temperature significantly affect the colony appearance. The medium is useful for the detection of mixed yeast infections, especially in blood, and for resolving identification problems. Other chromogenic media are now commercially available (see chapter 115 and Table 4). ChromID Candida (bioMérieux) and CandiSelect 4 (Bio-Rad, Marnes La Coquette, France) perform similarly to CHROMagar. No one medium detects all instances of mixed yeast blood cultures (198–200). Approximately 2 to 10% of C. albicans isolates produced white colonies rather than colored colonies on these chromogenic media, strongly supporting the concept that these media provide only a presumptive identification. Brilliance Candida agar (formerly Oxoid chromogenic Candida agar; Thermo Fisher Scientific, Basingstoke, UK) and HiChrome Candida Differential Agar (HiMedia Laboratories, Mumbai, India) have also been introduced recently.

Morphology Studies
While examination of a wet preparation gives a primary indication of the yeast involved, more extensive study of morphology on conmeal-Tween agar, rice agar, PCB (potato carrot bile) agar (Bio-Rad, France) or other similar agars offers the opportunity to correlate morphologic characteristics with results of biochemical testing, as these characteristics form part of the identification code for many commercially available kits. Microscopic examination should reveal the thick-walled chlamydospores of Candida albicans/ Candida dubliniensis; attention should be given to factors such as the size and shape of the pseudohyphae, the arrangement of blastoconidia along the pseudohyphae, and the presence of capsules (Fig. 1 and Table 4).

Germ Tube Test
One of the most valuable and simple tests for the rapid presumptive identification of C. albicans is the germ tube test (Fig. 5a). The test is considered presumptive because not all isolates of C. albicans will be germ tube positive, and false positives may be obtained, especially with C. tropicalis, despite well-trained staff (201). Also, C. dubliniensis is germ tube positive, although most isolates do not form germ tubes in a commercial synthetic germination medium (202). Microscopic observation of the preparation reveals that the short hyphal initials produced by C. albicans are not constricted at the junction of the blastoconidium and germ tube. Candida tropicalis can produce hyphal initials, but the blastoconidia are larger than those of C. albicans, and there is a definite constriction where the hyphal initial joins the blastoconidium (Fig. 5b). In addition to using a known culture of C. albicans as a positive test control, negative controls using C. tropicalis and C. glabrata also should be included. Optimum conditions are obtained by using colonies grown on Sabouraud glucose agar or blood agar at 30°C for 24 to 48 hours (unpublished observations). The test is performed by first lightly touching a colony with a bacteriological loop so that a thin film of organism is obtained, then transferring the inoc-
ultraviolet into the test substrate (e.g., fetal bovine serum) followed by incubation at 37°C for up to 3 hours. Germ tube tests should be read between 2 to 3 hours to prevent clumping of hyphal initials and to reduce the number of false positives. In addition, a heavy inoculum of yeasts and the presence of bacteria can each lead to false-negative results.

**Ascospore Formation**

Homothallic yeasts recovered from clinical specimens may be present in their teleomorphic (sexual) state. In order to enhance production of ascospores by ascomycetous yeasts, cultures should be inoculated onto media such as Fowell's acetate agar (203), V-8 juice agar, or yeast extract-malt extract (YM) agar, incubated at room temperature for 2 to 5 days, and examined by wet preparation for the presence of ascospores within asci. Some mycologists prefer to perform special stains to detect ascospores. The Ziehl-Nielson stain, routinely employed in mycobacteriology, can be used if needed; however, most ascospores can be detected easily in a drop of sterile distilled water. Ascospore production in homothallic yeasts can aid in identification when equivocal results are obtained by other identification methods (Table 5).

**Phenol Oxidase Test**

This screening procedure detects the ability of Cryptococcus neoformans and C. gattii to produce phenol oxidase on substrates containing caffeic acid. The most frequently used medium is "birdseed" agar (containing niger or thistle seeds), and a number of formulations showing varying degrees of success have been described. Test performance is related to the glucose content of the medium; the more glucose in the medium, the less likely a valid test will be obtained. C. neoformans and C. gattii colonies turn a dark brown in 2 to 5 days. Because of the wide variation in media formulations, the test must be subjected constantly to quality-control measures. Some laboratories advocate the use of birdseed agar as part of the primary plating for respiratory cultures for early detection of C. neoformans and C. gattii isolates. A rapid phenol oxidase test (Remel and other vendors) utilizes a caffeic acid disk that is rehydrated, then inoculated with several yeast colonies and incubated at 35 to 37°C for up to 4 hours. The disk should be examined every 30 minutes for the production of a brown pigment. If pigment is produced, it is presumptive for C. neoformans or C. gattii; if no pigment is detected but C. neoformans/C. gattii are suspected, further identification should be pursued.

**Urease**

This is a test to detect a yeast's ability to produce the enzyme urease. In the presence of suitable substrates, urease splits urea, producing ammonia, which raises the pH and causes a color shift in the phenol red indicator from amber to pinkish-red. The urease test aids in the identification of the urease-positive basidiomycetous yeasts (Cryptococcus, Saccharomyces, Candida).

Malassezia, Pseudozyma, Rhodotorula, Trichosporon) from the urease-negative ascomycetous yeasts (e.g., Candida, Saccharomyces, Geotrichum, Blastoschizomyces). Nearly all Candida spp. encountered in clinical specimens are urease negative, exceptions being Yarrowia (Candida) lipolytica and some strains of C. krusei, neither of which assimilates inositol. A rapid disk test can take 4 to 72 hours for a reaction to develop, while the more definitive urea agar slants can take from 24 to 72 hours.

Rapid Trehalose
The rapid trehalose test can provide a presumptive identification of C. glabrata within 3 hours. The Clinical and Laboratory Standards Institute (CLSI) has approved a rapid test procedure (document M35-A) for identification of C. glabrata based primarily on rapid trehalose assimilation (204). False positives occur with trehalose tests (205), but these can be reduced if the results are correlated with small cell size and failure to produce germ tubes. Several modifications of the rapid trehalose assay have been introduced (reviewed in references 163 and 192). The GLABRATA RTT (Fumouze Diagnostics Levallois Perret, France) combines hydrolysis of trehalose and maltose and includes a control (a sugar-free basal medium). C. glabrata hydrolyzes the trehalose rapidly, but not the maltose (which other yeasts may hydrolyze). The test provides acceptable sensitivity and specificity, but the choice of growth medium for the test inoculum influences the likelihood of obtaining false positives. Blood agar should be avoided because both C. albicans and C. tropicalis cause high false-positive results (202, 206). The most suitable media appear to be CHROMagar and Sabouraud glucose (4%) agar. Combining colony color on chromogenic agars with the GLABRATA RTT or the Rapid Trehalose test could help improve specificity (207, 208). Rapid trehalose and maltose hydrolysis have also been modified into a 30-second dipstick assay. This test provides adequate specificity and sensitivity, but these parameters are affected by the medium used to grow the test inoculum (207).

Phenotypic Systems
A variety of manual and semiautomatic single to multipheno
typic assay systems have been commercialized (Table 6 and reference 192). Most are designed to help identify the most common yeast etiologic agents. The systems vary in ease of use and accuracy. Generally, the systems designed to identify multiple genera and their species are less reliable with unusual or rare pathogens (e.g., C. inconspicua), although sometimes, rare isolates of common species such as C. parapsilosis, C. guilliermondii, and C. krusei can result in misidentification or poor species discrimination (209, 210).

Carbohydrate Assimilation Tests
The mainstay of yeast identification to the species level is the carbohydrate assimilation test (Table 1), which measures the ability of a yeast to use a specific carbohydrate as the sole source of carbon in the presence of oxygen. There are several reliable commercially available kits such as API 20C AUX (bioMérieux SA, Marcy l’Etoile, France), API ID 32C (not available in the United States), Auxacolor 2 (BioRad, Hercules, CA), and automated and semiautomated systems (e.g., ID 32C and Vitek 2 YST, produced by bioMérieux) on the market today (Table 6) that make the classic Wickerham-Burton method (211) unnecessary for routine clinical isolates. None of these tests is 100% concordant with the Wickerham-Burton method, and they do not unformly agree with each other. Assimilation reactions provided in reference books, such as Barnett et al. (212) and Kurtzman et al. (213), are based on the Wickerham-Burton method. Because commercial assimilation tests are only similar to the Wickerham-Burton tests, their assimilation reaction profiles may differ from those provided in reference books. A recent comparison of the API ID 32C, Auxacolor, and Vitek for 251 isolates encompassing 35 species concluded they were equally good at identifying the common species, but that the Vitek system was better at identifying the rare species (214). The most recent codebook or identification software should be used with any particular assimilation system.

Carbon assimilation and, occasionally, fermentation studies are needed to differentiate species (Table 1), but rapid confirmation tests for particular species are becoming available (see “Rapid Identification of Yeasts,” below, and Table 6). It is important to note that assimilation and fermentation tests may not discriminate among individual members of a species complex. Of the Candida spp. usually recovered from clinical specimens, C. guilliermondii is the only one to assimilate dulcitol (galactitol), and C. kefyr assimilates lactose. The assimilation of rhamnose can be helpful in separating C. lusitaniae from the biochemically similar but rhamnose-negative variants of C. tropicalis (215). For atypical isolates of C. lusitaniae, which can be confused with C. tropicalis, good growth on Trichophyton agar #1 with biotin but weak growth on vitamin-free medium indicates C. tropicalis (216). C. kefyr may assimilate cellobiose weakly and exhibit an assimilation pattern similar to that of C. parapsilosis. The inclusion of arabinose is helpful, since C. parapsilosis readily assimilates this carbohydrate, while most strains of C. tropicalis do not. Urease generally is not produced, nor is KNO3 utilized by the Candida species listed in Table 1. However, occasional isolates of C. krusei may be urease positive.

Nitrate Tests
The nitrate assimilation procedure is similar to that of the carbon assimilation test. It tests the ability of a yeast to utilize nitrate as a sole nitrogen source. The test is most beneficial when trying to identify Cryptococcus, Rhodotorula, and Pichia spp. In order for yeasts to utilize nitrate, they must reduce it. Nitrate reduction assays, however, have limited value for identification of yeasts and are used primarily for discrimination of Cryptococcus species.

Carbohydrate Fermentation Tests
Fermentative yeasts recovered from clinical specimens produce carbon dioxide and alcohol; therefore, production of gas indicates fermentation. The pH of the medium may not change. Fermentation studies are rarely needed to identify most of the commonly isolated yeasts if the mycologist is familiar with typical morphology on cornmeal agar. The test is most helpful in differentiating the various species of Candida; Cryptococcus and Rhodotorula spp. are nonfermentative.

Rapid Identification of Yeasts
Rapid identification of yeasts has an impact on patient management. This is particularly true given the recognition that various yeast species (e.g., C. glabrata, C. krusei, C. parapsilosis, C. lusitaniae, C. tropicalis, C. neoformans) are inherently or potentially resistant to amphotericin B, triazole agents, or echinocandins (59, 80, 83, 142) and that species-specific MIC breakpoints are now being used for the genus Candida (217, 218).

*Tests not available in the United States are indicated by *. 

Rapid tests are divided into those that provide definitive or presumptive identification within the same day (<24 hours) of colony formation and either are specific to a single species, are limited to a few species, or apply to multiple genera (Table 6). In general, tests listed within groups 1 and 2 of Table 6 are presumptive, and confirmation of the identification is needed.

Tests based on preformed enzymes may be acutely affected by incubation temperature (219) and are effectively limited to the more common yeast species isolated in the clinical laboratory. However, detection of specific exoenzymes can be useful for resolution of the confusion between two or three possible species. In particular, several rapid tests are available for this purpose, particularly for detection of Candida albicans (e.g., the Thermo Remel Candida albicans test kit [Thermo Fisher Scientific, Houston TX]). These tests are excellent for confirmation of a germ tube-positive organism such as C. albicans and could be used in place of more long-term identification tests for this purpose. However, similar results will be obtained for C. dubliniensis. Using these tests for confirmation purposes can provide financial savings to the clinical laboratory. Both tests depend on the production of two enzymes (proline aminopeptidase and β-galactosaminidase) instead of a single enzyme (β-galactosaminidase) which could otherwise lead to spurious results (220).

A rapid test to help distinguish some Cryptococcus species uses the ability to reduce nitrate on a rapid nitrate swab test (Thermo Remel). This can supplement the results of more comprehensive tests and help to distinguish C. neoformans and C. gattii (nitrate negative) from C. albicans and C. terreus (nitrate positive). Molecular-based tests and serologic tests appear to be promising rapid alternatives with higher sensitivity and specificity.

Molecular Methods

The obvious advantage of using molecular methods is speed, as results are often available within 24 hours of an isolated colony, whereas traditional methods usually take at least 48 hours. However, development of molecular databases and standardization remain issues before any of these tests become commonplace (discussed in references 179 and 221), and most of these tests will require validation and approval by regulatory agencies before they can be widely implemented.

Direct DNA Sequencing

DNA sequencing is increasingly being used for definitive identification of unknown yeast isolates. Characteristic assimilation profiles of unusual isolates may not be present in the commercially available phenotype databases, resulting in misidentifications. Also, individual members of species complexes are often not distinguished by kits based on phenotype. As a result, increasing use is being made of ribosomal DNA (rDNA) sequencing and comparison to genetic databases for conclusive identification. Two widely used databases are GenBank (http://www.ncbi.nlm.nih.gov/blast) and the Centraalbureau voor Schimmelcultures (CBS) Yeast database (http://www.cbs.knaw.nl/yeast/bioinformatics.aspx), with the latter containing databases for strains held in the culture collection. Lau et al. (177) highlight the need to be aware of how the genetic database being used is maintained. GenBank contains unreferred sequences, and errors are known to occur, whereas the CBS has a curated intervening transcribed spacer (ITS) sequence database. Reference texts such as the Atlas of Clinical Fungi (222) have included restriction maps of ribosomal operons for described fungi. Molecular approaches and guidelines to fungal identification are described in CLSI documents MM03-02 and CLSI MM18-A (223, 224).

In order to develop a universal genetic identification system for yeasts, the most reproducible, specific, and sensitive sequence for comparison must be identified, and most research has focused on the rDNA regions. The large subunit, specifically the D1/D2 region, was shown to be highly discriminatory for the ascomycetous yeasts (1) and, similarly, for the basidiomycetous yeasts (2, 225), although differentiation of some closely related species in the latter study (225) was achieved using the ITS and intericgenic
sequence (IGS) regions. Other studies have also used the ITS1 and ITS2 regions (226, 227). Chen et al. demonstrated that ITS-2 sequence alone can be sufficient for discriminating Candida species (228). Linton et al. (229) conducted a study assessing the value of direct 26S rDNA sequencing using over 3,000 isolates submitted to the UK Mycology Reference Laboratory. All 153 isolates that could not be identified using the Auxacolor 2 kit were unambiguously identified using 26S DNA sequencing. Ciardo et al. (230) compared ITS sequencing with the ID 32C system for yeast strains. ITS sequencing identified 98% of 113 yeast isolates, while the phenotype-based system identified 87% correctly.

Two systems for DNA sequencing and analysis are commercially available. Hall et al. (231) used the MicroSeq D2 large-subunit rDNA sequencing system (ABI) to identify 131 clinical yeast isolates and compared the results with those obtained by conventional methods, including the API 20C AUX system. When 100 isolates representing 19 species of Candida were compared using the MicroSeq kit, 98% matched with identifications using the API 20C AUX. For the remaining isolates, representing nine species, there was 81.4% concordance between the systems. Most of the discrepancies were attributed to the lack of available data in the relevant databases. The SmartGene Fungi system (SmartGene, Lausanne, Switzerland) is another commercial database used for identifying unknown isolates. In a recent evaluation with 2,938 specimens, 79% of 169 isolates that could not be identified using phenotypic tests were identified to species level using ITS sequencing and the SmartGene IDNS database (232). About half of the sequenced isolates were common pathogens with atypical biochemical profiles, and the remainder were rare yeast species.

Pyrosequencing, a novel method for rapid determination of a short stretch of DNA sequence, has been examined as a potentially fast identification method. Montero et al. (233) identified only 69.1% of 133 isolates representing 43 yeast species by comparing the sequences of the hypervariable ITS region to traditional methods, and it was not possible to speciate the Trichosporon or Cryptococcus isolates. In contrast, Boyanton et al. (234) obtained 100% agreement between pyrosequencing and traditional identification methods for 60 isolates of the species C. albicans, C. dubliniensis, C. glabrata, C. guilliermondii, C. krusei, C. lusitaniae, C. parapsilosis, and C. tropicalis. Also, Borman et al. demonstrated that pyrosequencing of 25 bp of the ITS2 region correctly identified most clinically important Candida species (235).

For organisms that are difficult to grow or require non-commercially available materials, these methods hold great potential. For example, identification of Malassezia species otherwise requires both specialized growth media and phenotypic identification tests. However, more research is needed before a universal genetic database can be devised, because the D1/D2 and ITS regions do not appear to identify all yeasts. Using the ribosomal 5.8S-ITS sequence, only 6 of 15 Debaryomyces species were correctly identified; the remaining species were differentiated using the sequences of the ACT1 (actin) gene (236). The ribosomal IGS region is required for species identification of Trichosporon isolates (25).

DNA-Based Methods that Do Not Involve Direct Sequencing

Restriction enzyme analysis (REA), karyotyping using pulsed-field gel electrophoresis, and the use of species-specific probes have all been used to identify yeast species and have been reviewed (177, 192, 237). However, it must be remembered that these techniques were developed before many of the species complexes were discovered and may not be able to distinguish among them.

Microarrays for fungal identification have been produced using the ITS regions. Leinhberger et al. (238) identified C. albicans, C. dubliniensis, C. krusei, C. tropicalis, C. guilliermondii, and C. lusitaniae. A further modification on this principle was able to distinguish among C. parapsilosis, C. orthosporus, and C. metapsilosis from among 24 other fungal pathogens, including 10 other Candida species (239). Other rapid identification systems developed include the DiversiLab system of automated repetitive sequence-based PCR (bioMérieux).

This method uses primers against noncoding repetitive sequences; amplified products are separated on a microfluidic chip to generate a fingerprint of intensity of fluorescence versus migration time. This technique was used to screen 115 clinical isolates of Candida species by sequence analysis of the contiguous ITS region and obtained 99% concordant results with traditional identification methods (240). Although results can be obtained within 24 hours of a pure culture being obtained, identification is dependent on a comprehensive library of species fingerprints for comparison. The Lumixin multianalyte profiling platform (described earlier) has been used on a number of types of clinical specimens and enables screening of a range of fungal pathogens simultaneously. Landlinger (241) used the ITS2 region to design 75 genus and species-specific hybridization probes to detect fungal infection in blood, pulmonary biopsy specimens, and bronchoatracheal secretions. Dekk used this method for rapid identification of 1,182 Candida isolates (242).

MALDI-Based Methods

An alternative method to DNA-based technologies is MALDI-TOF MS. This method requires a pure colony of yeast and produces a mass-spectrum fingerprint characteristic of the organism. Identification of fungal isolates using MALDI has been recently reviewed (243, 244). Recently, the technique was used to assess the identification of 346 yeasts directly from blood culture bottles and found 96% sensitivity for the detection and identification of C. albicans, 94% for C. parapsilosis, 87% for C. tropicalis, 84% for C. glabrata, and only 75% for C. krusei (245). The great advantage was that the result were available within 24 hours of the blood culture setup. However, Cassagne et al. (246) found that a direct smear of yeast culture or fast formic acid extraction yielded lower identification rates than a complete formic acid/acetonitrile extraction. As with other fingerprinting techniques, this method requires an adequate database of reference strains for comparison to the test isolate to facilitate rapid routine identification of clinical yeast isolates (247).

Troubleshooting Difficult Identifications

Laboratories encounter yeast isolates that do not fit easily into a specific species, particularly when commercial identification systems are used. Fortunately, there are key features that help separate troublesome organisms from others. For example, urease production separates basidiomycetous yeasts from ascomycetous yeasts. Maximum growth temperature, cycloheximide resistance, and the ability to assimilate cellobiose, inositol, or trehalose are helpful. For more difficult identifications, use of traditional auxanographic methods with carbon source-impregnated disks on yeast carbon base agar plates (rather than spotting the sugar on the edge of the plate, as done by Beijerinck) may provide the most accurate assimilation information. Differential media such as chro-
mogeneous agars or eosin methylene blue agar (C. glabrata and C. kefyr produce distinct colonies) may sometimes help (248). Fermentation tests should also be considered, as should a second commercial system but one that uses a different endpoint (e.g., growth versus exoenzyme production). Clinically relevant isolates that consistently fail to be identified by conventional tests should be sent to a reference laboratory for DNA sequencing or MALDI analysis.

ORGANISMS RESEMBLING YEASTS
Occasionally, organisms such as moulds and algae may grow on mycological media and produce colonies that resemble those produced by yeasts. However, careful attention to morphologic characteristics differentiates them. Examples of such organisms recovered from clinical specimens that can be superficially confused with yeasts include Geotrichum, black yeasts, and Prototheca species. Geotrichum candidum (dry, white colonies) can be separated from Trichosporon spp. by carbohydrate assimilations and the lack of urease and biotin production. Black yeasts (initially white to tan-colored colonies) are treated elsewhere in this Manual. Prototheca species (white to cream colored, dull or moist to mucoid colonies) are ubiquitous, achlorophyllous algae living on decaying organic material and rarely produce disease in humans and animals (249). P. wickerhamii is recovered most often from human infection.

TYPING SYSTEMS
In order to understand the epidemiology of infection, to distinguish between endogenous and exogenous infection (and in the latter, to locate the source), to examine transmission, or to monitor the spread of drug resistance, it is necessary to be able to distinguish between isolates within a species. Successful strain typing depends on the choice of technique(s) and experimental conditions for maximum discrimination, which has to be established for each species tested.

DNA-based typing methods began in the 1980s with REA, which required careful selection of the enzyme used to maximize discrimination. Other methods quickly followed. Some include blotting using species-specific or generic probes, karyotyping, pulsed-field gel electrophoresis-REA, and random amplified polymorphic DNA analysis. These methods are all subject to discrepancies due to mutation or laboratory reproducibility and have been reviewed (237, 250, 251). Most of these techniques have been superseded by more accurate and reproducible methods such as microsatellite typing and multilocus sequence typing (MLST). Gil-Laimagne et al. (237) and Taylor et al. (251) have critically reviewed the limitations and applications of these techniques.

Microsatellite typing is the amplification of short tandem repeat sequences that are polymorphic, resulting in bands of varying lengths related to the number of repeats contained therein. Variation in the number of repeats occurs during DNA replication, and this provides the characteristic fingerprint. This is a fast typing method but cannot be used to estimate isolate relatedness unless the bands are sequenced and the content compared (for example, see reference 252). MLST is an accurate and reproducible method of fingerprinting that uses the sequences of six to eight selected housekeeping genes and identifies polymorphic nucleotide sites. The method can be used to establish population structures by assessing variation in sequence for a set number of genes, and this has enabled databases to be developed for interlaboratory comparisons. The method has been used to type a number of yeast species (253–255) and recently demonstrated the spread of Cryptococcus gattii from Vancouver Island in Canada to the northwest United States (256).

MLST has been used to develop a consensus typing scheme for C. gattii and C. neoformans (257). MLST has been used to demonstrate that most patients with C. albicans carried the same strain at multiple sites or over time and to confirm that microvariation could be detected over time when some isolates are stored (258). However, while MLST provided detail on the population structure of clinical isolates of C. glabrata from Taiwan, greater typing discrimination was achieved using PFGE-REA (259).

SEEROLOGIC TESTS
Genus Candida
Invasive Candida infections are life-threatening, but detection by relatively noninvasive methods such as blood culture is problematic. A test for detection of antibody to Candida mannan is available (e.g., using the Platelet Candida Ab ELA kit [Bio-Rad Laboratories]), but such tests have poor sensitivity and specificity (177). These poor results are due to the presence of Candida species as part of the commensal flora and antibodies against cell wall components that may be found in colonized individuals. The utility of these tests is maximized when combined with detection of antigen levels because the antibody and antigen levels may show an inverse correlation during disease progression. More detail on antigen testing is in an earlier section.

ANTIMICROBIAL SUSCEPTIBILITIES
Details of susceptibility testing methods, antifungal resistance profiles, and mechanisms of yeasts and moulds are described in other chapters of this manual. Table 7 contains the MICs from a number of sources for 36 yeast species. The references in Table 7 have all used CLSI methods, with the following exceptions: Lass-Flörl et al. (260), who followed EUCAST methodology; the Atlas of Clinical Fungi (222); and Ashbee (211), which contains data from published work. The data on Malassezia from Ashbee’s reviews have been included because there is little information on the susceptibility of these organisms. Species-specific susceptibility breakpoints have been determined for several species of Candida and the major classes of antifungal drugs (217, 218). Most species of Candida are susceptible to the echinocandins, although there is some variation within species in susceptibility to caspofungin (261, 262), and echinocandin resistance has begun to emerge in C. glabrata (82–84). Candida krusei is intrinsically resistant to fluconazole but is susceptible to posaconazole and voriconazole, while some strains of C. glabrata may have elevated MICs to fluconazole. C. norvegensis and C. inconspicua are also fluconazole resistant. Few Candida species are resistant in vitro to amphotericin B, although C. lusitaniae may exhibit secondary resistance to amphotericin B. Therefore, clinical response to this drug may be poor despite in vitro susceptibility tests indicating that strains are susceptible (96, 263, 264). However, clinically relevant breakpoints have not been established for susceptibility testing of yeasts against amphotericin B (265).

* Abbreviations: Amb, amphotericin B; SFC, 5-fluorocytosine; Flucon, fluconazole; Itra, itraconazole; Voris, voriconazole; Pos, posaconazole; Casp, caspofungin; Terb, terbinafine; ND, not determined. 

C. famata from reference 227 for 5-fluorocytosine.
sive fungal infections due to rare yeasts other than Candida species. MICs of the six common human Trichosporon species indicate that all species have resistance to 5-fluorocytosine (6.25 to 50 μg/mL), have higher MICs to fluconazole than most Candida species (0.15 to 25 μg/mL), and are variably susceptible to amphotericin B (0.01 to >4 μg/mL), ketoconazole, and itraconazole (0.1 to 0.6 μg/mL) (49). Echinocandins are considered ineffective against Trichosporon and Cryptococcus species.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

As taxonomic relationships and rules are revised, the names of organisms change. To prevent confusion, it is recommended that clinical reports include the more familiar species names alongside any new classification being used. At this time, rather than change the name of Candida genus organisms from names that are deeply entrenched in the literature and in the minds of physicians and laboratory personnel, this Manual has retained their Candida genus taxon as well as the teleomorph names. This will likely change in the future, and laboratory staff should familiarize themselves with newer names as they are introduced.

As in clinical bacteriology, the significance of isolating a species known to be a member of the normal microbiota or a common contaminant depends on numerous factors, including but not limited to the patient’s underlying disease, geographic and hospital environment, specimen site, preceding antimicrobial and device management, specimen collection and quality, and specimen processing. In general, the isolation of yeasts from sterile body sites is suggestive of infection, but the influence of the method of collection (e.g., C. albicans in CSF collected by lumbar puncture) must be considered. The more challenging decision about significance is when the yeast is present in specimens obtained from nonsterile body sites.

Review of the literature reveals a surprising lack of evidence-based studies regarding development of criteria for establishing significance in nonsterile body sites. Clinical microbiology laboratories typically apply bacterial criteria to assess specimens for possible fungal infection. An example of this is to not report yeasts unless they are predominant (over bacteria). However, there are several problems with this approach. First, yeasts are not as abundant as bacteria in the normal microbiota, so an increase in relative abundance may reflect yeast infection. Roughly 10 times more bacteria than yeast can occupy the same volume of tissue. Secondly, a specimen from a patient who is receiving antibacterial agents may contain more abundant yeasts, the reporting of which may mislead the patient’s physician about the yeasts’ significance. Third, when the abundance of a yeast is considered insufficient to warrant further investigation, the species may not be reported. This could lead to unfortunate consequences because certain yeasts, such as C. tropicalis, are considered particularly aggressive in immunocompromised patients.

Two specimens that are particularly problematic are sputum and urine (clean catch, indwelling catheter, and “in-and-out” catheter). The significance of Candida species in sputum, regardless of quantity, has been questioned (266, 267). The presence of these yeasts in sputum has little influence as the respiratory tract is frequently colonized by Candida species in patients receiving ventilatory support. The latest Infectious Diseases Society of America guidelines recommend that antifungal therapy not be initiated on the basis of a positive respiratory tract culture, and in cases where Candida pneumonia is suspected, histopathological evidence should be sought (59). Similarly, the presence of a few C. neoformans colony-forming units in sputum does not necessarily imply etiologic significance unless patient information strongly suggests cryptococcosis. To prevent unnecessary testing but still provide useful information to physicians, Barendt et al. (266) recommend not reporting “yeast, not Cryptococcus” for all respiratory secretion specimens in which a rapidly growing yeast is obtained and confining full identification for patients in whom candidal pneumonia was indicated by histopathology. Patients for whom the limited form of identification was used were found to experience a shorter hospital stay, received fewer antifungals, had a lower mortality rate, and incurred fewer expenses. Cryptococcus species are ruled out using a rapid urease test. This approach allows physicians the opportunity to request further identification if desired. A similar approach to rapidly growing yeasts isolated from routine urine specimens (urinary tract infection is the only presentation) could also be used. However, in this situation, differentiation of C. glabrata from other common yeast uropathogens could be achieved by using one of the simple rapid tests.

The significance of yeasts in urine must be examined in the context of the clinical setting and whether therapy would be desirable (59). If the patient is asymptomatic and there is no predisposing condition, the situation should be monitored. If a predisposing condition is identified, treatment may be justified, but for patients with higher risk factors such as neonates or immunocompromised patients with fever and risk of candidemia, treatment should be commenced. Fluconazole is the front-line therapy unless C. krusei or C. glabrata infection is suspected; in these cases, irrigation of the bladder with amphotericin B may be indicated (59).

Although yeast species express different antifungal profiles, especially to the expanding spectrum of new antifungal agents (see reference 142 and Table 7), the most commonly isolated Candida species are generally susceptible to the triazoles, the polyenes, and the echinocandins. The two exceptions for the triazoles are C. glabrata and C. krusei (C. parapsilosis isolates are occasionally resistant to the echinocandins). C. krusei is relatively rarely isolated from infections. Thus the need to identify rapidly growing yeasts present in clinically significant quantities from nonsterile sites can be limited to performing a rapid screen for C. glabrata. It is more important to obtain a yeast’s antifungal susceptibility profile if there is failure to respond to antifungal therapy or if an azole-resistant isolate is suspected (59).

The yeast-like fungi in the genus *Pneumocystis* are extracellular, host-obligate, host-specific, and typically restricted to the lung tissues of mammals, although extrapulmonary manifestations have been reported (1, 2). Once known collectively by the single genus and species “*Pneumocystis carinii*,” it is now understood that distinct species of *Pneumocystis* infect different mammalian hosts. Current evidence suggests *Pneumocystis* can exist with little consequence in hosts with intact immune systems (3), but debilitation of the immune system, induced by various means including infectious or immunosuppressive agents, congenital defects, or malnutrition, can lead to organism proliferation within the lung alveoli, colonization, and potentially a lethal pneumonia if untreated. No species of *Pneumocystis* can be cultivated continuously outside the mammalian lung, impeding diagnostic capabilities as well as basic scientific research. Limited therapy is available with which to treat the pneumonia, since these fungi are not susceptible to such antifungal drugs as amphotericin B, the azoles, or the echinocandins.

**TAXONOMY**

Taxonomic problems have plagued the organisms known as “*Pneumocystis carinii*” since their original description in 1909 by Carlos Chagas, who mistakenly identified the cyst forms as life cycle stages of the protozoan parasite *Trypanosoma cruzi*. In 1914, these organisms were provided an identity of their own and given the binomial epithet that reflected their predilection for the lung, *pneum-*, the characteristic morphological form, -cystis; and, to honor the Italian investigator Antonio Carini, who provided the slides for study, *carinii*. The *P. carinii* organisms were presumed to be a protozoan parasite at the time of identification; the question of their potential fungal nature was first raised in the 1950s, and the controversy of their protozoan or fungal nature continued to the late 20th century. A more detailed early history of *Pneumocystis* identification and nomenclature can be found in reference 4.

The most recent phylogenetic classification based on gene comparisons with other fungi places *Pneumocystis carinii* in the phylum Ascomycota; subphylum Taphrinomycotina; class Pneumocystidomycetes; order Pneumocystidales; genus *Pneumocystis* (5). Within the Taphrinomycotina are the genera *Taphrina* (plant pathogens), *Neolecta* (associated with trees; may be parasitic), *Pneumocystis*, and *Schizosaccharomyces* (fission yeasts).

*Pneumocystis* species all appear to contain similar life cycle stages, although the clusters of organisms removed from the lungs of the different species can vary in presentation and size. For example, clusters of *P. jirovecii* can be much larger than those obtained from rodent lungs, stain more intensely with Wright-Giemsa-like stains, and form multilayered “mats” composed of several layers of organisms that hinder identification of individual life cycle stages (see Fig. 3B, D, and F for example). The term “*Pneumocystis carinii*” was thought to represent a single zoontic species until 1976, at which time Frenkel described serological differences between human- and rat-derived organisms that he suggested were representative of distinct species (6). It is now clear that the organism first identified as *Pneumocystis carinii* is actually a collection of many species within the genus *Pneumocystis* that likely number in the hundreds to thousands. Almost every mammal examined to date appears to harbor at least one species of *Pneumocystis* that is not found in any other mammal. Five *Pneumocystis* species have been formally described according to the International Code of Botanical Nomenclature: *Pneumocystis carinii* and *P. wakefieldiae* are found in rats; *P. murina* is found in the lungs of mice; *P. jirovecii* is found in humans (4); and *P. oryctolagi* resides in rabbits (7). The name *P. jirovecii*, though first resisted by some groups, has gained widespread acceptance within the scientific and clinical communities (8).

**DESCRIPTION OF THE AGENTS**

The terminology used to describe the various life cycle stages of *Pneumocystis* bears remnants of its earlier classification as a protozoan parasite. This discussion uses terms more suitable for its fungal identity, but identifies those commonly found in the literature for continuity. Three developmental forms are generally recognized: the trophic form (trophozoite), 1 to 4 μm (Fig. 1A); the sporocyte (precyst), 5 to 6 μm (Fig. 1B); and the ascus (cyst), 5 to 8 μm (Fig. 1C–E). *Pneumocystis* spp. reproduce extracellularly within the mammalian lung alveoli. The trophic forms appear ameboid in structure in electron micrographs, but in freshly prepared specimens they are ellipsoidal and often occur in clusters with other trophic forms and developmental stages. The nucleus and often the mitochondrion are visible in rapid Wright-Giemsa-stained specimens by light microscopy. The trophic forms do not stain with fungal stains designed to complex with the cell wall, such as methenamine silver. The sporocyte is smaller than the mature cyst and frequently

oval in shape. This stage contains a rigid cell wall that is lacking in the trophic forms and is stained with methenamine and other fungal wall stains. At the sporocyte stage, the nuclei are at varying levels of nuclear division (from two to eight nuclei) but have not yet been compartmentalized into separate spore structures. Aggregates of mitochondrion can also be seen in this stage. The mature cyst is spherical in shape; it contains eight spores (although these may not all be visible) and a thick cell wall that excludes methenamine silver. The cyst/ascus is considered the diagnostic morphological form. All developmental forms are often found in large, multilayered, tightly adherent aggregates or clusters in clinical specimens, making identification of each morphological form. The cyst/ascus is considered the diagnostic form. All developmental forms are often found in large, multilayered, tightly adherent aggregates or clusters in clinical specimens, making identification of each stage difficult (see Fig. 3B, D, and F).

**Epidemiology and Transmission**

Early animal studies showed that Pneumocystis infection was likely transmitted by an airborne route. Immunosuppressed, Pneumocystis-free rats could acquire the infection from infected rats housed in the same room or from infected cage mates (9). Recent air sampling studies using quantitative PCR, conducted around patients admitted with Pneumocystis pneumonia (PCP), showed the highest levels of detection within 1 m of the patients' heads (10). Although levels decreased with increasing distance from the patient source, samples were still positive in corridors outside the patients' rooms. Importantly, the genotypes of the P. jirovecii infecting the patients were the same as the genotypes outside the immediate patient area, confirming that the potential sources of transmission were these patients. These data provide evidence that supports historical and more recent descriptions of outbreaks in renal transplant units (11) and other clinical settings where patient-to-patient transmission can occur. The agent of transmission appears to be the cyst (ascus) form, as experiments using mice with infections composed almost exclusively of trophic forms could not transmit the infection (12).

**Putative Life Cycle**

Histochemical and ultrastructural studies form the basis of the current understanding of the life cycle of Pneumocystis, due to a historic lack of a long-term cultivation method outside the lung. Thus, any life cycle should be considered presumptive until it is possible to perform definitive kinetic analyses. There is no evidence for an intracellular phase, although the organisms can be frequently observed within macrophages as a result of the host response to the infection. Despite numerous attempts to find an environmental cycle or external reservoir for Pneumocystis, none has been identified. A growing body of evidence suggests that the reservoir for Pneumocystis is its mammalian host, a situation similar to other host-dependent pathogens like Entamoeba histolytica or Mycobacterium tuberculosis. Studies in humans and animal models support a role for neonates and immune-competent hosts as potential reservoirs that are colonized transiently or longer term (3).

A schematic of a proposed life cycle, based on a number of histological and ultrastructural studies, can be found in Fig. 2, with a detailed description provided in the legend. The various life cycle stages of Pneumocystis are most often found together in very large adherent clusters that resemble biofilms in vivo (Fig. 2B). The in vitro formation of biofilms by P. murina and P. carinii provides support for the formation of these structures in vivo, which could be responsible for intransigent infections that are unresponsive to current therapies (13, 14). Trophic forms are presumed to be the vegetative stages of the Pneumocystis life cycle and reproduce asexually by binary fission, not budding as most yeast do. It is likely that they also participate in the sexual mode of reproduction using a process similar to yeast mating type systems, although these processes are not fully defined. Several fungal meiosis-specific and mating type gene homologs have been identified in cDNA and genomic P. carinii databases, lending credence to the existence of these processes (15, 16). Subsequent to mating process and karyogamy (nuclear fusion), the zygotic nucleus undergoes meiosis and sporogenesis is initiated, resulting in formation of the precyst, or sporeocyte. Following meiosis, an additional mitotic replication occurs, with subsequent compartmentalization of the nuclei and organelles into eight ascospores. The end product of sporogenesis is the spherical cyst, or ascus. The process of spore release has not been described, but may involve a localized thickening at one pole of the ascus. It should be noted that, unlike other fungi, all the developmental stages of Pneumocystis contain a double membrane.

**Transmission**

Evidence from several different studies suggests that: (i) Pneumocystis is transmitted by an airborne route; (ii) it is likely to be acquired early in life; (iii) it is transmitted among immunologically intact individuals; (iv) immunosuppressed and infected hosts are able to transmit the infection to immunologically intact hosts; and (v) transmission requires a short period of exposure and low numbers of organisms.

- **EPIDEMIOLOGY AND TRANSMISSION**
  - Early animal studies showed that Pneumocystis infection was likely transmitted by an airborne route.
  - Immunosuppressed, Pneumocystis-free rats could acquire the infection from infected rats housed in the same room or from infected cage mates (9).

- **Putative Life Cycle**
  - Histochemical and ultrastructural studies form the basis of the current understanding of the life cycle of Pneumocystis.
  - Thus, any life cycle should be considered presumptive until it is possible to perform definitive kinetic analyses.

- **Transmission**
  - Evidence from several different studies suggests:
    - (i) Pneumocystis is transmitted by an airborne route.
    - (ii) It is likely to be acquired early in life.
    - (iii) It is transmitted among immunologically intact individuals.
    - (iv) Immunosuppressed and infected hosts are able to transmit the infection to immunologically intact hosts.
    - (v) Transmission requires a short period of exposure and low numbers of organisms.
Experimental evidence indicates that very few organisms are required to initiate Pneumocystis infection and that the fungi are very efficient in their method of transmission. Studies have shown that fewer than 10 P. carinii organisms were sufficient to establish a fulminant infection in immunosuppressed rats (17) and a 1-day period of exposure was all that was needed to transmit the infection from an infected scid/scid mouse to an uninfected scid/scid mouse (18). The widespread prevalence of Pneumocystis in commercial colonies housing healthy rats not only supports the very efficient dissemination of the infection throughout the members of a colony, but also shows that the organism thrives in the immune-competent host (19). Transmission from infected patients to immune-competent health care workers has been reported (20). Evidence that healthy human populations may also serve as reservoirs or sources of infection is accumulating. A recent study conducted in humans without underlying lung disease or immunosuppression found that 20% of the oropharyngeal wash samples from 50 individuals were positive for P. jirovecii by nested PCR targeting the mitochondrial large subunit ribosomal gene (21). In a study of 851 non-HIV–infected patients with pneumonia in China, P. jirovecii was detected in 14.5% by methenamine silver staining and in 24% by PCR (22).

Epidemiology

Beard et al. reported that the expansion of P. jirovecii carrying a double mutation in the DHPS gene in selected HIV-infected human populations provided strong support for transmission of P. jirovecii via a person-to-person route, and that this was illustrative of a positive selective mechanism as well (23). Previous and recent epidemiological surveys showing the clustering of specific P. jirovecii genotypes with patients’ place of residence or in clinical settings (many in renal transplant units) are consistent with the hypothesis of

FIGURE 2  Proposed life cycle of Pneumocystis. (A) The primary site of Pneumocystis infection is the lung alveoli. Three clusters of alveoli are illustrated. An expanded schematic of an alveolus (box) is shown in panel B. (B) Single alveolus with Pneumocystis organisms depicted as a hatched shape attached to the cells lining the alveoli in some areas (type I pneumocytes) and unattached to other alveolar cells (type II pneumocytes). (C) Putative sexual cycle of Pneumocystis in the lung alveoli: (1) opposite mating types fuse and undergo karyogamy resulting in a diploid zygote; (2) the zygote then undergoes meiosis resulting in four nuclei; (3) additional postmeiotic mitosis increases the number of nuclei to eight; (4) the nuclei and mitochondria (not shown) are compartmentalized by invagination of the inner plasma membrane, resulting in eight spores. Spores are released from the ascus (cyst) and presumably enter into the vegetative phase of the cycle. (D) Asexual replication cycle of Pneumocystis. Trophic forms undergo binary fission after mitotic replication of the nucleus. (Drawn with SmartDraw Suite, ed. 7.3.)

doi:10.1128/9781555817381.ch118.f2
person-to-person transmission of \textit{P. jirovecii} via the airborne route (11, 24). A report from Japan documented a PCP outbreak in a renal transplantation unit, with 27 cases in a single year that could be traced by molecular methods back to the outpatient clinic (25). The median incubation time was estimated to be 53 days, with a range of 7 to 188 days. Several such outbreaks have been reported over the past 2 decades, providing a cautionary note for immunosuppressed patients gathering in a community setting, as well as for appropriate prophylaxis therapy for susceptible populations. In some cases, the mortality rate was as high as 50% (26). Surprisingly, investigators recently showed that most cases of \textit{Pneumocystis} colonization in renal transplant patients were detected beyond 2 years after transplant rather than within the initial 2-year time period (26). However, a recent report on the epistemology of \textit{P. jirovecii} colonization in families showed only a 3.3% detection in children of HIV-infected adults, in which their colonization rate was 11.4%, suggesting that merely close contact with potential reservoirs is not sufficient to induce this state (27).

Serological studies performed in the 1970s through the 1980s showed \textit{P. jirovecii} was acquired early in life (28, 29). Most human beings become seropositive to \textit{P. jirovecii} organisms or antigens by the age of 2 to 4 years. Vargas et al. detected \textit{P. jirovecii} DNA in nasopharyngeal aspirates in 24 of 72 infants (32%) suffering from mild respiratory infections (30). Serocconversion developed in 67 of 79 (85%) of the same cohort of infants by 20 months of age. Thus, serological testing has not been useful for the diagnosis of PCP.

Colonization

Emerging reports of the detection of \textit{P. jirovecii} in populations without underlying immunosuppression, as well as populations who have chronic underlying diseases that have not been historically associated with its presence, may suggest colonization or expansion of host range (3, 31–33). Colonization, carriage, asymptomatic infection, and subclinical infection have all been used to describe the presence of \textit{Pneumocystis} organisms or DNA in the absence of PCP. The effects of the presence of low numbers of \textit{P. jirovecii} on the host have yet to be determined, and the role of carriage in mild respiratory infections, chronic lung disease, and progression to PCP are now being actively investigated. The most common underlying conditions associated with the presence of \textit{P. jirovecii} in non-HIV-positive individuals include asthma and chronic lung diseases, chronic obstructive pulmonary disease, cystic fibrosis, Epstein-Barr virus infection, lupus erythematosus, high-dose corticosteroid therapy, anti-tumor necrosis factor-\textalpha{} therapies for rheumatoid arthritis, thyroiditis, ulcerative colitis, and pregnancy. Children appear to have a higher rate of colonization than adults do. Serological studies showed early exposure occurred during the first few years of life; 32% of colonized infants manifested mild respiratory symptoms in a large study in Chile (30). Studies from the same group suggested an association with sudden infant death syndrome, but this was not supported by subsequent investigations. Should the presence of \textit{P. jirovecii} be confirmed as a causal agent in the underlying pathogenesis of any of these diseases, treatment of this cofactor could improve patient outcome.

\textbf{CLINICAL SIGNIFICANCE}

PCP remains the leading opportunistic infection associated with AIDS patients, even in the era of highly active antiretroviral therapy (HAART) (34). The mortality rate associated with PCP prior to and after the era of HAART (1996 forward) has not changed significantly in the United States, with an average of 10 to 13.5% (35, 36). In developing countries and within urban American cities, the mortality is much higher despite the availability of HAART (37, 38). The mortality rate for a medically underserved population in Atlanta, Georgia, from 1996 to 2006 was 37%, while patients who required aggressive intervention such as mechanical ventilation experienced an 80% mortality rate from PCP (38). In patients with cancer and other non-HIV diseases, there has been little improvement in mortality rates, and often these patients fared more poorly than patients with HIV. In one such study, the mortality of non-HIV-infected patients with PCP was 48% while HIV-infected patients experienced a 17% mortality (39). The mortality rate of \textit{P. jirovecii} pneumonia in rheumatoid arthritis patients receiving eight immunosuppressive therapies in Japan averaged about 15.5%, with the highest mortality in patients who received tacrolimus; only one patient treated with golumab developed PCP and did not die (40). Although the incidence of PCP in pediatric populations has declined, PCP and its association with immune reconstitution inflammatory syndrome (IRIS) (41) cause significant clinical problems in these populations and vulnerable adult populations worldwide.

Within the mammalian lung, the trophic forms of \textit{Pneumocystis} adhere to the type I pneumocytes, presumably through macromolecular bridges (42–44). Type I cells are responsible for the gas exchange between the alveolar capillaries and the alveolar lumen. Besides attachment to the type I cells, the various developmental stages of the parasite adhere to one another, producing large clusters that extend outwardly into the alveolar lumen. In severe, untreated infections, most of the alveoli are filled with organisms. Direct attachment to the cells responsible for gas exchange combined with the accumulation of organisms within the alveoli results in impaired gas exchange and altered lung compliance, as well as other physiologic changes associated with the pneumonia, such as hypoxia (45).

Histopathologic findings can be characterized by two traits: (i) alveolar interstitial thickening and (ii) a frothy eosinophilic honeycombed exudate in the lumina of the lung. The interstitial thickening is a result of hyperplasia and hypertrophy of the type II pneumocyte, interstitial edema, mononuclear cell infiltration, and in some cases mild fibrosis. The exudate is apparent upon staining with hematoxylin and eosin, which does not stain the organisms but clearly permits visualization of the eosin exudate. Methylene silver or another yeast cell wall stain must be used to visualize the cyst form of the organism, considered the diagnostic stage.

\textbf{Immune Reconstitution Inflammatory Syndrome}

Treatment with antiretroviral therapy improves immune function, with a concomitant increase of CD4 cells within a few months after start of therapy. This improvement in immune responses can be accompanied by a paradoxical, exaggerated inflammatory response manifested against infectious or noninfectious agents that often results in clinical worsening, referred to as IRIS (41). IRIS occurs more frequently in adults, but has been reported in children. In adults, IRIS has been associated with patients harboring mycobacterial infections; PCP; cryptococcal infections; cytomegalovirus, varicella virus, or herpes simplex virus infections; or progressive multifocal leukoencephalopathy.

\textbf{Presentation in Children}

PCP is a common manifestation among HIV-infected children. The highest incidence occurs during the first year of life, peaking at 3 to 6 months of age (41). Although a
significant and dramatic decline in PCP infection rates in U.S. infants has been reported by the Centers for Disease Control and Prevention (CDC) and Perinatal AIDS Collaborative Transmission Study. Pneumocystis, it remains a deadly neonatal disease in Africa, where postmortem analysis showed that 44% of children who died between 2000 and 2001 had PCP (46). Recent data indicate that P. jirovecii is a significant cause of pneumonia in HIV-infected children without appropriate antiretroviral therapy or prophylactic treatment, with high mortality rates ranging from 28 to 63% (47).

PCP was first described in children and was considered a pediatric infection in its early history (48). Prominent epidemics of “interstitial plasma cell pneumonia” in undernourished children housed in suboptimal conditions after World War II were manifestations of the disease that was later identified as P. jirovecii pneumonia. The infection in these children was characterized by a plasma cell infiltrate, in contrast to the type II cell hypertrophy and scanty mononuclear infiltrate described in adults with the pneumonia.

Clinical features of PCP in children include fever, tachypnea, dyspnea, and cough. Onset can be acute or subtle, associated with nonspecific conditions such as mild cough, loss of appetite, diarrhea, and weight loss. Fever may or may not be present, but most children will exhibit rapid breathing with short shallow breaths at the time the pneumonia is visible by radiographic methods. Bilateral basilar rales, respiratory distress, and hypoxia are often evident on physical exam. In HIV-infected children, four clinical variables are independently associated with PCP: age younger than 6 months; a respiratory rate of greater than 59 breaths per minute; arterial percentage hemoglobin saturation less than or equal to 92%; and the absence of vomiting (41, 49).

Most children manifest frank hypoxia, with low arterial oxygen pressure of less than 30 mm Hg. The CD4+ count is often less than 200 cells/mm³, but can be higher. Children older than 5 years have a percent CD4+ of less than 13%. Like adults, children will often have bilateral diffuse parenchymal infiltrates with a ground-glass appearance, but such manifestations may be altogether lacking or mild.

**Presentation in Adults**

Adults with Pneumocystis pneumonia frequently present with dyspnea, nonproductive cough, inability to breathe deeply, chest tightness, and night sweats (45). A low-grade fever (e.g., 38.5°C) and tachypnea are often present, while hemoptysis or sputum production is rare. On physical examination, few pronounced abnormalities are detected, but various degrees of respiratory distress, small respiratory volumes, and fine basilar rales can be observed. Patients with AIDS often have a more insidious progression to clinical disease than patients who are not infected with HIV but are immunosuppressed.

The chest radiograph may appear normal or reflect a disease state. Diffuse, symmetrical, interstitial infiltrates are most commonly present, while focal infiltrates, lobar consolidations, cavities, and nodules are less common. Infiltrates in early infection may be widely distributed, but consolidation increases as the disease progresses. Administration of aerosolized pentamidine as a prophylactic measure has been associated with increased frequency of apical infiltrates and pneumothoraces. The severity of abnormalities on the chest radiograph is considered prognostic and can be correlated with higher mortality.

If the radiograph is normal or unchanged from a prior radiograph, a test for the diffusing capacity of the lung for carbon monoxide (DLCO) is recommended if the patient’s symptoms consist of a nonproductive cough or shortness of breath, with or without fever. If the DLCO (corrected for hemoglobin) is ≤75% of the predicted value or decreased ≥20% from baseline, the patient should undergo diagnostic evaluation or bronchoscopy or both (50).

The oxygenation impairment induced by pneumocystosis can be detected in most patients by a widening of the alveolar-arterial oxygen gradient [(A–a)DO₂] correlated with severity of disease and respiratory alkalosis (50). However, it should be noted that a significant number of patients can have a normal (A–a)DO₂ gradient at rest. Impaired diffusing capacity, alterations in lung compliance, total lung capacity, vital capacity, and hypoxemia are other physiologic changes that may be associated with P. jirovecii infection (45). Abnormalities in surfactant proteins also occur in infected individuals with increases in surfactant protein A and D most notable, since these proteins are considered components of innate immunity (51, 52).

**High-Resolution Computerized Tomography**

Chest radiography (X-ray) has been used to diagnose PCP, but the findings of "ground-glass" opacities and other characteristics are not definitive for the pneumonia, and about one third of patients with PCP have normal radiographic findings. High-resolution computerized tomography (HRCT) of PCP patients reveals extensive ground-glass opacity with a central distribution in a background of interlobular septal thickening, a mosaic pattern, or diffuse distribution in some patients (53). In some rare cases, unusual multiple nodular changes are observed (54). Pulmonary cysts of varying shapes and sizes are increasingly detected in up to one-third of patients on chemoprophylaxis. In some cases, a reversed halo sign may be indicative of PCP. Such a finding is observed as a round area of ground-glass attenuation surrounded by a crescent or ring of consolidation. First described as being specific for cryptocogenic organizing pneumonia, it can be observed in several other infectious and noninfectious diseases.

**Extrapulmonary Pneumocystosis**

The incidence of Pneumocystis organisms in sites other than the lung has been estimated to range from 0.6 to 3% of postmortem examinations of patients with pulmonary P. jirovecii infections (1, 2, 55). This is likely an underestimate due to the limited number of autopsies currently performed and the lack of suspicion of extrapulmonary pneumocystosis. Methenamine silver staining or immunofluorescent kits served to identify the cyst stage of Pneumocystis in tissue samples and fine-needle aspirates in antemortem cases. The lymph nodes were the most frequent site of extrapulmonary involvement in a series of 52 patients (44%), followed by the spleen, bone marrow, and liver (33%). P. jirovecii has been detected in the adrenal glands, gastrointestinal tract, genitourinary tract, thyroid, ear, liver, pancreas, eyes, skin, and other sites. Infection of multiple extrapulmonary sites was associated with a rapidly fatal outcome. Pathological findings correlated with the organ where the infection was present. For example, retinal cotton wool spots were reported in infected eyes, and pancytopenia was observed in patients with bone marrow lesions.

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

P. jirovecii pneumonia should be considered in any immunocompromised patient who presents with fever, respiratory
symptoms, or infiltrates on chest X-ray. While mostly restricted to the lung, *P. jirovecii* have been found as extrapulmonary masses (e.g., pleural, intra-abdominal) in HIV-positive patients and should be included in a differential diagnosis in these patients. As no symptoms are specific for *P. jirovecii* pneumonia, a definitive diagnosis is usually made by morphologic identification of the organism, though molecular methods are gaining in usage. Algorithms for clinical evaluation and treatment of PCP and differential diagnosis for HIV-associated pneumonias have been published and the reader is referred to these reviews for further details (45, 56, 57).

Because *P. jirovecii* cannot be cultured, the diagnosis of PCP relies on efficient sampling as most diagnostic methods still rely on microscopic techniques. The fungus can be detected in a variety of respiratory specimens, including induced sputum, bronchoalveolar lavage fluid (BALF), tracheal aspirate fluid, tissue obtained by transbronchial biopsy, cellular material obtained by bronchial brush, pleural fluid, and tissue obtained by open thorax lung biopsy. The diagnostic yield is dependent on the underlying disease state of the patient and the expertise of the staff obtaining the sample. In some hospitals where the staff are trained to obtain sputum samples and there is a large population with AIDS, 80% of diagnoses of PCP were made from induced sputum (58). In contrast, the diagnostic yield from non-AIDS patients can be quite low and bronchoalveolar lavage or other methods may be needed to ensure an appropriate diagnosis (59). Multiple slides from non-AIDS patients should be examined, especially when there is a high degree of suspicion. Hospitals serving a diverse population often rely on methods other than induced sputum. A notable drawback of using induced sputum as the primary procedure for the diagnosis of PCP is the lack of information concerning other infections or disease processes that may be present in the lung. The diagnosis of extrapulmonary pneumocystosis relies on accurate sampling of the infected organ and subsequent staining of the histological sections. For infants and young children who are unable to produce sputum or in whom this method is not warranted, tracheal aspirate fluid, open thorax lung biopsy, or respiratory specimens must be obtained by a special pediatric bronchoscopy service (30, 60).

**Bronchoalveolar Lavage**

 Fluid obtained by bronchoalveolar lavage is sufficiently liquid and does not require treatment with mucolytic agents. Twenty to 30 ml should be concentrated by centrifugation at 3,000 × g for 15 min. The resultant pellet is reconstituted in 0.5 to 1.0 ml of buffer or saline, and a sterile wooden applicator is used to smear the sediment on glass slides, which are then fixed in absolute methanol, acetone, or a commercial fixative in rapid staining kits. Samples in limited quantities can be concentrated by use of a Cytospin Centrifuge (ThermoScientific, Waltham, MA) or equivalent. Addition of 1 drop of 22% bovine serum albumin to 500 μl of sample will aid in adherence to the slide. Slides are air dried and then processed for staining. Morphological criteria for recognition of *P. jirovecii* stained by various procedures are discussed below and summarized in Table 1.

**Induced Sputum Collection**

 Sputum collection is best done in a centralized facility by pulmonary function laboratory technicians, respiratory therapists, or specially trained assistants. Deep inhalation of nebulized 3% sodium chloride solution by the patient will result in osmotic accumulation of fluid in and irritation of the respiratory passages with subsequent coughing and expectoration of bronchoalveolar contents. The patient should vigorously brush the teeth, tongue, and gums with a toothbrush and normal saline for 5 to 10 minutes prior to sputum induction, followed by thorough rinsing, to remove as much cellular debris of oral origin as possible. Toothpaste should not be used, as it can interfere with subsequent processing and staining of the specimen. The induced sputum specimen is usually mucoid and translucent in appearance; only rarely is it purulent. When *P. jirovecii* clusters are present in the unstained sputum, they are typically 0.1 to 0.2 mm in diameter and cream to light tan in color. Sputum smeared directly on slides and subsequently stained was shown to be a less sensitive method than treatment with a mucolytic agent followed by concentration of the specimen (61).

 Induced sputum is mucolyzed by the addition of an equal volume (at least 2 ml) of freshly prepared 0.0065 M dithiothreitol (Stat-Pak Sputolysin; Caldon-Biotech, Carlsbad, CA) or 0.5% N-acetyl-l-cysteine and incubation on a rotary shaker at 35°C with intermittent vigorous vortexing until the specimen is almost completely liquefied (complete liquefaction will lead to dispersal of the *P. jirovecii* clusters, making microscopic detection more difficult). Some protocols require the addition of a clearing reagent for optimal results (e.g., the Light Diagnostics Pneumocystis carinii DFA Kit [Millipore, Billerica, MA]). The specimen is then concentrated by centrifugation at 3,000 × g for 5 min and the sediment is smeared on glass slides, which are air dried and heat fixed by exposure to a heating block (50 to 60°C). Prolonged heat fixation is important in fixing the material to the slide (~30 min), since most of the natural cellular adhesions are removed during mucolysis. Slides containing the fixed material are then stained and examined microscopically (see below). Samples can be concentrated using a Cytospin centrifuge as described for BALF (above).

**Open Thorax Lung Biopsy**

Open thorax lung biopsy is the most invasive of the sampling procedures and is not routinely performed. This technique also suffers from a lack of sensitivity (57). However, should the laboratory receive such a specimen, the tissue should be blotted onto sterile gauze to reduce excess fluid (which would interfere with a diagnostic imprint) and used to make touch imprints by pressing several cut surfaces onto sterile glass slides. The remainder of the tissue can be used for histological sections, for microbiological cultures, or for nucleic acid extractions and subsequent PCR techniques. Glass slides with touch imprints should be air dried and then treated with absolute methanol or fixatives included in commercial kits of rapid Wright-Giemsa-like stains, such as Protocol Hema 3 (Fisher Scientific Inc., Cincinnati, OH). Infected tissue stained in this manner will reveal the presence of clusters of trophic forms and cysts with reddish purple nuclei and blue cytoplasm; cysts are surrounded by a halo of dye exclusion (see “Microscopic Identification” for a more detailed description). Slides should be fixed in acetone or a vendor-recommended fixative for immunofluorescent staining. Alternatively, a more concentrated sample can be achieved by a tissue homogenization using tabletop instruments like the gentleMACS Dissociator (Miltenyi Biotec) or the Stomacher Lab Blender (Tekmar Inc., Cincinnati, OH) following vendor recommendations for tissue type and weights. Slides are prepared with 10-μl drops of the homogenate, which are then air dried, fixed, and stained as desired.

Samples are then centrifuged at 2,900 × g in physiologic saline (0.9% NaCl) for a period of 1 min (21). In which more invasive techniques of sampling are problematic for infectious diseases is becoming widespread. These methods are based on quantitative PCR techniques. Handling of OW and NPA samples is crucial for accurate diagnosis by PCR with P. jirovecii-specific primers. These minimally invasive techniques have been shown to have high sensitivity, specificity, positive predictive value, and negative predictive values for the diagnosis of P. jirovecii pneumonia versus microscopic methods when used in conjunction with quantitative PCR techniques. Handling of OW and NPA samples is presented here since the use of PCR for the diagnosis of infectious diseases is becoming widespread. These methods will be extremely useful for sampling of pediatric populations in which more invasive techniques of sampling are problematic or where the yield is low.

OW samples are obtained by gargling with 10 ml of sterile physiologic saline (0.9% NaCl) for a period of 1 min (21). Samples are then centrifuged at 2,900 × g for 5 min and kept frozen at −20°C until DNA is extracted. After digestion with proteinase K at 56°C for 2 h, DNA or RNA can be extracted using any number of commercial kits available.

NPA are collected with a suction catheter and sterile saline (30). If the amount of collected specimen is small or it is highly viscous, sterile saline should be washed through the catheter to dilute the specimen or added to the final collection tube. The sample can then be treated with a mucolytic agent and subsequently stained (as described above) or prepared for the PCR by DNA or RNA extraction (described below).

DIRECT EXAMINATION AND IDENTIFICATION

Microscopy

A variety of stains have been used for the identification of P. jirovecii organisms. One of the most common stains used by pathologists for tissue sections, hematoxylin and eosin, does not stain the organism but rather the foamy exudates within the lung alveoli, often described as honeycombed in appearance. Stains that illustrate the morphology of the organism by microscopic examination are those used for diagnosis in the clinical laboratory.

A common staining procedure used for the diagnosis of P. jirovecii is methenamine silver, which also stains other fungi (Table 1; Fig. 3C). Cell wall and membrane polysaccharides of fungi are oxidized to aldehydes by treatment with periodic acid, which in turn reduce the silver ion to metallic silver at alkaline pH. Addition of gold salts stabilizes the complex and excess silver is removed by a sodium thiosulfate rinse. Variations of the methenamine silver stain (e.g., Grocott, Gomori) are used for both tissue sections and bodily fluids such as BALF or induced sputum (64–66). Disadvantages to the use of the silver staining process have been the instability of solutions, the capricious nature of the metal impregnation, and the length of time required for staining (1 to 2 h or 6 to 24 h; see Table 1). These disadvantages have been largely overcome with kits using standardized laboratory microwave ovens for controlled processing and supplied reagents (e.g., ACCUSTAIN Modified GMS Microwave staining kit; Sigma-Aldrich, St. Louis, MO). Unlike other pathogenic fungi, P. jirovecii does not bud, and this feature can be used to discriminate between these organisms and other fungi found in the lung that do bud, e.g., Histoplasma capsulatum. Silver-stained cysts have a distinctive, black, cup-shaped morphology against green-colored host cell architecture. In some staining reactions, cyst wall thickenings appear as a double-comma morphology. More often, the folds in the wall stain a dark brown to black to produce a crinkled, raisin-like appearance (Fig. 3C). Intracystic daughter forms cannot be seen with this stain, and cysts that are empty (nonviable) appear the same as those with the full contingent of eight spores.

Other stains that complex with components of the cyst wall include periodic acid-Schiff, toluidine blue, cresyl echt violet, and calcofluor. The reactions to some of the more commonly used stains are described in Table 1. Cresyl echt violet stain produces results similar to toluidine blue O (Fig. 3E) and has the same drawbacks, since a mixture of sulfuric acid and glacial acetic acid is necessary for the step prior to staining with the dye. Cysts stained with toluidine blue are similar in appearance to those stained with methenamine silver, except for the light purple color. Staining with calcofluor, whether in commercial kits (e.g., Fungi-fluor; Polysciences, Inc., Warrington, PA) or prepared in-house, can produce variable effects. Designed to detect only the cysts, excitation at 420 to 490 nm with a suppression filter of 515 nm produces a yellow-green or apple-green fluorescence, often with a characteristic double-parentheses staining body within the cyst (Fig. 3A). Excitation in the UV range (340 to 380 nm) with a suppression filter of 330 nm produces a fluorescent blue color that is not as intense and is sometimes difficult to visualize. Refer to the vendor instructions for optimal filter requirements.

In contrast to the cyst wall stains, Giemsa and rapid Giemsa-like stains do not stain the cyst wall, but instead stain the nuclei of all the various life cycle stages a reddish purple and the cytoplasm a light blue (Fig. 3B). The cyst wall excludes the dyes and appears with a circumscribed clear zone surrounding the reddish purple nuclei of the daughter forms within. Note the thick mat type of appearance, characteristic of the human infection. Lung cells are often present; their nuclei are much larger than those of Pneumocystis and stain a deep reddish purple (Fig. 3B). The rapid variants of the Giemsa stain are recommended for the diagnosis of PCP using BALF, induced sputum, or impression imprints because of the low cost, ease, and rapidity of the staining procedure. Commercial kits such as Protocol Hema 3 (Fisher Scientific Co., Cincinnati, OH) produce similar results. The staining procedure requires less than a minute to perform and all forms of the organism are detected. Since there are approximately 10-fold more trophic forms than cysts, the sensitivity of detection is likely to be increased. This stain also permits assessment of specimen quality of BALFs by demonstration of host alveolar macrophages, which should be present in a productive sample. In addition, the distinctive Giemsa-stained morphological appearance of other organisms likely to be encountered in the lung environment, such as H. capsulatum, permits rapid diagnosis of pulmonary infections caused by these pathogens which may not be detected with other stains. Because background host cells will also stain, training and expertise in interpret-
FIGURE 3  Morphology and tinctorial characteristics of *P. jirovecii* in clinical samples stained with various stains (magnification, × 960, unless stated otherwise). (A) Calcofluor stain of BAL fluid. Cyst walls with internal thickenings (double comma) are highly fluorescent (color varies with barrier filter used). (B) Rapid Giemsa-like (Diff-Quick) stain of BALF. Thick cluster of mostly trophic forms (2 to 3 μm) with small reddish-purple nuclei and light blue to red-violet cytoplasm. Boundaries of trophic forms are rarely discernible with this stain. Trophic forms overlay each other to produce darker staining blue cytoplasm. Large dark purple host nuclei are admixed in the cluster. (C) Gomori methenamine silver stain (Grocott) of organisms from BALF. Cyst walls and thickenings (double comma) can be observed as well as collapsed, cup shapes and crinkled raisin-like appearance. Note the lack of budding. Trophic forms are not stained with silver-based stains. (D) Papanicolaou’s stain of BALF. Note the distinctive alveolar cast morphology; magnification, ×400. (E) Toluidine blue O stain of *P. jirovecii* in BALF. Cyst walls are stained light purple. The crinkled appearance of the cysts is illustrated with this stain, as well as darker central staining body. Note the lack of budding with this and other cyst wall stains. Trophic forms are not stained. (F) Direct fluorescent antibody stain of organism cluster from BAL. Note apple-green fluorescence distributed unevenly over the cluster, with accumulation on a cyst wall (lower left of cluster). Structures within the cysts are unstained and appear black. doi:10.1128/9781555817381.ch118.f3

ing cellular elements in Giemsa-stained preparations is necessary. Laboratories with a lower volume of *P. jirovecii* specimens may prefer to use immunofluorescent staining or one of the other stains described in Table 1.

Direct and indirect fluorescein-conjugated monoclonal anti-*P. jirovecii* antibodies used for immunofluorescent assay (IFA) are targeted to a family of surface glycoproteins that contain both common and distinct epitopes, within and among *Pneumocystis* species (67). Depending on the monoclonal antibody supplied with the kit, staining may target only the cyst form or all forms of the organism. Since trophic forms are more numerous than cysts, kits using those antibodies directed to all forms of the organism, such as Bio-Rad’s MONOFLUO *Pneumocystis jirovecii* IFA Test Kit, a direct immunofluorescence assay for the detection of all *P. jirovecii* life cycle forms, are more sensitive. The typical fluorophore conjugated to the antibody or used in an indirect assay is fluorescein isothiocyanate, which produces a brilliant apple green color. The staining reaction shows a diffuse surface pattern distributed over the entire cluster of organisms (Fig. 3F) and often stains the matrix in which the organisms are embedded. Single cysts will usually appear with a distinctive rim of fluorescence and duller interior fluorescence. It should be noted that kits using a direct staining procedure may not react with *P. jirovecii* on slides fixed in ethanol, and fixation in acetone or vendor recommendations for fixation should be followed (68).

Papanicolaou’s stain, frequently used for cytopathological specimens, stains the clusters of extracellular organisms a greenish color, although thick clusters of organisms can collect the stain and appear bicolored with pink to purple and green/turquoise staining as in Fig. 3D. A diagnostic criterion is the presence of distinctive alveolar casts, as shown in panel D. Organism architecture is better observed with the Giemsa-like stains. Gram’s stain produces a negative (pink) reaction with poorly defined organism morphology.
Serum (1→3)-β-D-glucan

An assay that measures the serum levels of (1→3)-β-D-glucan in patients suspected to have *P. jirovecii* is proving to be a successful diagnostic modality, especially for patients who cannot produce appropriate sputum samples or where bronchoscopy may not be safe (69). (1→3)-β-D-Glucan is a component of the ascus (cyst) cell wall and is secreted in significant amounts during infection with *Pneumocystis* spp. Except for *Cryptococcus* and *Mucor* species, most other fungi also secrete (1→3)-β-D-glucan during infection, but the high amounts observed during infection with *P. jirovecii* have proven to be a useful diagnostic modality. A licensed detection kit uses a modification of the *Limulus* amoebocyte lysate (LAL) pathway. The Fungitell Assay reagent (Associates of Cape Cod, Falmouth, MA) is processed to eliminate factor C and is therefore specific for (1→3)-β-D-glucan (http://www.acciusa.com/clinical/fungitell/index.html). The reagent does not react with other polysaccharides, including beta-glucans with different glycosidic linkages. Normal human serum contains low levels of (1→3)-β-D-glucan, typically 10 to 40 pg/ml, presumably from commensal yeasts present in the alimentary canal and gastrointestinal tract. At present, the Fungitell assay is indicated for presumptive diagnosis of fungal infection and should be used in conjunction with other diagnostic procedures. Other kits that measure (1→3)-β-D-glucan are available from Seikagaku Corp., Tokyo, Japan, and from Wako Pure Chemical Industries Ltd., Osaka, Japan, but are not yet approved by the U.S. Food and Drug Administration.

It is very important to follow the vendor’s instructions for handling of patient serum as (1→3)-β-D-glucan can be an environmental contaminant. Serum is the only sample type that is currently approved for use with the Fungitell assay. Serum that is hemolyzed, lipemic, or visuallyicteric or turbid is not suitable for use with the Fungitell assay. Because a fungal infection is a dynamic process, repeat testing, typically 2 to 3 times per week, improves sensitivity.

Values below 60 pg/ml are considered negative for fungal infection; those between 60 and 79 pg/ml are “indeterminate,” while values of >80 pg/ml are positive for a fungal infection.

Cutoff levels specifically for the diagnosis of *P. jirovecii* pneumonia vary slightly. Recent studies have reported that elevated plasma (1→3)-β-D-glucan levels of >80 pg/ml have a high predictive value for diagnosis of *P. jirovecii* pneumonia in AIDS patients with respiratory symptoms (70), while another study suggested a threshold of 100 pg/ml (71). In a recent meta-analysis that evaluated the use of (1→3)-β-D-glucan for diagnosis of *P. jirovecii* pneumonia in a variety of patient settings, the sensitivity was found to be 94.7% using a range of cutoffs (72). The recommendation from this study was to use a slightly higher cutoff level than the >80 pg/ml that is recommended in general for fungal infections, e.g., 100 pg/ml. It should be cautioned that measurement of (1→3)-β-D-glucan levels has not been shown to track with therapeutic efficacy and should not be employed for this purpose. Also, although a high (1→3)-β-D-glucan level is likely to be diagnostic for *P. jirovecii* pneumonia, another confirmatory test is recommended at this time.

**Nucleic Acid Detection**

Amplification of *P. jirovecii* DNA for the diagnosis of PCP in the clinical laboratory setting is increasingly becoming a routine diagnostic assay. With the advent of real-time PCR, detection of *P. jirovecii* is a more sensitive and specific method than microscopic detection methods and the standard PCR or nested PCR techniques (73, 74). However, with this high degree of sensitivity, diagnosis should be in conjunction with clinical manifestations of PCP, as colonisation with these organisms can be detected by these highly sensitive assays (3). PCR methods can also be used for identification of potentially resistant strains or species of the organism by targeting of specific genes such as dihydropteroate synthase, for mutations associated with resistance (23).

Although the significance of infections with multiple genotypes of *P. jirovecii* is currently unclear, PCR-based detection systems would also be able to detect PCP caused by single or multiple genotypes. Quantitative PCR tests for PCP are being conducted by commercial firms such as ViraCor IBT laboratories (www.viracom.cor), but such tests have not been cleared or approved for diagnostic use in the United States by the Food and Drug Administration. Samples must be sent to the commercial vendor at this time. Detection limits are from 84 to 1×10^8 copies/ml for BAL, bronchial wash, nasopharyngeal wash, or nasopharyngeal aspirate and 213 to 1×10^8 copies/ml for whole blood.

Values below 60 pg/ml are considered negative for fungal infection; those between 60 and 79 pg/ml are “indeterminate,” while values of >80 pg/ml are positive for a fungal infection.

Cutoff levels specifically for the diagnosis of *P. jirovecii* pneumonia vary slightly. Recent studies have reported that elevated plasma (1→3)-β-D-glucan levels of >80 pg/ml have a high predictive value for diagnosis of *P. jirovecii* pneumonia in AIDS patients with respiratory symptoms (70), while another study suggested a threshold of 100 pg/ml (71). method permits pre-aliquotting of PCR reagents; allows the use of the entire system outside a specified PCR area, reducing cross-contamination; and requires little technician input, reducing potential human error. Like other nucleic acid-based detection methods, the BD Max platform has not yet received FDA approval. In addition, use of such kits demands evaluation in the clinical setting and should be approached with caution. Thresholds of each assay to distinguish colonization versus infection remain a concern.

In a recent study using real-time PCR with mtLSUrRNA as the target gene, cutoff values of $1.6 \times 10^3$ copies/ml and an upper cutoff level of $2 \times 10^4$ copies/ml achieved 100% sensitivity and 100% specificity for determining colonization versus infection. Combined with a 100-pg/ml threshold for $(1\rightarrow3)$-$\beta$-D-glucan, these suggested copy numbers could discriminate PCP from colonization (71).

ISOLATION PROCEDURES

Detection of Pneumocystis by growth in artificial media or tissue culture is not a diagnostic option, since no species of this genus can be continuously cultivated outside the mammalian lung.

TYPING SYSTEMS

There is no consensus for a typing system for P. jirovecii.

SEROLOGIC TESTS

Serological assays to detect anti-P. jirovecii antibodies are useful for epidemiological studies, but not for diagnosis of PCP. Most human beings become seropositive for P. jirovecii antibodies early in their childhood, between 2 and 4 years of age, and likely come in contact with the organism many times over their lifetime. In some cases, a rise in antibody titer can be detected in some PCP patients over time; in others, antibody titers can just as frequently drop or remain the same.

A number of other laboratory tests have been used for the diagnosis of PCP, but do not provide a definitive diagnosis. These include an increased arterial-alveolar gradient, an elevation of serum lactic dehydrogenase levels, and gallium and diethylenetriamine pentaacetic scans. The latter two tests are not routinely used due to higher costs. Reduced S-adenosylmethionine (AdoMet) levels have been reported to reflect infection with P. jirovecii (76, 77); however, another study conducted to evaluate the diagnostic utility of AdoMet versus $(1\rightarrow3)$-$\beta$-D-glucan levels found that AdoMet levels did not discriminate between infected and noninfected patients, while $(1\rightarrow3)$-$\beta$-D-glucan levels correlated with a high level of sensitivity and specificity using a cutoff of 60 pg/ml (78).

ANTIMICROBIAL SUSCEPTIBILITIES

Two drugs comprise the mainstay of therapy for acute PCP, trimethoprim-sulfamethoxazole (TMP-SMX) and pentamidine isethionate (79). Secondary treatments, such as atovaquone and clindamycin- primaquine, have been used for milder forms of the disease, and treatment with corticosteroids has been used to improve the clinical outcome in some patients. However, there have been significant rates of relapse and recurrence with such second-line therapies.

atovaquone (at least 1,500 mg/day) is recommended. Aerosolized pentamidine (300 mg every 4 weeks), or oral thrice-weekly administration of 960 mg (81). If patients for PCP prophylaxis is also TMP-SMX, with a daily or antimicrobial treatment is complete. The drug of first choice started at the same time as therapy and withdrawn before adjunctive therapy for patients with moderate to severe infections associated with HIV infection. It is thought that deleterious inflammatory responses are reduced with their administration. Steroids are usually given in high doses for 5 to 7 days, with a reduction in dose and continued treatment for an additional 2 weeks. Steroid treatment may be started at the same time as therapy and withdrawn before antiinflammatory treatment is complete. The drug of first choice for PCP prophylaxis is also TMP-SMX, with a daily or thrice-weekly administration of 960 mg (81). If patients are intolerant to TMP-SMX, oral dapsone (100 mg/day), aerosolized pentamidine (300 mg every 4 weeks), or oral atovaquone (at least 1,500 mg/day) is recommended.

Pentamidine is a cationic diamidine that was first used to treat African trypanosomiasis, or sleeping sickness, and later found to be efficacious as PCP therapy. The mode of action of this drug is not known but may involve suppression of mitochondrial activity, inhibition of topoisomerases, or binding of the minor groove of DNA (82). Pentamidine and TMP-SMX have significant side effects including nephrotoxicity and, in the case of TMP-SMX, severe rash, fever, and neutropenia that often necessitate a change to alternative treatment. In a recent study of HIV-1-infected patients with first episode PCP, only 64% completed TMP-SMX treatment (83). Neither drug is considered pneumocysticidal. Administration of pentamidine via an aerosolized route delivers the drug efficiently to the areas of infection, but it has been shown to be less effective than other drugs in the treatment of PCP as well as being associated with dispersal of *P. jirovecii* and other respiratory pathogens (12).

PCP remains refractory to most common antifungal drugs such as the azoles or amphotericin B. Echinocandins, (1,3)-β-D-glucan inhibitors, are a relatively new family of antifungal drugs that are fungicidal against candidal infections and fungistatic against Aspergillus infections (84). Reports of the efficacy of echinocandins for PCP have been contradictory, due in large part to the anecdotal nature of the reports (85, 86). Systematic studies of three clinically available echinocandins—caspofungin, anidulafungin, and micafungin—in rodent models of PCP revealed dramatic reductions in cysts, but much less of an effect on trophic forms, suggesting that use as monotherapies would not be efficacious, but a combination with TMP-SMX may provide beneficial to some patients (12).

Mutations in the DHPS gene of *P. jirovecii* associated with sulfa resistance in other pathogens have been identified in about 50% of the PCP isolates in certain geographic areas (23). The presence of the mutations in the DHPS gene of *P. jirovecii* was associated with previous TMP-SMX therapy, but the impact of the mutations in terms of outcome and response to therapy is not yet clear.

It may become desirable in the future to track the emergence of *P. jirovecii* strains that are resistant to TMP-SMX, or to evaluate the potential for therapeutic response. In anticipation of this goal, the primers targeting the regions of the dihydropteroate gene (DHPS) associated with sulfa resistance in other pathogens are shown in Table 2. The nucleotide (nt) positions in which the mutations occur are at nt 165 and nt 171. Changes at these nucleotide positions result in changes in amino acids. The following are the four genotypes for this target gene: genotype 1, nt 165 (A)/nt 171 (C) = Thr/Pro; genotype 2, nt 165 (G)/nt 171 (T) = Ala/Pro; genotype 3, nt 165 (A)/nt 171 (T) = Ala/Ser; and genotype 4, nt 165 (G)/nt 171 (T) = Ala/Ser. The last genotype, GT, represents a double mutation in the DHPS gene that has been associated with drug resistance and is emerging as the dominant genotype for *P. jirovecii* isolates in some areas (17). Although atovaquone resistance in PCP has been associated with mutations in the mitochondrial cytochrome b1 gene (87), resistance to TMP-SMX is much more problematic, and identification of mutations in the DHPS gene will likely be the more critical genetic region to evaluate in the clinical setting.

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

The microscopic demonstration of *P. jirovecii* in tissue and fluids by staining with Gomori methenamine silver or a rapid variant of the Wright-Giemsa stain, by IFA, or by other stains such as Papanicolaou stain should be considered sufficient for diagnosis. In many cases, the fungi are present as large clusters of organisms, in which it may be difficult to differentiate the life cycle stages within the dense assemblage by using the Wright-Giemsa or Papanicolaou stains. Because of this, it is recommended that a stain which only visualizes the cyst form of Pneumocystis (e.g., Gomori methenamine silver) be used for diagnosis because it is easier to interpret. The rapid stains can be used as a preliminary diagnostic technique, followed by the definitive cyst stain. IFA can be helpful in laboratories that are less familiar with *P. jirovecii* morphology, but this requires a fluorescent microscope, which may not always be available. The outcome of IFA staining depends on the monoclonal antibody target. Some kits use monoclonal antibodies targeting the surface glycoprotein present on all of the life cycle stages, but these also stain the dense matrix in which *P. jirovecii* is embedded, resulting in a highly fluorescent mass with little detail. Since there are no other species of the genus that are known to cause pneumonia in humans, the presence of these fungi can be reported as *P. jirovecii* or *Pneumocystis* spp. The name “Pneumocystis carinii” should not be used, as this species infects rats. Treatment should be initiated upon demonstration of *P. jirovecii* by microscopic methods and based on clinical evaluation of the patient. Moderate to severe PCP is treated with a combination of corticosteroids and intravenous TMP-SMX, clindamycin/primaquine, or pentamidine. Mild to moderate PCP is treated with TMP/SMX, TMP-dapsone, pentamidine, atovaquone, or clindamycin/primaquine (50).

**Aspergillus Species**

**Taxonomy**

The genus Aspergillus is classified in the family Trichomaceae of the Ascomycota. Taxonomic assignment of members of this genus has evolved substantially with over 250 species now described (1, 2; http://www.aspergilluspenicillium.org). The majority (64%) of species show no sexual reproduction (3), with the anamorphic (asexual) genus Aspergillus sensu stricto phylogenetically related to the anamorphic genera **Penicillium** sensu stricto and **Paecilomyces** (4).

Raper and Fennell in 1965 first classified 132 Aspergillus species into 18 subgroups (Aspergillus candidus, A. clavatus, A. cervinus, A. cremeus, A. flavipes, A. flavus, A. fumigatus, A. glaucus, A. nidulans, A. niger, A. ochraceus, A. ornatus, A. restrictus, A. sparsus, A. terreus, A. ustus, A. versicolor, and A. wentii) and 18 varieties based on their morphological characters (5). With advancements in molecular phylogeny, however, taxonomic changes in species classification have been made, resulting in new subdivisions, subgenera, and sections (6–8).

Most recently, using multigene phylogeny based on four genetic loci—(i) β-tubulin, (ii) calmodulin, (iii) internal transcribed spacer (ITS) and large subunit (LSU) of the rDNA gene cluster, and (iv) RNA polymerase II (RPB2)—a need for further taxonomic revision was demonstrated. Using this approach, Peterson established five subgenera, Aspergillus, **Circumdati**, Fumigati, **Nidulantes**, and Ornati, which he subdivided into 16 sections (section Aspergillus, Candidi, Cervini, Clavati, Circumdati, Cremei, Falci, Flavipes, Fumigati, **Nidulantes**, Nigi, Restricti, Sparsi, Terrei, Usti, and Versicolor), either retaining formerly recognized sections or reclassifying them (9). This restructuring resulted in a number of important changes within the genus, including the fact that specific groups of aspergilli now contain uniseriate and biseriate species as well as species characterized by different colony colors. This was not the case previously, when phenotypic characteristics such as colony color were used as key features to separate different groups of aspergilli. The application of this polyphasic phylogenetic species concept has led to the discovery and description of new cryptic or sibling species within the most frequent pathogens, e.g., **A. lentulus** (10) and **A. alahamensis** (11). In the latest taxonomic revision, Samson and Varga (2) extended the work of Peterson (9) and grouped more than 250 species into eight subgenera (Aspergillus, Fumigati, **Circumdati**, Candidi, Terrei, **Nidulantes**, Warucaip, and Ornati) which are subdivided into sections or species complexes.

It is now obvious that it is necessary to establish sequence-based associations between the anamorph and teleomorph (sexual) stages for aspergilli (where relevant) independent of whether mating occurs. At the time of writing, the anamorphic species of the genus Aspergillus are associated with nine teleomorphic genera (Chaetosartoria, Dichotomomyces, Emericella, Eurotium, Fenniella, Neocarpenteles, Neopetromyces, Neosartorya, and Petromyces) within the taxon Trichomaceae (2, 12). Peterson had suggested to split the genus Aspergillus based on the teleomorph states associated with particular monophyletic lineages (9); however, this would have deemphasized the most common morphological features associated with the genus Aspergillus. With the establishment of the “one fungus = one name” principle in 2011 at the International Botanic Congress in Melbourne, Australia, as a new “International Code of Nomenclature for Algae, Fungi, and Plants” (13), and the abolishment of the priority of the teleomorph designation for fungi (14), the naming of Aspergillus species has been debated. The Aspergillus working group in 2012 agreed to retain the name Aspergillus and not adopt the teleomorph nomenclature (sensu Raper and Fennell [5]). This decision has significant consequences, as it results in the loss of the well-known teleomorph genera Emericella, Eurotium, and Neosartorya. The argument for maintaining Aspergillus for the whole genus is ensuring stability for nomenclature of most medically important Aspergillus species, and their clinical interpretation. For the present, discussions are ongoing whether to use the anamorph name for the whole genus or to split the genus according to teleomorph form; this chapter follows the current official view on nomenclature by using the anamorphic name followed by its teleomorph stage in parentheses (for more information, see http://www.aspergilluspenicillium.org).

Of known Aspergillus species, the majority of human infections are caused by A. *fumigatus* (teleomorph synonym: Neosartorya *fumigata*), followed by A. *flavus* (teleomorph synonym: Petromyces *flavus*), A. *terreus*, and A. *niger*. In addition, at least another 48 Aspergillus species have been implicated in disease (15). These uncommon but important pathogens are shown in Table 1. The phylogenetic relationships, based on ITS1 and ITS2 rDNA sequence analysis, of most of these species are shown in Fig. 1.

Description of the Agent

Aspergillus species are ubiquitous. They grow rapidly and form powdery colonies on mycological media. Colony color varies with species and is influenced by growth conditions and factors such as whether vegetative hyphae, conidial heads, and/or sexual structures are present. The color of the aerial part of the colony may also be different from the pigment exhibited by the portion in the growth medium. The growth rate of Aspergillus species and their colony diameter in media and at a certain age are important features to aid species identification, as well as the appearance of the colony at its margins. The margins can be sharply delineated or thin and diffuse, smooth over its entirety or irregularly lobed, and submerged or aerial. Colony texture of the surface which ranges from velvety, floccose to granular, and which may show a zonation, is also used to assist with species designation (15) (see "Identification").

Aspergillus spp. form nonseptate stipes or conidiophores (walls), which commonly terminate in a vesicle (distinct inflated part) from which phialides are produced synchronously. They reproduce via conidia, which are formed in dry chains on the end of the phialides. The phialides can be formed directly from the vesicle (uniseriate) or alternatively they can form metulae (intermediate series of cells) (bisericate) (15). Figure 2 provides a schematic of the more important structural features of aspergilli. Morphological characteristics of clinically relevant sections/species are listed in Table 2.

Epidemiology and Transmission

Aspergillus species are environmental saprophytes that thrive in decaying vegetation and are readily cultured from soil, water, certain foods, and air. Although conidia are continually inhaled from the environment, they are eliminated from healthy hosts via mucociliary clearance or following phagocytosis by alveolar macrophages (16). In hosts with altered lung function, they may colonize the respiratory tract or cause allergic or invasive pulmonary disease. Severely immunocompromised individuals are at particular risk of invasive pulmonary aspergillosis, which may also spread to contiguous sites or disseminate to other body sites via the bloodstream (17, 18).

In health care facilities, Aspergillus has been cultured from unfiltered air, ventilation systems, dust, food, hospital water supplies, and related wet environments, including shower outlets (19–21). Numerous outbreaks of hospital-acquired invasive infection have been described, mostly following inhalation of airborne spores originating from construction or demolition activities (22, 23). Aerosolization of water from contaminated sources or surfaces may also occur (20, 21, 24). Warris and Verweij have proposed control measures for the prevention of waterborne infection in hospitals, though the importance of water as a source of hospital outbreaks remains uncertain (24). Most outbreaks are associated with invasive pulmonary aspergillosis, but clusters of surgical wound and skin infections have also been described (25). In some studies, identification of a common source was supported by molecular genotyping (19, 22), though in addition to clonally related genotypes and microvariants, multiple genotypes have typically been found in clinical and environmental samples (26). Not all researchers have detected genetic relatedness between environmental and clinical isolates (24). Concentrations of airborne fungi in patient-care areas during outbreak investigations have ranged from 0 to >100 spores/m³. Though higher concentrations of airborne spores have been associated with outbreaks (26), a threshold below which patients are considered safe has not been determined. Determining this threshold may not be possible due to use of variable sampling methods, rapid temporal variation in spore counts, delayed sampling as a result of delays in clinical presentation after exposure, differences in host susceptibility to infection, and other factors (19). The Centers for Disease Control and Prevention and the Healthcare Infection Control Practices
Advisory Committee have published guidelines on prevention of aspergillosis in health care facilities (23). *A. fumigatus* is the commonest cause of invasive aspergillosis in developed and developing countries, accounting for at least 65% of cases, especially in the highest risk group, patients with hematological malignancies (27–30). Other pathogenic species include *A. flavus*, *A. terreus*, *A. niger*, and, infrequently, *A. nidulans* and *A. ustus* (31). *A. flavus* infections are more common in developing countries and in arid climates where they comprise the majority of cases of allergic aspergillosis, trauma-associated endophthalmitis, and sino-orbital-cerebral disease (28, 32, 33). Nosocomial outbreaks of aspergillosis are most common in patients with hematological cancers and are almost always caused by *A. fumigatus* or *A. flavus* (19). In the U.S.-based Transplant-Associated Infection Surveillance (TRANSNET) study conducted from 2001
to 2006, 67% of isolates were identified as A. fumigatus; cryptic species of A. fumigatus comprised 6% of this complex (30).

**Clinical Significance**

Aspergilli can cause disease as a result of ingestion of mycotoxins or other metabolites; direct inoculation into traumatized skin, eyes, or other sites; and inhalation of spores causing hypersensitivity or invasive disease. Aspergillosis most commonly involves the lungs but almost every organ can be involved as a result of primary infection, contiguous spread, or dissemination (34, 35). Lung infection presents as a spectrum of disease, depending on the extent of immunosuppression, genetic factors, and structural abnormalities within the respiratory system. Certain species are associated with specific forms of disease (Table 3).

Invasive aspergillosis is the second most common hospital-acquired fungal infection, after invasive candidiasis (36), and is associated with high morbidity and mortality especially in patients with hematological malignancies or allogeneic stem cell or lung transplants (37, 38). Other groups at increased risk and with poor outcomes include patients who have had heart, liver, and, less commonly, renal transplants; patients receiving immunomodulators such as infliximab or tumor necrosis factor alpha inhibitors; and patients with advanced AIDS, malnutrition, or other underlying immune deficiencies, including patients with a primary neutrophil defect. Critically ill patients and patients with chronic respiratory tract disease are also at risk of invasive pulmonary aspergillosis (18, 27, 28–30, 39).

In diagnosing aspergillosis, positive cultures (or antigen- or nucleic acid-based tests) for Aspergillus from clinical speci-

*Modified from previous versions of this chapter.

*Modern concepts have replaced group names with subgenera and sections.

*Refer to “Taxonomy” above for description of terms.

*Only species producing potent toxins are noted as toxigenic, but other species may produce toxins of lesser significance.

mences may not in themselves indicate a pathological process. The distinction between colonization of the respiratory tract and invasive disease is particularly difficult in highly immunosuppressed patients and those with chronic airway disease (40, 41), but the probability of requiring treatment increases with increasing immunosuppression. To enable standardization in assisting diagnosis, and for the purpose of clinical trials in patients with hematological malignancies, consensus definitions of proven and probable aspergillosis are published by the European Organization for Research and Treatment of Cancer and the Mycoses Study Group (EORTC/MSG). These incorporate host immune status, lung imaging (computed tomography [CT]) findings, antigen-based biomarker tests, histology and culture findings, but not as yet nucleic acid detection tests (42). Criteria have also been developed for diagnosis of invasive aspergillosis in patients with chronic obstructive lung disease and for the entity of chronic pulmonary aspergillosis (43, 44). hyphae in tissue or other clinical samples, and culture of a heavy growth of Aspergillus from a single specimen or the same species from multiple specimens, point to invasive disease in the appropriate clinical context. Culture of at least three good-quality sputum specimens is recommended whenever fungal infection is suspected. Antigen- and nucleic acid-based diagnostics are discussed below.

Collection, Transport, and Storage of Specimens

Methods to collect appropriate clinical specimens (see chapter 114) are especially important for diagnosis of invasive pulmonary aspergillosis due to uncertainty in differentiation of Aspergillus colonization (or even contamination) from Aspergillus disease. Diagnosis can be difficult (36, 45) and appears to be most problematic in nonneutropenic hosts and in patients with compromised airways (e.g., lung transplant recipients). The most convincing evidence of aspergillosis is provided by recovery of the fungus from lung biopsy tissue and other normally sterile sites and/or by histopathologic demonstration of hyphae in tissue. Yet nonsterile specimens such as sputum and bronchoalveolar lavage (BAL) fluid represent the more frequent specimens submitted for culture where recovery of aspergilli may reflect colonization (46). Culture results should be interpreted in combination of an assessment of clinical, radiographic, and other diagnostic tests.

Other than the respiratory tract, Aspergillus can be recovered from culture of any body site including sinus, cerebrospinal fluid (CSF), skin, other tissue, the eye, and heart valves. In Aspergillus endocarditis, as with other invasive infections, blood cultures are typically negative. Conversely, positive blood cultures for Aspergillus are often indicative of contamination even in populations at high risk for invasive aspergillosis (47), although they uncommonly are helpful in disseminated infection (48). All specimens should be transported to the laboratory as soon as practicable for culture and other diagnostic testing. For detection of Aspergillus DNA in archived samples, such as paraffin-embedded (PE) tissue, tissue should be sent in thin (approximately 10 × 10 μm) sections in a sterile receptacle (49). It is advisable to discard the first section due to possible contamination with fungal spores.

Direct Examination

Microscopy

Microscopic examination of fresh and/or stained specimens of tissue, BAL fluid, sputum, tissue aspirates, and other specimens may reveal fungal structures, but this method is insensitive and specimens are often positive only in advanced disease. Hyphal elements can be observed using routine potassium hydroxide preparations, or with a fluorescent stain such as calcofluor white or Blankophor P. In tissue biopsy sections, hyphae may be seen when using specific fungal stains including Gomori methenamine silver (GMS) or Grocott’s stain and periodic acid-Schiff (PAS). In hematoxylin and eosin (H&E)-stained tissue, hyphae can also be visualized, although care must be taken not to traumatize tissue. Viable hyphae are typically basophilic to amphophilic while damaged or necrotic hyphae are more often eosinophilic (50).

Although species identification of Aspergillus is not possible, microscopy provides relevant preliminary diagnostic information; some assessment of fungal morphology and demonstration of fungal hyphae in tissue is a requirement of
the EORTC/MSG classification for a “proven” or “definite” fungal infection (42). Aspergillus hyphae are typically hyaline, septate, and 6 μm in diameter and branch dichotomously at acute (≈45°) angles, although not all the above features may be evident (see Fig. 3A for an H&E-stained section of lung). Hyphae have smooth parallel walls with no or slight constrictions at the septa (15, 50). Where invasion has occurred, hyphae may extend throughout the tissue and form parallel or radial arrays. Aspergilli in chronic lung cavities grow as tangled masses of hyphae and may exhibit atypical hyphal features such as swellings measuring up to 12 μm in diameter and/or absence of conspicuous septa. Unusual features such as swelling of the terminal elements in tissue sections and may allow presumptive identification of the fungus. For example, in tissue A. terreus displays distinctive aleuroconidia along the lateral hyphal walls (51). Calcium oxalate crystals have been associated with A. niger infection (32). However, culture, immunohistochemical staining, or nucleic acid amplification is required to identify the pathogen. Specificity of microscopic methods is low for distinguishing non-Aspergillus hyaline moulds from Aspergillus (53). Techniques, such as in situ hybridization with a specific fluorescent antibody that binds to fungal elements in tissue, may aid diagnosis; in one study, Fusarium was distinguished from Aspergillus elements in tissue sections with a 100% positive predictive value (PPV) (54), although the use of immunohistochemistry has not been validated for this purpose.

Antigen Detection
Galactomannan (GM) is a major polysaccharide constituent of the cell walls of Aspergillus, most Penicillium (and/or Talaromyces) species, and certain other moulds, which is released in vivo from growing hyphae. Commercial assays for GM are well validated. The Platelia Aspergillus enzyme linked immunosorbent assay (ELISA) (BioRad Laboratories, Hercules, CA) is a double sandwich ELISA that utilizes a rat monoclonal antibody (mAb) EBA-2, directed against the galactofuranoside side chain of the GM antigen (reviewed in reference 55), and it is data on this test that resulted in inclusion of GM in the revised EORTC/MSG definitions of invasive aspergillosis in immunosuppressed patients (42). These definitions were developed for use in clinical and epidemiological research; in clinical practice, they must be taken in context with clinic-pathologic descriptions and classifications (34) (see “Clinical Significance”).

Although the EORTC/MSG definitions include GM detection in plasma, serum, BAL fluid, or CSF, extensive clinical validations have only been performed for serum and, following release of a newer format of the above assay from Bio-Rad, BAL fluid, especially in patients with hematological malignancies (for reviews and meta- and systematic analyses, see references 55–60). Based on a meta-analysis, the sensitivity and specificity of serum GM, using a cutoff optical density index (ODI) of 0.5 for the diagnosis of invasive aspergillosis, are 71 and 89%, respectively, with a low PPV of 26 to 53% but high negative predictive value (NPV) of 95 to 98% (56), suggesting that GM is more suitable as a screening to exclude aspergillosis than as a diagnostic test. The sensitivity and specificity of serum GM testing vary substantially in different studies, mainly due to differences in study design and study populations. It is much more sensitive when used in neutropenic and hematopoietic stem cell transplant recipients than in patients with solid organ transplants (61, 62) or critically ill patients with chronic obstructive pulmonary disease, presumably because of the higher incidence of angiogenesis in neutropenic patients (63, 64). As a diagnostic test in patients with hematological malignancies, the specificity and PPV were increased to 98.6% when two consecutive samples were positive at an ODI of at least 0.5 (65). It has been recommended that a single positive GM index of ≥0.7 or two consecutive samples of ≥0.5 should prompt a diagnostic workup (65). Use of mould-active antifungal agents reduces the sensitivity of the serum GM test (66), and false positives have occurred in patients receiving piperacillin-tazobactam or amoxicillin-clavulanate in association with Bifidobacteria in the gut of neonates and with ingestion of foods containing GM (63). Some non-Aspergillus moulds may yield positive GM results (Takaromyces marneffei, Histoplasma capsulatum, Fusarium oxysporum, Paecilomyces, and Alternaria species) (59).

Recently three systematic reviews/meta-analyses of the utility of GM in BAL fluid in patients with hematological malignancies or mixed comorbidities were published (58–60). All acknowledged limitations of the studies analyzed but concluded that the BAL GM assay was more sensitive than serum GM, though different cutoff ODI for BAL GM positive samples were recommended: 1.0 by Zou et al. (58), 1.5 by Heng et al. (59). Data regarding the effect of mould-active agents on level of BAL-GM are conflicting, and standardization across studies is needed to resolve these differences (59). There is emerging evidence that BAL GM is more sensitive and specific than serum GM in critically ill patients with chronic obstructive pulmonary disease, though a proposed cutoff of 0.8 for the ODI requires confirmation (67).

Aspergillus Antigen Detection Using Lateral Flow Technology
Recently, a simple test that is more specific than the GM assay and that does not require specific equipment has been developed as a rapid diagnostic tool, although the current need for a pretreatment step in testing serum (but not BAL fluid) samples reduces its utility as a point-of-care test. The test relies on binding of a mouse monoclonal antibody (Mab JF5) to an extracellular glycoprotein of Aspergillus, which is present in cell walls of growing germ tubes and secreted at growing hyphal tips but absent from ungerminated conidia (68, 69). The Mab JF5 does not cross-react with fungal antigens that cross-react with Mab EB-A2 used in the GM assay, namely, those of T. marneffei, H. capsulatum, F. oxysporum, and Alternaria species. However, both antigen tests demonstrate cross-reactivity against Paecilomyces and non-Talaromyces Penicillium species (68) (see “Penicillium”). Testing of samples from patients with hematological malignancies suggests that the Aspergillus lateral flow assay is as specific as, but may be more sensitive than, GM; that it can be used on BAL samples; and that both sensitivity and specificity may be improved by using it in combination with PCR-based assays (70–72). It should be noted that, at the time of writing, the Aspergillus lateral flow test is not widely available.

(1,3)-β-D-Glucan
Other than tests to detect Aspergillus GM and, now, novel Aspergillus-specific antigens (68), colorimetric detection of
(1,3)-β-D-glucan in the serum of patients represents another strategy for diagnosis of invasive aspergillosis. As with Aspergillus GM, detection of (1,3)-β-D-glucan has been added as a diagnostic criterion in the EORTC/MSG assessment for probability of invasive aspergillosis (42). This antigen is a major component of the fungal cell wall, and circulating (1,3)-β-D-glucan can be quantified in the serum of patients with invasive aspergillosis (73–76). Concentrations approaching 1 pg of antigen/ml can be detected, with a level of ≥ 200 ng/ml (Fungitell Assay; Associates of Cape Cod Inc., Falmouth, MA) considered indicative of fungal infection.

However, the inability of the test to discriminate between Aspergillus-related infections and those caused by other fungi—i.e., its low PPV (approximately 50% at best)—is a key limitation of the assay for diagnosing aspergillosis. The sensitivity, specificity, and NPV of the assay for asymptomatic fungal infection are described to be approximately 93, 77, and 98%, respectively (73, 74). In a meta-analysis of 16 studies encompassing a variety of fungal infections in hematology and other patient populations, the pooled sensitivity was 76.8%, specificity was 85.3%, positive likelihood ratio was 5.2, and negative likelihood ratio was 0.29 (77). Data indicate that the sensitivity for invasive aspergillosis ranges widely, from 60 to 100%. Despite these limitations, the serum (1,3)-β-D-glucan test may be useful as a negative predictor of aspergillosis if combined with more specific tests; exposure to mould-active antifungal agents reduces the sensitivity of the test (75–77). Conversely, false-positive results are common under conditions of hemodilution (cellulose membranes), treatment with immunoglobulin products, and exposure to glucan-containing material (55, 77). Cross-reactivity with amoxicillin-clavulanic acid and cell wall components of Gram-positive organisms has occurred. Test results should be interpreted within the clinical context, and further validation is required to determine its usefulness for monitoring therapeutic response.

Nucleic Acid Detection

Aspergillus DNA can be detected in clinical specimens either by nucleic acid amplification methods specifically targeting Aspergillus or by panfungal PCR assays followed by DNA sequencing for species identification. The former has the better sensitivity and faster turnaround time (no need for DNA sequencing), but panfungal assays have broader diagnostic potential. Both strategies may identify Aspergillus spp. directly in tissue, blood, CSF, and respiratory samples (49, 78–80) with good overall sensitivity and specificity, although with wide interstudy variability in performance (40 to 100% for sensitivity; 60 to 100% for specificity) (reviewed in reference 55). Badiee et al., studying 194 hematology patients with proven/probable aspergillosis, verified values for molecular detection of Aspergillus spp. of 66, 96, 63, and 97%, respectively, for sensitivity, specificity, PPV, and NPV (80). Technical advances in amplicon detection methods have enabled real-time detection and quantification of Aspergillus DNA using TaqMan, LightCycler, high-resolution melt curve analysis, or nucleic acid sequence-based amplification; these methods are detailed elsewhere (55, 81–83). Yet the clinical utility of Aspergillus PCR tests remains incompletely defined.

Prior to initiatives to formally address the limited clinical application of Aspergillus PCR assays (see below), Mengoli et al. undertook a systematic review to assess assays for their (i) diagnostic value (specifically diagnostic odds ratios [DORs]) or (ii) role in screening for invasive aspergillosis (84). Sixteen studies that employed PCR on blood, serum, or plasma samples (> 10,000 samples from 1,618 patients at high risk for invasive aspergillosis) were included. The meta-analysis showed that a single PCR-negative result was sufficient to exclude a diagnosis of proven/probable aspergillosis if PCR was used as a screening tool from the start of the at-risk period. Two positive PCR results are required to maximize specificity. Calculated pooled sensitivity was 75% (95% confidence interval [CI], 54 to 88), specificity was 87% (95% CI, 78–93), PPV was 15.2 to 81%, and NPV was > 97%. The at-risk populations studied varied, and there was great heterogeneity in PCR methodology, nature of samples (e.g., whole blood versus serum), and volume of sample tested (84). Indeed, 1-ml serum volumes when compared with 100 μl volumes yielded superior sensitivity (100% versus 76.5%) (85).

PCR performed on BAL samples has good potential to assist diagnosis of invasive pulmonary aspergillosis (86–88). A recent evaluation of a real-time pan-Aspergillus PCR in lung transplant patients showed a sensitivity and specificity of 100 and 88%, respectively, with similar performance characteristics noted for an A. fumigatus-specific PCR (86). Despite assay differences, studies have demonstrated a high NPV and good sensitivity, with variable PPVs reflecting differences in diagnostic certainty.

Because of these limitations, the European Aspergillus PCR Initiative (EAPCRI) working group of the International Society for Human and Animal Mycology (ISHAM) has devised standards for Human and Animal Mycology (ISHAM) for Aspergillus PCR which would allow clinical validation and subsequent wide use of a PCR assay. Notably, the following factors are critical in influencing the quality and success of Aspergillus PCR assays: the type of specimen, volume of specimen, the DNA fungal extraction method, and potential for automation of the PCR process itself (to increase sensitivity). This international collaboration thus far has established a recommended methodological process to detect Aspergillus in EDTA-blood using standardized DNA extraction (89, 90). Guidelines for DNA extraction from serum specimens and for Aspergillus DNA detection have also been published (90). There was no significant difference in sensitivity between the use of whole blood or serum for PCR-based diagnosis of aspergillosis, although in one study there was a trend for whole blood to be more sensitive (85% versus 79%) and to show earlier positive results (36 days versus 15 days) compared with serum (91). Against this finding is the reduced false-positivity rate using serum, which is also easier to process. The optimum sample type should be determined by the local requirement.

A further advance is the commercial MycoAssay Aspergillus assay (Mykonostica, Manchester, UK), a real-time platform that detects Aspergillus spp. and allows standardized detection using quality-controlled reagents. However, the kit does not distinguish between individual species and is not cleared by the U.S. Food and Drug Administration (FDA) for use. When tested on lung and other tissue samples containing Aspergillus, the sensitivity was 82% and specificity was 79% relative to microscopy, and 90% and 64%, respectively, compared to culture (92). In high-risk hematology patients, the kit had a sensitivity of 65% and specificity of 95% when performed on serum and BAL fluid (93, 94). In nonhematology patients with invasive lung aspergillosis, the sensitivity, specificity, PPV, and NPV on lower respiratory tract samples were 86.7, 87.6, 34.1, and 92.2%, respectively; sensitivity increased when multiple samples were analyzed (95). The median time to detection of Aspergillus was 4 hours. At present, the kit should be used to...
complement culture methods to ensure accurate species identification.

**Clinical Utility of Combined Antigen Detection and Nucleic Acid Amplification Test**

The above descriptions of GM/(1,3)-β-D-glucan antigen and Aspergillus PCR testing for the diagnosis of invasive aspergillosis have highlighted a number of limitations of both strategies. Test performance can vary considerably, and the (1,3)-β-D-glucan test is not specific for Aspergillus spp. Much progress has been made in standardizing Aspergillus PCR procedures, although more work is required prior to enabling its wider deployment.

Nonetheless, it is clear from numerous publications that it is the use of these tests in combination that assists in the earlier diagnosis of invasive aspergillosis. In a recent randomized trial of the Aspergillus GM and Aspergillus PCR versus culture and histology methods in high-risk hematology patients, the use of GM and PCR to direct therapy reduced the use of empiric antifungals, enabled more diagnosis of probable aspergillosis a median of 4 days earlier, and was most effective in patients receiving fluconazole, itraconazole, or no antifungal prophylaxis (96). Rogers et al. demonstrated that addition of PCR to GM monitoring in the setting of hematological malignancy provided greater diagnostic accuracy for invasive aspergillosis (97). Others have reported that GM or PCR can diagnose invasive aspergillosis a median of 2 to 9 days earlier than culture and high-resolution CT scans in up to 88.8% of patients (98, 99).

A recent retrospective clinical evaluation of the Aspergillus lateral flow test gave good clinical performance, especially if combined with PCR (100% sensitivity and 100% specificity) for proven/probable aspergillosis (72).

**Isolation Procedures**

Aspergillus species are not fastidious in their growth requirements. They are typically easily recovered on standard mycological media and will also grow on bacteriological media such as blood agar. On occasions where respiratory tract specimens may be inoculated on media selective for certain non-Aspergillus moulds (e.g., dichloran rose bengal agar for selective isolation of Scedosporium species [100]), and where the presence of potential opportunistic moulds may be clinically relevant, it should be noted that growth of aspergilli is inhibited on these media.

Most isolation schemes utilize specific media and incubation conditions for the description of characteristics, such as colony color and size (diameter) (Fig. 3). Aspergillus species usually grow without difficulty at 25°C but also at higher temperatures. Although isolation procedures do not require specific biohazard precautions, it is good laboratory practice to handle all culture material in a class II biosafety cabinet to avoid dispersal of spores through the environment and cross-contamination. The culture process usually requires several days.

**Identification**

Culture-based identification of aspergilli remains important. Diagnostic features of the more common pathogenic species/complex are summarized in Table 2. For keys to taxa and additional information, see also de Hoog et al. (15). Figure 2 presents a diagrammatic key to several species. Some species commonly produce sexual structures (i.e., cleistothecia and ascospores), which may aid identification. The respective teleomorph names of common Aspergillus species are given in parentheses (e.g., *Emericella, Neosartorya* [Table 2]).

Phenotypic identification of Aspergillus requires the assessment of both macroscopic and microscopic morphological characteristics. Isolates are usually inoculated at three points on potato dextrose agar, Czapek Dox agar (with or without 20 to 30% added glucose) or 2% malt extract agar and incubated at 25°C (6, 15). These media are necessary since aspergilli tend to reproduce in the asexual form when grown on Sabouraud dextrose agar (SDA). Most species sporulate within 7 days, but the teleomorph form takes longer to develop. Descriptions are primarily based on colony pigmentation and morphology of the conidial head with reference to those in expert monographs (4, 8).

**Macroscopic Features**

Colony diameters on standard media at 25 and 37°C, obverse and reverse colors, texture, topography, and presence of exudate droplets and diffusible pigments may be recorded after 7 days (see Fig. 3B–3I) (15, 101). Isolates not identifiable should be retained for longer for possible development of ascomata or other structures that may aid identification.

**Microscopic Features**

Microscopic mounts are best made using sticky tape flag or slide culture preparations mounted in lactophenol cotton blue (101). A drop of alcohol is usually required to remove bubbles and excess conidia. Key features are hyaline hyphomyces showing distinctive conidial heads with flask-shaped phialides arranged in whorls on a vesicle (Fig. 2). Specifically, important features are differences in size, shape, color, and wall ornamentation of various structures including the stipe, shape and size of vesicles, and arrangement of phialides. A stipe or conidiophore arises either directly from the vegetative hyphae or from a specialized hyphal cell called a foot cell; it is typically nonseptate and varies in color, length, and wall ornamentation according to spe-
cies. The stipe ends in a variably shaped (globose, subglobose, hemispherical, pear-shaped or clavate [club-shaped]), swollen vesicle (Fig. 2); either the entire vesicle or its upper portion is covered with phialides which give rise to the conidia. Conidial head morphology in Aspergillus is either ustulate in arrangement, where the phialides arise directly from the vesicle, or biserate, where they arise from an intermediate series of cells, the metulae, or a combination of both, as occurs in A. flavus (Fig. 2, Table 2).

The conidia themselves may be borne in a single column (columnar), or columns may be split with some arising at right angles to the stipe (radiate). A dissecting microscope is required to make this distinction. Conidia are usually ellipsoidal or globose, may be echinulate, and vary in size, color, and wall markings depending on the species. At times, contrast microscopy may be required to delineate morphologies (102).

Sclerotia are firm, fruiting-body-like structures comprising swollen hyphal cells but without internal spores. Hülle cells are variably globose with thick refractile walls (Fig. 3I). They commonly occur within the growing mycelium near the colony center, where their presence is indicated by droplets of exudate. They are often associated with cleistothecial ascomata (Table 2). The interiors of cleistothecia are filled with asc and ascospores. Shape, color, size, and wall features of these structures are important in distinguishing the different teleomorphic forms.

Poorly Sporulating Species or Variants Where sporulation is poor, identification may be problematic, although incubation at 25°C in light and allowing the cultures to experience the normal diurnal cycles of light and dark may help to induce sporulation (102, 103). Poorly sporulating “A. fumigatus” isolates are not uncommonly recovered from clinical specimens (8, 102). When this occurs, A. fumigatus species complex could be considered if an atypical, sometimes waxy or cerebriform mould was grown at 45°C (all members of section Fumigati grow at this elevated temperature [Table 2]); it is now well established that various cryptic species such as A. lentulus and other closely related sibling species of A. fumigatus demonstrate a poorly sporulating phenotype (10, 102). A. lentulus does exhibit smaller vesicles (Table 2, Fig. 3E) and, unlike A. fumigatus, cannot grow at 48 or 50°C, but in practice it cannot be distinguished by morphological methods alone from A. fumigatus without scanning electron microscopy (SEM) or other sophisticated microscopy. As A. lentulus has low in vitro susceptibilities to the azoles, amphotericin B, and caspofungin (10), it is important to accurately identify all clinically significant isolates. Since the discovery of A. lentulus as a new species, subsequent screening studies of “A. fumigatus” isolates have uncovered pathogens misidentified as A. fumigatus, including N. pseudofischeri and N. udagawa (30, 102); these isolates also demonstrate variable susceptibility to antifungal drugs in vitro. As for A. lentulus, phenotypic identification methods will not differentiate them from A. fumigatus. For these, other cryptic species of the A. fumigatus complex, and also for members of other Aspergillus species complexes, DNA sequencing (see below) of one or more sections of the fungal genome is required for species identification.

Molecular Identification Where conventional phenotypic methods cannot identify Aspergillus isolates or identification is uncertain (e.g., with nonsporulating isolates), DNA sequencing can be helpful. In particular, the ITS, including the 5.8S rRNA gene regions, has emerged as the most common target(s) for molecular identification (104, 105); the ITS regions are generally more discriminatory than the D1-D2 domain of the 28S subunit for the identification of aspergilli. Other gene targets useful in species identification include the β-tubulin, rodlet A, and mitochondrial cytochrome b genes (10, 102). ITS sequencing is of clinical utility in identification of Aspergillus to species complex level but often cannot discriminate between species within the complex. The ISHAM Aspergillus Working Group recommends the use of a comparative sequencing-based identification method that uses the ITS regions for species complex-level identification and of a protein coding locus (β-tubulin region) for identification of species within each Aspergillus species complex (106).

This approach successfully identified 218 Aspergillus isolates collected for TRANSNET, USA (30).

Non-sequence-based identification methods include real-time PCR and Aspergillus species-specific microsphere-based assays using Luminex xMAP technology (Luminex Corp., Austin, TX). Alonso et al. developed a real-time PCR followed by combined probe hybridization and high-resolution melt analysis to identify section Fumigati and non-Fumigati Aspergillus isolates; the detection limit was 10² conidia/ml (82). Microsphere-based Luminex (Luminex Corp.) assays have also enabled species complex level identification as well as differentiation of species within the A. fumigatus complex (107).

The preciseness of reporting of an identification of Aspergillus depends on (i) clinical need to accurately identify the fungus species (e.g., from a tissue biopsy compared with recovery from sputum) and (ii) access to molecular identification methods. In smaller laboratories, the use of the term “species complex” aids correct identification since isolates are relatively reliably identified to the section level by morphological methods. For example, a laboratory can identify a fungus as “A. fumigatus species complex” by phenotypic methods and indicate that molecular identification is required to identify the isolate as a species within the complex.

Mass Spectrometry Identification Methods Identification of mould cultures using matrix-assisted laser desorption ionization-time of flight mass spectrometry (MALDI-TOF MS) is increasingly undergoing evaluation to reduce the turnaround time for identification of Aspergillus. Despite initial technical difficulties posed by the relatively complicated morphology and Aspergillus cell wall, the technology has utility in identifying isolates not only to the species complex level, but also to identify species, and in some cases, to delineate strain variation (108–115).

Bille et al. reported an overall identification rate for Aspergillus spp. of 98.4% (63/64 isolates) using the Andromas system (Andromas SA, Paris, France) and Alano et al. reported an identification rate of 98.6% (138/140 isolates) (111, 112). In another study, 82% of 44 Aspergillus isolates were identified correctly (resolved by gene sequencing) using the Vitek-MS platform (bioMerieux, France); correct identification was contingent on appropriate spectra being contained in the database (110). Hetrick et al. used MALDI-TOF MS to derive spectra for 12 Aspergillus species and five different strains of A. flavus; classification of each species and strain of Aspergillus tested was achieved with 100% accuracy (113). When analyzing invasive Aspergillus isolates,
Pan et al. reported that more of the differential spectral peaks were present at the second stage of sporulation, which contains differentiated structures, than at the first stage, which is comprised primarily of vegetative hyphae (114).

All studies have stressed the need for adequate sample preparation for MALDI-TOF MS and the construction of libraries of robust spectra from known strains, independent of the MALDI-TOF MS system (reviewed in reference 108). Use of MALDI-TOF MS has not been approved for the identification of Aspergillus or other moulds by the FDA.

**Typing Systems**

Genotyping of Aspergillus is central to the understanding of epidemiological relationships between clinical and environmental isolates, and to identify the origin and track the spread of nosocomial infections (see "Epidemiology and Transmission" above), especially in responding to public health situations (116). Genotyping also assists in determining if a patient is colonized with the same strain over long periods or becomes re-colonized by different strains. Aspergillus may be genotyped by a range of molecular typing techniques; these include random amplified polymorphic DNA (RAPD) analysis, restriction fragment length polymorphism (RFLP) analysis, DNA fingerprinting, PCR fingerprinting, amplified fragment length polymorphism (AFLP) analysis, multilocus microsatellite typing (MLMT), multilocus sequence typing (MLST), and cell surface protein (CSP) gene typing.

RAPD analysis was first used to differentiate isolates of *A. fumigatus* (117) but has also been applied to genotype other species including *A. flavus* (118) and *A. tereus* (119). RFLP analysis was likewise first applied to genotype *A. fumigatus* using XhoI and SalI enzymes and then for species identification among a heterogeneous Aspergillus group, where it correctly identified *A. flavus* isolates (120). RFLP analysis does not enable strain differentiation within a species.

DNA fingerprinting has utility in genotyping using probes such as those containing retrotransposon-like elements, namely, Aft1, Aft2, and Aft4 (121–123), while clinical and environmental *A. flavus* isolates from a neonatal intensive care unit have been successfully typed with the species-specific probe pAF28 (124). AFLP analysis is another approach that has determined genetic diversity within *A. fumigatus* (125) and within the sections *Flavi* (126) and Nigri (127). More recently, MLMT analysis using four, then later nine, different microsatellite markers was developed to form the STRAf scheme for genotyping *A. fumigatus* (128); this approach has been extended to include other species including *A. flavus* (seven markers [129]), *A. niger* (six markers) and *A. nidulans* (seven markers) (130, 131). MLST analysis with a panel of seven genetic loci has also been applied for strain typing of *A. fumigatus* (132). Finally, a single-locus sequence typing scheme, detecting tandem repeats in a gene encoding a putative cell surface protein, CSP, has been developed (133). Strain variation is a result of both repeat number variation and nucleotide sequence variation. In one study, CSP typing was compared with PCR fingerprinting using minisatellite (core sequence of the bacteriophage M13) and microsatellite (GTG)4 and (GACA)n specific single primers and MLMT analysis to differentiate between *A. fumigatus* strains; only MLMT separated all clinical and environmental isolates implicated in a case cluster (22).

RAPD and AFLP studies in particular have been hampered by low interlaboratory reproducibility due to their reliance on pattern-based typing techniques. This limitation has been overcome by using the highly reproducible and discriminatory MLMT, MLST, and CSP typing techniques, which yield unambiguous and portable data. Microsatellite based approaches and MLST analysis are species specific.

**Serologic Tests**

The detection of Aspergillus GM and Aspergillus-specific recombiant proteins in serum and other body fluids is discussed in "Antigen Detection," above. Methods to detect other Aspergillus antigens or anti-Aspergillus antibodies against these antigens in patients with aspergillosis, including reactivity in skin tests, are also developed, but their clinical utility is less well defined. The main reasons for this have traditionally been related to the nature and purity of the antigen. Although antigen preparations may be available commercially, their quality is variable and they demonstrate cross-reactivity with non-Aspergillus antigens. However, hybridoma technology and monoclonal antibody-based detection systems may be changing the state of immunodiagnostics of aspergillosis.

A number of reviews detail Aspergillus antigens that have been evaluated as candidates for incorporation into immunoassays (68, 133, 135). Antigens tested include somatic preparations, either crude or purified, whole cell extracts, *Aspergillus* metabolites, mannoproteins, and more recently, expressed and purified recombinant antigens. Of purified somatic antigens, one, a 19-kDa basic protein, was shown to be a major circulating antigen in the urine of patients with invasive aspergillosis (68). This protein was also present in the serum of patients with aspergillosis. Molecular characterization has subsequently shown it to be Asp1, an IgE-binding protein (and potent allergen) related to the mitogillin family of cytotoxins. Other potential serodiagnostic antigens include an 88-kDa dipetidyl peptidase, a 33-kDa alkaline protease, the recombinant mannoproteins antigens Afp1 and Afp2, and a recombinant 19-kDa Cu-Zn superoxide dismutase (68, 136, 137). Various test formats have been explored to detect antibodies to these antigens. Double immunodiffusion and counterimmunoelectrophoresis were initially used and still are, as they are simple to perform (134). In many laboratories, these are now replaced by enzyme immunoassays (ELISA) and immunofluorescence assays, including commercial systems.

However, rather than detecting antigen, most serological evaluations have focused on detecting the humoral response to these antigens. Although many assays proved sensitive, their routine use has been limited by substantial interlaboratory variability, cross-reactivity between different fungi, and the type of antigen used in the assay, but probably most importantly, the inability to mount diagnostic antibody responses in immunocompromised hosts. Nonetheless, in one study, IgG anti-*A. fumigatus*-specific mitogillin was detected by ELISA in the serum of all (32 of 32) patients with aspergillosis and in 64% (31 of 42) of patients with invasive lung aspergillosis (138); serum IgG and IgM antibodies were found in only 1.3% of healthy volunteers. However, the optimal cutoff value for the ELISA is not clearly established. Humoral antibody responses to Afp1 detected by ELISA were demonstrated with high sensitivity (100%) for patients with aspergillosis, whereas in invasive aspergillosis the sensitivity was only 33.3% (137). Combined immune responses to Afp1 and Afp2 may increase sensitivity (139). The measurement of these antibody responses is largely restricted to allergic forms of aspergillosis and aspergilloma. However, recent work showed that total antibody specific to Aspergillus-specific thioredoxin reductase (GliT) was detected in nonneutropenic patients with invasive aspergillosis with a sensitivity of 81% and specificity of 96% (140). Further
studies are required to determine the diagnostic potential of these assays.

Detection of circulating antibodies may also be useful in aiding diagnosis of allergic aspergillosis in patients with cystic fibrosis and in those with severe asthma with fungal sensitization (SAFS) (Table 3). Anti-Aspergillus IgE and IgG and A. fumigatus precipitins are established markers of ABPA and are criteria included in its diagnosis (141). Further, immuno- 
globulin subclass measurements may add valuable information. Recently, detection of specific IgE to recombinant A. fumigatus allergens, such as those of the rAsp family, and detection of thymus activation-regulated chemokine TARC/ 
CCL17 have been identified as new biomarkers of ABPA (142). Consensus opinion indicates that measurements of serum IgG subclasses, especially IgG4, against A. fumigatus are useful in screening for and classifying ABPA, at least in cystic fibrosis patients, whereas IgA measurement could be useful to determine prognosis of ABPA (142,143). Quantitation of serum IgG4 may improve specificity of diagnosis. Further, the biomarker TARC has shown greater test accuracy for ABPA diagnosis compared to antibody responses to A. fumigatus IgE and IgG may be measured by commercial assays such as the ImmunoCap assay (Phadia, Uppsala, Sweden) and Platelia Aspergillus IgG assay (Bio-Rad, Marnes-la-Coquette, France); in a recent study, both these two ELISA assays were more sensitive than counterimmunoelectrophoresis (CIE; >93% versus 63%) in diagnosing ABPA (144).

Antimicrobial Susceptibilities

Drugs Used to Treat Invasive Aspergillosis

Amphotericin B, the triazoles (voriconazole and posaconazole), and echinocandins form the backbone for treatment of invasive aspergillosis, although itraconazole may be useful in the more chronic forms of disease. Consensus opinion informed by a landmark randomized, controlled trial recom-
mends voriconazole as first-line therapy (145) for invasive lung aspergillosis as well as extrapulmonary and disseminated infection (146). Oral voriconazole is preferred for “step-down” or maintenance therapy. Other antifungals approved for treating aspergillosis are lipid amphotericin B formulations (e.g., the liposomal compound, for primary therapy or salvage treatment) (146) and the echinocandins, although only caspofungin is licensed for this indication in many countries (147) (also for primary/salvage therapy). Posaconazole, amphotericin B, and caspofungin have been used in salvage therapy, all with response rates between 40 and 50% (146). Though there are insufficient data to recommend antifungal combinations for primary/salvage treatment, a clinical trial of voriconazole versus voricona-
zeole-aniidafungin for initial treatment of proven/probable aspergillosis showed a trend towards improved survival in hematolgy patients (148). For detailed treatment practices for aspergillosis, the reader is referred to the 2010 Infectious Diseases Society of America guidelines document (146).

In Vitro Antifungal Susceptibility Testing

In vitro susceptibility testing of Aspergillus isolates may help guide therapy. Resistance to azoles, the only orally active group of antifungals for aspergillosis, used to be uncommon and was limited to patients receiving long-term azole therapy or prophylaxis (149); in one study, there was a positive correlation between prolonged itraconazole use and high MICs of posaconazole (150). Given the increasing azole resistance among both clinical and environmental A. fumigatus isolates in some countries (151), routine testing of aspergilli for anti-
fungal susceptibility in these regions is important for clinical decisions and to monitor trends. Rates of azole resistance were 5.3% in the Netherlands (152), 5.8% in the ARTEMIS global surveillance study (153), and up to 20% in the United King-
dom, although the U.K. study contained many isolates from patients with chronic aspergillosis who had received long-
term azole therapy (154). Knowledge of susceptibility patterns for new and cryptic species of Aspergillus is of importance for future diagnostic testing.

The majority of azole-resistant A. fumigatus (and other As-
pergillus species) isolates were found to contain an alteration in the target protein sterol 14a-demethyle (or Cyp51), in-
hibiting drug binding. These changes are as a result of single 
nucleotide polymorphisms in the gene CYP51A encoding the protein leading to amino acid substitutions. Mutational hot spots confirmed to cause resistance have been located at amino acid positions G54 and L98 among others, of which the L98 alterations require a tandem repeat (TR) in the promoter region of CYP51A to cause resistance, the TR/L98 mutation (151). Mechanisms of azole, as well as echinocandin, resis-
tance are detailed in chapter 131.

Methodologies and MIC Determinations

In the past few years, standardization of two reference meth-
ods for susceptibility testing of conidium-forming moulds has provided guidelines for antifungal susceptibility testing of Aspergillus. These methods are (i) the Clinical Laboratory Standards Institute (CLSI) M38-A2 methodology and (ii) the European Committee on Antimicrobial Susceptibility Testing (EUCAST) standard (155, 156) (see chapter 131). With either approach, MIC determinations (and minimum inhibitory concentration determinations) are relatively straightforward for azoles and amphotericin B due to the growth-versus-no-
growth pattern of inhibition, and MICs obtained by these reference methods are in close agreement (151).

Interpretative CLSI breakpoints to recognize susceptibility or resistance have not yet been established for any drugs for Aspergillus. Nonetheless, amphotericin B, itraconazole, voriconazole, posaconazole, and the echinocandins are active in vitro and demonstrate the lowest MIC values (157, 158). Using EUCAST methodology, clinical breakpoints (CBPs) for amphotericin B, voriconazole, posaconazole, and itraconazole have been published, primarily for A. fumigatus (159, 160); epidemiological cutoff MIC values (ECOFF) of wild-type Aspergillus strains have also been published (161, 162). The derivation of CBPs and ECOFF values is detailed in chapter 131. Importantly, MICs may vary with species and with geographic region. However, A. terreus is consid-
ered resistant to amphotericin B, as this species is a poor target for this drug; MICs are as high as 16 μg/ml and susceptibility testing is not required for this species (160).

Infections due to A. terreus are expected to be associated with poorer responses to amphotericin B compared with those caused by, e.g., A. fumigatus. Overall, there is no clear correlation of amphotericin B MICs with clinical response since there is a narrow distribution of MICs with no clear resistance phenotype (163).

With regard to the correlation ofazole MICs and clinical outcomes, earlier work indicated that there was good corre-
lation between high MICs and treatment failure in animal models of invasive aspergillosis (164). Recently, voricona-
zeole MICs were predictive of treatment results in A. terreus murine infections (165). However, in another study there was no relationship between increasing MICs and response to voriconazole in mice with A. fumigatus infection (166). Baddley et al. observed that MICs of voriconazole exceeding the ECOFF value (i.e., 1 μg/ml) were not associated with increased mortality in patients with A. fumigatus infection receiving voriconazole (167). For other Aspergillus species,
correlation of azole MICs and outcome is also uncertain (168). Susceptibility endpoints for the echinocandins against Aspergillus fumigatus by CLSI methodology may be uncertain due to significant trailing growth. Thus, a minimum effective concentration (MEC) is employed, where the MEC is the lowest concentration leading to macroscopically aberrant growth as microcolonies or granular growth when compared to the growth control wells. MEC determination is time-consuming and requires a microscope to determine morphological changes, and interlaboratory reproducibility is suboptimal. Correlation between MECs and in vitro outcomes is uncertain. One report found clinical failure and in vitro resistance in an animal model for an isolate with an MEC in the wild-type range (169). There are no CBPs for the echinocandins with EUCAST.

In practice, both reference methods may be performed by specialist mycology laboratories, but they are not suitable for use in most clinical laboratories as they require extensive training. Commercial kits for susceptibility testing of Aspergillus, such as the Etest (AB Biodisk, Solna, Sweden), are often useful. The Etest has excellent correlation with the CLSI reference method for voriconazole (170) and between 80 and 100% agreement for itraconazole and posaconazole (171, 172). The SensiTiter Yeast YO10 system (incorporating prefilled trays of nine antifungal agents [Trek Thermofisher Diagnostics, Cleveland, OH]) is based on the CLSI method. The visual endpoint allows easier reading, and it shows good correlation with the azoles and amphotericin B. Another approach is to use azole-containing agars, for example, itraconazole at 4 mg/liter, to screen forazole resistance; this technique has been evaluated for A. fumigatus (151). Cross-resistance between azoles occurs in up to 74% of cases (151, 154). Research methods include isothermal microcalorimetry for real-time susceptibility testing (173).

Evaluation, Interpretation, and Reporting of Results

The diagnostic mycology laboratory's aims are to provide timely, clinically meaningful information using accurate and up-to-date methods. Criteria have been proposed by the EORTC/MSG for the analysis of patient data in clinical trials to help to standardize interpretation of results. Identification of Aspergillus fungi to species level should be undertaken when they are recovered from sterile specimens and from patients at high risk of invasive aspergillosis. Certain species may be more resistant to antifungal agents. A. terreus complex is resistant to amphotericin B, while the A. nidulans complex and A. ustus are less susceptible to many agents compared to A. fumigatus (51, 174). Aspergillus recovered from nonsterile specimens including BAL fluid in immunocompetent patients may not be responsible for disease and may not require species identification. Workup of isolates should involve dialogue between the requesting clinician and the microbiologist.

Diagnosis of invasive aspergillosis is difficult, as clinical and radiological features are nonspecific. Although diagnosis is straightforward when Aspergillus is visualized in and cultured from clinical specimens, more often it relies collectively on non-culture-based testing from sterile specimens and from patients at high risk of invasive aspergillosis. Certain species may be more resistant to antifungal agents. A. terreus complex is resistant to amphotericin B, while the A. nidulans complex and A. ustus are less susceptible to many agents compared to A. fumigatus (51, 174). Aspergillus recovered from nonsterile specimens including BAL fluid in immunocompetent patients may not be responsible for disease and may not require species identification. Workup of isolates should involve dialogue between the requesting clinician and the microbiologist.

Aspergillus and Penicillium

Therapy approach. Using these biomarkers, prospective screening for infection in feasibility studies and one randomized, controlled clinical trial demonstrates the utility of further diagnostic workup (96, 98) and has led to earlier diagnosis of aspergillosis without decreasing mortality.

Despite progress made by the EUCAST movement in defining CBPs and ECOFF values for antifungal agents, correlation between MICs and clinical outcomes is not yet established. Interpretation of MIC testing of Aspergillus remains problematic. Nonetheless, given the rise in azole resistance among A. fumigatus in some countries, susceptibility testing to azoles against this species is warranted in these regions and if there is therapeutic failure. The widespread use of EUCAST methodology is limited by the expertise and training needed to perform these tests. Useful information regarding expected antifungal susceptibility may be obtained by identifying the fungus to species level (e.g., A. lentulas).

**PENICILLIUM SPECIES**

**Taxonomy and Position of Talaromyces marneffei (formerly Penicillium marneffei)**

Early work on the taxonomy of the genus Penicillium (otherwise referred to as *Penicillium sensu lato*) is based on the studies of Thom (175) and Raper and Thom (176). The genus contains more than 300 species (http://www.aspergillus.uspenicillium.org). These species have traditionally been separated based on their morphology, specifically conidiophore branching, into four anamorphic subgenera—*Aspergilloides, Furcatum, Penicillium, and Biverticillium*—within the family Trichocomaceae (4, 177). However, more recent multi-gene phylogenetic analyses have shown that three of these subgenera, *Aspergilloides, Furcatum, and Penicillium* (i.e., *Penicillium sensu stricto*), are polyphyletic, whereas the fourth, *Biverticillium*, forms a monophyletic group (178), which is characterized by the presence of symmetrical biverticate conidiophores (179). The distinctive morphological and physiological features of *Biverticillium* have resulted in its evolving taxonomic status and suggestions to separate the subgenus *Biverticillium* from *Penicillium sensu stricto* (4, 177–179).

Rationale for Separation of Members of *Biverticillium from Penicillium sensu lato*

*Penicillium sensu lato* is associated with two teleomorphic genera: *Eupenicillium* (now synonymous with *Penicillium sensu stricto*) and *Talaromyces* (now the teleomorph stage of *Biverticillium*). These two teleomorph genera are separated by distinctive ascomata. The sclerotium-like ascomata of *Penicillium sensu stricto* are thick-walled isodiametric cells maturing over several months and forming in most cases no ascospores, whereas *Talaromyces* cells are characterized by soft ascomatal walls comprising multiple layers of interwoven hyphae leading to mature ascomata within weeks. In comparison with *Penicillium sensu stricto*, the members of *Talaromyces* often have darker green conidia, produce pigmented and encrusted aerial hyphae, and show yellow, orange, or red to purple colony color on reverse. Additionally, phylogenetic studies have increasingly provided evidence that *Penicillium sensu stricto* and *Talaromyces* should be considered subfamilies as demonstrated by genetic relatedness employing the fungal rRNA and calmodulin genes (180–183). The subdivision of these genera was finally confirmed using a multigene approach (178).

As true for *Aspergillus,* the ability to correlate anamorphic and teleomorphic genera with modern taxonomic tools...
has led to the one fungus = one name concept (13). By removing the primacy of the teleomorphic name over the anamorph-typified name (14), this has likewise had a major impact on what was known as the genus *Penicillium*. The name *Penicillium* is now used for *Penicillium* sensu stricto (i.e., comprising the subgenera *Aspergilloides*, *Furcatum*, and *Penicillum*) while the term *Talaromyces* is now defined as a pleomorphic genus, representative of the anamorphic species formerly within the *Penicillium* subgenus *Biurcetillum* (184).

It is notable that the only species known to be a human and animal pathogen is *Talaromyces* (formerly *Penicillium*) *marneffei*, a member of the subgenus *Biurcetillum*. This species is dimorphic, growing as a yeast at 37°C in the host and as a filamentous fungus at 25°C in the environment. As a result of the revised nomenclature, *P. marneffei* is now correctly classified as *T. marneffei* (Segretain, Capponi & Sureau) Samson, Yilmaz, Frisvad & Seifert, comb. nov. MycoBank MB560656 (184, 185), rendering *P. marneffei* [Segretain, Capponi & Sureau apud Segretain (1959)] the basionym of the new taxonomic assignment.

**Epidemiology and Transmission**

*T. marneffei* is an emerging pathogen and is a particular health problem in areas of endemicity in tropical Asia, especially Thailand, northeastern India, China, Hong Kong, Vietnam, and Taiwan (186–189). The arrival of HIV/AIDS has led to increased risk (192). Yet, despite extensive efforts, attempts to recover the organism from soil and decaying material especially under humid and rainy conditions is likely the critical risk factor (186, 191); agricultural occupations have been independently associated with increased risk (192). This and the absence of budding help distinguish the condition of *T. marneffei* in histologic sections using rabbit antihuman antibodies to yeast antigens of *T. marneffei* has also been developed (203).

**Nucleic Acid Detection**

A number of molecular techniques have been developed to directly detect and identify *T. marneffei* in clinical specimens. Many are in-house assays. Methods include single-step PCR and nested and seminested PCR assays to detect *T. marneffei* in PE tissue was evaluated using inner primers (Pm1 and Pm2) specific to *T. marneffei*. Amplification of a species-specific fragment of approximately 400 bp was successful for tissue from all 14 patients studied as well as for tissue from 10 bamboo rats with *T. marneffei* infection, with an analytical sensitivity of 14 fg/μl (206). In other studies, a multiplex ligation-dependent probe amplification (MLPA) assay detected *T. marneffei* DNA in PE tissue with high specificity (207), as has a loop-mediated isothermal amplification assay (208).

**Isolation Procedures**

Culture remains the gold standard method of diagnosis, even though it is slow and requires collection of clinical specimens with invasive procedures. *T. marneffei* is easily cultured from clinical specimens and grows well on SDA
without cycloheximide; culture of bone marrow is the most sensitive (100%) followed by skin (90%) and blood culture (76%) (189). Mould-to-yeast conversion is achieved by subculturing onto brain-heart infusion agar and incubating at 37°C (202). Identification of *T. marneffei* is based on colony morphology (see below). In Europe, Australia, and New Zealand, *T. marneffei* is classed as a risk group 3 (RG-3) pathogen and represents a biohazard to laboratory personnel. Therefore, specimens and cultures should be handled in a containment level 3 (or above) facility to avoid inhalation of conidia or accidental inoculation into skin.

**Identification**

Members of the genus *Talaromyces* are ubiquitous laboratory moulds and are grown easily from most nonsterile specimens, especially respiratory specimens. Differentiation of *T. marneffei* from other penicillia is not usually problematic since *T. marneffei* is thermally dimorphic. Diagnosis is made by observing the conversion of the mould to yeast form at 37°C or the reverse at 25°C.

Colonies on SDA at 25°C are fast growing, downy, and white with yellowish-green conidial heads. Colonies become grayish pink to brown with age and produce a diffusible brown-red pigment particularly evident on the reverse (Fig. 4), which is an early indication that an isolate may be *T. marneffei*. However, red pigment may be produced by nonpathogenic *Penicillium* species including *P. citrinum*, *P. janthinellum*, *P. pararoseum*, and *P. rubrum*. Colonies on brain heart infusion agar (37°C) are rough, glabrous, and tan-colored. Microscopic yeast-like cells are spherical to elliptical and are 2 to 6 μm in diameter.

Morphology of *T. marneffei* is distinctive, with hyaline smooth-walled conidiophores with terminal verticils comprising three to five metulae (secondary branches) with conidia, each bearing three to seven phialides. Conidia are globose to subglobose, 2 to 3 μm in diameter, smooth walled, and produced in basipetal succession from the phialides, producing a typical “penicillus” or brush-like fruiting structure (15, 202).

Together with direct detection of the fungus in clinical specimens, molecular tools enable *T. marneffei* cultures to be identified by PCR in combination with DNA sequencing or probe hybridization and distinguished from other *Penicillium* species that may be incidentally present. Since species identification can be problematic within the genera *Penicillium* and *Talaromyces*, a polyphasic approach is recommended. Morphological approaches should be combined with molecular strategies. Assays typically amplify one or more of the ITS rRNA, ITS region, β-tubulin, calmodulin, actin, or RNA polymerase genes (186). Introduction of molecular methods of identification would depend on clinical need.

**Typing Systems**

A number of typing systems have been developed to (i) study the population structure and genetic diversity of *T. marneffei* and (ii) investigate clusters of infection should they arise. A MLMT system was developed using 23 genetic loci (209) and applied to clinical isolates from Southeast Asia; 21 of 23 tested loci were polymorphic, revealing a high degree of genetic diversity. A clear separation between the population of strains from the eastern region (China, Hong Kong, Indonesia) and from the western region (Thailand, India) was observed, with the eastern clade being more polymorphic than the western clade (210). An independent study confirmed the clustering of isolates from these regions into two clades (211). The separation of these clades may be due to potential isolation of these populations or for reasons not yet known, and/or resulting from a clonal reproductive mode.

In addition to MLMT, MLST analysis incorporating eight genetic loci (transcription factor [AbaA], [CpeA], homeodomain transcription factor [SidA], isocitrate lyase [Idl]), polyaromatic amino acid biosynthesis [PAA], NADH-dependent glutamate synthase [NGS], lovastatin nonaketide synthase [LNS], a cell wall mannoprotein [MP1], and a gene fragment of the cytochrome oxidase subunit 1 gene [COX1] of the *T. marneffei* mitochondrial genome) has also been developed as a typing tool. In one study, no nucleotide polymorphisms were observed within the COX1, AbaA, and NGS loci. However, the remaining five loci showed a high degree of genetic diversity and again indicated geographic separation between isolates from China or Thailand, but also mixed clades. Identical MLST types between different patients have been shown, supporting an asexual mode of reproduction (212). Other investigations have found identical MLMT types among strains from humans and bamboo rats; however, the role of contact with bamboo rats or bamboo rat burrows in the transmission of human disease remains unclear (186, 213).

**Serologic Tests**

Serologic tests may help in diagnosis of infection, although no standardized commercial tests are available. Assays have been developed to detect antibodies to *T. marneffei*. *T. marneffei* antigen, or both in serum and other body fluids in various test formats including immunodiffusion, indirect immunofluorescence, and ELISA (186, 199).

Immunodiffusion tests to detect precipitin antibodies using *T. marneffei* mycelial exoantigens had low sensitivity when tested on serum in HIV-positive patients (214). Using an indirect fluorescent approach for detecting IgG antibodies against germinating conidia and yeast forms, patients with *T. marneffei* infection were shown to have higher titers (>160) than those without (<40) (215). An ELISA-based antibody test using recombinant *T. marneffei* mannoprotein (Mp1p) diagnosed infection with 80% sensitivity and 100% specificity (216). In another study, an ELISA-based test detected and measured Mp1p in sera of patients with a sensitivity of 65%; however, combining Mp1p-based anti-

**FIGURE 4** White colonies of *Talaromyces marneffei* on Sabouraud dextrose agar (25°C) with yellow-green conidial heads. With age, the diffusible brownish-red to wine-red pigment is evident. doi:10.1128/9781555817381.ch119.44
Other *Penicillium* (and *Talaromyces*) Species

As many *Penicillium* species are completely or strongly inhibited at 37°C, they have rarely caused human infection. Even repeated isolation of *Penicillium* from patient specimens does not necessarily indicate an etiological role. This includes the isolation of the fungus in patients with chronic lung disorders, including bronchiectasis and cystic fibrosis, where *Penicillium* can colonize airways for prolonged periods. The role of *penicillia* in allergy and hypersensitivity pneumonitis is well established (227). Nonetheless, infections due to a range of *Penicillium* and *Talaromyces* species, resulting in keratitis, otomycosis, peritonitis, pneumonia, and endocarditis, are reported, typically after the fungus is repeatedly isolated. Species implicated in infection include *P. citrinum*, *P. commune*, *P. chrysogenum*, *P. aurantiogriseum*, *P. brevicompactum*, *T. verrucosum*, *T. piceus*, *T. purpureogenus*, and *T. rugulosus* (15, 228, 229).

Identification of *Penicillium* species requires expertise with growth of an isolate on several media and careful microscopic examination. No thermal dimorphism is displayed. Isolates are inoculated at three points on Czapek Dox agar, 2% malt extract agar, and/or 25% glycerol nitrate agar and incubated at 25°C. Colonies are fast-growing, in shades of green (sometimes white), consisting of a dense felt of conidiophores. Most species sporulate within 7 days. Microscopic mounts are best made using a sticky tape flag or slide culture mounted in lactophenol cotton blue. A drop of alcohol is often needed to remove bubbles and excess conidia. Molecular techniques may be required for species identification. The phylogenetic relationships of *penicillia* based on the ITS1/2 region are shown in Fig. 5.

**Evaluation, Interpretation, and Reporting of Results**

*T. marneffei* is the only member of the genus *Talaromyces* that has been linked unequivocally to human infection. Diagnosis of *penicilliosis marneffei* should include positive culture, direct smear, and molecular detection/identification in a patient with an appropriate history of exposure to the area of endemicity. Most other *Penicillium*/*Talaromyces* species have low potential for causing human infection.

We thank David Ellis for his generous assistance with preparation of the photographs for Figs. 3B, C, D, E, F, and G and Fig. 4.
also thank Carolina Firacative for her help in the preparation of Fig. 1 and 5.

The opportunistic hyaline or lightly colored moulds (also referred to as moniliaceous) constitute a phylogenetically diverse group of common to rare anamorphic (asexual) and teleomorphic (sexual) fungi that typically occur as saprobes in soil, in air, on plant litter, or as facultative plant pathogens. Some may be recovered from patients without having any clinical significance. Others are isolated infrequently enough to challenge the proficiency of a diagnostic laboratory, and critical assessment is required to evaluate the significance of their recovery. While several of the genera treated in this chapter include species that have either lightly colored or dark (melanized) conidia, the emphasis is on those fungi that grow in tissue in the form of hyaline or lightly colored, septate hyphae.

The term “fusariosis” is used to define infections caused by species of Fusarium (1) (Table 1), but the practice of coining disease names based on the fungal genus is disadvantageous for infections caused by uncommon or rare pathogens. The wide variety of fungi involved makes it difficult to place the organisms into accessible groups, and problems arise when fungal names are changed. To avoid unnecessary name changes for disease names based on a genus, two major disease groups have been proposed: hyalohyphomycosis and phaeohyphomycosis (2). Although the groups were defined as encompassing similar clinical spectrums, they were distinguished by the presence of septate hyphae in tissue without (hyalohyphomycosis) or with (phaeohyphomycosis) pigmentation or melanin in the fungal cell wall. However, some fungi, such as Scedosporium species and Neoscytalidium dimidiatum (formerly Scytalidium dimidiatum [Nattrassia mangiferae]) (3), which form darkly pigmented colonies and conidia in vitro, produce hyaline or lightly pigmented hyphae in tissue. Similarly, rare fusariosis cases have been reported to produce darkly pigmented colonies in vitro and in vivo (4). The Masson-Fontana silver stain helps to detect melanin pigmentation of fungal elements in tissue, but the results are not always conclusive (see also the discussion in chapter 113). Some fungi with variable pigmentation may stain faintly or inconsistently. In practice, the terms for the disease categories have been used to designate infections caused by fungi that are either hyaline or pigmented (melanized, phaeodermateceous) in vitro. Although it may be useful to have terms for broad categories of mycotic diseases, there are problems in categorizing fungi by color. A subcommittee of the International Society for Human and Animal Mycology (ISHAM) has suggested that fungal diseases be named by providing a specific description of the pathology and naming the causative agent, e.g., subcutaneous cyst caused by fungus x (5, 6).

**TAXONOMY AND IDENTIFICATION**

The opportunistic hyaline moulds include an ever-increasing number of genera. Most do not produce a telemorph (meiotic or sexual stage) in culture and comprise taxa that are either anamorphs of the Ascomycota and Basidiomycota or genera for which no sexual state has been described (see chapter 113). Today the relationships between many anamorphs and their sexual relatives are known through discovery of teleomorphs or are inferred by phylogenetic analysis of DNA sequence data. This knowledge is extremely important in understanding fungal relationships and has allowed placement of asexual fungi next to their sexual relatives in fungal phylogenies. Rapid developments in this area have led to significant changes in genus and species concepts, particularly among the fusaria (7–17). Teleomorphs may develop in culture from homothallic, self-fertile species (see chapter 113); however, they may be difficult to obtain without the use of specialized media and extended incubation. Recent modifications relative to the naming of pleomorphic fungi, however, have prohibited the use of this dual nomenclature after 1 January 2013 (18, 19), and many changes regarding accepted taxa are expected. One such significant change is the proposed unitary use of the name *Fusarium* over various teleomorph names (20), in part because fewer than 20% of fusaria are known to reproduce sexually. In this chapter, the teleomorph name will continue to be used for species that are identified mainly by their sexual structures.

Most of the pathogenic moulds considered in this chapter are classified in the form class Hyphomycetes (genera which bear their conidia freely) (21–23). Phenotypic identification of Hyphomycetes is based on morphology of the conidia and the mechanisms by which conidia are formed (conidogenesis; see chapter 113). Three basic tools are necessary for practical observation of these features. (i) An ocular micrometer is essential for determining sizes of conidia or sexual spores when present. Identification of moulds often requires comparison with published taxonomic descriptions in which size is often a key criterion for species distinction. (ii) A dissecting microscope with magnifications of up to...

Adapted from references 56, 65, 72, and 99. Patients infected with other fungi discussed in this chapter may present with similar clinical syndromes, and fungal structures in tissue may resemble those of *Aspergillus* species.

*x60 and basal illumination is useful for the examination of colonies in plates or tubes for the presence of conidia in chains or slimy heads, specialized structures, such as Hülle cells, sclerotia, and conidiomata, or sexual fruiting bodies forming under the aerial mycelium or embedded in the agar.

(iii) Microscopic mounts that allow observation of how a fungus forms its conidia also are necessary. Slides with perfect preparations are excellent for many fungi and generally necessary for those with small, delicate conidia (24, 25); however, rapidly growing species, such as those in the genus *Trichoderma*, should be examined early by tease mounting. Morphologic features important for identification of conidial fungi include (i) conidium size, shape, and pattern of septation; (ii) the color of the conidia and conidiophore, whether light (hyaline) or dark (melanized or phaeoid); (iii) developmental aspects of conidiogenesis, including the nature of the conidigenous cell; (iv) the mechanism of conidium liberation or dehiscence; and (v) the structure of the conidioma (if present). Differences in conidial shape and septation are useful characters for preliminary distinction and have been used traditionally for grouping conidial fungi. Conidia may be nonseptate or may have one or more septa. Some fungi produce septe and nonseptate conidia.
microscopic features. A continuing and vexing problem is that authenticity of reports cannot be verified if the fungus is inadequately described and illustrated and if isolates are not deposited in publicly accessible culture collections. This chapter describes the salient colony and microscopic features of medically important species in the genus Fusarium (Table 2) and other selected hyaline opportunists (Table 3). Detailed descriptions of species listed are found in several reference manuals (15, 24–34) as well as the current literature. Due to the rapid discovery of novel species via multilocus sequence typing (MLST) over the past decade, most clinically important species within Fusarium appear to be undescribed (35). Two Internet-accessible websites have been developed for identifying Fusarium, Fusarium-ID (http://fusariumdb.org/index.php) (36) and the Fusarium MLST database (http://www.cbs.knaw.nl/fusarium/). Identifications are conducted via BLASTn searches of either database using a partial translation elongation factor 1α (eEF1α) sequence of the unknown as the query or sequences from several other loci.

CLINICAL SIGNIFICANCE

The spectrum of disease caused by hyaline moulds is diverse. The disease is determined largely by the local and general immunologic and physiologic state of the host and may be symptomatic or asymptomatic. In most instances, the portal of entry for fungal propagules is likely by way of the lungs or skin, though a break in the epidermis due to trauma. Exceptions to this include introduction by means of contaminated surgical instruments, intraocular lenses, prosthetic devices, or other contaminated materials or solutions associated with surgery or routine health care. Individuals whose resistance is lowered as a result of a severe debilitating disease or immunosuppressive therapy. Opportunistic moulds are variably sensitive to cycloheximide, so media containing this selective agent should be used cautiously. Suspicious isolates, including bronchopulmonary mycosis and sinusitis in atopic patients.

Although the majority of saprobic and plant-pathogenic moulds are not considered pathogenic for humans and other animals and appear unlikely to be able to adapt to or take advantage of risk factors predisposing individuals to opportunistic infection, those capable of growing at or near body temperature must be considered to have latent pathogenic capability. The diversity of fungi that have invaded human tissue has increased dramatically in recent years, as reflected by new reports of proven infection. Moreover, certain fungi are isolated often enough to be suspicious for pathogenic potential. Still, there is a need for definitive evidence of infection due to a normally saprobic mould. The laboratory procedure for confirming fungal etiology includes (i) detection in the specimen of hyphae that are compatible with the morphology of the isolated mould, (ii) isolation of several colonies of the fungus or isolation of the same fungus from two or more specimens over time, (iii) accurate identification of the isolated mould, and (iv) confirmation of the mould's ability to grow at or near body temperature. Species of Fusarium or other hyaline moulds isolated from all deep tissue or body fluids must be considered potential invasive opportunistic pathogens. No fungal isolate should be discarded as a contaminant without thorough examination of the clinical specimen. Quality control measures to ensure that isolation media are not contaminated and inspection of the slant or plate to evaluate where the fungus is growing relative to where the specimen was placed may also be important in evaluating whether an isolate is involved in disease. Close communication between microbiologists and physicians also is essential, especially for rare or unusual opportunists seen in individuals maintained on long-term immunosuppressive therapy.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Clinical specimens from patients suspected of having mycosis should be collected with prudence and transported to the laboratory and processed as soon as possible by using the standard procedures described in chapter 114 of this Manual. Because of the diverse clinical manifestations, various sites may need to be examined for fungal elements. Biopsy material, transtracheal aspirates, and sputum samples collected in the early morning all may be useful specimens for the isolation and detection of hyaline moulds, as are infected nails. Swabs taken from mucous membranes and skin lesions are not recommended. Although the reliability of determining whether an isolate is a possible pathogen is increased if cultures of two different specimens yield the same organism, a tissue biopsy specimen is more informative since the significance of culture can be verified by histological examination of the tissue. While blood cultures are generally of limited use for the detection of invasive hyaline moulds that produce dry conidia (microconidia in chains), such as Aspergillus (37), Fusarium and other species with slimy conidia (microconidia in clusters or balls) may be reliably detected (38). For optimum recovery, the specimen should be inoculated onto several types of media and incubated at 28 to 30°C. Opportunistic moulds are variably sensitive to cycloheximide, so media containing this selective agent should be used cautiously. Suspicious isolates, especially of uncommon species, should be tested for their ability to grow at 35 to 37°C. Potentially neurotropic species may also grow at 40°C and beyond (39, 40).

FUSARIUM SPECIES

Taxonomy

Fusarium species are cosmopolitan soil saprobes and facultative plant pathogens that can cause infection or toxicosis in humans and other animals (15, 26, 41, 42). They belong to the order Hypocreales, family Nectriaceae. Clinically significant species are mostly heterothallic, with only the anamorphic (asexual) state seen in culture. Teleomorphs occur in Gibberella, Neocosmospora, and other genera; however, these taxa should be reported under the Fusarium anamorph name (20). Several molecular phylogenetic studies have shown that organisms once considered individual species by morphologic features are now known to represent species complexes (SCs) (7, 8, 14–17, 36, 43, 44). Multilocus phylogenetic studies have revealed that the most frequently recovered clinically important fusarias are nested within the Fusarium solani species complex (FSSC) (Fig. IA). This SC comprises over 60 phylogenetically distinct

species within three major clades, with the human isolates restricted to clade 3 (12, 45). Clade 3 was also shown to be associated with four major species-level lineages, designated groups 1 through 4, with many strains clustered in groups 1 and 2 (8, 17, 46). Subsequently, more-robust typing studies identified 34 species within clade 3 of the FSSC (12). The FSSC currently also includes Fusarium petrophilum (FSSC 1), Fusarium keratoplasticum (FSSC 2), and F. falciiforme (FSSC 3+4) account for most infections caused by members of the FSSC (12, 46). Although the names Fusarium incarnatum, Fusarium falciiforme, and Fusarium semitectum are commonly applied to members of the FIESC, these names should not be used until it is determined what species they represent.

<td>Schizophyllum</td>
<td>Colonies are fast growing, white, woolly or cottony, and cycloheximide sensitive, and growth is enhanced at 37°C. They are usually sterile. Hyphae bearing clamp connections resemble aspergilli and short, thin pegs or spicules, but both may be absent (Fig. 2G). Clamped isolates usually develop fan-shaped, gilled basidiocarps (mushrooms) on sporulation media after 3–6 weeks (Fig. 2H).</td>
<td>S. commune</td>
<td>Clinical picture resembles aspergillosis and clampless isolates by histopathology (Fig. 2F).</td>
</tr>
<tr>
<td>Sclerotinia</td>
<td>Colonies are fast growing, white, and dark to grayish brown. Conidiophores are solitary, slender (ca. 2 μm wide), mostly unbranched, awl (needle)-shaped phialides. Conidia are 1 celled and straight or curved and grow in slimy masses.</td>
<td>A. sclerotigenum, A. egyptiacum, A. implicatum, A. reicipi, A. persicinum, A. fusidioides, Acremonium spp.</td>
<td>Differs from Fuscariurn by having a low growth rate, narrower hyphae (mostly &lt;2 μm in width), and more slender and needle-like phialides. Compare with Arthrocheta and Phialostrum.</td>
</tr>
<tr>
<td>Cylindrocarpon</td>
<td>Colonies are fast growing, felty or cottony, yellowish white, tan, orange, or purple and sometimes diffuse pigments. Conidiogenous cells are awl-shaped phialides with a single opening; they are solitary in branched structures or in sporodochia (conidiophores are crowded in a compact mass of hyphae). Macroconidia are straight or slightly curved with rounded ends and multicelled; microconidia are not clearly distinguished from macroconidia. Chlamydospores are sometimes present.</td>
<td>C. destructans, C. cyanescens</td>
<td>Distinguished from Fusariurn by rounded apical cells and the absence of foot cells.</td>
</tr>
<tr>
<td>Acremonium</td>
<td>Colonies are slow growing (&lt;3 cm in 10 days), often white, cottony, fasciculate (spiky), globose or moist, and pink or salmon colored. Conidiogenous cells are solitary, slender (ca. 2 μm wide), mostly unbranched, awl (needle)-shaped phialides. Conidia are 1 celled and straight or curved and grow in slimy masses.</td>
<td>A. fusipora</td>
<td>Growth at 40°C.</td>
</tr>
<tr>
<td>Arthrographis</td>
<td>Colonies are slow growing and cycloheximide tolerant. They are initially white and yeastlike but become hyphal and buff with a yellow reverse. Growth is enhanced at 37°C. Conidiophores are dendritic (treelike), bearing lateral branches. Arthroconidia are formed by fragmentation of branches or from undifferentiated hyphae.</td>
<td>A. kahae</td>
<td>Compare with Ortyschola and Hormographiella.</td>
</tr>
<tr>
<td>Beauveria</td>
<td>Colonies are slow to moderately fast growing and yellowish white. Conidiogenous cells are solitary (in whorls or in sporodochia) and basally swollen, proliferating sympodially at the tip in a zigzag (geniculate) fashion. Conidia are 1 celled and subglobose.</td>
<td>B. bassiana</td>
<td>Compare with Entocondinium album and Sporothrix. A biological control agent for insects.</td>
</tr>
<tr>
<td>Chrysosporium</td>
<td>Colonies are slow to moderately fast growing and yellowish white (Fig. 3B). Conidia are single celled and smooth to rough; aleurioconidia are sessile or at the ends or on the sides of unswollen stalks (Fig. 3C). Arthroconidia are sometimes present. (See Aphanoascus and Emmonsia.)</td>
<td>C. zonatum, C. ophiodicola (anamorph of Nannizziopsis vriesii)</td>
<td>Reports of infection by unnamed species are difficult to evaluate because isolates are not adequately described to confirm etiology.</td>
</tr>
<tr>
<td>Coniochaeta</td>
<td>Colonies are white to salmon, moist or fasciculate (spiky), or tan, darkening to black in patches. Conidiogenous cells are adelphialdialdialdialdial (short, stumpy phialides without a basal septum), as well as awl-shaped phialides. C. mutabilis forms brown chlamydospores, while C. hoffmannii does not.</td>
<td>C. hoffmannii, C. mutabilis</td>
<td>Distinguished from Acremonium by predominance of adelphialdialdialdialdialdialdial. Hyphal elements usually are reported as hyaline. Also see chapter 124.</td>

</table>

*Species listed produce their teleomorph (sexual structures) in culture.

*On potato dextrose agar (PDA) after 4 days of incubation at 25°C unless otherwise noted. See references cited in the text for a more detailed description of the features noted in this table. The list is not all inclusive.

(FCSC) is also phylogenetically diverse and represents four species based on multilocus genotyping (13). Similarly, the Fusarium dimerum species complex (FDSC) (Fig. 1E and F) currently contains seven named and five unnamed species (53). Members of the FDSC are unlike these in the aforementioned SCs in that they frequently display slower growth, and aerial mycelium is either absent or only sparsely developed, so colonies appear mucoid to slimy (usually some shade of orange).

**Description of Agents**

As can be seen from the taxonomic discussion, the Fusarium species cited as etiologic agents of human and animal diseases mostly fall within six SCs. Based upon our current understanding of the genus, and recognizing the likelihood of future taxonomic changes, the more common species within these complexes are as follows: FSSC, Fusarium falciforme, Fusarium petrophilum, Fusarium keratothlasticum; FOSSC, Fusarium oxysporum (phylogenetically diverse but the species limits are not resolved currently); FFFC, Fusarium verticillioides, Fusarium thapsinum, and Fusarium proliferatum; FCSC, Fusarium chlamydosporum; FDSC, Fusarium dimerum and Fusarium delphinae; and FIESC, unnamed species frequently reported incorrectly as Fusarium incarnatum/Fusarium palidoroseum/Fusarium semitectum. See also Table 2.

**Epidemiology and Transmission**

There are numerous toxic secondary metabolites produced by Fusarium species that have been implicated in human disease, especially associated with the consumption of contaminated grain (see chapter 126). Alimentary toxic aleukia was described in individuals who ate grain contaminated with trichothecene mycotoxins produced by Fusarium sporotrichioides or Fusarium poae (54). Systemic effects of exposure to inhaled mycotoxins, in addition to orally ingested mycotoxins, have also been attributed to Fusarium, although these effects have been much less characterized (55). The more common clinical presentation in human disease is associated with fusarial conidia gaining access to the host and germinating and subsequent tissue invasion by hyphae. The portal of entry, however, is unknown in most cases of invasive infection. Ingestion or access through mucosal membranes may occur in some (56, 57). Disseminated infection may also follow onychomycosis, often associated with cellulitis (58). Hospital water supply and distribution systems have also been implicated as a source of infection in immunocompromised patients by Anaissie et al. (51) and O'Donnell et al. (14). The most common mode of transmission, however, appears to be inhalation of airborne conidia (59).

Although invasive infection by Fusarium is uncommon, an increased incidence of disseminated infection has been seen in neutropenic patients with hematologic cancer, in recipients of solid-organ transplants, and in recipients of allogeneic hematopoietic stem cell transplants (HSCTs) (1, 38, 42, 57, 60–69). The incidence of fusariosis among allogeneic HSCT recipients varied between 4.21 and 5.0 per 1,000 cases in related, human leukocyte antigen (HLA)-matched transplant recipients and 20.19 per 1,000 cases in HLA-mismatched transplant recipients (68). Among allogeneic HSCT recipients, a trimodal distribution was observed: a first peak before engraftment, a second peak at a
few macroconidia are also present. (C) Chains of microconidia produced by the aerial mycelium are also present (thick arrow). (B) Member of the FOSC bearing microconidia on short monophialides. A FIGURE 1 (A) Member of the FSSC. Microconidia are borne on long monophialides (thin arrow). Macroconidia borne in Fusarium in the FDSC. Note that conidia are two celled and that the septum is in the middle. (F) Macroconidia of dimerum described in reference 137 was glabrous and sterile when grown on potato dextrose agar for 15 days at 30°C. doi:10.1128/9781555817381.ch120.f1

Clinical Significance

Fusarium species can cause a spectrum of diseases in both healthy and immunocompromised hosts. A frequent infection in the normal host is keratitis resulting from trauma and penetration of the cornea, contamination of soft contact lenses and/or solutions (11, 46, 66, 70–72), or local immunosuppression by corticosteroids (66). The keratitis outbreaks recognized in Hong Kong (72), Singapore (71), and the United States (46) in 2005 and 2006 in contact lens wearers using ReNu with MoistureLoc solution (Bausch & Lomb, Rochester, NY) resulted in the largest investigation and molecular characterization of fusarial keratitis isolates to date and clearly demonstrated that these strains occurred in nearly the full spectrum of clinically significant fusarial SCs. Other presentations in the immunocompetent host include those listed in Table 1. Cutaneous lesions in various stages of evolution (68, 73), fungemia (74), rhinocerebral involvement, pneumonia, endogenous endophthalmitis (75, 76), or combinations of these are common clinical findings in disseminated fusarial disease (38, 42, 57, 65–69, 77, 78). Unlike in invasive cases of aspergillosis, recovery of Fusarium species from the blood in disseminated disease approaches 60% (38, 67). Members of the FSSC (typically reported incorrectly as Fusarium solani) are the most frequently cited agents of disease, and most cases involve keratitis (26, 79). Mayayo et al. (80) consider members of this SC to be the most virulent, and it has been suggested that production of cyclosporine may contribute to their pathogenicity (81). Members of the FOSC (14) and Fusarium verticillioides (82) in the FFSC appear to be the next-most-common organisms recovered, with a similar spectrum of infection. Fusarium verticillioides was the most frequently isolated species in deep-seated infections in Italy (83). Given our current understanding of the genus, it is now difficult to attribute older clinical case reports to the newly defined species. See references 26, 35, 53, 83, and 84 for a complete list of Fusarium species known as etiologic agents in human and animal disease.

Collection, Transport, and Storage of Specimens

Methods of collection, transport, and storage of specimens are detailed in chapter 114. Like invasive aspergillosis, invasive Fusarium infections are difficult to diagnose and usually require a combination of clinical, cultural, and radiographic findings. However, unlike Aspergillus, Fusarium is frequently recovered from blood, nails, and skin lesions of immunocompromised or immunosuppressed patients (36, 85). The recovery from a normally sterile site and microscopic evidence of invasive growth in tissue provide the most convincing evidence of invasive fusariosis.

Direct Examination

Microscopy

In direct examination of tissues, hyphae of Fusarium species resemble those of Aspergillus, Paecilomyces, or Scedosporium species in size (3 to 6 mm in width), septation, branching pattern, and predilection for vascular invasion. The hyphae are irregular in width and may show areas of collapse. Hyphae exhibit both dichotomous branching (i.e., branching at 45°), as is commonly seen in invasive aspergillosis, and branching at right angles (86, 87). Microconidia and, rarely, macroconidia and budding cells, as well as phialides, may be found in blood vessel lumens or in aerated tissues (87). Immunohistological methods may help to distinguish between infections caused by some hyaline moulds, but cross-reactivity is problematic and serological tests are not in common use (88). Definitive diagnosis requires isolation and identification of the fungus, along with demonstration of fungal elements in tissue.

Antigen Detection

No commercial system is available for detection of genus-specific or species-specific antigens released by Fusarium species in human infection. The diagnostic utility of polyclonal fluorescent-antibody reagents to members of the FSSC in tissue sections from patients with invasive fusariosis was evaluated, but extensive cross-staining was observed with sections containing aspergilli, P. farinosa, and Pseudallescheria boydii (88).

There is one report that describes 9 out of 11 hematologically normal patients with disseminated or deep-seated Fusarium infection who had repeated serum-positive reactions with the Platelia Aspergillus galactomannan (GM) enzyme-linked immunosorbent (ELA) assay (Bio-Rad, Marne La Coquette, France) in the absence of Aspergillus spp. (89). Exoantigen extracted from Fusarium species, including F. oxysporum, F. fischerianum, F. falciforme, and F. verticillioides, produced positive reactions when tested undiluted by the GM ELISA assay in vitro (89), suggesting that Fusarium species may produce an exoantigen that is cross-reactive with the Platelia Aspergillus assay. Antigens prepared from F. verticillioides were also found to cause borderline cross-reactivity with the Platelia Candida antigen assay (Bio-Rad) (90). This reactivity appeared to be specific for F. verticillioides, since extracts prepared from members of the FSSC and FOSC showed no cross-reactivity in vitro.

Although (1→3)-β-D-glucan is not immunogenic, it is an important cell wall polysaccharide in most fungi that can be detected in serum via activation of a β-D-glucan-
Most Fusarium species grow rapidly on PDA in the absence of cycloheximide, which can be inhibitory. See chapter 114 for detailed information on specimen collection and processing.

**Identification**

For the limited number of Fusarium species that can be identified using phenotypic data, microscopic features of phialide shape, number of openings on the phialides (i.e., monophialides or polyphialides), formation of conidia in heads or chains, micro- and macroconidial shape and septation, the presence and arrangement of chlamydospores, colony features (including growth rates and color of colony obverse and reverse) (103), and color of conidial masses are important characters. However, considerable proficiency is required to identify Fusarium species with certainty, and a reference laboratory should be consulted. Although fusaria grow well on most mycological media, the medium can profoundly influence the colony morphology, color, and conidium development. Synthetic nutrient agar, PDA, and tap water agar supplemented with either sterilized carnation leaves or potassium chloride are widely employed (42, 104). Use of a rich medium to maintain isolates can result in cultural degeneration. Alternatively, molecular tools to help identify clinical Fusarium isolates are being developed (35, 100, 105). With the wide application of matrix-assisted laser desorption–ionization time of flight mass spectrometry (MALDI-TOF MS) in clinical microbiology laboratories, this technique may allow for the rapid and accurate genus- and species-level identification of Fusarium isolates (106, 107). A recently recommended biosafety level (BSL) classification for fusaria is either BSL 1 or BSL 2, depending upon the species (26). Clinical isolates should be handled in a biological safety cabinet.

**Typing Systems**

As with Aspergillus and Candida, multilocus DNA sequence typing (MLST) systems have been developed to differentiate clinically and veterinarily important isolates of Fusarium (43, 44, 108, 109). Recently, the Clinical and Laboratory Standards Institute published a document for identification of bacteria and fungi by DNA target sequencing (110), and a consortium of international experts assembled as an ISHAM working group on fungal identification has provided clinical laboratories with initial recommendations for molecular typing of Aspergillus, Fusarium, and the Mucorales (111). These single-locus (internal transcribed spacer [ITS]) guidelines for placing fusaria within an SC are based upon knowledge gained from multilocus sequencing (ITS-LSU, EF-1a, β-tubulin [β-TUB], calmodulin [CAM], and RP22) analyzed by phylogenetic methods (8–14). These guidelines propose that if the ITS sequence yields a >99% identity with a type or reference strain by comparative sequence analysis with GenBank/EMBL/DDBJ sequences, then the isolate can be placed within one of the six SCs. DNA sequence data from some of the loci mentioned above are essential for identification of most clinically important fusaria to the species level (111). In addition to the NCBI’s GenBank, two dedicated websites are available for identifying fusaria via the Internet (35, 36).

**Serologic Tests**

Conventional serologic tests have been developed and used to measure exposure of specific patient populations to Fusarium, most commonly in the setting of occupational exposure or indoor dampness problems (112–114). In these popu-
Antimicrobial Susceptibilities
The typical antifungal susceptibility profiles of Fusarium species indicate relative resistance to most antifungal agents (116). The MICs of amphotericin B and triazoles are elevated relative to those seen for Aspergillus species. In vitro studies show relatively high MICs of amphotericin B and itraconazole for members of the FSSC (MIC₉₀, 4 and >8 μg/ml, respectively) and FOSC (MIC₉₀, 1.0 and >8 μg/ml, respectively) (117). Universal antifungal activity was found in four clades in the FSSC (118), and testing of this SC by the European Committee on Antimicrobial Susceptibility Testing method indicated a lack of activity by any agent tested (119). Voriconazole, posaconazole, itraconazole, and ravuconazole show varied to no in vitro activity against clinical isolates of Fusarium (120, 121). In one series, voriconazole was active against an unidentified member of the FSSC (reported as Fusarium moniliforme) (MIC₉₀, 2 μg/ml) but was not fungicidal against most isolates (122, 123). Although voriconazole and posaconazole exhibit only modest activity in vitro against isolates of Fusarium, both of these triazoles have been used successfully in some patients with amphotericin B-refractory fusariosis (124–126). The echinocandins show no meaningful activity against Fusarium in vitro (127, 128); the fks1 gene appears to confer intrinsic resistance to echinocandins in an unidentified member of the FSSC (129). In vitro testing of less frequent Fusarium species in the FSSC, FCSC, and FIESC showed that terbinafine was the most active agent against all species except for a member of the FIESC (reported as Fusarium incarnatum), against which amphotericin B was the most active agent (84, 130). In contrast, terbinafine showed high MIC₉₀ against members of the FSSC and FOSC (131). Synergy studies of a murine model with F. oxysporum showed prolonged survival and reduced fungal burden with a combination of amphotericin B and posaconazole (132); silver nitrate also exhibited in vitro activity against several fusaria from ocular infections (133).

Evaluation, Interpretation, and Reporting of Results
Early diagnosis of fusariosis is often key to appropriate management strategies, and the recovery of a Fusarium species should be reported to the clinician long before a final identification is made. With few exceptions, fusaria identified by phenotypic features and/or ITS ribosomal DNA (rDNA) sequence data should be reported as members of one of the SCs.

OTHER OPPORTUNISTIC HYALINE MOULDS

Taxonomy
Other opportunistic hyaline moulds known to cause human or animal disease are distributed among various taxonomic groupings, as evidenced in Table 3. A few are homothallic ascomycetes and filamentous basidiomycetes; however, the majority are anamorphic members of the Ascomycota. Most are hyaline or only lightly pigmented; however, some, like Acrophialophora, become dark centrally. Others, such as Phialemonium, Phialocephalosphora (134), and Coniochaeta (formerly Lecythophora) (135), have been treated as agents of phaeohyphomycosis but are included here as they are frequently pale in culture. A few coelomycetous genera, such as Colletotrichum and Phoma, are also included. Unlike the hyphomycetes, which bear conidia freely, coelomycetes produce conidia within semienclosed or enclosed structures known as acervuli or pycnidia, respectively. Coelomycetes are frequently acquired as a result of some type of implantation of the fungus following trauma rather than inhalation (136, 137).

Description of Agents

Ascomycetes

Homothallic Ascomycetes
Homothallic ascomycetous genera that may be seen in culture include those producing cleistothecia (ascomata without openings or ostioles), such as Thermascus, Aphanoclados, and Cephalotheca, those that produce perithecia (ascomata with ostioles), such as Achaetomopsis (Fig. 1G), Chaetomium, and Microascus (Fig. 2C), and those whose ascospores are borne in naked clusters, as in Gymnascella. Thermascus species are nonostiolate, thermophilic ascomycetes that grow to 50°C. They produce pale-yellow, elliptical, thick-walled ascospores and have anamorphs in the genus Fuscilomycetes. Aphanoclados is a keratinolytic ascomycete characterized by yellowish, lens-shaped reticulate ascospores and a Chrysosporium anamorph. Cephalotheca foveolata is characterized by cleistothecial ascomata covered with yellow to brown hairs, foveolate ascospores that are delicately pitted or dimpled, as seen by scanning electron microscopy (Fig. 2D), and a Phialemonium-like anamorph (Fig. 2E) (138). Achaetomopsis and Chaetomium produce brown lemon-shaped to fusiform ascospores within ascomata that are ornamented with hairs (or setae), especially around the upper part near the opening. Anamorphs are uncommon. Microascus species produce yellowish to reddish-orange, variously shaped ascospores extruded in long cirri (like toothpaste squeezed from a tube) and have anamorphs in the genus Scopulariopsis. Species identification in the genus Microascus is based primarily on features of the perithecia, such as size and length of necks, and ascospore shape. Gymnascella species produce clusters of ascospores surrounded by yellow or orange filaments, but differentiated ascomata are not formed (Fig. 1H and 2A and B). Both a case isolate and the reference isolate of this species displayed false-positive results in the Gen-Probe test for Blastomyces dermatitidis (139).

Basidiomycetes

Schizophyllum and Other Genera
Filamentous basidiomycetes are uncommon causes of human disease and are still poorly characterized. However, those that have been well documented are included in genera that may remain sterile in culture. A clinical isolate may be confirmed as a basidiomycete by the presence of clamp connections on the hyphae, but these diagnostic structures may be lacking. A nonsporulating hyaline mould may be suspected as a basidiomycete when the isolate is fast growing, displays growth on benomyl agar, grows at 37°C, and fails to grow on medium with cycloheximide (140). A positive urae test result may also suggest basidio-
mycetous affinities; however, bacterial contamination should always be considered when evaluating positive results.

_Schizopyllum commune_ is recognized as a significant cause of allergic sinusitis, allergic bronchopulmonary mycosis, and related allergic disease and as an occasional cause of invasive infection in both immunocompetent and immunosuppressed patients (141). In culture, isolates of _Schizopyllum commune_ may be dikaryotic, producing diagnostic spicules and clamp connections on the hyphae (Fig. 2G), as well as basidiocarps (mushrooms) when incubated under light (Fig. 2H). Other isolates are monokaryotic, remain sterile, and lack clamps and sometimes spicules. When spicules are absent, hyphae of _S. commune_ then resemble those of _Aspergillus_ species or other moulds both in culture and in tissue (140, 142, 143) (Fig. 2F). Monokaryotic isolates can be difficult to identify, and techniques such as vegetative compatibility tests or sequencing of the ITS rRNA may be required to confirm their identification as _S. commune_ (143, 144).

Other uncommon basidiomycetes causing disease in humans and other animals include _Franosus tropicalis_ (Fig. 3A) (145, 146), _Oxyporus corticola_ (147), _Ceriporia lacera_ (148), _Tripe lacteus_ (149), a _Perenniporia_ sp. (150), _Volvariella volvacea_ (151), _Coprinus species_ with arthroconidium-forming _Hormoglyphrella_ anamorphs (152, 153), and the _Sporothrix_ like organism previously reported as _Hormoglyphrella_ (154). Another basidiomycete whose pathogenic potential remains to be determined is _Sporotrichum pruinatum_, the anamorph of _Phanerochaete chrysosporium_ (156).

*Hyphomycetes*

**Scopulariopsis**

The anamorphic genus _Scopulariopsis_ (Fig. 4F) contains both lightly colored and darkly pigmented species, some of which have teleomorphs in the genus _Microascus_ of the _Microascales_ (27, 157, 158) or the genus _Kernia_. Members of the genus _Scopulariopsis_ are common soil fungi that are noted for their deterioration of cellulolic substrates. Of the 30 species known, only a few are reliably reported from human infections; however, several new species in both genera are currently being described based on molecular phylogenetic data.

_Acremonium, Sarocladium, Coniochaeta, Phialemonium, and Phialoendomyces_

Fungi belonging to the genera _Acremonium_, _Sarocladium_, _Coniochaeta_ (formerly _Lecythophora_), and _Phialemonium_ form single-celled conidia in slimy masses or chains from long slender phialides or short, intercalary conidiogenous cells referred to as adelophialides; conidia are also formed from sporodochium-like masses in _Phialoendomyces_. The polyphyletic genus _Acremonium_, formerly called _Cephalotheca_, includes approximately 100 species associated with soil, insects, sewage, rhizospheres of plants, and other environmental substrates. Telemorphs, where known, are in the genera _Nectria_, _Emericellatepsis_, and _Thielavia_, which are placed in different ascomycete orders. Telemorph connections and molecular data provide evidence for some reclassification of the genus along phylogenetic lines (26, 159, 160). The most frequently seen clinical species in the United States include _Acremonium kiliense_ and _Acremonium sclerotigenum, Acremonium corylopticum_. A more recent phylogenetic overview of _Acremonium_ and related taxa has placed several clinical species in the genus _Sarocladium_, e.g., _S. kiliense_, _S. strictum_, and _S. bacillisporum_ (162). The species _Lecythophora_, which contained two significant species, _L. hoffmannii_ and _L. mutabils_, has been transferred to the genus _Coniochaeta_ based on the name’s priority (and in keeping with elimination of a dual nomenclature after 1 January 2013) and now contains nine species, including _C. hoffmannii_ and _C. mutabils_ (135). Human etiologic agents in the genus _Phialemonium_ previously included _P. obovatum_ and _P. curtatum_ (26). _P. obovatum_ is retained in the genus, and new species added include _Phialemonium atrogriseum_ ( _Acremonium atrogriseum_), _Phialemonium inflatum_ ( _Paciolomyces inflatus_), and _Phialemonium globosum_. However, species that produced sporodochium-like structures (species previously considered _Phialemonium curtatum_) have been transferred to the genus _Phialoendomyces_, which now includes _P. curtata_, _P. planiloculosa_, _P. cornearis_, and _P. oculatis_ (134). Three species of _Phialoendomyces_ were formerly distinguished by conidial shape and colony color, including a green diffusing pigment in _P. obovatum_ (163). However, based on PCR-restriction fragment length polymorphism banding patterns that indicated a close relationship between _P. curtatum_ and _P. dimorphosporum_, these two species were synonymized (164). Subsequently, these species were transferred to _Phialoendomyces_ and are distinguished from other genera by the presence of sporodochium-like conidiomata. As many of the aforementioned genera are very similar morphologically, identification to the species level is very difficult without molecular characterization. Thus, many reports of infection are based on unidentified species (15, 160). The genus _Phaeoacremonium_, including _P. parasiticum_ and some other species associated with human infection, is distinguished from _Acremonium_ by its brownish-pigmented hyphae and conidiophores (see chapter 124). The genera _Coniochaeta_ and _Phialoendomyces_ differ from _Acremonium_ by their formation of short, stumpy phialides without basal septa (called adelophialides) in addition to the more spindle-shaped phialides (163), but these distinctions are not always readily observed. _Coniochaeta mutabils_ differs from _C. hoffmannii_ in forming brown accessory chlamydospores on sporulation media.

**FIGURE 2.** (A) Same isolate of _Gymnascella hyalinopspora_ as in Fig. 1H turned yellow on oatmeal agar, with clusters of ascospores after 15 days at 30°C. (B) Ascospores of _Gymnascella hyalinopspora_ observed by scanning electron microscopy. Magnification, ×6,000. (C) Perithecium of a species of _Microascus_. (D) Brown ascospores of _Cephalotheca foveolata_ that formed after 8 weeks on carnation leaf agar at 25°C. (E) _Phialemonium_-like anamorph of _Cephalotheca foveolata_ showing adelophialides (reduced phialides without a septum) and ellipsoidal conidia. (F) Tissue section stained with _Gomori methenamine silver stain_ showing monokaryotic (clamless) hyphae of _Schizopyllum commune_ in a pulmonary fungus ball. (G) _Schizopyllum commune_ in slide culture preparation showing clamp connections and narrow pegs or spicules (arrows). Magnification, ×580. (H) dikaryotic culture of _Schizopyllum commune_ showing development of gilled fruiting bodies on potato dextrose agar after 7 weeks in the light.

doi:10.1128/9781555817381.ch120f2
Arthrographis, Onychocha, and Scytalidium

The genera Arthrographis, Onychocha, and Scytalidium are hyaline, arthroconidium-forming fungi. The thermotolerant Arthrographis kahaei is a rare opportunist recovered from skin, lung, corneal ulcer, and sinus (31, 165, 166). Because initial growth is often yeastlike, an isolate may not be recognized as a pleomorphic mould and thus incorrectly subjected to tests commonly used for yeast identification. Onychocha canadensis (Fig. 3F and G) is a cycloheximide-tolerant hyphomycete. Scytalidium cuboides (Arthrographis cuboides), recently reported from respiratory specimens, including a lung mass and a nasal sinus, is differentiated from other species in the genus by orange colonies and its yellow cuboid arthroconidia. Although it was not previously documented to cause disease, growth at 37°C suggests potential pathogenicity (167).

Beauveria and Engyodontium

Beauveria and Engyodontium species produce solitary conidia borne sympodially. The Beauveria bassiana species complex comprises insect pathogens with limited virulence for humans (168). Engyodontium album is closely related (26) and was segregated from the genus Beauveria.

Chrysosporium, Myceliophthora, Myriodontium, and Nannizziopsis

Members of the genera Chrysosporium (Fig. 3B and C), Myceliophthora, Myriodontium, and Nannizziopsis (Fig. 3E) produce solitary, usually single-celled conidia that are called aeluroconidia because of their lytic method of conidium dehiscence (24). Members of these genera are related to the dermatophytes and the dimorphic pathogens, sharing with them a tolerance to cycloheximide and producing telomorphs that are classified in the ascomycete order Onygenales (24, 30). The recently described family within the Onygenales, Nannizziopsiaceae, contains several species of Nannizziopsis that are pathogens primarily of various reptiles (169).

Metarhizium and Trichoderma

A multilocus phylogenetic analysis of the Metarhizium anisopliae complex, an insect pathogen of wide distribution, revealed that it comprises multiple species-level lineages (170). A taxonomic revision of the genus was made by Driver et al. (171). Conidia are produced in chains, and the thermotolerant species closely related to T. longibrachiatum (26, 172). An oligonucleotide barcode program, TrichOKEY, was published in 2006 for sequence-based identification (173).

Pacilomyces, Purpureocillium, Acroplialphora, Phialosimplex, and Rasamsonia

The polyphyletic species of Pacilomyces occur worldwide as soil saprophytes, insect parasites, and agents of biodeterioration. Recent studies show that the medically significant Pacilomyces variotii is actually a complex comprising five species, with P. variotii and P. formosus being the most important clinically (174). Their affinities are within the ascomycete family Trichocomaceae, which also includes Penicillium and Aspergillus; some other Pacilomyces species have teleomorphs in the genus Thermoascus (Thermoascaceae). The colony (Fig. 3H) and morphological features of the P. variotii complex are described in Table 3. A similar species not confirmed as an agent of infection, P. marquandii, displayed a yellow diffusing pigment and failed to grow at 37°C (141).

Purpureocillium is a new genus for the medically important Paecilomyces lilacinus now placed within the family Ophiocoelangiaceae (175). Colonies are typically lilac in color, the growth rate is lower than for Paecilomyces spp., and chlamydospores are absent.

Acroplialphora is a thermotolerant and potentially neurotropic genus widespread in temperate to tropical regions. Colonies are initially pale but darken centrally at maturity. Also described under the name Pacilomyces fusisporus, it differs by producing unbranched, erect, brown, echinulate conidiophores that are fertile at the apex and anchored by a foot cell and basally swollen monophialidic but occasionally polyphialidic conidia. Conidia are borne in chains, and distinct spiral bands may be present (176). The organism may superficially resemble Scedosporium prolificans (177, 178).

Phialosimplex is a newly described species having phylogenetic affinity to the Trichocomaceae, seen primarily in dogs (179). Colonies are moderately fast growing, white to gray to yellowish, and distinguished from other species in the genus by production of a yellow diffusible pigment (Fig. 40). Hyaline truncate conidia that are subglobose to pyriform to ovoid are borne in long chains or heads from single, narrow, mostly monophialidic conidiogenous cells (Fig. 4E). Sagenomella chlamydospora (180) and Sagenomella sclerotialis (181) were transferred to Phialosimplex as Phialosimplex chlamydosporus comb. nov. and Phialosimplex sclerotialis comb. nov., respectively.

Rasamsonia is a new genus in the family Trichocomaceae that accommodates thermostolerant or thermophilic species segregated from Geosmithia (182). It is distinguished from Penicillium species by roughened stipes, metulae, and phialides and by conidiogenesis to ellipsoidal conidia (Fig. 3D). Rasamsonia argillacea under the name Geosmithia argillacea caused a disseminated disease in a German shepherd dog.

Figure 3 (A) Setal hyphae of Inonotus tropicalis in a slide culture preparation on potato flakes agar at 10 days and 25°C. Bar, 20 μm. (B) Colony of Chrysosporium zonatum on potato dextrose agar at 14 days at 37°C. (C) Conidia of Chrysosporium zonatum formed on short curved stalks. (D) Rough-walled stipe, metulae, and phialides of Rasamsonia argillacea. Note also that conidia are initially cuneiform (wedge shaped). Bar, 10 μm. (E) Conidia of Myceliophthora thermophila in various stages of maturity. Mature conidia are dark and rough. Bar, 10 μm. (F) Culture of three different isolates of Onychocha canadensis. (G) Colony of Paecilomyces variotii on potato dextrose agar after 7 days. doi:10.1128/9781555817381.ch120.f3
and is an emerging agent in cystic fibrosis patients (184) and those with chronic granulomatous disease (185). A recent phylogenetic study of the genus has differentiated this complex into 6 clinically important species.

Coelomycetes

**Colletotrichum and Phoma**

Coelomycetous fungi are being documented as agents of disease more frequently, particularly in patients maintained on long-term immunosuppressive therapy. Infections are typically acquired through some type of direct implantation of the fungus, unlike with the hyphomycetous genera, which are acquired by inhalation. Two of the more common genera addressed here are *Colletotrichum* and *Phoma*. *Colletotrichum* species are acervular coelomycetes occasionally recovered as agents of disease. They produce fast-growing colonies of various shades that are most easily recognized in the laboratory by the production of brown, variably shaped appressoria. Honey-colored masses of conidia as well as setae and sclerotia in some species may be present in culture. Cano et al. described the salient features seen in clinical strains (186). Species in the genus *Phoma* are pycnidial coelomycetes that may be pale or darker in culture. They are usually recognized by small dark pycnidia that form on the surface or are immersed in the agar. Boerema et al. published a *Phoma* identification manual (187); however, species differentiation is best handled in a reference laboratory. A recent review of coelomycetous fungi seen in clinical laboratories cites several species documented to cause disease, gives salient features for their morphologic identification, and provides in vitro antifungal susceptibility data for selected genera/species (188). Also see chapter 124 for additional coelomycetous genera.

**Epidemiology and Transmission**

The methods of transmission and sources of infection for the other opportunistic hyaline moulds are similar to those seen in aspergillosis and fusariosis, and acquisition is typically through inhalation or traumatic implantation. Coelomycetous fungi, although ubiquitous, are mostly reported from cases of keratitis and subcutaneous mycoses in compromised individuals (189) and appear to be acquired primarily through external inoculation (136).

**Clinical Significance**

**Ascomycetes**

**Homothallic Ascomycetes**

Species of *Chaetomium* and *Achaetomium* (Fig. 1G) are neurotropic agents causing cerebral infection (39, 40, 190), while *Chaetomium globosum* occurs most commonly as a contaminant or as a rare agent of onchomycosis (6, 31). *Microascus* spp. are also agents of deep infections, including endocarditis (191) and a brain abscess (192) by *Microascus cinereus*, disseminated infections by *Microascus cirrosus*, and a fatal pneumonia by *Microascus trigonosporus* (193). The genus *Microascus* is currently being revised with the expectation that novel clinically relevant species will be described. Additional rarely implicated genera include *Gymnascella* (Fig. 1H and 2A and B) and *Cephalotheca* (Fig. 2D and E). Please see references 26, 139, and 191–195.

**Basidiomycetes**

**Schizophyllum and Other Genera**

Filamentous basidiomycetes, as well as species of smuts that may appear yeastlike (Ustilaginaceae and Tilletiaceae), are commonly isolated from respiratory specimens and sometimes from blood; however, their significance can be difficult to evaluate (140, 196).

*Schizophyllum commune* is recognized as a significant cause of allergy-related sinusitis and pulmonary disease, including allergic bronchopulmonary aspergillosis and bronchial mucoid impaction (140, 142, 143, 197–200) as well as infections of the brain, lungs, and buccal mucosa in both immunocompetent and immunosuppressed patients (31, 140, 199, 201, 202). *Coprinus cinereus* or its anamorph *Hormographiella aspergillata* has been reported from prosthetic-valve endocarditis, fatal lung infections in leukemic patients, a lung abscess in a patient with non-Hodgkin’s lymphoma, keratomycosis in a dog, and cutaneous lesions (31, 152, 153, 203, 204). *Inonotus tropicalis* was reported as an agent of osteomyelitis in a patient with X-linked chronic granulomatous disease (145, 146) and has also been seen in an additional patient with this disease (D. Sutton, unpublished data). *Ceriporia lacerata* was reported in four cases from pulmonary sites (148), *IrpeX lacteus* was recovered from a pulmonary abscess in an immunosuppressed child (149), a *Perenniporia* sp. was the etiologic agent in a pulmonary fungal ball (150), and *Volvariella volvacea* incited invasive disease and death in a Hodgkin’s lymphoma patient (151).

**Hypomycetes**

**Scopulariopsis**

*Scopulariopsis brevicaulis* (Fig. 4F) and other species are occasional agents of onychomycosis (24, 30, 157). They are also rarely invasive, causing otomycosis, keratitis, protheticovalve endocarditis, sinustitis, pneumonia, brain abscess, and subcutaneous and bone invasion in immunocompetent and immunosuppressed individuals (26, 194, 205–209). *Scopulariopsis candida* and *S. acermonium* have been reported from invasive sinustitis, but few details concerning the latter species were provided in the report (210, 211). Brain abscess caused by *Scopulariopsis brumptii* and invasive cutaneous infection caused by *Microascus cirrosus* have been reported to occur in liver transplant and bone marrow recipients, respectively (194, 212). A case of fatal *S. acermonium* was reported to occur in a lung transplant recipient (213). As noted above for *Microascus* spp., the genus is currently being revised.
Acremonium, Sarocladium, Coniochaeta, Phialocephalum, and Phialocephalopsis

Many reports concerning Acremonium involve infections of the nail, skin, eye, or mycetoma (see also chapter 125) (24, 26); however, many of these species are now classified in other genera. Localized and disseminated infections occur in patients following valve replacement, dialysis, or transplantation or in patients with hematologic or solid organ malignancies (6, 15, 26, 160, 214, 215). Fungemia is common. Several cases of invasive Sarocladium (Acremonium) strictum have been reported (216–218). C. mutabilis was reported to cause prosthetic-valve endocarditis in a diabetic patient (219), and C. hoffmannii was reported to cause chronic sinusitis in a HIV-infected patient (220). Phialocephalum obtovatum was an agent of endocarditis (221), while arthritis, fungemia, endovascular infections, and ophthalmitis have been reported for Phialocephalum curvatum (Phialocephalum curvatum) (164, 222–224).

Arthrobotrys, Onychocola, and Scytalidium

The thermotolerant Arthrobotrys katrae is a rare opportunist recovered from skin, lung, corneal ulcer, and sinus (31, 165, 166). Onychocola canadensis (Fig. 3F and G) causes distal subungal onychomycosis or, less commonly, white superficial onychomycosis and infection of the glistening skin (24, 30, 225, 226). Although O. canadensis is a relatively uncommon agent of onychomycosis, more than 60 isolates from nails have been recovered from New Zealand, Australia, Europe, and the United States, with two additional cases from Spain (227). The growth of S. cuboideum at 37°C suggests its pathogenic potential (167).

Beauveria and Engyodontium

Beauveria bassiana has caused several cases of fungal keratitis (228, 229). A recent molecular study comparing clinical keratitis isolates with Environmental Protection Agency–competent and immunocompromised patients (6, 15, 26, 250–252). The clinical manifestations, treatment options, and outcomes for P. lilacinum have been reviewed (253, 254). The species has also been noted to reside in water distribution systems, including those of a bone marrow transplant unit (175). Acrothophora fassae was the etiologic agent in a brain abscess in a child with leukemia (176) and has been recovered in pulmonary infections (255, 256) and cases of keratitis (255). It also appears to be a frequent colonizer in patients with cystic fibrosis (257, 258). Phialocephalum canum sp. nov., seen primarily in dogs, has also been recovered from pleural fluid and tissue from a human (179). Rasamsonia arglacea (formerly Geosmithia arglaca) has been described as an emerging cause of invasive fungal infection in human chronic granulomatous disease (259) and has also been reported to cause a pulmonary and aortic-graft infection in an immunocompetent patient (260).

Chrysosporium, Myceliophthora, and Nanizziopsis

The thermotolerant Chrysosporium zonatum is an etiologic agent of human pneumonia and osteomyelitis (234) (Fig. 3B and C). In a review of human infections caused by Emmonsia and Chrysosporium, those caused by Chrysosporium typically occur in immunocompromised individuals (235). The thermophilic species Myceliophthora thermophilia (Fig. 3E) has been reported to cause fatal aortic vasculitis in two patients, was isolated from the brain of a patient who developed a bacterial cerebral abscess after trauma, and is an agent of severe osteomyelitis following a finger injury (236–239). While some Chrysosporium species pathogenic for reptiles have been retained in this genus, i.e., Chrysosporium ophiodicola (240), others, such as the Chrysosporium anamorph of Nanizziopsis movei and Chrysosporium guarroii (241), have been transferred to the genus Nanizziopsis.

Metarhizium and Trichoderma Species

The Metarhizium anisopliae complex contains multiple phylogenetically distinct species that are widely distributed insect pathogens. They are also documented to cause keratitis, sinusitis, invasive infections, and disseminated skin lesions (242–245). Species of Trichoderma in the section Longibrachiatum, which includes T. longibrachiatum (Fig. 4G and H) and T. citrinoviride, appear to be the most important pathogenic species (246–249).

Paeclomycetes, Purpureocillium, Acrophialophora, Phialosimplex, and Rasamsonia Species

Clinical manifestations of both Paeclomycetes variostii and Purpureocillium lilacinum include cutaneous and subcutaneous infections, pulmonary infection, pyleonephritis, sinusitis, cellulitis, endocarditis, and fungemia in both immunocompetent and immunocompromised patients (6, 15, 26, 250–252). The clinical manifestations, treatment options, and outcomes for P. lilacinum have been reviewed (253, 254). The species has also been noted to reside in water distribution systems, including those of a bone marrow transplant unit (175). Acrothophora fassae was the etiologic agent in a brain abscess in a child with leukemia (176) and has been recovered in pulmonary infections (255, 256) and cases of keratitis (255). It also appears to be a frequent colonizer in patients with cystic fibrosis (257, 258). Phialocephalum canum sp. nov., seen primarily in dogs, has also been recovered from pleural fluid and tissue from a human (179). Rasamsonia arglacea (formerly Geosmithia arglaca) has been described as an emerging cause of invasive fungal infection in human chronic granulomatous disease (259) and has also been reported to cause a pulmonary and aortic-graft infection in an immunocompetent patient (260).

Coelomycetes

Colletotrichum and Phoma

Colletotrichum species are primarily phytopathogens but occasionally are recovered as agents of keratitis (26). There are also rare reports of subcutaneous infection following trauma (189). A case of phaeohyphomycotic cysts caused by Phoma species was reported in a patient (261).

Collection, Transport, and Storage of Specimens

Methods of collection, transport, and storage of specimens are detailed in chapter 114. As with other invasive mycoses, infections are difficult to diagnose and usually require a combination of clinical, culture, and radiographic findings. The recovery from a normally sterile site and microscopic evidence of invasive growth in tissue provide the most convincing evidence of disease.

Direct Examination

Microscopy

Histopathological findings for most opportunistic hyaline moulds are typically indistinguishable from species of Aspergillus, Fusarium, and Pseudallescheria (208). Ascospores may occasionally be observed, as was demonstrated with Gymnoasciella (139), and clamp connections may also be present in tissue sections with Schizotyphillum commune (201). Budding forms may also rarely be seen (87, 214, 215).

Antigen Detection

Detection of (1→3)-β-D-glucan (91, 93) in patients with invasive hyalohyphomycosis may assist with an early diagnosis, but monitoring of this marker needs to be combined with clinical examination of the patient and other diagnostic procedures, such as high-resolution computed tomography scanning.

Nucleic Acid Detection

Luminex microbead hybridization technology has recently been reported to detect a variety of fungal pathogens from
clinical blood and pulmonary samples (102). This method appears to have promise for the early detection and identification of various invasive fungal pathogens.

**Isolation Procedures**

Opportunistic hyaline moulds are usually cultured easily on routine mycological media, and there are no specific growth requirements; however, media with and without cycloheximide should be employed. The fungicide benomyl at a final concentration of 10 mg/ml in the culture medium can be useful to distinguish filamentous basidiomycetes, which are tolerant to benomyl, from ascomycetes, which may be sensitive to benomyl (262). Coelomycetes grow well on most fungal media; however, they are notorious for remaining sterile without extended incubation (up to several weeks for some genera) (136). See chapters 114 and 115 for detailed information on appropriate media for initial plating and isolation.

**Identification**

More-detailed descriptions of these hyaline fungi are found in several identification manuals and in the references cited therein (24–33). Many can be identified to the genus level with little difficulty; however, identification of most clinically relevant moulds to the species level requires DNA sequence data. Furthermore, MALDI-TOF MS has the potential capability of speeding up genus- and species-level identification (106). See Table 3 for salient phenotypic features of the organisms reviewed.

**Typing Systems**

Although comparative sequence analysis of clinical isolates is becoming more common in large tertiary-care and research centers, it is far from standardized. Various methods of DNA extraction are available (263), and several different genes or portions thereof may be sequenced (8–14, 17, 53, 110, 111, 264, 265). The use of DNA sequence data to identify isolates that remain sterile in culture is largely dependent on the accuracy of and interpretation of data in publicly accessible databases, such as the NCBI’s GenBank. The validity of this approach was demonstrated by DNA sequence-based identification of several nonsporulating moulds (266); this approach will continue to be used more widely. It should be highlighted, however, that numerous database entries in public databases are incorrect, making comparative sequence analysis without phenotypic correlation a challenge that requires that the top sequence matches be examined critically (111). On the other hand, molecular characterization has become the “gold standard” for classification of species for taxonomic categorization and will continue to provide a better understanding of the evolutionary relationships of clinically significant fungi (8–14, 53, 267).

**Serologic Tests**

Serologic procedures currently have little clinical utility in the diagnosis of uncommon hyaline opportunistic fungi.

**Antimicrobial Susceptibilities**

Uncommon hyaline moulds display various antifungal susceptibility patterns. Susceptibility testing of uncommon moulds is useful for empirical antifungal therapy; however, patient isolates should be assessed individually for appropriate patient management. For published in vitro data, see references relating to the genera of interest. Chaetomium infections that failed to respond to treatment with amphotericin B alone or in combination with itraconazole have been reported (268). However, voriconazole and the experimental triazoles ravuconazole and albaconazole showed potent activity in vitro against Chaetomium spp., with MICs less than 0.5 μg/ml (268); however, the echinocandins micafungin was not active in vitro. Evaluation of antifungal activity against 44 clinical isolates of filamentous basidiomycetous fungi, including Schizophyllum commune (n = 5), Coprinus spp. (n = 8), Bjerkandera adusta (n = 14), and sterile, uncharacterized basidiomycetes (n = 17), demonstrated low MICs of amphotericin B, itraconazole, voriconazole, and posaconazole, in contrast to those of fluconazole and flucytosine (269). No statistically significant differences among the genera were noted.

Antifungals, including amphotericin B and itraconazole, have limited in vitro activity against Scopulariopsis spp., and conflicting results have been reported for voriconazole and terbinafine (131, 270). A promising interaction was observed between terbinafine and fluconazole, itraconazole, and voriconazole in vitro against isolates of S. brevicaulis, although clinical experience with combination therapy is very limited (271). When Paecilomyces species were evaluated by the European Committee on Antimicrobial Susceptibility Testing methodology (119, 272), amphotericin B, terbinafine, and the echinocandins showed poor activities against 27 strains of P. lilacinum; however, the newer triazoles voriconazole, ravuconazole, and posaconazole and the allylamine terbinafine showed low MICs. In contrast, for 31 strains of P. variotii, the MICs of all of the above agents except voriconazole and ravuconazole were low (273).

**Evaluation, Interpretation, and Reporting of Results**

The early diagnosis of invasive hyalohyphomycosis caused by fusaria and other hyaline moulds is often key to appropriate management strategies. Identification of uncommon hyaline moulds should always be evaluated in light of the patient’s immune status as well as the anatomic site of recovery and frequency of isolation.

Mucormycosis and entomophthoromycosis are invasive fungal infections caused by environmental nonseptate filamentous fungi. Mucormycosis is caused by the ubiquitous Mucorales and mostly occurs in immunocompromised patients or those with diabetes mellitus. These fungi are responsible for rhinocerebral, pulmonary, cutaneous, or disseminated infections characterized by angio-invasion and necrosis and severe prognosis despite current antifungal and surgical therapies. Entomophthoromycosis, which occurs mostly in immunocompetent hosts, is caused by members of Entomophthorales (responsible for conidiobolomycosis) and Basidiobolales (responsible for basidiobolomycosis), both mostly found in warm climates. Entomophthoromycosis presents as subcutaneous infections with favorable outcome after prolonged azole therapy, although it is potentially associated with disfiguring lesions.

TAXONOMY

The classification of the kingdom of Fungi has been constantly modified over the last decades. Recently, a comprehensive phylogenetic study based on multigene sequence analyses (1) proposed a classification that accepts one kingdom, one subkingdom, seven phyla, 10 subphyla, 35 classes, 12 subclasses, and 129 orders. The most important modifications were the creation of subphylum Dikarya, which includes members of Angycomycota and Basidiomycota and the redistribution of taxa located in phyla Zygomycota and Chytridiomycota. The etiological agents responsible for mucormycosis (order Mucorales) and those responsible for entomophthoromycosis (orders Entomophthorales and Basidiobolales) were traditionally assigned to the lower fungus phylum Zygomycota. In the study by Hibbett et al., this phylum is no longer accepted due to its polyphyletic nature (1). Taxa are redistributed between Glomerosporomycota and four new subphyla of uncertain position (incertae sedis): Mucoromycotina (which includes three orders; the core group of Mucorales, Endogonales, and Mortierellales), the Entomophthoromycotina (with the order Entomophthorales), the Zoopagomycotina (with the order Zoopagales), and finally, the subphylum Kickxellomycotina (which includes the orders Kickxellales, Dimargaritales, Harpellales, and Asellariales).

Over the last years, phylogenetic interactions among members of the order Mucorales have been studied (2–4). These studies have mainly shown the polyphyletic nature of families (Thamnidaceae, Mucoraceae, and Chaetocladiaceae) and genera such as Absidia and Mucor. The family structure of Mucorales was recently studied based on the phylogenetic analysis of four markers (5). Rhizopodaceae is one of the newly erected families, which include the genus Rhizopus and other pathogenic genera.

Revisions of other genera have been published in recent years and will be detailed below (3, 6–10). Of note, the first analysis of a genome sequence from a member of the Mucorales (Rhizopus arrhizus) was published in 2009 (11). The genome annotation for the species Mucor circinelloides var. circinelloides is now available (http://www.broadinstitute.org).

Table 1 displays the Mucorales species that have been described as human pathogens or potential human pathogens considering the new family structure published by Hoffmann et al. (5).

Recently, the subphylum Entomophthoromycotina was elevated to the phylum Entomophthoromycota. The monophyly of these organisms was then confirmed by multigene phylogeny analysis (12, 13). This newly erected phylum comprises more than 250 species distributed among three classes (Basidiobolomycetes, Neozygitomycetes, and Entomophthoromycetes) and six families (Basidiobolaceae, Neozygitaceae, Ancylistaceae, Completoriaceae, Entomophthoraceae, and Meristraclaceae). There are more than 25 species in the genus Conidiobolus but only 3 (C. coronatus, C. lamprauges, and C. incongruus) have been recovered from clinical specimens, while in the genus Basidiobolus, Basidiobolus ranarum is the only species of the genus to provoke human disease (14, 15).

MUCORMYCOSIS

Epidemiology and Transmission

Mucorales are ubiquitous fungi widely distributed in the environment (soil, plants, and decaying organic material) (16). They are frequent pathogens of plants and contaminants of grains and food such as fruit or bread. Airborne spores are considered the infectious particles responsible...
for disease, particularly in immunocompromised individuals, explaining the most frequent body localizations (skin, sinuses, and lungs). Of note, immunocompetent patients may develop posttrauma skin infections, representing up to 18% of all mucormycosis cases in a comprehensive study of cases diagnosed in France (17). In addition, necrotizing cutaneous cases have been recently reported after a tornado in Joplin, MO (18), or as a cause of infections following combat-related injuries in Afghanistan (19). These species are easily found as laboratory contaminants and can be a source of nosocomial infections, including outbreaks (20–22). Specific geographical distribution and environmental niches will be described for relevant species in the corresponding section.

Some reports have suggested an increasing incidence of mucormycosis based on single-center studies (23–27). In a retrospective analysis of hospital records in France, our group recently provided a population-based estimate of mucormycosis incidence and trends for the country over a 10-year period (28). We then better estimated the real burden of mucormycosis infections through a capture-recapture method using two available sources of information (29) and found different incidences according to the region, suggesting local ecological specificities at a country level (30). The incidence significantly increased over time with an average 0.9/10^6 annual incidence rate different from the annual incidence reported in a population-based study in California, MO (18), or as a cause of infections following combat-related injuries in Afghanistan (19).

Among patients with hematological malignancies, which represented 50% of the cases in France (17), those with acute leukemia (profound neutropenia or relapse) or alloge neic stem cell transplantation are more prone to develop mucormycosis. Mucormycosis most often occurs more than 3 months after transplant in the setting of graft versus host disease (24, 25, 37–38). Mucormycosis now represents 7 to 8% of invasive fungal infections in bone marrow transplant patients (43, 44). An increased incidence of mucormycosis was observed in patients with hematological malignancies or stem cell transplant in France (28), as already noted in the 1990s in one U.S. center (27). In that population, the potential role of prior exposure to antifungals lacking activity against Mucorales, such as voriconazole and caspofungin, has been reported (24, 25, 37–48).

Mucormycosis represents 2% of invasive fungal infections during SOT, mostly in kidney transplantation (49). In a recent international study of SOT recipients, renal failure, diabetes mellitus, and prior voriconazole and/or caspofungin use were associated with a higher risk whereas tacrolimus was associated with a lower risk of mucormycoses (37). Liver transplant recipients were more likely to have disseminated disease and developed infection significantly earlier after transplantation than other SOT recipients.

Mucormycosis can also develop in HIV-infected patients or intravenous drugs abusers. It can affect otherwise healthy individuals following cutaneous injuries with contaminated soil in almost 20% of the cases in some studies. Finally, it

In the latter study, 131/178 cases were observed in uncontrolled diabetic patients (73.6%), and more importantly, mucormycosis led to the diagnosis of diabetes in 56 cases (42.7% of diabetes cases). Diabetes mellitus was also found in 15% (type 1 = 13%) of 157 pediatric cases (36). Diabetes was an independent risk factor for mucormycosis in patients with leukemia and/or bone marrow transplantation (24) and significantly influenced the occurrence of mucormycosis during solid organ transplantation (SOT) (17, 37).
may present as community-acquired or as a health care-related disease. A careful review of cases published between 1970 and 2008 revealed a total of 169 individual (with 29% of them children) mucormycosis cases associated with health care, of which 72% were published after 1990 (21). Outbreaks of mucormycosis are rare but have been related to building construction and use of contaminated adhesive tape, ostomy bags, or wooden tongue depressors.

**Clinical Manifestations**

Localized and disseminated diseases need to be differentiated (40). The most frequent localized forms are sinusitis and pneumonia, representing 25 to 39% and 24 to 30% of clinical sites involved, respectively, in three recent series (17, 33, 50). Dissemination rates vary from 3% to more than 50% in patients with hematological malignancies (depending to some extent on the underlying diseases and the site of infection) (33, 40, 41).

Sinus involvement (isolated sinusitis, rhinocerebral, and sino-orbital forms) is the most common presentation in diabetic patients and intravenous drug abusers, while pulmonary infection is the second most common presentation, and the reverse is true in hematologic patients (24, 33). Infection causes necrosis and hemorrhage and may be localized or associated with dissemination. Clinicoradiological presentation is similar to that of invasive aspergillosis in patients with hematological malignancies, although the presence of a reversed halo sign may be suggestive of (51) but not specific to (52, 53) mucormycosis. In a recent study of 58 SOT patients with mucormycosis, pulmonary localization was present in 31 (53%), including 23 with localized infection (54).

Localized cutaneous lesions are most often encountered in immunocompetent hosts (33) and follow injury and contamination with airborne spores or soil (35, 56, 154) and, less often, surgery or burns. Local extension and hematogenous dissemination may occur. In contrast, skin lesions resulting from dissemination from other sites are rare. Cerebral infection can complicate sinusitis or occur independently, especially in intravenous drug abusers. Cognitive disturbances and focal neurological deficit are often present.

Gastrointestinal lesions are described in 7% of cases and occur in low-birth-weight premature infants and malnourished individuals and after peritoneal dialysis (33). They are decreased incidence of the disease in the hematologic population over recent years, although posaconazole has been available since 2007 (30).

**Treatment**

**Prophylaxis**

In immunocompromised patients, there is no benefit of the prophylactic use of azoles such as fluconazole or itraconazole due to of the lack of (major) activity against Mucorales (27, 41, 42). The best preventive measure is the reduction of environmental exposure, notably with the use of high-efficiency particulate air-filtered rooms (41). The specific role of posaconazole as a prophylactic agent against mucormycosis has not been demonstrated (57, 58), and there is no decreased incidence of the disease in the hematologic population over recent years, although posaconazole has been available since 2007 (30).

**Curative Treatment**

In Roden et al.‘s review, survival of untreated patients was 3% while 64% of patients who received antifungal therapy survived (33). A combined medical and radical surgical treatment, especially for rhinocerebral and skin localizations, in association with correction of the underlying disease wherever possible (i.e., acidosis, hyperglycemia, neutrophil recovery, and modulation of immunosuppressive therapy) offers the best chance of survival (59).

Lipid derivatives of amphotericin B (AMB) given early in the course of the disease are probably more effective and better tolerated than AMB deoxycholate (60). Clinical response has been obtained with a high dose of liposomal AMB in patients who failed with conventional dosages (61, 62); therefore, one of the two available options (lipid complex or liposomal formulation) should be first-line therapy (63, 64). Oral posaconazole in its current oral formulation can only be considered second-line therapy, iron overload should not be used, and echinocandins in combination with polyenes are considered a second-line therapy option. Global case fatality rates vary from 84 to 47% (33), with those of rhinocerebral forms ranging from 20 to 69% (26, 35). Survival is reduced in cases of hematological malignancies compared with diabetes mellitus (17).

**Collection, Transport, and Storage of Specimens**

Mucormycosis is one of the most rapidly progressing invasive fungal infections. The diagnosis of mucormycosis should be considered an emergency, since delaying therapy will impact outcome (65). Although clinical features are not specific, some early radiological features may make the diagnosis of mucormycosis more probable compared to other invasive fungal infections, particularly invasive aspergillosis (51). A combination of well-known predisposing factors and clinical and/or radiological signs must alert the physician and prompt the institution of immediate diagnostic procedures. Since currently available methods developed for the diagnosis of invasive fungal infections are based on antigens that are not produced by Mucorales (66), the diagnosis relies primarily on direct examination and/or recovery of the fungus and/or detection of their nucleic acids in pathological tissues, body fluids, or exudates. Blood cultures are not appropriate for the diagnosis. In high-risk patients, specimens, preferentially from deep lesions and sterile sites, have to be rapidly and aseptically collected in sufficient quantity. Larger volumes will increase the likelihood of fungal recovery and will allow more diagnostic procedures (direct examination, culture, DNA extraction for PCR, histopathology) as well as storage of the sample for further analyses. For rhinocerebral localization, nasal discharge or scraping, sinus aspirate, or tissue specimen from normally vascularized areas should be obtained. For pulmonary localization, sputum and bronchoalveolar lavage fluids can be examined, taking into account the low sensitivity of these specimens (67, 68). If negative, transbronchial or percutaneous computerized tomography-guided biopsies of pulmonary lesions can be performed, keeping in mind the potential of induced morbidity (69).

Separate specimens must be sent for microbiological and histological analysis, since formalin used for histopathology inhibits fungal growth. Direct examination remains the most rapid diagnostic technique, and culture is essential to identify the isolate at the species level and to test susceptibility to antifungal drugs. The transport container should be sterile and humidified with a few drops of sterile saline. The specimen should not be refrigerated and should ideally be transported to the laboratory within 2 h after collection and processed rapidly, since Mucorales are easily damaged and sensitive to environmental stresses (70). Biopsy specimen
grinding is deleterious for the Mucorales due to the coenocytic nature of the hyphae. Biopsy specimens should be sliced into small pieces of tissue that are then dispatched for direct examination and culture.

Direct Examination and Histopathology
Demonstration of hyphae in clinical samples provides strong evidence of mucormycosis, since Mucorales are environmental airborne moulds that could be present in conidial form in nonsterile specimens, with false-positive cultures as a result. Direct examination is a key test for two reasons: (i) culture from clinical samples is frequently negative (71) and (ii) histology requires multiple steps that necessarily delay diagnosis.

Microscopy
Direct examination can be performed using wet mounts of the sample or after addition of chlorazol black. However, optical brightener (calcifluor white, Blankophor, or UViteX 2B) that specifically stains the chitin contained in the cell wall, coupled with a clearing and dissociating agent, such as KOH, provides better sensitivity (67). It is always a good idea to examine the slides again the following day, especially in the presence of thick samples because of possible false negatives resulting from insufficient dissociation of tissues.

The morphological characteristics suggestive of Mucorales hyphae are specific and can be differentiated from those of Aspergillus, Fusarium, or Scedosporium. Hyphae are large (5 to 25 μm), irregular, hyaline, non- or pauciseptate, and thin walled with a ribbon-like morphology. A twisted or folded appearance of the hyphae is frequently observed. In contrast to hyalohyphomycetes for which an acute (45°) branching pattern is observed, wide branching angles (>90°) are suggestive of Mucorales. If hyphae are fragmented, the typical features are missing, which makes it difficult to make a reliable diagnosis based solely on direct microscopy. However, the same characteristic features can be observed in tissue samples after histopathological preparation based on Gomori methenamine-silver or periodic acid-Schiff staining. Of note, the detection of Mucorales is difficult using hematoxylin-eosin stain. Sometimes, if only a few hyphae are present and the tissue section contains cross-sections through the hyphae, it can produce the appearance of yeast or vacuole-like structures, making the morphology difficult to interpret. Classically, Mucorales are angio-invasive, with invasion of venous and arterial walls frequently associated with infarction of the surrounding tissue (72). The inflammatory response is varied, ranging from none at all to a neutrophil infiltrate alone, granulomatous response alone, or both together. Perineural invasion can also be observed (72). Immunohistochemistry techniques based on commercially available kits can be used in difficult cases (73).

Antigen Detection
There are currently no specific antigen detection methods available for the diagnosis of mucormycosis. Moreover, testing for the presence of B-h-glucan is not helpful.

Isolation Procedures
Recovery of Mucorales from clinical specimens is difficult, with positive culture in only 15 to 25% cases (71). However, culture is suitable for the definitive diagnosis of mucormycosis, especially in cases of negative direct examination, keeping in mind that the lack of galactomannan antigen detection may indirectly suggest the diagnosis of mucormycosis. Indeed, clinical or radiological features are not specific for invasive fungal infection, nor can they distinguish between mucormycosis and other invasive fungal infection due to Aspergillus, Fusarium, or Scedosporium, especially in the hematological setting. However, the therapeutic management is different and isolation of a fungus is sometimes the unique diagnostic element. Culture is also of prime importance for identification to the species level, especially since morphological structures are not species specific in tissues, and for antifungal susceptibility testing of the isolate (74). Primarily, culture is typically performed on rich medium such as Sabouraud dextrose agar with additional antibiotic to inhibit bacterial growth. Cycloheximide-containing media should not be used, since inhibition of fungal growth can be observed for some species. After inoculation, plates must be incubated between 25–30°C and 37°C to allow growth of thermotolerant and thermointolerant isolates (75). However, Sabouraud dextrose agar is often not appropriate for morphological identification purposes, and growth on potato dextrose agar (PDA) is more suitable.

Detection of Nucleic Acids in Clinical Materials
In many cases, histopathology and/or direct examination are positive but culture fails. Species identification is, however, important for epidemiological purposes and because of species-specific antifungal susceptibility profiles. PCR-based molecular identification can be performed using formalin-fixed, paraffin-embedded (76) frozen or fresh tissue specimens. In formalin-fixed, paraffin-embedded tissues, extracted DNA is often of poor quality due to fragmentation after fixation (77). Furthermore, extracted DNA usually contains small amounts of fungal DNA relative to the large quantity of human DNA. Consequently, PCR-based identification must rely on amplification of small fragments of DNA that should ideally allow sequence discrimination between species upon sequencing. PCR based on internal transcribed spacer 1 (ITS1) and ITS2 primers developed by sequencing has been proposed in formalin-fixed, paraffin-embedded organs recovered from mice with experimental mucormycosis (78). It has also been evaluated in formalin-fixed, paraffin-embedded human tissues with identification of Mucorales in 7/18 samples harboring nonseptate hyphae based on histopathological reporting (76). Seminested PCR technique based on the 18S ribosomal DNA locus has also been used with Mucorales identification in 13/23 samples for which nonseptate hyphae were observed by histology (79). This molecular tool has also been prospectively evaluated with identification of Mucorales in six samples, of which five were culture positive (80, 81). An approach based on real-time PCR has been developed based on cytochrome b locus amplification. It allowed discrimination between different genera of Mucorales using analysis of melting curves (identification of 35/62 formalin-fixed, paraffin-embedded tissue samples) (82). Multiplex PCR coupled with electrospray ionization in direct-positive/culture-negative unfixed clinical samples seems potentially interesting, allowing genus and species identification (A. Alanio and S. Bretagne, unpublished results).

Fluorescent dye-labeled oligonucleotide with direct hybridization (fluorescent in situ hybridization) on the pathologic tissue is a promising tool, since it does not require DNA extractions or PCR amplification and can be performed on formalin-fixed, paraffin-embedded tissue samples. It uses fluorescent DNA probes that are specific for 5.8S or 18S RNA of different groups of fungi. After hybridization, fluorescence of the microorganism can be observed directly on the slide (83, 84). Localization of the fluorescence can...
provide additional information that can reinforce the diagnosis. This tool seems particularly adapted when the yield of DNA extraction or the quality of the extracted DNA is poor. Indeed, PCR-negative fluorescent in situ hybridization-positive results have been observed (84).

**PCR-Based Diagnosis in Serum: Mucormycosis Screening**

In addition to the molecular methods developed for fungal identification from tissues, another strategy, inspired by the screening strategy for patients at risk of aspergillosis, is emerging for the diagnosis of mucormycosis. In a population with a relatively high prevalence of mucormycosis, one recent study proposed to screen sequential serum samples by PCR targeting of Mucorales genes (three genus-specific independent PCR). Using this method, the authors were able to establish the diagnosis of mucormycosis between 68 and 3 days before that based on histopathology or culture (85). This strategy can be envisioned for use in the future in high-risk populations to shorten the current delay in diagnosis.

**Identification**

### 11.1. Phenotypic Identification

#### General Description

Routine identification of Mucorales to the species level is mainly based on the examination of their macroscopic and asexual microscopic characteristics, although some other criteria such as physiological tests (86) or maximum growth temperature can be used. The formation of zygospores is not useful in routine identification unless the species is homozygous. The use of media with high carbohydrate content favors production of an abundant mycelium which inhibits the production of asexual fruiting bodies by which the species can be identified. Therefore, media such as 2% malt, potato dextrose, and cherry decoction (acidic) agars are recommended for subculture of most of the Mucorales species, although some of these media are not commercially available. To trigger sporulation in genera such as *Apophysomyces* or *Saksenaea*, which are emerging pathogens (87-89), nutritionally deficient media containing a low percentage of yeast extract solution are advisable (90). Multiple factors such as light and temperature also influence the growth, the morphology, and the sporulation of these fungi. Several species are thermotolerant, capable of growing at temperatures well over 40°C. Mycelial development of the Mucorales tends to be rapid (24 to 48 h) and extensive. Colony appearance varies according to the species, the age of the culture, and the mycological media used. It is recommended for an accurate morphological study of Mucorales to use subculture at 27 to 30°C. Macroscopic examination involves the description of the colonies (height, color, texture) and the sporangioverse spatial branching configuration that can be observed under a 10× objective or a binocular loupe. For microscopic characteristics, a detailed study of adhesive tape mounts or teased mounts (small piece of mycelium plus fruiting bodies placed in a water drop and gently needle teased) is essential for the description of the sporulating structures of the species. Fungi in the order Mucorales are characterized by branched, nonseptate, wide mycelia (10 to 20 μm) with chitinous walls. Sexual reproduction occurs by means of zygospore formation after fusion of hyphal branches from the same (monothallic) or from sexually differentiated mycelia (heterothallic) (91). The mature zygospore is often thick walled and undergoes an obligatory dormant period before germination. Asexual multiplication is by means of nonmotile sporangiospores (endospores) borne in closed sac-like structures named sporangia. They can exist as multispored sporangia or sporangiola (small sporangia) having few (to one) spores. Sporangia are supported by specialized hyphae named sporangiophores. In some species, they arise from a branched system of rhizoids, which anchor the sporangiophore to the substratum. These rhizoids are connected by a rooting branch called a stolon. Additional morphological structures are the columellae (central axis of the sporangium) and the apophysis (a swelling of the sporangiophore just below the columella). Some species can produce thick-walled and/or thin-walled swollen structures named chlamydospores and oidiol, respectively. The liberation of sporangiospores occurs by breakage or deliquescent of the sporangial wall (Fig. 1). Structures of Mucorales used for routine identification include branching of sporangiophores, type of sporangia (merosporangia or sporangiola), shape, color, presence or absence of apophys and columellae, and presence or absence of rhizoids or chlamydospores.

### Description of Specific Genera and Species

Morphological (macroscopic and microscopic) characteristics of those species frequently implicated in human infections are described below. Only major features are mentioned based on our own experience and descriptions from specialized books (14, 20, 92). All colony morphology descriptions are made from subcultures on MEA (2% malt agar) at 30°C (unless otherwise specified). The colonies of Mucorales have mostly floccose textures with colors varying from white (*Saksenaea*) to yellow (*Mucor*), brownish (*Apophysomyces*), or gray (*Lichtheimia, Rhizomucor*). *Rhizopus* produces high aerial mycelium, whereas *Rhizomucor* produces a low aerial turf of 2- to 3-μm-high mycelium. The morphology of sporangiophores (height, branching) can vary depending on the genus. It can be branched as in *Lichtheimia* or *Mucor*, irregularly branched as in *Rhizomucor*, or mostly unbranched as in *Rhizopus*. In addition, the site from which the sporangiophore arises (between rhizoids or directly from the stolon) is a supplementary clue for the identification of the different genera (Fig. 2). A morphological key to the principal genera of Mucorales is illustrated in Fig. 3. The combination of asexual fruiting bodies and criteria such as maximum growth temperature are useful for the differentiation of these fungi to the species level. The phenotypic differences described below refer to species defined by nucleotide sequence analysis.

#### Family Lichtheimiaceae

**Genus Lichtheimia Vuill. 1903 (formerly Absidia or Mycocladus).** The genus *Absidia* has been revised on the basis of phylogenetic, physiological, and morphological characteristics (7). The thermotolerant species of *Absidia corymbifera*, *A. blakesleeanana*, and *A. hyalospora* were placed in the new family of Mycocladaceae and the genus *Mycocladus*. The same group suggested revision of the nomenclature rectification to create the family Lichtheimiaceae (instead of Mycocladaceae) and the reassignment of the genus *Lichtheimia* in place of *Mycocladus* (93). The multigene sequence analysis of 38 isolates morphologically identified as *Lichtheimia corymbifera* uncovered the presence of a different species (named *L. ramosa*), which differs in morphology and nucleotide sequences from *L. corymbifera* (6). Of the five
FIGURE 1  Schematic drawing of morphological structures observed in Mucorales. Sporangio-
phores (A) bear sporangia containing sporangiospores (D), can be anchored to the substrate by
rhizoids (B), and expand by the means of stolons (C). The columella (E) is produced at the apex
of the sporangiophore, and in some species, an apophysis (G) is present. For some species, after
liberation of sporangiospores, a thin sporangium membrane may be visible (F). Sporangia with
single or few spores are called sporangiola (H), and sporangia with few spores aligned in rows are
called merosporangia (I). Thick-walled chlamydospores (J) and oidia (thin-walled swollen vesicles)
(K) can be observed. Drawings by Dea Garcia-Hermoso. doi:10.1128/9781555817381.ch121.f1

recognized species of the genus Lichtheimia, only L. corymbifera, L. ornata, and L. ramosa are of clinical relevance (8).
These species seem to have a worldwide distribution and have been isolated from diverse substrates including seeds,
soil, and decaying vegetable debris. They produce white, fast-growing, woolly colonies, which become grayish brown
with age. Maximum growth temperature is between 46°C and 52°C. L. ramosa differs from L. corymbifera and L. ornata
by faster growth at high temperatures (8). Microscopically, sporangiophores are usually erect and highly branched and
arise singly or in small corymbs from stolons but not opposite the rhizoids as in Rhizopus. Rhizoids are present but
don’t have to be recognized. Sporangia are multispored, apophyses are absent, and most species are thermophilic.
Sporangiospores are round, hyaline, and smooth walled (Fig. 5). The species differ in the size of sporangia, sucrose
assimilation, and the capacity to grow in presence of thiamine. R. miehei has smaller sporangia than R. pusillus (60
μm versus 100 μm in diameter) and fails to assimilate sucrose, and its growth depends on the presence of thiamine.

Family Mucoraceae

Genus Mucor Fresen. 1850. Four species are considered human pathogens: Mucor circinelloides, M. irregularis (for-
merly R. variabilis var. variabilis), M. indicus, and M. ramosissimus (10, 95).

Colonies of the genus Mucor are usually fast growing and white to yellow, becoming gray with time. Tall sporangi-
phores (they can reach several centimeters in height) are simple or branched, supporting multispored nonapophysate sporangia. Sporangiospores are hyaline and subspherical to elliptoidal. In some species, residues of the sporangial wall (collarette) can be present, and some species can produce rhizoids and chlamydospores (Fig. 6).

Mucor circinelloides is a species complex comprising four varieties based mainly on differences in the shape of colu-
mellae and sporangiophores. Major phenotypic differences within the thermotolerant Mucor species involved in human
infections are summarized in Table 2. Maximum growth temperatures for pathogenic Mucor species range from 35°C
(M. circinelloides) to 42°C (M. indicus). The identification of these species can be complicated under unsuitable growth
conditions which can induce morphological variations such as sterile sporangia, swelling in sporangiophores, and modifications in size and shape of sporangia, columellae, and sporangiospores (96).

Genus Cokeromyces Shanor 1950. Cokeromyces recurvatus remains a rare agent of mucormycosis. It has been mostly recovered from soil or from rabbit, rat, or lizard dung in North America (United States and Mexico). Colonies are slow growing (less than 1 mm high) and grayish to brown. Microscopic features include the presence of long, recurved, twisted stalks arising from terminal vesicles of unbranched sporangiophores, globose sporangiola (8 to 11 μm in diameter) borne on those stalks, and smooth-walled spherical sporangiospores 2 to 4 μm in size (Fig. 7). A yeast-like form can be obtained by subculturing on media such as brain heart infusion or yeast extract peptone agar. Yeast-like forms are thin to thick walled and spherical, measuring 10 to 100
μm in diameter. Some cells produce single buds across their entire surface, producing a ship's wheel appearance similar to that of *Paracoccidioides brasiliensis* (20). The species is homothallic and produces lemon-shaped zygospores.

**Family Saksenaeaceae**

*Genus Apophysomyces* P.C. Misra 1979. The members of the genus *Apophysomyces* are soil fungi with a tropical to subtropical distribution. They produce fast-growing white to gray colonies. General features are erect sporangiophores, unbranched and single, bearing multispored sporangia, usually pyriform, of 20 to 60 μm in diameter. Columellae are hemispherical, cylindrical, trapezoidal, or ellipsoidal; the sporangiophores are smooth walled. The production of prominent vase-shaped, bell-shaped, or funnel-shaped apophyses is a distinctive feature of this species (Fig. 8). Good growth is observed at 42°C (92). The use of poor nutrient media (water-yeast extract medium) can improve sporulation, as suggested by Padhye and Ajello (90). Czapek medium at 30 or 37°C also induces sporulation. Microscopically, sporangiophores are unbranched with melanized rhizoids. The length of sporangiophore and sporangia, the shape and size of sporangiospores, and the maximum temperature for growth are useful parameters for the recognition of the different species. Figure 9 shows the distinctive flask-shaped multisporanged sporangia, which is a key feature for the identification of this genus.

**Family Rhizopodaceae**

*Genus Rhizopus* Ehrenb. 1821. *Rhizopus arrhizus* (syn. *R. oryzae*) and *Rhizopus microsporus* are the most common pathogenic species. This genus is commonly found in the air, soil, and compost characterized by the rapid production of white cottony colonies, which turn brownish to black with time due to the presence of pigmented sporangiophores and sporangia. Table 3 indicates useful features allowing the distinction between the pathogenic species of the genus *Rhizopus*. The sporangiophores are unbranched, arising singly or in groups, with well-developed rhizoids at the base, which distinguishes the genus *Rhizopus* from the genera *Lichtheimia* and *Rhizomucor*.

The microscopic features of *R. arrhizus* include single or clustered brown sporangiophores of 1 to 2 mm in height bearing multisporanged sporangia (150 to 170 μm in diameter). Colu-
mellae are ellipsoidal and brown to gray, and they generally have a truncate base. Rhizoids are well developed and easily observed under the stereomicroscope. Sporangiospores are angular and round to ellipsoidal, with longitudinal ridges 6 to 8 μm by 4.5 to 5.0 μm in size. Chlamydospores (10 to 35 μm in diameter) can be present (Fig. 10). This thermotolerant species can grow at 40°C but not at 45°C. R. arrhizus differs from the nonpathogenic R. stolonifer which harbors longer sporangiophores (>2 mm) and larger columellae (up to 275 μm in diameter) and does not grow at 40°C (98).
According to one recent U.S. epidemiological survey, *R. microsporus* is the second most frequent agent of mucormycosis (99). It can be isolated from soil or wood products. Colonies are pale brownish gray with sporangiophores arising from stolons and measuring up to 400 μm in length (100). Sporangia are dark brown (up to 80 μm diameter), columellae are conical, and sporangiospores are striate and angular to ellipsoidal (Fig. 11). In addition to the typical *R. microsporus* var. *microsporus* there are three supplementary varieties: *R. microsporus* var. *chinensis*, *R. microsporus* var. *oligosporus*, and *R. microsporus* var. *rhizopodiformis*. They can be distinguished on the basis of the morphology of sporangiospores and temperature tolerance. These differences observed between varieties are not supported genetically (101). Table 3 indicates major differences among the species of the genus *Rhizopus*.

**Family Cunninghamellaceae**

Genus *Cunninghamella* Matr. 1903. Traditionally, *Cunninghamella bertholletiae* was considered the only clinically relevant species of the genus. Although rarely involved in human disease, *C. bertholletiae* has the capacity to infect immunocompetent individuals. Other species such as *C. elegans*, *C. echinulata* (102), and more recently, *C. blakesleeanus* (103) have also been implicated in cases of human mucormycoses. *C. bertholletiae* is a thermotolerant fungus isolated from soil. It produces white to dark gray expanding colonies. Sporangio- phores are erect with lateral branching at the apical zone. Each branch produces a globose vesicle (up to 40 μm in diameter), which bears 1-spored sporangiola. At maturity, each sporangiola will become a finely echinulate spherical sporangiospore (7 to 11 μm in diameter) (Fig. 12). Key features for the identification of *C. bertholletiae* are essentially its growth at 45°C (with a maximum of 50°C) and the presence of monosporic sporangiospore borne on terminal vesicles.

**Family Syncephalastraceae**

Genus *Syncephalastrum* J. Schröt. 1886. Species from the genus *Syncephalastrum* have a worldwide distribution and have been isolated from soil, plants, and diverse foodstuffs (16). The only species associated with cases of human infection is *S. racemosum*, which is described below.

In culture, *S. racemosum* grows rapidly and produces expanding white grayish colonies, which turn darker due to the formation of sporangia and resemble the colonies formed by *Rhizopus* spp. The maximum temperature for growth is 40°C. Sporangiophores are short, erect, and mostly branched, arising from rhizoids and forming terminal globose vesicles. The whole surface of these vesicles is covered with cylindrical merosporangia containing (3 to 14) smooth-walled, spherical to ovoid merosporules arranged in single rows (Fig. 13). This is a distinctive feature of the genus compared to other members of *Mucorales*.

**Molecular Identification**

The species identification of *Mucorales* using phenotypic methods remains a difficult task due to the common morphological features among the members of this group. In addition, some pathogenic species, such as members of *S. vasiformis* species complex and *A. elegans* species complex, regularly fail to sporulate on standard mycological media (104). Therefore, sequence-based identification is of interest as it provides fast and easily comparable data (105). In search of reliable DNA barcode markers for *Fungi*, Schoch and collaborators compared the performance of six markers: three nuclear ribosomal regions (ITS, ribosomal large subunit, ribosomal small subunit) and portions of three protein-coding genes on 17 fungal lineages. The ITS was finally proposed as the primary fungal

disometerically abnormal site consistent with an infectious sterile procedure from a normally sterile and clinically or radiologically abnormal site consistent with an infection accompanied by evidence of associated tissue damage or the recovery of a mould by culture of a specimen obtained by a needle aspiration or biopsy shows hyphae. In vitro antifungal susceptibility can be evaluated using the reference microdilution broth techniques from the CLSI (110) and the EUCAST (111) or, alternatively, using a commercially available test (Etest) (112). Although Mucorales share most antifungal susceptibility patterns, there is some specificity depending on genus and even species. AMB is the most active drug against the majority of Mucorales as shown both in vitro (74, 113–117) and in animal models of infection (118–122). Among the new azoles, voriconazole has poor activity, which is highlighted by breakthrough mucormycosis in patients treated with voriconazole (123) and in experimental models (124). In contrast, posaconazole has relatively low in vitro MICs (74, 113, 114, 115, 122, 125), and the in vivo efficacy of posaconazole has been demonstrated as curative and prophylactic treatment in animal models (126, 127). Echinocandins have no significant activity (128, 129), despite the fact that Rhizopus arrhizus possesses the target enzyme for this class of compounds. In vivo, caspofungin alone exhibits modest efficacy (57) while it showed promising clinical efficacy in combination with AMB in some patients (96).

Typing Systems

By definition, typing methods are developed to study the diversity and relatedness of isolates (environmental or clinical isolates) within a given species. Few methods have been evaluated for the typing of clinical isolates of Mucorales (24, 108, 109). These methods proved to be inefficient due to their low discriminatory power. Whole-genome sequencing may provide the key to designing efficient typing methods in the future (87).

Serologic Tests

No commercial assays are available at this time.

Antifungal Susceptibilities

In vitro antifungal susceptibility can be evaluated using the reference microdilution broth techniques from the CLSI (110) and the EUCAST (111) or, alternatively, using a commercially available test (Etest) (112). Although Mucorales share most antifungal susceptibility patterns, there is some specificity depending on genus and even species. AMB is the most active drug against the majority of Mucorales as shown both in vitro (74, 113–117) and in animal models of infection (118–122). Among the new azoles, voriconazole has poor activity, which is highlighted by breakthrough mucormycosis in patients treated with voriconazole (123) and in experimental models (124). In contrast, posaconazole has relatively low in vitro MICs (74, 113, 114, 115, 122, 125), and the in vivo efficacy of posaconazole has been demonstrated as curative and prophylactic treatment in animal models (126, 127). Echinocandins have no significant activity (128, 129), despite the fact that Rhizopus arrhizus possesses the target enzyme for this class of compounds. In vivo, caspofungin alone exhibits modest efficacy (57) while it showed promising clinical efficacy in combination with AMB in some patients (96).

Evaluation, Interpretation, and Reporting of Results

Culture results should always be interpreted in light of the clinical presentation and along with the results of direct examination and/or histopathology. A positive culture of Mucorales can be due to contamination during collection of the sample or processing of the sample in the laboratory. A study in Spain showed that less than 8% of the Mucorales isolates recovered in the laboratory were from patients with invasive mucormycosis (32, 130). In the revised definitions of the EORTC/MSG study group for the diagnosis of invasive fungal infections, proven disease requires that “histopathologic, cytopathologic, or direct microscopic examination of a specimen obtained by needle aspiration or biopsy shows hyphae accompanied by evidence of associated tissue damage” or “the recovery of a mould by culture of a specimen obtained by a sterile procedure from a normally sterile and clinically or radiologically abnormal site consistent with an infectious...

disease process, excluding bronchoalveolar lavage fluid, a cranial sinus cavity specimen, and urine" (131). However, "the failure to meet the criteria for invasive fungal infection does not mean that there is none, only that there is insufficient evidence to support the diagnosis. This is the most compelling reason for not employing these definitions in daily clinical practice." One may thus have proof of an invasive fungal infection and a high suspicion of mucormycosis without evidence of the latter in the absence of positive culture. As mentioned before, attempts to establish the definite diagnosis are important to offer the best management for the patient.

ENTOMOPHTHOROMYCOSIS

Epidemiology and Transmission

The majority of members of the Entomophthoromycota are pathogens of arthropods and other animals. They are present in soil, decaying vegetables, and dung worldwide but more abundantly in warm climates of Africa and Asia (20). Infections due to Basidiobolus ranarum are described in Asia (Indonesia, where the first cases were described; India; and Myanmar) and in several African countries (mostly Uganda and Nigeria) but rarely in South America. B. ranarum has recently
emerged with gastrointestinal presentations in the United States (132). Infections due to Conidiobolus spp. are described in Africa, Madagascar, Mayotte, India, China, Japan, and South America (133–135).

**Clinical Manifestations**

One of the major differences between mucormycosis and entomophthoromycosis is that the former occurs mainly in predisposed individuals, whereas the latter occurs mostly in apparently immunocompetent hosts. *B. ranarum* is responsible for subcutaneous infections which mostly affect the limbs, buttocks, trunk, and perineum and less often the face and neck. The disease presents mostly in male children as a woody, hard, brawny, painless nodule that enlarges peripherally without affecting the overlying skin (136). Invasive infections with gastrointestinal involvement (132, 137) have been described in a small cluster in Arizona (138) and sporadically worldwide. Disseminated infections are extremely rare (139).

In contrast to basidiobolomycosis, infections due to *Conidiobolus* spp. affect adults (mostly males) and outdoor workers and are usually limited to the nose and face. The onset of the infection is thought to take place in the nasal mucosa after inoculation of spores following a minor trauma. Swelling extends locally to the nose, the nasolabial folds, cheeks, eyebrows, the upper lip, and even the palate and pharynx, producing the characteristic facies in severe forms (140). Conjunctival inoculation of the fungus has been documented once in Brazil (141). Rare cases of dissemination have been reported in immunosuppressed individuals (142). Tissue lesions caused by *C. coronatus* and *C. incongruus* are similar (143).

**Treatment and Outcome**

Therapeutic strategies for basidiobolomycosis and conidiobolomycosis are not standardized because of the lack of clinical trials for these rare infections. Surgical excision, potassium iodide, and prolonged azole therapy have been used successfully for infection due to Basidiobolus (26, 133). For infections due to *Conidiobolus* spp., potassium iodide was historically used with variable results. Prolonged oral azole therapy should now be used and is successful (134).

**Collection, Transport, and Storage of Specimens**

As several differential diagnoses are possible, a confirmation of the fungal agent should be obtained and tissue biopsy specimens of the affected area are the best diagnostic specimens. The diagnosis relies on classical procedures combining direct examination and culture in unfixed samples and/or histology in fixed samples. In the gastrointestinal form of basidiobolomycosis, biopsy specimens obtained during endoscopy are the

| TABLE 3 Main characteristics allowing distinction among Rhizopus species | Growth at temp (°C): |

Neg, negative.
gold standard. Specimens should be processed immediately and should not be refrigerated (136).

Direct Examination
A direct examination of fresh specimens can be performed after dissolution of the tissue sample in KOH and staining with calcofluor white. For histology, classical stains, including hematoxylin and eosin, periodic acid-Schiff, and Gomori Grocott, could be performed. Typically, hyphae are broad, thin walled, and generally more septate than those of the Mucorales. Simultaneous acute and chronic inflammatory reactions are observed in the affected tissue. Hyphae can be observed using routine staining procedures. The presence of a Splendore-Hoeppli reaction associated with typical hyphae in tissue sections stained with hematoxylin-eosin is highly suggestive of entomophthoromycosis. The pink structure corresponds to a sheath of amorphous eosinophilic material around hyphal fragments. Even if the presence of a Splendore-Hoeppli phenomenon is strongly suggestive of entomophthoromycosis, it can be observed in various bacterial, fungal, and parasitic infections as well as in noninfectious diseases (144). In contrast to mucormycosis, there is typically no necrosis and no invasion of blood vessels.

Antigen Detection
No antigen tests are currently available for the detection of entomophthoromycosis.

Detection of Nucleic Acids in Clinical Materials
A PCR-based technique targeting Basidiobolus has been developed for the diagnosis of entomophthoromycosis in human samples (145).

Isolation Procedures
Biopsy samples should be sliced or minced (not ground) and placed on Sabouraud agar or PDA. Media containing cycloheximide should be avoided because of inhibition of Basidiobolus and Conidiobolus growth. Cultures must be incubated at both 37°C and 25 to 30°C because of various optimum growth temperatures of these organisms. Basidio-
bolus grows well at 30°C but less rapidly at 37°C, whereas Conidiobolus spp. grow rapidly at 37°C (16).

**Identification**

**Phenotypic Identification**

Members of Entomophthoromycota are characterized by the presence of coenocytic hyphae or short hyphal bodies and of primary and secondary conidia, which can be forcibly discharged at maturity. Primary conidia with papillate bases are produced straight from the thallus in repetitive cycles (14). They generate a germ tube or can produce smaller secondary conidia (similar in morphology to the primary conidia) in the presence of suitable substrate conditions. Villose conidia (old conidia with hair-like appendages) can also develop. Passive release of microconidia may also occur. In some species, thin
sporangiophores bear capilliconidia at their apex. These spores are characterized by an adhesive tip. Zygospores (thick, bilayered, walled spores) are produced after conjugation of undifferentiated gametangia and can have beak-like appendages coming from gametangial remains (14, 20, 92). Sporulation occurs after 3 to 10 days of culture. Colonies are usually waxy or powdery with radial folds and with colors ranging from white to tan-brown (14, 20). A key feature of these fungi is their capacity to forcibly discharge conidia. Therefore, placing a cover slide inside the Petri dish lid can be helpful to recover the papillate conidia. For a detailed description and additional information, see the taxonomic classification study by Ben-Ze’ev and Kenneth (146).

Class Entomophthoromycetes, Order Entomophthorales

Family Ancylistaceae

Genus Conidiobolus Bref. 1884. The genus Conidiobolus includes saprobes, facultative invertebrate, and vertebrate pathogens (13). The three species causing human conidiobolomycosis are C. coronatus, C. incongruus, and C. lampragues.

Conidiobolus coronatus is a fast-growing fungus present in soil and on decaying leaves (92). It is most frequently isolated in the tropical forests of Africa (147). C. coronatus is an occasional pathogen of insects and has been recovered from diverse animals such as dolphins, chimpanzees, and horses (16).

Colonies are hyaline, radially folded, with an initially waxy appearance becoming powdery when mycelia become visible. The inside of the lid of the dish can be covered with conidia forcibly discharged by the conidiophores. These primary conidia are spherical (40 μm in diameter) and possess a prominent papilla. Villose conidia are present in older cultures (Fig. 14). Replicative passively discharged microconidia are regularly produced (14). C. coronatus can be differentiated from the two other pathogenic species by the absence of zygospores on PDA medium and the presence of villose conidia. Similarly, C. incongruus produces zygospores, which differ from those of C. lampragues by the size and the formation of small globules inside the mature zygospores (148).

Class Entomophthoromycetes, Order Entomophthorales

Family Basidiobolaceae

Genus Basidiobolus.

Basidiobolus ranarum EIDEM. Basidiobolus ranarum is present in decaying fruit and vegetable matter (92). It can be present as a commensal in the intestinal tract of amphibians and reptiles (149). Colonies on PDA are yellowish and waxy, have radial folds, and do not form aerial mycelium when young. They grow well at 25 to 37°C. The microscopic examination after 7 to 10 days of culture reveals large asep-
tate mycelia which can break up into free hyphal elements basically uninucleated. B. ranarum is homothallic. Sexual reproduction occurs by gametangial conjugation, producing thick-walled zygospores with lateral protuberances of gametangial remains (beaks) (Fig. 15). Primary conidiophores with swollen apices forcibly discharge spherical primary conidia. Secondary conidia are pyriform (clavate) and are passively released from the sporophore. These conidia possess a knob-like adhesive tip. Occasionally, elongated cells with a terminal adhesive tip (capilliconidia) are present (14, 147).

**Molecular Identification**

There is no technique published for the molecular identification of *Entomophthoromycota*.

**Typing Systems**

To date, there is no typing method developed for *Entomophthoromycota*.

**Serologic Tests**

There are no commercially available diagnostic tests.

**Antifungal Susceptibilities**

*In vitro* susceptibility data are scarce, and some technical issues (such as inoculum preparation) remain to be addressed. Potassium iodide shows no *in vitro* activity despite *in vivo* efficacy (150). Both *Conidiobolus* and *Basidiobolus* species exhibit relatively high MICs when tested with AMB, azoles, and echinocandins (151–153). Recently, Tondolo and colleagues reported terbinafine as an active drug against *C. lamprauges* (153). Overall, *Basidiobolus* spp. are more susceptible than *Conidiobolus* spp. to the different antifungals tested.

**Evaluation, Interpretation, and Reporting of Results**

In areas of endemicity, final diagnosis is based on the combination of direct examination showing broad thin-walled hyphae with a Splendore-Hoeppli phenomenon without necrosis or invasion of blood vessels. In case of positive cultures, results of antifungal susceptibility testing do not currently influence the therapeutic decision.

Histoplasma, Blastomyces, Coccidioides, and Other Dimorphic Fungi Causing Systemic Mycoses*

GEORGE R. THOMPSON III AND BEATRIZ L. GÓMEZ

TAXONOMY

The dimorphic fungi causing systemic disease belong to the class Eurotiomycetes, order Onygenales. The Onygenales share several general characteristics: their sexual stages (teleomorphs) form rudimentary asci surrounded by a network of hyphae, which may have complex appendages; and their asexual (anamorph) species generally possess one of two forms, either unicellular aleuroconidia or arthroconidia in chains of alternately viable and nonviable cells.

The order Onygenales contains the families Ajellomycetaceae and Onygenaceae. Ajellomycetaceae contains the species Ajellomyces dermatitidis, Ajellomyces capsulatus, Ajellomyces duboisii, and Ajellomyces crescentis, the anamorphs of which are placed in the genera Blastomyces, Histoplasma, Histoplasma, and Emmonsia, respectively (1). The teleomorph of Paracoccidioides brasiliensis has yet to be discovered; however, DNA sequence data have placed Paracoccidioides in the Ajellomycetaceae family as well (2). Onygenaceae contains the species Coccidioides immitis and Coccidioides posadasii, and similarly, the teleomorphs of these genera have yet to be identified despite evidence that sexual reproduction and gene acquisition are ongoing in nature (3). Molecular phylogenetic studies have indicated that species of the Onygenales are divided into several clades (descendants of a common ancestor). The Onygenaceae and Ajellomycetaceae are well separated from the Arthrodermataceae (dermatophytes). In all of these phylogenetic trees, pathogenic organisms are interspersed with nonpathogenic relatives, which suggests that the capacity to infect humans has arisen numerous times during the evolution of the Onygenales.

This chapter covers the dimorphic members of the families Onygenaceae and Ajellomycetaceae, which include Blastomyces dermatitidis, Histoplasma capsulatum, Blastomyces duboisii, P. brasiliensis, and C. immitis and C. posadasii as well as Emmonsia species. Nonpathogenic species of Chrysosporium, Uncinocarpus, and other related genera are not covered here. It should be noted that taxonomic updates have taken effect as of 1 January 2013 and dual nomenclature for pleomorphic fungi has been discontinued (4). The ending of separate names for anamorphs and teleomorphs (one fungus now equals one name) has been a long-awaited change in mycology. The majority of fungi are likely to keep their more widely used anamorph name, however.

Histoplasma capsulatum

Historically, H. capsulatum was divided into three varieties: H. capsulatum var. capsulatum, a human pathogen found in North and South America; var. duboisii, a human pathogen found in Africa; and var. farciminus, a pathogen of horses and mules found in parts of northern Africa and the Middle East. Phylogenetic studies have defined at least eight clades within H. capsulatum: North American class 1, North American class 2, Latin American group A, Latin American group B, Australian, Netherlands (Indonesian), Eurasian, and African clades (5). Seven of these eight clades comprise genetically and geographically distinct populations that can be regarded as phylogenetic species. The single exception, the Eurasian clade, originated from within the Latin American group A clade. H. capsulatum var. farciminus was placed within the Eurasian clade. In addition to the seven phylogenetic species, another seven lineages represented by single isolates from Latin America were identified (5). These may represent additional phylogenetic species. Recent studies using multilocus sequence typing of H. capsulatum in formalin-fixed, paraffin-embedded tissues from cats living in regions where the pathogen is not endemic revealed a new phylogenetic clade. The H. capsulatum sequences recovered from the cats were most closely related to the North American class 1 clade but clustered separately outside this clade, suggesting that the H. capsulatum infecting the animals may represent a separate clade or phylogenetic species (6).

At this time, the disease African histoplasmosis is considered a distinct entity, but the taxonomic placement of H. capsulatum var. duboisii has been called into question by the finding of one var. capsulatum isolate from South Africa that was placed in the African (var. duboisii-containing) clade (5). This extends the results of earlier studies that had shown that var. duboisii had mitochondrial DNA restriction patterns identical to those of var. capsulatum strains.

The genome of H. capsulatum has an estimated size of between 28 and 39 Mbp, and currently sequence assemblies and annotations are available for four strains (http://www.broadinstitute.org/annotation/genome/histoplasma_capsulatum).

*This chapter contains information presented by Mary E. Brandt, Beatriz L. Gomez, and David W. Warnock in chapter 120 of the 10th edition of this Manual.
Phylogenetic analysis of *Paracoccidioides brasiliensis*

The genus *Paracoccidioides* has previously been represented by a single species, *P. brasiliensis*, yet more recent work has challenged this notion and suggested that *P. brasiliensis* includes a cryptic subspecies or a separate species (7). Subsequent phylogenetic analysis using nuclear loci has placed *Paracoccidioides* isolates into one of two monophyletic clades: *B. dermatitidis* and the novel species *Blastomyces gilchristii* (8). Concordant with this work, genotyping studies of *B. dermatitidis* have revealed an association between clinical phenotype and genetic groups—findings suggesting that genotyping of isolates may help to predict patient clinical associations (9). Whole-genome sequence assemblies and annotations for four *B. dermatitidis* strains, including the highly virulent clinical strain SLH14081 and the relatively avirulent strain ER-3, can now be queried via the Broad Institute server (http://www.broadinstitute.org/annotation/genome/paracoccidioides_dermatitidis).

**Coccidioides Species**

Phylogenetic studies have led to the recognition of two species within the genus *Coccidioides*. The species name *C. immitis* is now restricted to isolates from California, while the name *C. posadasii*, in honor of Posadas, the author of the first description of coccidioidomycosis in Argentina in 1892 (10), has been proposed for all other isolates belonging to this genus. These two taxa were initially thought not to interbreed; however, more recent evidence has shown that genetic exchange between these species has occurred, with evidence of hybridization and genetic introgression (11). Later, a more extensive population sample, including isolates from Venezuela, Mexico, and Brazil, was studied by using a set of nine microsatellite markers (12). This study showed that two major clades could be distinguished. These clades, now named *C. posadasii* and *C. immitis*, correspond to the previous group I (non-CA [for non-Californian]) and group II (CA), respectively. Ongoing work using whole-genome sequencing will further assist our understanding of *Coccidioides* genotyping (13). Genome sequence assemblies and annotations of *C. immitis* and *C. posadasii* have been completed (14); the annotations of four strains of *C. immitis* and two strains of *C. posadasii* are now available for querying or downloading from http://www.broadinstitute.org/annotation/genome/coccidioides_group.

**Paracoccidioides brasiliensis**

Phylogenetic analysis of *P. brasiliensis* has shown that this fungus can be divided into at least three distinct species that appear to be confined to regions of endemicity: S1, FS2, and PS3 (15). These species have not been formally named. A proposal has also been made to name the highly divergent “Pb01-like” group “Paracoccidioides lutzii” (16, 17). Recent genomic and morphologic analyses strongly support the existence of a sexual cycle in species of the genus *Paracoccidioides* (18). Comparison of 18S and chitin synthetase sequences has indicated that *P. brasiliensis* is related to the uncultivable pathogen *Lacazia loboi*, the agent of lacaziosis (19) (chapter 127). However, these sequences demonstrated sufficient differences for *L. loboi* to be kept as an independent genus (19).

Since 2009, the Broad Institute has completed the sequencing, assembly, and annotation of the genomes of two strains of *P. brasiliensis* and one strain of *P. lutzii* (20): see http://www.broad.mit.edu/annotation/genome/paracoccidioides brasiliensis.

*Emmonsia Species*

The genus *Emmonsia* currently includes three species: *E. crescens*, *E. parva*, and *E. pasteuriana* (21). The last has thus far only been recovered from a single case of disseminated cutaneous infection in a patient with AIDS (22), although a recent report from South Africa suggests that a new *Emmonsia* species related to *E. pasteuriana* may be more common than previously recognized (23).

*E. crescens* is known to form a sexual stage in the genus *Ajellomyces*, but *E. parva* has no known teleomorph. The assembly and annotation of *E. parva* and *E. crescens* genome sequences are currently under way (http://www.ncbi.nlm.nih.gov/bioproject/179100).

**DESCRIPTION OF THE AGENTS**

**Histoplasma capsulatum**

*H. capsulatum* is a thermally dimorphic fungus, displaying a filamentous mold form in the environment and in culture at temperatures below 35°C and a yeast phase in tissue and at temperatures above 35°C. The mold phase may contain two types of conidia (Fig. 1). Macroconidia are thick walled with a diameter of 8 to 15 μm and display characteristic tubercles or projections on their surfaces. Microconidia, smooth walled with a diameter of 2 to 4 μm, are the infectious particles (24, 25). The yeast phase develops as small, oval, budding cells with a diameter of 2 to 4 μm, often within macrophages (Fig. 2 and 3A). The yeast cell found in African histoplasmosis is thick walled and larger, 8 to 15 μm in diameter.

*H. capsulatum* is found in soils throughout the world. It grows best in soils with a high nitrogen content, particularly those enriched with bird or bat guano. Birds do not become colonized or infected with *H. capsulatum* (due to their high body temperatures), and their droppings are primarily a nutrient source. Soil samples from sites where birds have roosted have remained contaminated for at least 10 years after the roost has been cleared (26). Histoplasmosis is the most common endemic mycosis in North America, but it is also found throughout Central and South America (24, 27). In the United States, the disease is most prevalent in states surrounding the Mississippi and Ohio Rivers, but foci of endemicity exist throughout the

![FIGURE 1](https://example.com/figure1.png)

eastern half of the continent. Other regions of endemcity include parts of Africa, Australia, and eastern Asia, in particular India and Malaysia.

**Blastomyces dermatitidis**

*B. dermatitidis* is thermally dimorphic, converting from the mold phase to the yeast phase under appropriate conditions of temperature and nutrition. At room temperature, a flocose, white mold can be recovered (Fig. 4). The microconidia are oval or pyriform (pear shaped) with a diameter of 2 to 10 μm; no macroconidia are produced. Large, round, thick-walled yeast cells, 5 to 15 μm in size, with broad-based, budding daughter cells are found in tissue and on appropriate media at 37°C (Fig. 5). Yeast cells may occur inside or outside macrophages.

The natural habitat of *B. dermatitidis* is the soil, particularly near waterways, although the ecology of Blastomyces has not been completely defined due to the difficulty in isolating the organism in nature (28). It appears to survive best in moist acidic soils that contain a high nitrogen and organic content. Higher soil temperatures and recent rainfall facilitate growth of the fungus.

The largest number of cases of blastomycosis has been reported from North America, but the disease is also endemic in Africa and parts of Central and South America. In the United States, the organism is most commonly found in states surrounding the Mississippi and Ohio Rivers; in Canada, the disease occurs in the provinces that border the Great Lakes (29).

**Coccidioides Species**

In the environment and in culture at room temperature, the *Coccidioides* fungus exists as a mold producing septate hyphae and arthroconidia that usually develop in alternate hyphal cells (Fig. 6). As the arthroconidia mature, the alternating disjunctor cells undergo lytic degradation, releasing the barrel-shaped arthroconidia, ~2 to ~5 μm, which are the infectious particles. Inside the host and on special media, the arthroconidia transform into a structure called a spherule. A spherule is a large (up to 120 μm), thick-walled, spherical structure containing hundreds to thousands of endospores, each ~2 to ~4 μm, which can be released if the spherule ruptures (Fig. 7). Each endospore can develop into a spherule as well, continuing the process within the host.

*Coccidioides* is a soil-inhabiting fungus with a restricted geographical distribution (30). It is confined to regions of the Western Hemisphere that correspond to the Desert

Southwest, and although an animal reservoir has been pos-
tulated, this has yet to be definitively demonstrated (31).
In the United States, the region of endemicity includes
central and southern California, southern Arizona, southern
New Mexico, part of Utah, and western Texas. The region
of endemicity extends southwards into the desert regions
of northern Mexico and parts of Central and South America.

Paracoccidioides brasiliensis

*P. brasiliensis* is a thermally dimorphic fungus. At room tem-
perature, it grows as a mold. Growth requires a lengthy incu-
bation, of up to 30 days. Isolates incubated on rich media
produce thin, septate hyphae and occasional chlamydo-
spores. Under conditions of nutritional deprivation, some iso-
lates produce conidia, which vary in structure from arthro-
conidia to microconidia of <5 μm. Conidia respond to
temperature changes, germinating into hyphae at 20 to 24°C
or converting into yeasts at 36°C on appropriate media. Yeast
cells are mostly oval and characteristically display a mother
cell surrounded by multiple buds, a structure thought to re-
semble a ship’s pilot wheel (Fig. 3B and 8).

Although *P. brasiliensis* has been isolated from soil, un-
derstanding of its precise environmental habitat remains
limited. The region of endemicity extends from Mexico
(23° N) to Argentina (34° S), sparing certain countries
(Chile, Suriname, the Guyanas, Nicaragua, Belize, and most
of the Caribbean islands) within these latitudes. Within
countries where the disease is endemic, the mycosis is diag-
nosed only in areas with relatively well-defined ecologic
characteristics (presence of tropical and subtropical forest,
abundant watercourses, mild temperatures, high rainfall, and
coffee/tobacco crops). The greatest numbers of reported
cases have come from Brazil, Colombia, and Venezuela (32,
33). *P. brasiliensis* has been repeatedly recovered from human
clinical samples; tissues of the nine-banded armadillo, *Dasy-
pus novemcinctus*; and more rarely from the northern naked-
tailed armadillo, *Cabassus centralis*. Occasionally *P. bra-
siliensis* has also been isolated from dogs and detected in
other animal species (32).

Emmonsia Species

In the environment and in culture at room temperature, *Em-
monsia* species exist as a mold that produces small, single-
celled conidia (~4 μm in size) on the sides of the hyphae or
on short side branches. Inside the host, the conidia of *E. cres-
cens* and *E. parva* transform into structures termed adiaspores,
which resemble the spherules of *Coccidioides* species (Fig. 9).
Although adiaspores enlarge to become enormous, thick-
walled structures, no endospores are produced and the spores
Persons with underlying illnesses are at increased risk for some forms of histoplasmosis. Disseminated infection is more common among individuals with underlying cell-mediated immunological defects, including those with HIV infection, transplant recipients, and individuals receiving tumor necrosis factor alpha inhibitors for rheumatoid arthritis. Immunocompromised persons with histoplasmosis have a higher mortality rate than those who are not immunosuppressed.

**Blastomycosis**

Inhalation of conidia is the usual mode of infection leading to blastomycosis. The incubation period has been estimated to be 4 to 6 weeks, although in some cases, disease manifests only months following exposure (36). Blastomycosis is not contagious.

Outbreaks have been associated with occupational and recreational activities, often along streams or rivers, and have resulted from exposures to moist soil enriched with decaying vegetation. Apart from outbreaks, blastomycosis is more commonly seen in adults than in children. More men than women are affected, and a disproportionate number of Asians compared with non-Asians were affected in a recent outbreak (37). The disease often occurs in individuals with an outdoor occupation or recreational interest.

*Paracoccidioidomycosis*

Inhalation of arthroconidia is the usual mode of infection leading to coccidioidomycosis in humans. The incubation period is 1 to 3 weeks. In contrast to what is observed with histoplasmosis, once individuals have recovered from *Coccidioides* infection, they are usually immune to reinfection. The infection is not contagious, but occasional person-to-person spread has occurred via contaminated fomites (39) or by transmission from an organ donor to a recipient (40).

The major risk factor for infection is environmental exposure. The risk depends on a number of factors including the nature of the environmental site, the activities performed, and the duration and degree of dust or soil exposure. Infection has been associated with ground-disturbing activities, such as building construction, landscaping, farming, archaeological excavation, and numerous recreational pursuits (41). Natural events that result in the generation of dust clouds, such as earthquakes and windstorms, have been associated with an increased risk of infection and have resulted in large outbreaks (42).

Disseminated infection is more common among those of black, Asian, or Filipino race and among pregnant women in the third trimester. Individuals with underlying cell-mediated immunological defects, such as those with AIDS and those receiving immunosuppressive medications, are also at increased risk of disease dissemination (43).

**Paracoccidioidomycosis**

Inhalation of conidia is the usual mode of infection leading to paracoccidioidomycosis in humans. The incubation period is unknown, but it is clear that the fungus can remain dormant for very long periods in the lymph nodes following asymptomatic primary infection. Paracoccidioidomycosis is not contagious (32).

Paracoccidioidomycosis predominates in adults, who display 85 to 95% of cases, and in persons in agriculture-related occupations. The disease is more often diagnosed in males than in females (ratio of 15:1). Estrogen-mediated inhibition of the mold-to-yeast transformation could help to account for this (32). Sporadic cases have been reported in
individuals with underlying immunosuppressive conditions, including HIV infection.

**Adiaspiromycosis**

Inhalation of conidia is the usual mode of infection leading to adiaspiromycosis in animals and humans, and even in cases with skin lesions, it is likely that this represents dissemination following inhalational exposure given the systemic manifestations (including liver function abnormalities) (44). The incubation period is unknown, although circumstantial evidence has suggested that symptoms may develop 1 to 3 weeks following exposure. No risk factors have been identified.

**CLINICAL SIGNIFICANCE**

**Histoplasmosis**

There is a wide spectrum of clinical manifestations of histoplasmosis, ranging from a transient pulmonary infection that subsides without treatment to chronic pulmonary infection or to more widespread disseminated disease (24, 25). Many healthy individuals develop no symptoms when exposed to *H. capsulatum* in a setting of endemicity. Higher levels of exposure result in an acute symptomatic and often severe flu-like illness. The symptoms, which include fever, chills, headache, nonproductive cough, myalgia, pleuritic chest pain, loss of appetite, and fatigue, usually disappear within a few weeks. The most severe form of this disease is disseminated histoplasmosis. The clinical manifestations range from an acute illness that is fatal within a few weeks if left untreated (often seen in infants, persons with AIDS, and solid-organ transplant recipients) to an indolent, chronic illness that can affect a wide range of sites.

Hepatic infection is common in nonimmunosuppressed individuals with disseminated histoplasmosis, and adrenal gland destruction is a frequent problem. Mucosal ulcers are found in >60% of these patients. The mouth and throat are often affected, but lesions also occur on the lip, nose, and other sites. Central nervous system disease occurs in 5 to 20% of patients, presenting as chronic meningitis or focal brain lesions. In persons with AIDS, disseminated histoplasmosis is usually associated with low CD4 T-lymphocyte counts and presents with nonspecific symptoms, such as fever and weight loss. Mucosal lesions are uncommon, but multiple cutaneous lesions may be present. Central nervous system involvement occurs in 10 to 20% of cases (24, 25).

**African Histoplasmosis**

The clinical manifestations of African histoplasmosis differ from those of classical histoplasmosis. The illness is indolent at onset, and the predominant sites affected are the skin and bones. Individuals with more widespread infection involving the liver, spleen, and other organs have a febrile wasting illness that is fatal within weeks or months if left untreated. Multiple cutaneous lesions often develop on the face and trunk. These lesions often enlarge and ulcerate. Osteomyelitis occurs in ~30% of patients. The infection may spread into contiguous joints, causing arthritis, or into adjacent soft tissue, causing a purulent subcutaneous abscess.

**Blastomycosis**

Blastomycosis encompasses a wide clinical spectrum, ranging from a transient pulmonary infection that subsides with-
recently reported (23,50), can occur in immunocompromised patients. Severe or even fatal cases of adiaspiromycosis can be found in immunocompromised patients. It has a poor prognosis.

The hallmarks of the chronic adult type of disease are significant lung involvement and extrapulmonary lesions. This is the predominant form, occurring in ~90% of cases (32). In 80% of cases, the disease involves the lungs. The disease is slowly progressive and may take months or even years to become established. Ulcerative mucocutaneous lesions of the face, mouth, and nose are the most obvious presenting sign. Other sites of infection include the small or large intestine, liver and spleen, adrenal glands, bones and joints, central nervous system, and renal genitourinary tract. In 60 to 80% of cases, active pulmonary involvement and residual fibrotic lesions are observed. A residual form is also recognized in 50 to 80% of cases and is represented by fibrotic scarring occurring at the sites of previously active lesions, which can alter respiratory function and incapacitate the patient. P. brasilensis infection may become dormant, to be reactivated later under the influence of ill-defined conditions prevalent in rural settings, such as chronic alcoholism, malnutrition, and smoking (32).

**Adiaspiromycosis**

In most cases, adiaspiromycosis is a self-limited, localized pulmonary infection with few or no symptoms. Because the adiaspores enlarge but do not reproduce, symptoms and clinical signs depend on the number of conidia inhaled. In some patients, the disease is discovered incidentally during the evaluation of other pulmonary conditions. However, nonproductive cough, dyspnea, and fever are not uncommon in those with adiaspiromycosis. Severe or even fatal cases are rare, although they have been reported (22), and, as recently reported (23, 50), can occur in immunocompromised individuals with cutaneous manifestations and elevated liver function tests. A single outbreak of ocular adiaspiromycosis has also been reported (51).

### COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

**Clinical Specimens**

Methods of collection, transport, and storage of specimens are detailed in chapter 114. Tissue samples should be obtained when appropriate and should be divided and submitted for microbiological and histopathological examination. If possible, special tissue stains such as the Grocott-Gomori methenamine silver (GMS) and periodic acid-Schiff (PAS) stains should be requested. Since colonization with the dimorphic fungal pathogens does not occur, their microscopic detection and/or isolation in culture is consistent with proven infection. Blood, urine, and cerebrospinal fluid (CSF) can also be collected as appropriate for antigen and/or antibody testing.

**Histoplasma capsulatum**

H. capsulatum organisms can be isolated from sputum or bronchoalveolar lavage fluid specimens in 60 to 85% of cases of chronic pulmonary histoplasmosis if multiple specimens are tested (52). In disseminated disease, useful specimens for culture include blood, urine, lymph node, and bone marrow samples. Bone marrow cultures are positive in >75% of cases. Blood cultures collected with the Isolator lysis-centrifugation system (Wampole Laboratories, Princeton, NJ) or Bactec Mycolytic bottles (BD Diagnostic Systems, Franklin Lakes, NJ) show the greatest sensitivity. Biopsy specimens of oral, cutaneous, and gastrointestinal lesions, adrenal glands, or liver and spleen also have provided a diagnosis. Histoplasma meningitis is difficult to diagnose, with CSF cultures being positive in no more than two-thirds of cases. The best results are obtained when large volumes of CSF (10 to 20 ml) are cultured on multiple occasions.

**Blastomyces dermatitidis**

Sputum samples, bronchoalveolar lavage fluid, or lung biopsy specimens may be submitted. Skin biopsy specimens are useful in the diagnosis of cutaneous disease. Collection of urine after prostatic massage may be helpful in the diagnosis of genitourinary blastomycosis.

**Coccidioides Species**

In addition to lower respiratory tract samples, material for microscopy and culture can be collected from suppurative cutaneous and soft tissue lesions. Organisms can be recovered only infrequently from CSF (~30% of patients), and usually only after culture of large volumes (10 to 20 ml) (53).

**Paracoccidioides brasiliensis**

In addition to lower respiratory samples, material can be collected from oral or pharyngeal lesions, cutaneous lesions, lymph nodes, adrenal glands, and the gastrointestinal tract. In these specimens, a simple wet mount suffices to reveal P. brasiliensis in >85% of patients.

**Emmonsia Species**

Sputum and bronchoalveolar lavage fluids are seldom cultured positive in patients with disease. The diagnosis is usually based on observation of its unique histopathologic appearance, typically a single, large, thick-walled adiaspore within a granuloma, yet more-recent reports have found yeast in skin biopsy and blood smear specimens.

### DIRECT EXAMINATION

**Microscopy**

Direct microscopic examination of clinical materials may provide a rapid presumptive diagnosis of a systemic fungal infection. However, it is important to appreciate that tissue-form cells of H. capsulatum and B. dermatitidis can appear similar to each other as well as to yeast cells of various Candida species, Cryptococcus neoformans, Cryptococcus gattii, and Talaromyces marneffei (formerly Penicillium marneffei) and to endospores of Coccidioides species. It is often helpful to stain fresh, wet preparations of sputum, bronchoalveolar lavage fluid, CSF, urine, pus, or other material with calcofluor white, a fluorescent compound that binds to the fungal cell wall, to assist with preliminary evaluation.

**Histoplasma capsulatum**

Giemsa and Wright’s stains can be used to detect yeast cells of H. capsulatum in blood or bone marrow smears. These cells can also be seen in tissue sections stained with GMS or PAS but usually not with hematoxylin and eosin (H&E). Detection of the small (2- to 4-μm), oval, budding yeasts allows a presumptive diagnosis of histoplasmosis. Organisms can be found within macrophages or free in the tissues. It is unusual to find yeast cells on cytological examination of sputum or other respiratory tract fluids. The thick-walled,
narrow-based, budding yeast cells causing African histoplasmosis, \( \sim 10 \) to \( \sim 15 \) \( \mu \text{m} \) in diameter, are about 4-fold larger than those of classical \( H. \) capsulatum in tissue sections and on occasion may be confused with Blastomyces spp.

**Blastomyces dermatitidis**

Direct calcofluor white or KOH mounts or Gram stains of sputum, tissues, and exudates often permit the detection of the large, round yeast cells of Blastomyces spp. The broad-based buds often attain the same size as the parent cells before becoming detached. On occasion, larger “giant” yeast forms (>40 \( \mu \text{m} \)) or filmentous forms may be found in tissue. Histopathological examination using PAS or GMS stains also can be of value.

**Coccidioides Species**

Tissue sections should be stained with PAS, GMS, or H&E to permit the detection of the characteristic large, thick-walled spherules of *Coccidioides* species. Microscopic examination of wet preparations of sputum, bronchoalveolar lavage fluid, pus, or other samples treated with KOH is also helpful but is less sensitive. *Prototheca* wickerhamii may resemble small spherules, and *Rhinosporidium seeberi* may simulate larger ones.

**Paracoccidioides brasiliensis**

The characteristic translucent-walled yeast cells of *P. brasiliensis* with multiple buds can often be found in direct microscopic examination of sputum, bronchoalveolar lavage fluid, pus from draining lymph nodes, or tissue biopsy specimens. Staining of wet preparations with lactophenol cotton blue, methylene blue, Gram stain, or calcofluor white can be helpful. Tissue sections can be stained with PAS, GMS, or H&E.

**Emmonsia Species**

Tissue sections stained with PAS or GMS are most helpful in demonstrating the characteristic adiaspores of *Emmonsia* species in lung tissue. It is important to appreciate that in the chronic stage the organism may collapse, forming various shapes that may resemble other fungi, helminths, or pollen grains. Adiaspores must also be distinguished from the spherules of *Coccidioides*. Adiaspores do not contain endospores, and adiaspores are typically much larger than empty *Coccidioides* spherules.

**Antigen Detection**

**Histoplasma capsulatum**

One well-known *Histoplasma* polysaccharide antigen (HPA) test is a microtiter plate-based double-antibody sandwich enzyme immunoassay (EIA) to detect antigen in urine, serum, or CSF in cases of disseminated histoplasmosis with a sensitivity of up to 95% (54). This test is also useful in the early diagnosis of acute pulmonary histoplasmosis and during treatment follow-up (55). Ten milliliters of urine, 5 ml of serum, or 1 ml of CSF is the preferred volume for the HPA test, although a minimum volume of 0.3 ml of any specimen is required for a single test. To obtain maximum test sensitivity, it is recommended that both serum and urine specimens be tested in parallel. Treatment success or failure may be assessed by collecting specimens at least 14 days after starting treatment and testing the newly acquired samples in parallel with the last specimen that was positive before initiation of treatment.

This test is performed on a fee-for-service basis by MiraVista Diagnostics (Indianapolis, IN) (http://miravistalabs.com). More recently, an antigen-capture enzyme-linked immunosorbent assay (ELISA) to detect *H. capsulatum* antigenemia in immunocompromised patients was described. The assay, which is not commercially available, uses polyclonal antibodies against *H. capsulatum* and has a reported sensitivity of 81% and specificity of 95% (56). Similar tests have also been developed for detection of antigenemia (Specialty Laboratories, Valencia, CA; and ImmunoMycoligics [IMMY], Norman, OK) (57, 58), although varying results were reported when these tests were compared (59).

The detection of serum (1→3)-\( \beta \)-D-glucan, a component of the fungal cell wall, has undergone limited evaluation in histoplasmosis; however, preliminary evidence suggests that it is useful in the detection of histoplasmosis (87% sensitivity and 65% specificity) (60). A positive result must be confirmed with *Histoplasma*-specific testing.

It is worth mentioning that a commercial and widely used EIA, Platelia Aspergillus, showed cross-reactivity with *H. capsulatum*, *P. brasiliensis*, and *Cryptococcus* spp. (61). However, no similar false positives have been observed in any of the *Histoplasma* antigen assays described here.

**Blastomyces dermatitidis**

The Blastomyces antigen test is a microtiter plate-based double-antibody sandwich EIA to detect antigenuria and antigenemia in disseminated blastomycosis. The sensitivity is 89% in disseminated blastomycosis, with higher sensitivity in urine than in serum (62). However, specificity is modest, only 79% overall, due to cross-reactivity with other endemic mycoses (63). This test is performed on a fee-for-service basis by MiraVista Diagnostics.

The detection of serum (1→3)-\( \beta \)-D-glucan has been incompletely evaluated in blastomycosis; however, preliminary evidence suggests that it is not useful in the detection of Blastomyces (60).

**Coccidioides Species**

A coccidioidal urinary antigen test (MiraVista Diagnostics) has been developed and exhibited a sensitivity of 71% in a largely immunosuppressed population (64). In a veterinary population, the sensitivity has been shown to be much lower (<20%) (65). The findings call into question the usefulness of antigen testing in nonimmunosuppressed populations. The sample requirements are the same as those for the HPA test.

Serum (1→3)-\( \beta \)-D-glucan has undergone limited evaluation in the detection of coccidioidomycosis and has a limited role (44% sensitivity) in this population (66).

**Paracoccidioides brasiliensis**

At present, paracoccidioidomycosis antigen testing is not available as a routine diagnostic test. A 43-kDa glycoprotein and an 87-kDa heat shock protein have been described as useful targets for serum antigen detection (67, 68). Several reports have described the detection of *P. brasiliensis* antigen in urine, CSF, and bronchoalveolar fluid samples (68). Others have noted that antigen levels in serum diminished or even disappeared during successful treatment (69).

**Emmonsia Species**

No antigen test exists at this time for the diagnosis of adiaspiromycosis in humans.

**Nucleic Acid Detection in Clinical Materials**

No commercially available systems exist for detection of fungal nucleic acids in human clinical samples. However,
a number of “in-house” methods remain under investigation, several of which are highlighted in this section. Conserved regions of rRNA genes have been used as targets in a number of PCR-based detection assays. It is important to appreciate that amplification of conserved genes can result in products derived both from pathogenic fungi and from genetically related nonpathogenic fungal species. The nonspecific nucleic acids could arise from colonization of the original sample with saprophytic organisms, from contamination during sample collection, or from contamination of PCR reagents with fungal DNA. It is very important that the identity of amplicons detected using conserved genes be verified by direct sequencing. In more-recent studies, genes specific for the fungus of interest have been chosen as PCR targets, thus eliminating this specificity problem.

Histoplasmosis
An increasing number of publications have described the use of PCR to detect *H. capsulatum* DNA in fixed, paraffin-embedded tissue samples, blood, bronchial lavage fluids, bone marrow, and ophthalmic samples. Early studies targeted the internal transcribed spacer (ITS) rRNA gene region, but the use of targets unique to *H. capsulatum* has provided better assay specificity. Bialek et al. designed a nested PCR that targeted the gene coding for a unique 100-kDa protein of *H. capsulatum* (70), which has successfully been used to detect *H. capsulatum* DNA in clinical samples from patients with histoplasmosis in French Guiana and Colombia (sensitivity, 100%; specificity, 95%) (71, 72). The original format of nested or seminested PCR has recently been adapted to real-time PCR with promising results (73). A consensus group recently started evaluation of the reproducibility of the most common in-house tests used (74).

Blastomycosis
PCR assays of ribosomal genes, the ITS region, repetitive sequences, and species- or genus-specific genes have all been evaluated for the molecular detection of *B. dermatitidis*. The majority of these tests have been evaluated in paraffin-embedded tissue, although a real-time PCR assay to identify *B. dermatitidis* in culture specimens, bronchial washings, bronchoalveolar lavage fluid, pleural fluid, sputum, and blood has been published (75, 76).

Coccidioidomycosis
Various PCR assays have proven extremely sensitive and specific on isolate material (77) and from sputum in active cases (unpublished data); however, direct detection from other clinical samples (serum, pleural fluid, CSF, and joint fluid) has not been as successful to date. Few studies have been published, although it appears that the sensitivity of PCR in clinical samples is similar to that of culture (~50%) (77, 78).

Paracoccidioidomycosis
The number of tests developed and evaluated so far for the detection of *P. brasiliensis* in clinical samples is very limited (79). The preferred target sequences have been gp43 and rRNA genes. A real-time PCR assay targeting the ITS-1 region was developed to detect *P. brasiliensis* DNA in both cultures and clinical specimens. Although this molecular test was evaluated with a small number of patients, the authors reported 100% sensitivity and specificity (80). A nested-PCR assay targeting the immunogenic gp43 gene was evaluated in the detection of *P. brasiliensis* DNA in lung homogenates from infected and uninfected mice, with 91% sensitivity (81). A test based on the 5′ nuclease assay using a fluorescent probe derived from the sequence of the gene coding for the gp43 antigen was used and could detect at least 10 copies of this DNA sequence (82).

Adiaspiromycosis
A panfungal PCR assay targeting the ribosomal ITS-1 and -2 regions identified *E. crescens* from a bronchoalveolar lavage fluid sample of a patient with confirmed adiaspiromycosis (83).

ISOLATION PROCEDURES

Biosafety
The mere lifting of a culture plate lid is often sufficient to release large numbers of conidia into the air, and screw-cap tubes or sealed plates should be used. Should a sporulating culture be dropped, millions of conidia may be dispersed. It is also important to note that local infections including granuloma formation have been reported following accidental inoculation during injection of laboratory animals, or while performing autopsies of humans with histoplasmosis, coccidioidomycosis, or blastomycosis.

All procedures involving the manipulation of sporulating cultures of *Coccidioides* species, *B. dermatitidis*, and *H. capsulatum* and for processing soil or other environmental materials known or likely to contain these organisms should be performed inside a class II biological safety cabinet under conditions of biosafety level 3 containment. Biosafety level 2 practices and facilities are recommended for handling and processing clinical specimens and animal tissues (84). Hyaline molds of unknown identity should always be examined and manipulated inside a class II biosafety cabinet. Such molds should never be handled on an open laboratory bench. Recommendations for handling inadvertent exposure to *Coccidioides* in the laboratory have been published (85).

Biosecurity
In the United States, both species of *Coccidioides* were previously classified as select agents, although in 2012 they were removed from this list.

Culture for Mold Phase
In general, the organisms discussed in this chapter can be readily cultivated in the mold phase on general fungal media such as Sabouraud dextrose agar or potato dextrose agar incubated at 25°C. Incubation at 37°C is also helpful to recover the yeast phase of most dimorphic organisms. Media containing antibiotics such as chloramphenicol or gentamicin should be used when culturing clinical materials, such as sputum, that may be contaminated with bacteria. Media containing cycloheximide are useful to inhibit saprophytic fungi and to provide a useful differential tool in identification. Many unrelated saprophytic soil fungi fail to grow on media containing cycloheximide, fail to grow altogether at 37°C, or fail to convert to the yeast phase at 37°C. Screw-capped slants are preferable to plates for culturing dimorphic fungi. If plates are used, they should be sealed so that mold spores cannot escape into the ambient air. Seals that are permeable to air such as Shrink Seals (Scientific Device Laboratory, Des Plaines, IL) are useful for this purpose. In general, colonies develop within 3 to 7 days, but some strains of *H. capsulatum* and *P. brasiliensis* may require incubation for as much as 4 to 6 weeks.
Culture for Yeast Phase

*Histoplasma capsulatum*. *B. dermatitidis*, and *P. brasiliensis* can be recovered in the yeast phase by using appropriate media incubated at 37°C. *E. parva* and *E. crescens* produce adiaspores at elevated temperatures.

**Histoplasma capsulatum**
The yeast phase of *H. capsulatum* can be recovered in rich media such as brain heart infusion (BHI) agar or BHI with blood (BHIB). Plates or slants should be incubated at 37°C under aerobic conditions for at least 4 weeks.

**Blastomyces dermatitidis**
The yeast phase of *B. dermatitidis* can be recovered in rich media such as BHI agar, BHIB, Pine's medium, or Kelley's agar by incubation at 37°C under aerobic conditions. Yeasts are usually visible within 1 week, but media should be held for at least 4 weeks before being discarded.

**Paracoccidioides brasiliensis**
The yeast phase of *P. brasiliensis* can be recovered in media such as BHI agar, Pine's medium, or Kelley's agar by incubation at 37°C. The organism grows slowly, and plates or slants should be held for at least 4 weeks.

**Emmonsia Species**
*E. parva* and *E. crescens* produce adiaspores in vitro when cultivated on phytone yeast extract agar, BHI agar, or BHIB at 37 to 40°C depending on the species. *E. pasteuriana* produces yeast-like cells after culture on BHI agar at 37°C for ~10 days. The species recently recognized in South Africa does not produce adiaspores at 37 or 40°C, although the mycelial cultures were converted to the yeast phase by incubating streaked or single-colony subcultures on BHI agar at 37°C after 10 to 14 days.

**Histoplasma capsulatum**
The mold phase can be recovered after incubation at 25°C. The colony is initially white or buff-brown. Both types may be isolated from the same patient, and eventually the brown type may convert to the white type. The brown type generally produces more of the characteristic tuberculate macroconidia than the white type. On subculture, only ~30% of macroconidia show tubercles. Microconidia are abundant in fresh isolates of *H. capsulatum*. After multiple subcultures, the production of both macroconidia and microconidia may be diminished. The presence of both macroconidia and microconidia is not required for identification of *H. capsulatum*, as authentic *H. capsulatum* isolates that fail to produce either macroconidia or microconidia have been recognized. Macroconidia but no microconidia can also be seen in the saprophytic fungus *Scedonella* as well as in the related fungus *Renispora flavissima*. Authentic *H. capsulatum* isolates can be recognized by their thermal dimorphism as well as by their growth on inhibitory mold agar.

Once the characteristic morphology has been recognized, mold-phase *H. capsulatum* isolates can be confirmed by conversion to the yeast phase. The isolate is transferred to BHI or BHIB agar and incubated at 37°C for at least 7 to 10 days. Hyphal cells may form buds directly or develop enlarged, transitional cells that subsequently begin to bud. The microconidia may also convert to budding yeast cells. Complete conversion rarely is achieved, and multiple transfers to fresh BHI or BHIB medium may be required. The colony develops a white, smooth, yeast-like appearance, and microscopic examination reveals oval, budding yeasts approximately 1 to 3 by 3 to 5 μm. The cells have a narrower base of attachment between the bud and parent cell than do those of *B. dermatitidis*.

The AccuProbe test (GenProbe, San Diego, CA) can also be used to confirm isolates as *H. capsulatum*. This test requires actively growing cultures: mold-phase cells not more than 4 weeks of age or yeast cells not older than 1 week. Isolates can be taken from solid media or broth cultures. In this assay, formation of specific DNA-RNA hybrids is quantitated in relative light units by use of a luminometer. Extracts that display relative light unit values of >50,000 are considered positive. The AccuProbe test has largely replaced exoantigen testing for identification of *H. capsulatum*. Several studies have shown that this test is sensitive and specific for *H. capsulatum* (86–88), although false-positive results can be obtained when isolates that are genetically related to the *Ajellomyces* are tested (89). An exoantigen testing kit to identify the organism is commercially available from IMMY. African *Histoplasma* isolates display colonial morphology similar to that of non-African isolates and yield positive results in the AccuProbe test for *H. capsulatum* (87). Histopathological examination of tissue forms is required to distinguish members of the African clade.

**Blastomyces dermatitidis**
At 25 to 30°C, isolates of *B. dermatitidis* produce a variety of forms ranging from a fluffy, white colony that is visible within 2 to 3 days to a glabrous (waxy), tan, nonconidiating colony that grows more slowly. Microscopic examination shows microconidia that are oval or pyriform, usually smooth walled, and formed on short lateral or terminal branches along the hyphae. *B. dermatitidis* also grows readily on inhibitory media containing cycloheximide. Conidia of the hyaline hypomyxete *Scedonella apioperdum* of some *Chrysosporium* species, and of the dermatophyte *Trichophyton rubrum* are morphologically similar and can be mistaken for *B. dermatitidis*. These species either fail to grow at 37°C (some *Chrysosporium* species) or grow as molds when incubated at 37°C ( *S. apioperdum* and *T. rubrum*).

The identification can be confirmed by conversion to the yeast phase. Generally, isolates of *B. dermatitidis* convert readily to the yeast phase on BHI or BHIB agar or Pine's or Kelley's medium incubated at 37°C. Yeast cells are hyaline, smooth walled and thick walled, generally 8 to 15 μm in diameter, with the bud connected to the parent cell by a broad base of up to 4 to 5 μm in diameter. Conversion can be accomplished in 2 to 3 days, although occasional isolates may take several weeks.

Identification can also be confirmed using the AccuProbe test for *B. dermatitidis*. False-positive *B. dermatitidis* Gen-Probe results were obtained with *P. brasiliensis* (90) and with *Gymnascella hyalinospora*, so care must be taken to distinguish these organisms. An exoantigen testing kit to identify the organism is commercially available from IMMY.

**Coccidioides Species**
At 25 to 30°C, isolates of *Coccidioides* species display considerable variation in colony morphology. Colonies can range from moist, glabrous, and grayish to abundant, floccose, and
white. Colonies may become tan and even red with age (91). Microscopic examination shows hyphae that are thin and septate, with fertile (spore-producing) hyphae usually arising at right angles. Arthroconidia are hyaline, ovoid-celled, short, cylindrical to barrel shaped, moderately thick walled, smooth walled, and 2 to 8 by 3 to 5 μm. Arthroconidia alternate with thin-walled empty disjunctor cells. At maturity, the disjunctor cells undergo lytic degradation, releasing the arthroconidia. After this fragmentation, the arthroconidia may display frill-like remains of the disjunctor cells. The resulting yeast cells display an appearance that can be misinterpreted as arthroconidia. True arthroconidia due to cytoplasmic shrinkage, display an appearance that can distinguish true alternate arthroconidia from aging mycelia that, such as species. It is also important to distinguish this organism from similar soil saprophytes that grow well on media and increased CO.

Paracoccidioides brasiliensis

When incubated at 25 to 30°C, isolates display slow growth and produce a variety of forms ranging from glabrous, leathery, brownish, flat colonies with a few tufts of aerial mycelium to wrinkled, folded, floccose colonies to velvety, white-to-beige forms. The colonies are very similar in appearance to those of B. dermatitidis. Most strains grow for long periods of time without the production of conidia.

When cultures are transferred to 37°C on rich media and increased CO₂ tension, the organism can produce spherules, but this procedure is rarely performed on routine clinical isolates.

The AccuProbe for Coccidioides may be used for confirmation of unknown isolates as Coccidioides species. This test is generally sensitive and specific, although pretreatment of isolates with formaldehyde leads to false-negative results. The test does not distinguish between the two species of Coccidioides. An exoenzyme testing kit to identify the organism is commercially available from IMMY (92).

Emmonsia Species

At 25°C, Emmonsia species organisms grow as glabrous, colorless colonies, which produce yellowish white aerial mycelia in time. Some strains display pale orange to grayish orange aerial mycelia. The colonies often have areas that alternate between a tufted mycelium and a glabrous consistency. Reverse pigmentation is pale gray to grayish brown. On microscopic examination, the hyphae are septate and branching. Sporulation is enhanced on potato dextrose or Pablum cereal agar. Numerous conidia are produced either directly from the sides of the hyphae or on short stalks that branch at right angles from the hyphae. Each stalk bears a single terminal conidium. Sometimes the swollen end may bear one to three secondary spine-like pegs, which in turn form a secondary conidium in a flower-like arrangement (21). The conidia are round, oval, or pyriform and measure 2 to 4 μm by 3 to 5 μm. The conidial wall is smooth but may roughen with age. E. parva and E. crescens are indistinguishable in morphology and appearance at 25°C.

E. crescens displays no hyphal growth at 37°C and forms larger adiaspores (20 to 140 μm in diameter) on BHL or phytone yeast extract agar at this temperature. E. parva produces hyphae at 37°C and produces smaller adiaspores (8 to 20 μm in diameter) at 40°C. E. pasteuriana displays features at 25°C that are similar to those of E. crescens and E. parva. At 37°C on BHIB, this species produces yeast-like cells that are oval or lemon shaped, budding on a narrow base, and 2 to 4 μm. The colonies are creamy and smooth. This species does not produce adiaspores in vitro or in vivo (93).

Typing Systems

In general, typing systems have been used to show geographic differences among isolates and species of Paracoccidioides brasiliensis and E. crescens. In some genera, diversity can be shown among isolates collected from a single geographic area.

Histoplasma capsulatum

Isolates can be divided into at least eight clades as described earlier (5). This typing system can be used to place an unknown isolate into one of the major worldwide geographic groupings. For further delineation, restriction fragment length polymorphism (RFLP) typing with the yeast phase-specific nuclear gene yps-3 and/or mitochondrial DNA probes and random amplified polymorphic DNA-based and ITS-based typing methods have been used in several studies (reviewed in reference 94). These studies have shown that considerable polymorphisms can be demonstrated among individual patient isolates from a particular geographic location (94); that animal and soil strains from Brazil display indistinguishable subtypes (95); and that strains from patients in Brazil, where mucocutaneous histoplasmosis is much more common than in the United States, display distinct ITS and yps-3 subtypes not seen in strains from U.S. patients (96). Recently a study compared multiple typing methods that have been developed to study H. capsulatum epidemiology in 51 environmental, animal, and human isolates from Brazil. The M13 PCR fingerprinting and PCR-RFLP analyses produced very similar results and separated the H. capsulatum isolates into three major groups (97).

 Blastomyces dermatitidis

In a study using RFLP with several rRNA gene probes to study 59 isolates from the United States, India, and Africa, three major groups were defined. These groups were further divided using random amplified polymorphic DNA fingerprinting into 5, 15, and 12 types, respectively, that correlated with the geographic origin of the isolate (98). Interestingly, these studies showed that soil isolates collected from an outbreak of blastomycosis in Eagle River, WI, were not responsible for the majority of cases of disease in that outbreak. A study exploring polymorphisms in the promoter region upstream of the BAD-1 virulence gene revealed further genetic diversity, with large insertions in the promoter
region (99). Further work examining microsatellite markers revealed two genetically distinct groups, suggesting a possible new species (7), and recent evidence has confirmed the separation of Blastomyces spp. into B. dermatitidis and B. gilchristii (8).

**Coccidioides Species**

Two major clades, corresponding to the two species C. immitis and C. posadasii, were defined when an extensive population sample, including isolates from Venezuela, Mexico, and Brazil, was studied using a set of nine microsatellite markers (12). Typing of isolates to C. immitis (CA) or C. posadasii (non-CA) species can be accomplished by examining any of 17 sites fixed for alternate alleles (100). Microsatellite typing conducted with 121 clinical isolates from Arizona concluded that this disease in Arizona could not be linked to a dominant strain of C. posadasii (101). Ongoing work will further clarify the population genetics of this organism.

**Paracoccidioides brasiliensis**

Multilocus sequence typing at eight loci demonstrated the existence of at least three distinct species within this organism (15). The gp43 gene encoding a dominant glycoprotein antigen has been studied by several groups as a useful target for subtyping. In an earlier study, microsatellite sequences were compared as markers to discriminate among a set of P. brasiliensis human isolates causing either chronic or acute disease (102). These authors did not observe any clustering of isolates associated with either acute or chronic disease.

**Emmonsia Species**

Based on ITS sequences, isolates of E. crescens fall into two phylogenetic groups, North American and Eurasian, depending on the continents from which the isolates were obtained (1). Isolates of E. parva separate into two groups as well, one group isolated from the North American prairies and the second group from the desert southwest of the United States or from Italy.

### SEROLOGIC TESTS

#### Histoplasmosis

Serologic tests have an important role in the rapid diagnosis of several forms of *H. capsulatum* infection but are most useful for persons with chronic pulmonary or disseminated histoplasmosis (103). Of the different methods that have been developed, the immunodiffusion (ID), complement fixation (CF), and latex agglutination (LA) tests are the most popular. The principal antigen used in these tests is histoplasmin, a soluble filtrate of mycelial-phase broth cultures. Histoplasmin contains *H. capsulatum* species-specific H and M antigens as well as C antigen. The H antigen is a β-glucosidase against which antibodies are formed during acute histoplasmosis. The M antigen is a catalase against which antibodies are produced during all phases of the disease. The H and M antigens were once thought to be specific proteins for the detection of anti-*H. capsulatum* antibodies. The M antigen, however, was found to be not specific unless used in a deglycosylated form.

The ID test is a qualitative method that detects precipitins to the H and M glycoprotein antigens of *H. capsulatum* present in histoplasmin. Both serum and CSF can be used. Patients with negative serum reactions during the acute phase of infection should have additional samples taken 3 to 4 weeks later. ID test kits and reagents are available from Gibson Laboratories (Lexington, KY), IMMY, and Meridian Bioscience (Cincinnati, OH). Commercial kits include mycelial-phase culture filtrates containing *H. capsulatum* H and M antigens, positive-control sera containing antibodies against both H and M antigens, and ID plates. Positive-control sera must be included each time the test is performed and must react with both the H and M antigens. The ID test is a useful screening procedure or can be used as an adjunct to the CF test. It is more specific but less sensitive than the CF test.

The CF test is a quantitative procedure in which two antigens are employed: histoplasmin and a suspension of intact, merthiolate-killed *H. capsulatum* yeast-phase cells. The latter is more sensitive (1 to 2%) than histoplasmin. Serum, peritoneal fluid, or CSF can be used in the CF test. Patients with negative serum reactions during the acute phase of infection should have additional samples taken 3 to 4 weeks later. No commercial kits are available, but antigens, antisera, and other reagents can be purchased from several commercial sources (e.g., IMMY and Meridian). Negative-control serum and positive-control serum from human histoplasmosis cases demonstrating a CF titer of 1:32 or greater with the homologous antigen should be tested each time the CF test is performed.

More recently, an ELISA for the detection of antibodies to *H. capsulatum* using metaperiodate-treated purified histoplasmin was reported, with sensitivities of 100% in acute disease, 90% in chronic disease, 89% in disseminated infection in individuals without HIV infection, 86% in disseminated disease in the setting of HIV infection, and 100% in mediastinal histoplasmosis (104). This test is, however, not commercially available.

An LA test using histoplasmin as antigen is commercially available (LA-Histo antibody system; IMMY). This quantitative test detects IgM antibodies and is used primarily for the presumptive diagnosis of acute histoplasmosis. It is less helpful for the detection of chronic infection.

#### Blastomycosis

Substantial improvement in the performance of serologic tests for blastomycosis has been achieved by the use of two purified surface antigens of *B. dermatitidis*, one termed the A antigen and the other the WI-1 antigen. Both molecules are released from the yeast phase of *B. dermatitidis* by autolysis and can be recovered from culture filtrates. Immunological comparison of the two antigens has shown that they are very similar, but WI-1 is a 120-kDa protein that is not glycosylated while the A antigen is a 135-kDa glycosylated protein (105).

However, serologic testing for blastomycosis still lacks both sensitivity and specificity. The most useful serologic test is the ID test, which measures the antibody to *B. dermatitidis* A antigen. This test is relatively specific, yet sensitivity ranges from 28 to 64% (106). Patients with negative serum reactions during the acute phase of infection should have additional samples taken 3 to 4 weeks later.

CF testing has also been evaluated, although this test has shown even lower sensitivity and specificity (9 to 43%) (107). Newer ELAs have shown improved sensitivity; however, it has been at the expense of specificity (108).

ID test kits and reagents are available from Gibson, IMMY, and Meridian. Commercial kits include purified *B. dermatitidis* A antigen, positive-control serum containing antibodies against A antigen, and ID plates. The positive-control serum must be included each time the test is performed and must react with the homologous reference antigen to form the A precipitin line.
Coccidioidomycosis

Despite the fact that sensitive procedures such as EIA have been developed, the ID and CF tests remain the most reliable methods for the serologic diagnosis of coccidioidomycosis. The principal antigen used in these tests is coccidioidin, a soluble filtrate of mycelial-phase broth cultures.

The simultaneous use of heated and unheated antigens permits the ID test to be employed to detect either IgM or IgG antibodies on a single plate. The ID test for tube precipitin (TP) antibodies (IDTP) utilizes heated coccidioidin as antigen, detects IgM, and gives results comparable to those obtained with the classical tube precipitin test. It is most useful for diagnosing recent infection. The IDCF test utilizes unheated coccidioidin, detects IgG antibodies, and gives results comparable to those obtained by the CF method (see below). It is less sensitive but more specific than the CF test (109). Commercial kits are available (Gibson, IMMY, and Meridian) and include unheated and heat-treated coccidioidin antigens, positive-control sera containing IgM or IgG antibodies, and ID plates. The sensitivity of the IDTP and IDCF tests can be improved by 10-fold concentration of serum prior to testing. Positive-control sera must be included each time the test is performed and must react with the homologous reference antigen to form a precipitin line. The ID test is useful for initial screening of specimens and can be followed by other tests if positive.

The CF test is a sensitive quantitative method in which unheated coccidioidin is used to detect IgG antibodies. The major disadvantage of CF is that it is a laborious and time-consuming procedure that requires experienced personnel for optimum performance. No commercial kits are available, but reagents for in-house use can be obtained from several commercial sources (IMMY and Meridian). Negative-control serum and a positive-control serum from a human case of coccidioidomycosis (with a titer of ≥1:32) should be included each time the test is performed. Anticomplementary activity in serum samples can occur and may be resolved by subsequent ID testing. In addition to serum, the CF test can be performed with CSF, pleural, or joint fluid samples.

A qualitative LA test using heat-treated coccidioidin as antigen is available from several commercial sources (e.g., LA-Cocci antibody system from IMMY and Coccidioides latex agglutination system from Meridian). This test is simple and rapid to perform; however, the false-positive rate is higher than that observed with the IDTP and/or CF methods. It is not recommended for screening CSF specimens, because false-positive reactions can occur (105).

The Premier Coccidioides EIA (Meridian) is a qualitative test for detection of IgM and IgG antibodies in serum or CSF specimens. The antigen used in this test is a mixture of purified TF and CF antigens. False-positive reactions have been obtained with sera from some patients with blastomycosis and in patients with alternative diagnoses, and this test is now often used for "screening," with positive EIA results evaluated by IDTP and IDCF tests for confirmation (110).

Paracoccidioidomycosis

The most popular serologic methods for diagnosis of paracoccidioidomycosis are ID and CF, but other tests, such as ELISAs, counterimmunoelectrophoresis, dot blot, and immunoblotting, have also been employed (32). The ID test demonstrates circulating antibodies in >90% of cases. A reactive result allows a diagnosis to be made. The CF test allows a more precise evaluation of the patient’s response to treatment, but cross-reactions with H. capsulatum antigens can occur. The principal antigens used in these tests are derived from culture filtrates of mycelial-phase or yeast-phase broth cultures of P. brasiliensis. The major diagnostic antigen found in these preparations is a 43-kDa glycoprotein. Cell wall antigens have proved less useful than culture filtrate antigens, largely because cell wall antigens are dominated by cross-reactive galactomannan (32). Commercial mycelial-form culture filtrate antigen can be obtained for in-house use from IMMY. No commercial kits are available for this test. The CF test is performed with P. brasiliensis yeast-form culture filtrate antigen. No commercial kits or reagents are available.

Improvements in serodiagnosis include the detection of antibodies against chemically characterized and/or recombinant P. brasiliensis antigens, notably gp43, pb27, and the 87-kDa heat shock protein. A combination of two recombinant products has resulted in increased sensitivity (92%) and specificity (88%) (111, 112).

Adiaspiromycosis

No serologic tests are available for diagnosis of adiaspiromycosis.

ANTIMICROBIAL SUSCEPTIBILITIES

Established treatment options for H. capsulatum, B. dermatitidis, Coccidioides species, and P. brasiliensis include amphoteracin B and the azoles voriconazole, posaconazole, itraconazole, ketoconazole, and fluconazole. The echinocandins have a limited, if any, role in the treatment of endemic fungi. In vitro antifungal susceptibility testing for dimorphic fungi remains unstandardized, and no susceptibility breakpoints have been determined for these organisms (113). Table 1 lists the in vitro susceptibilities of these organisms to established and investigational antifungal agents as reported in studies that were performed in accordance with Clinical and Laboratory Standards Institute documents M38 (for filamentous fungi) (113) and M27 (for yeast) (114). Fluconazole treatment failures have been reported in some cases of histoplasmosis and coccidioidomycosis, partially attributed to organisms that demonstrated drug MICs of ≥64 μg/ml, although they remained responsive to itraconazole (115, 116).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Histoplasmosis

The definitive diagnosis of histoplasmosis can be accomplished by direct microscopic detection of H. capsulatum in clinical specimens or its isolation in culture. However, isolation and identification may take 2 to 4 weeks.

Antigen detection complements other diagnostic methods for histoplasmosis and is particularly useful in immunocompromised patients with more extensive disease, often providing a rapid diagnosis before positive cultures can be identified. HPA has been detected in serum, urine, CSF, and bronchoalveolar lavage fluid specimens obtained from individuals with disseminated histoplasmosis. The sensitivity of antigen detection in disseminated histoplasmosis is higher in immunocompromised patients than in immunocompetent patients and in patients with more severe illness. Antigen levels are higher in urine than in serum. For patients with AIDS and disseminated histoplasmosis, sensitivity is between 81 and 95% in urine and 86% in serum.

*NR, not reported.

Specificity is ~98%. Antigen has been detected in the CSF of patients with Histoplasma meningitis.

Antigen levels in the urine and serum decline with effective treatment, becoming undetectable in most patients (55). Failure of antigen concentrations to fall during treatment suggests therapeutic failure. In patients who have responded to treatment and in whom antigen levels have previously fallen, an increase in antigen levels in the urine or serum is suggestive of relapse.

The LA test for Histoplasma antibodies is most useful for the diagnosis of acute infection, positive results being obtained within 2 to 3 weeks after exposure. An LA titer of 1:16 is presumptive evidence of infection, and a titer of ≥1:32 is considered strong presumptive evidence of active or recent infection (103). Because false-positive reactions can occur, the results should be confirmed by the ID test. Low-titer results from single specimens should be interpreted with caution. In such cases, the test should be performed on another specimen collected 4 to 6 weeks later.

In the ID test, precipitins to the M antigen of H. capsulatum are the first to appear (4 to 8 weeks after exposure) and can be detected in up to 75% of persons with acute histoplasmosis. However, they can also be found in nearly all individuals with chronic pulmonary infection, as well as in those who have undergone a recent skin test with histoplasmin. Precipitins to the H antigen are specific for active disease but occur in <20% of cases. They usually disappear within the first 6 months of infection and are seldom, if ever, found in the absence of M precipitins. The presence of precipitins to both H and M antigens is highly suggestive of active histoplasmosis, regardless of other serologic test results.

The CF test is useful in the diagnosis of acute, chronic, disseminated, and meningeal forms of histoplasmosis. In acute infections, antibodies to the yeast antigen are the first to appear (~4 weeks after exposure) and the last to disappear after resolution of the infection. Antibodies to histoplasmin appear later and reach lower titers than those observed for the yeast antigen. In contrast, histoplasmin titers are usually higher in persons with chronic histoplasmosis. CF test results can be difficult to interpret because cross-reactions can occur with sera from persons with blastomycosis, coccidioidomycosis, and other fungal infections. In such instances, titers usually range between 1:8 and 1:32 and occur mainly against the yeast-form antigen. However, many serum samples from culture-confirmed cases of disseminated histoplasmosis yield titers in the same range. CF titers of ≥1:8 with either antigen are considered presumptive evidence of histoplasmosis. Titers of ≥1:32 and rising titers in serial samples offer stronger evidence of infection.

Titers of CF antibodies to H. capsulatum decrease following resolution of the infection but increase in individuals with chronic progressive disease. However, clinical and microbiological findings should also be considered in assessing the patient’s prognosis or making treatment decisions. In some patients, positive CF titers decline slowly and persist long after the disease has been cured. The significance of persistently elevated or fluctuating CF titers is unclear, as is the effect of antifungal treatment on antibody clearance (25).

Serologic tests are particularly useful in patients with Histoplasma meningitis. The detection of precipitins to H and M antigens in CSF specimens is sufficient to make a
diagnosis in the appropriate clinical setting and often is the only positive diagnostic test.

**Blastomycosis**

Although microscopic examination and culture remain the most sensitive means of establishing the diagnosis of blastomycosis, serologic tests can also provide useful information. A positive reaction in an ID test using the A antigen of *B. dermatitidis* is specific and diagnostic for blastomycosis (106). However, a negative ID test does not rule out the diagnosis because the sensitivity of this method has been reported to range from ~30% for cases of localized infection to ~90% for cases of disseminated blastomycosis. In established cases of the disease, a decline in the number or the disappearance of precipitin lines is evidence of a favorable prognosis.

With urine specimens, the Blastomyces antigen test has been reported to have a sensitivity of 89% for disseminated infection and 100% for pulmonary disease. However, cross-reactive antigens occurred in urine from all patients with paracoccidioidomycosis and from 96% of patients with histoplasmosis (62).

**Coccidioidomycosis**

Although the definitive laboratory diagnosis of coccidioidomycosis depends on microscopic examination and culture, serologic tests are of proven usefulness in diagnosis and management. A positive IDTP test result is indicative of acute coccidioidomycosis. IDTP-reactive IgM antibodies can be detected in up to 75% of cases within 1 week of symptom onset, and ~90% are positive within 3 weeks. Although infrequent, a positive IDTP test result with CSF is indicative of acute meningitis. In cases where the IDTP test is negative but the CF test is positive, patients should be investigated for microbiological or histopathological evidence of histoplasmosis or blastomycosis. In addition, sera should be obtained at 3-week intervals and examined by CF and ID tests for coccidioidomycosis, histoplasmosis, and blastomycosis. False-positive IDTP reactions have been reported to occur in 15% of sera obtained from cystic fibrosis patients in the absence of a positive culture (109).

A positive IDCF test result is presumptive evidence of recent or chronic infection. IDCF-reactive IgG antibodies can usually be detected within 2 to 6 weeks after onset of symptoms. Although the IDCF test is generally not performed as a quantitative test, it can be used in this manner. Titers obtained using the quantitative IDCF are not identical to titers obtained from the CF test, but the observed trends are comparable.

The LA test is more sensitive than the IDTP test in detecting acute infection but is less specific. For this reason, a positive test result with undiluted serum should be confirmed by the ID and/or CF test. The CF test does not become positive until about 4 to 12 weeks after infection, but CF antibodies persist for long periods in individuals with chronic pulmonary or disseminated coccidioidomycosis. Testing of serial specimens to detect rising or falling titers can reveal the progression or regression of illness and the response to antifungal treatment. A CF titer to coccidioidin at any dilution should be considered presumptive evidence of coccidioidomycosis. In most instances, the titer is proportional to the extent of the infection, and failure of the CF titer to fall during treatment of disseminated coccidioidomycosis is an ominous sign (30). Titers of 1:2 or 1:4 are usually indicative of early, residual, or meningeal disease. CF titers of >1:16 should lead to a careful assessment of the patient for possible spread of the disease beyond the respiratory tract. More than 60% of patients with disseminated coccidioidomycosis have CF titers of >1:32. However, false-negative results can occur in immunocompromised individuals, such as persons with AIDS. Patients with clinical presentations consistent with coccidioidomycosis but with negative or low serum CF titers should be retested at 3- to 4-week intervals.

The detection of CF antibodies in the CSF is usually diagnostic of coccidiodial meningitis and remains the single most useful test for diagnosis of that infection.

**Paracoccidioidomycosis**

The definitive diagnosis of paracoccidioidomycosis depends on microscopic examination and culture. However, isolation and identification of *P. brasiliensis* from clinical specimens may take up to 4 weeks.

Serologic tests are useful for the rapid presumptive diagnosis of paracoccidioidomycosis, particularly in cases of disseminated infection (32). The ID test with yeast-form culture filtrate antigen is highly specific and is positive in 65 to 100% of cases of acute or chronic pulmonary infection or disseminated paracoccidioidomycosis. The CF test with yeast-form culture filtrate antigen is less specific than the ID test, and cross-reactions can occur with cases of histoplasmosis. However, CF titers of ≥1:8 are considered presumptive evidence of paracoccidioidomycosis. Low CF titers are usually associated with localized infection, while higher titers are found in those with multifocal disease. Falling CF titers are often predictive of successful treatment, and high or fluctuating CF titers are suggestive of a poor prognosis. Some reports, however, have indicated that ID and CF results do not correlate well with the clinical status of the patient (69).

**Adiaspiromycosis**

The definitive diagnosis of adiaspiromycosis can be accomplished by direct microscopic detection of *Emmonsia* species in clinical specimens or their isolation in culture.

**REFERENCES**

TAXONOMY

The etiologic agents of dermatophytosis are classified, along with some nonpathogenic relatives, in three genera: *Trichophyton*, *Microsporum*, and *Epidermophyton*. These generic names are historically based on anamorphic (asexual state) names. Any dermatophytes capable of reproducing sexually, i.e., producing ascomata with asci and ascospores, also had historical teleomorph names in the genus *Arthroderma* (1). After current “one fungus, one name” nomenclature (2) came into force on 1 January 2013, it appeared likely that the clinically familiar anamorph names would be chosen over *Arthroderma* for ongoing use in this group of fungi. The redisposition of a few species that only have valid names in *Arthroderma* has not yet been effected. Despite these nomenclatural changes, the dermatophytes currently remain in the family *Arthrodermataceae* of the order *Onygenales* (3), phylum *Ascomycota*. The clinically recorded species of the dermatophytes as well as the dermatophytoïds (i.e., the soilborne *Trichophyton* and *Microsporum* species that are best not called “dermatophytes” [Greek for “skin plants”] because they are not pathogenic [4, 5]) are given in Table 1. The long-used *Arthroderma* names are included in the table to facilitate comparison with earlier literature.

As part of the ongoing molecular revolution in biology, fungal taxonomy is ever more strongly influenced by our greatly increased understanding of population genetics (6). Dermatophytes show two population genetics patterns differing among species having “population hosts” (7) in different zoological families, orders, or classes (8, 9). (A population host, which is the normal epidemiological reservoir of the species, is distinguished from “occasional host” species that may acquire infection but that do not support ongoing populations; for example, *Microsporum canis* has mostly feline population hosts, and while humans are frequently infected by feline carriers, the species is seldom directly transmitted from human to human, making our species only an occasional host.) Some dermatophyte species, including pathogens with population hosts in the rodent, rabbit, pig, dog, and cat families, are potentially sexual, with sexual reproduction occurring only off the host, i.e., on hair or other keratinous debris in contact with soil. Other species, particularly those with human, ungulate, equine, or avian population hosts, have no access to a soil-based location suitable for sexual reproduction and host reinfection; not surprisingly, these species are found on investigation to be asexual and clonal. They consist, in all known cases, of genetically highly uniform isolates (10–12) sharing, where known, a single mating type factor (8, 13). Most appear to have evolved from a single strain of a sexual ancestral species that was able to make the rare, successful switch to ongoing contagious infection of a new animal host. A few epidemiological and phenotypic characters in the clonal species appear to have undergone accelerated evolution due to strong selection for increased compatibility with the new host. This process has tended to produce differences allowing relatively easy laboratory identification of these species. At the same time, the basic cellular “housekeeping” genes investigated in phylogenetic taxonomic studies have evolved at a normal rate and thus strongly tend to resemble forms seen in ancestral species complexes or in sibling species. This has led to considerable recent confusion about species concepts. Although most recent phylogenetic studies continue to support the ongoing classification of dermatophytes in the three traditional anamorph genera mentioned above, long-recognized dermatophyte species, such as *Trichophyton equinum* and *Microsporum gali nicue*, that have distinct epidemiologies and that are easily identified in the routine diagnostic laboratory have nonetheless been suggested not to be distinct species as traditionally conceived (14, 15), since their ribosomal internal transcribed spacer (ITS) region sequences and some other sequences are strongly similar to those of related species (e.g., *Trichophyton tonsurans* and *Arthroderma grubyi*, respectively, for the examples mentioned). The ITS sequences of the dermatophytes proposed for synonymy, however, generally show a small number of consistent sequence polymorphisms compared with sequences of the species with which synonymy has been proposed. This suggests that further genetic study will tend to support the lineages in question as recently diverged but nonetheless separate at the species level. *T. equinum*, for example, was reinstated as a recognized distinct species after more detailed genetic study (16, 17). In this respect, it is important to note that recent proteomic approaches support essentially the same phylogenies as those previously proposed based on phenotypic, clinical, and epidemiological characters (18).

<sup>c</sup>Unlikely to be seen except in region where endemic or proficiency test or soil isolation experiment.
EPIEMIOLOGY AND TRANSMISSION

Dermatophytes are keratinophilic fungi that are capable of invading the keratinous tissues of living animals. They are grouped into three categories based on host preference and natural habitat (Table 2) (20). Anthropophilic species almost exclusively infect humans; animals are rarely infected. Zoophilic species are soil-associated organisms, and soil per se or soilborne keratinous debris (e.g., shed hairs or molted feathers) is a source of infection for humans as well as other animals. Zoophilic species are essentially pathogens of nonhuman mammals or, rarely, birds; however, animal-to-human transmission is not uncommon. Understanding this ecological classification for case isolates may be helpful in determining the source of infection; e.g., human infections caused by M. canis are often the result of contact between susceptible children and newly acquired or stray kittens (21). Clinical species identification of dermatophytes assists in controlling infections that may have a family pet or other domesticated animal as an ongoing source of inoculum. Moreover, scalp infections with M. canis require a treatment regimen differing from that used for scalp infections caused by the more common agents of tinea capitis. This underscores the importance of correct identification of the etiologic agent.

Some dermatophytes, e.g., *Trichophyton rubrum*, are cosmopolitan, whereas others, e.g., *Trichophyton concentricum*, are geographically limited (22). *T. concentricum* is found only in the Pacific Islands and regions in Southeast Asia and Central and South America. However, the ability of dermatophytes to spread to new geographical niches in conjunction with population movements should not be underestimated. In the United Kingdom, the large-scale introduction of *T. rubrum* and the emergence of *Microsporum audouinii* in rural areas can be correlated respectively with troop repatriation from the Far East and evacuation of children from major cities during the First and Second World Wars. Similarly, the reemergence of *T. tonsurans* as the preponderant agent of tinea capitis in British cities has been driven by large-scale immigration from the Caribbean (23). Thus, care should be taken against complacent assumptions based on historical epidemiological patterns.

Anthropophilic fungi are usually transmitted either directly through close human contact or indirectly through sharing of clothes, combs, brushes, towels, bed sheets, etc. Tinea capitis is highly contagious and may spread rapidly within a family, institution, or school. Transmission of tinea cruris is associated with shared clothing, towels, and sanitary facilities. The transmission of tinea pedis and tinea unguium often involves communal showers, baths, or other aquatic facilities but may depend on both environmental and host factors (24, 25). Acquisition of chronic *T. rubrum* tinea pedis has been suggested to require a dominant autosomal susceptibility gene (26).

Infections with geophilic dermatophytes involve transmission of soilborne inoculum to humans or other mammals. Outbreaks originating from infected soil with secondary human-to-human transmission have been reported (27). Infections by zoophilic species result from animal-to-human contact (cats, dogs, cattle, laboratory animals, etc.) or from indirect transmission involving fomites. The fungi may then be transmitted among humans to a limited extent, especially in institutions (28).

CLINICAL SIGNIFICANCE

The dermatophyoses (tinea or ringworm) generally manifest as infections of the keratinized tissues (hair, nails, skin, etc.) of humans, other mammals, and birds. Cutaneous infections resembling dermatophytoses may occasionally be caused by yeasts or by unrelated filamentous fungi that are normally saprobes or plant pathogens; these infections are referred to as opportunistic dermatomycoses (25).

Dermatophytes are among the very few fungal species that cause contagious, directly host-to-host-transmissible diseases of humans and animals. The transmission of these fungi is usually carried out by arthroconidia that have formed in or on infected host tissue. These conidia may be spread by direct skin-to-skin contact or via fomites containing free arthroconidia, shed skin scales, or hairs. Typical fomites include such divergent materials as hats, shoes, shower room floors, bedding, clothing of nursing staff in chronic care institutes, animal bedding and nesting material, and farm fence posts used by animals for scratching. Tissue invasion is normally cutaneous; dermatophytes are usually unable to penetrate deeper tissues as a result of nonspecific inhibitory factors in serum (29), inhibition of fungal keratinases (30), a barrier formed of epidermal keratinocytes (31), and other immunological barriers (32, 33). In acute cases, there is a strong Th1 reaction mediated in part by CD4+ lymphocytes (34), while in chronic cases, there is an immediate hypersensitivity-type reaction characterized by high levels of IgE and IgG4 antibodies and production of Th2 cytokines by mononuclear cells (35).

*Normally nonpathogenic, soil-associated dermatophytoïds such as *T. terrestris* and *M. cookei* are not included in this table.*
Dermatophytes tend to grow in an annular fashion on most affected skin regions, producing a “ringworm” infection form with a more or less raised and erythematous active area at the periphery and a relatively scalie inactive zone at the center of established lesions. The organism can often only be isolated from the active, peripheral ring. Infection may range from mild to severe, partly as a consequence of the reaction of the host to the metabolic products of the fungus. Also important in determining the severity of infection are the virulence of the infecting strain, the anatomic location of the infection, the status of the host’s immune system, and local environmental factors. Occasionally, especially in immuno-compromised patients, subcutaneous tissue may be invaded, e.g., in Majocchi’s granuloma, kerion, mycetoma-like processes (36, 37), or, more rarely, a generalized systemic infection (38). A *T. rubrum* infection suggestive of cutaneous blastomycosis has been reported in an immunocompromised patient (39), and a fungal culture-negative chronic ulcerated foot lesion was diagnosed by PCR and DNA sequencing as *T. rubrum* tinea pedis in a chronic granulomatous disease patient (40). In general, the principal current risk factors for common forms of dermatophytosis are age (younger for *tinea capitis* or advanced age for onychomycosis); family history of chronic dermatophytosis; participation in athletics featuring extensive body contact (e.g., wrestling and judo) or foot maceration (e.g., marathon running); barefoot use of communal aquatic facilities (showers and swimming areas); exchange of headgear, footwear, or inadequately cleaned bedding; contact with feral domestic animals (especially street kittens) or animals recently supplied by en masse breeding operations (especially cats, guinea pigs, rabbits, laboratory rats, and cattle); inhabitation of rodent-infested dwellings; and, especially for children in developing countries, contact with livestock suffering from untreated dermatophytosis and contact with barbering instruments that have not been effectively disinfected (26, 33, 41–48).

**Anatomic Specificity**

Infections caused by dermatophytes are named according to the anatomic location involved, e.g., *tinea barbae* (beard and moustache), *tinea capitis* (scalp, eyebrows, and eyelashes), *tinea corporis* (face, trunk, and major limbs), *tinea cruris* (groin, perineal, and perianal areas), *tinea pedis* (soles and toe webs), *tinea manuum* (palms), and *tinea unguium* (nails). Different dermatophyte species may produce clinically identical lesions; conversely, a single species may infect many anatomic sites.

*Tinea barbae*, usually caused by zoophilic fungi, e.g., *Trichophyton verrucosum* and granular, zoophilic forms of the *Trichophyton mentagrophytes* complex, is typically highly inflamed and may present as acute pustular folliculitis that can progress to supplicative, boggy lesions (kerion). A less severe form that appears as dry, erythematous, scalie lesions also occurs. *Tinea capitis* may vary from highly erythematous, patchy, scalie areas with dull gray hair stumps to highly inflamed lesions with folliculitis, kerion formation, alopecia, and scarring. *T. tonsurans* and *M. canis* are the most common agents, depending on the precise geographic location (22, 23). Favus (*tinea favosa*), usually caused by *Trichophyton schoenleinii* but also potentially caused by *Trichophyton violaceum* or *Microsporum ypsilenum*, is a now very rare, chronic infection of the scalp and glabrous (bald-looking) skin characterized by the formation of cup-shaped crusts (scutula) resembling honeycombs. *Tinea corporis*, which can be caused by any dermatophyte but is often associated with zoophiles, classically manifests as circular, erythematous lesions with scaly, raised, active, and often vesicular borders. Chronic lesions on the trunk and extremities usually are caused by *T. rubrum*, in particular by Afro-Asiatic forms of this fungus (formerly often called *Trichophyton raubitschekii*). *Tinea cruris* (“jock itch”), usually caused by *T. rubrum* or *Epidermophyton floccosum*, typically appears as scaly, erythematous to tawny brown, bilateral, and asymmetric lesions extending down to the inner thigh and exhibiting a sharply margined border frequently studded with small vesicles. *Tinea pedis* varies in appearance: the most common manifestation is maceration, peeling, itching, and painful fissuring between the fourth and fifth toes, but an acute inflammatory condition with vesicles and pustules can also occur, as can a hyperkeratotic chronic infection of the sole (“moccasin foot”). Members of the *T. mentagrophytes* complex frequently cause the more inflammatory type of infections, whereas *T. rubrum* usually causes the more chronic type. Infection of the sole by human-adapted forms of *Trichophyton interdigitale*, one of the members of the *T. mentagrophytes* complex, can be recognized by the formation of bollus vesicles in the thin skin of the plantar arch and along the sides of the feet and heel adjacent to the thick plantar stratum corneum (49). *Tinea unguium*, or nail infection by dermatophytes, is a subcategory of the more general phenomenon of onychomycosis, fungal nail infection. It is most often caused by *T. rubrum* and usually appears as thickened, deformed, friable, discolored nails with accumulated subungal debris. This type of presentation results from invasion of the underside of the distal nail and is therefore termed distal-subungal onychomycosis. A less common infection type usually caused by *T. interdigitale* typically manifests, especially in its earlier stages, as “superficial white onychomycosis,” i.e., white patches in the superficial portions of the nail. “Proximal-subungal tinea unguium” may also occur. This infection, in which the nail is subungually infected beginning near its point of origin in the area of the lunula, is usually caused by *T. rubrum* and often signals immunosuppression, e.g., AIDS (50).

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

**Preliminary Patient Examination**

In areas where *tinea capitis* caused by *M. canis* is common, patients may be examined with a Wood’s lamp (filtered UV light with a wavelength of 365 nm) in a darkened room for the presence of bright green fluorescent hairs. These are ideal for collection as laboratory specimens, though in some cases diagnosis may be done by Wood’s light alone. The fluorescent hairs, considered “Wood’s light positive,” typically show a small-arthroconidial, ectothrix type of hair invasion in direct microscopy. Apart from *M. canis*, *M. audouinii* and *Microsporum ferrugineum* also cause this type of fluorescent ectothrix infection. Hairs infected with *T. schoenleinii* may show a dull green color (48). The Wood’s lamp can also be used to differentiate between dermatophytosis and nonfungal skin conditions that may be similar clinically, e.g., erythrasma. In erythrasma, the skin fluoresces orange to coral red, whereas in the dermatophytosis, the skin is not fluorescent.

**Sampling Preparations and Practice**

Sufficient clinical material should be collected for both direct microscopic examination and culture. However, if quantities of clinical material are limited, direct microscopic examination should always be preferred over fungal culture. It is the
more sensitive technique (23), and the microscopic detection of fungal elements in dermatology specimens is diagnostic of fungal infection and should be sufficient to elicit antifungal therapy. Whenever feasible, aseptic technique should be used to minimize contamination during the collection and transport of specimens. The following equipment should be available: forceps for epilating hairs; sterile no. 15 scalp blades or sharp curette; sterile nail clippers; scissors; sterile gauze squares; 70% alcohol for disinfection; sterile water for cleaning painful areas; and clean pill packets or clean paper envelopes to contain and transport the clinical specimens, such as hairs, skin scrapings, or nail clippings. Black photographic paper or strong black paper may be used for collecting and better visualizing scrapings. After collection, the paper is folded, tightly taped in the corners, and placed in an envelope for transport. There are several commercial transport package systems available; the MycoTrans Specimen Transport System (MycoTrans, Biggar, Lanarkshire, United Kingdom) and Dermapak (Dermaco, Bedford, Bedfordshire, United Kingdom) are two of these. Closed tubes are not recommended for specimens, since they retain moisture, which may result in an overgrowth of bacterial as well as fungal contaminants. Disposable sterilized brushes have been recommended for collection of specimens from the scalp or from the fur of animals (51). Indeed, in the United States, disposable toothbrushes are often used to sample skin, with the bristle portion being pushed into the culture media in several locations after sampling. If histopathological processing is done, the nail plate may be placed in a 4% formaldehyde solution (52). Culture media (detailed below) may be inoculated directly on collection.

Hairs from the scalp should be epilated with sterile forceps. If the specimen is Wood’s light positive, epilate only fluorescent hairs. Nonfluorescent hairs, especially those infected with endothrix fungi such as T. tonsurans, may need to be dug out with the tip of a sterile scalpel blade because the hairs often break off at scalp level and are thus difficult to grasp with a forceps. Rubbing with a sterile moistened swab has been successful with pediatric patients (53). In the rare event that favus is seen, the scutulum at the mouth of the hair follicle is suitable for culture and microscopic examination. In lower-body dermatophytoses, lesions with defined borders should be preliminarily disinfected with alcohol or cleansed with sterile water and then active border areas should be scraped with a scalpel (or toothbrush; see above) to collect epidermal scales. Where borders are not visible to indicate the area of maximal fungal activity, as in tinea manuum, the preliminarily cleansed infected area can be broadly scraped to obtain specimens from a variety of areas that may imperceptibly differ in current fungal activity. In vesicular tinea capitis, the tops of the vesicles should be removed with sterile scissors for direct examination. Culture of the vesicle fluid is not recommended.

Nails should be disinfected with alcohol gauze squares. The most desirable material for culture in typical subungual onychomycosis is the waxy subungual debris, which contains the fungal elements. The highest proportion of viable elements for culturing is often found close to the juncture of the nail bed. To remove contaminating saprobiic fungi and bacteria, the crumbly debris directly underneath the nail near the tips is removed with the scalpel before material is collected for culture. Some investigators clip the nail short first and perform this scraping-away of contaminated material on the clipping. If the dorsal nail plate is diseased (superficial white onychomycosis), scrape and discard the outer surface before underlying material is removed for culture. In rare cases with a presentation consistent with Trichophyton soudanense endonyx nail infection (54), in which the internal strata of the nail plate are milky white but the upper and lower nail surfaces appear relatively unaffected, clippings may be taken or the milky area may be exposed and scraped.

Any specimen needing to be transported, or for any other reason not processed immediately, should be retained in the paper packets described above. Closed tubes are not recommended for specimens since they may retain moisture, resulting in an overgrowth of contaminants. Dermatophytes in dry specimens of skin, hair, and nails may be stored for years in viable condition, provided the material is not subjected to temperature extremes.

LABORATORY TESTING OF SPECIMENS

Direct Microscopic Examination

Direct microscopic examination of skin, hair, and nails is the most rapid method of determining fungal etiology and is traditionally accomplished by examining the clinical material in 10% potassium hydroxide (KOH) (freely interchangeable with the cheaper sodium hydroxide [NaOH]) (55, 56). Another common procedure is to use 25% potassium or sodium hydroxide mixed with 5% glycerin to impede desiccation (55). Addition of fluorescent brighteners such as calcofluor white (Sigma-Aldrich, St. Louis, MO) or Blankophor (Blankophor GmbH, Leverkusen, Germany) significantly increases accuracy, especially where staff are not highly experienced in visual detection of fungal elements (57, 58). In nails, histopathology based on staining nail biopsy material with periodic acid-Shiff stain has been shown to have potential for generating results more accurate than those afforded by hydroxide-based direct microscopy (59). The suggestion, however, that biopsy/periodic acid-Shiff can also replace culturing (59) is unsound, in that this technique does not permit reliable distinction of dermatophytes from other nail-invading species (60).

Nail clippings should be aseptically cut into smaller fragments and, where possible, either pounded with a heavy object inside their collection packet or scraped with a sterile scalpel blade to release friable, flaky material containing the greatest amount of dermatophyte inoculum. Skin or nail scrapings, nail fragments, or hair roots are placed in 1 or 2 drops of one of the above-mentioned KOH or NaOH solutions on a clean glass slide. A coverslip is placed on top, and the preparation is heated gently (short of boiling) by being passed rapidly over a Bunsen burner or other heat source three or four times and then allowed to sit at room temperature for a few minutes for clearing. The exact time needed depends on the concentration of hydroxide used, thickness of specimen fragments, and exact amount of heat imparted by contact with flame. A slide warmer set at 51 to 54°C may also be used to heat the slides for 1 h (55). Alternatively, samples may be incubated with alkali in closed sterile microtubes at room temperature for 1 to 2 h, prior to addition of fluorescent enhancer. Clearing is evident to the naked eye as a pronounced decrease in the opacity of the scraping. Laboratories using a 10% KOH or NaOH solution for skin may find that nail scrapings may require a stronger alkali solution (up to 25% KOH or NaOH). Demonstration of fungal elements may be facilitated by use of glucan-binding fluorescent brighteners such as calcofluor white (56) or Congo red (55). These require use of a fluorescence microscope set up to visualize the specific fluorescence obtained. Calcofluor white is added directly to the KOH drop on the slide as an approximately equal drop of 0.1%
solution (61). All preparations should be examined under low power and confirmed under high power.

Skin and nails infected by dermatophytes may reveal one or more of the following: hyaline hyphal fragments; septate, often branched hyphae; and chains of arthroconidia (Fig. 1). The appearance of infected hairs depends on the invading dermatophyte species. Hyphae invade the hairs, and arthroconidia are formed by fragmentation of these hyphae. The appearances and locations of the arthroconidia may suggest the infecting genera or species (Table 3), as may the sizes (48). Three main types of colonization (ectothrix, endothrix, and favic) are observed by direct microscopic examination. The terms “ectothrix” and “endothrix” refer to the location of the arthroconidia in relation to the hair shaft (“ecto-” and “endo-” meaning “outside” and “inside,” respectively), while “favic” refers to the distinctive infection caused by T. schoenleinii, a fungus that is now extremely rare except in some parts of central Asia and the African Sahel.

In ectothrix colonization, arthroconidia appear as a mosaic sheath around the hair or as chains on the surface of the hair shaft (Fig. 2). In M. canis, M. audouinii, and M. ferrugineum infections, colonized hairs fluoresce green under Wood’s lamp; other ectothrix infections (Table 3) are non-fluorescent. Endothrix hair invasion is observed as chains of arthroconidia filling the insides of shortened hair stubs (Fig. 3). Hairs are Wood’s lamp negative. In favic hairs, hyphae, air bubbles, or tunnels and fat droplets are observed within the hair (Fig. 4). These hairs are dull green under the Wood’s lamp. In general, infected hairs from all infection types show hyphae within the hair shaft at some time during the course of infection, usually during the early stages.

Isolation Procedures
Scrapings, hairs, and other materials collected as outlined above for direct examination are plated on selected isolation media and incubated at 32°C for optimal growth; temperatures between 24 and 32°C are also acceptable if the total incubation time is suitably adjusted to compensate for slower outgrowth expected at lower temperatures. Generally from 5 to 15 skin or nail fragments are planted per plate or tube used for isolation, and these fragments are separated so that antibiotic-resistant mould or bacterial contaminants from one piece cannot overgrow the others. Hairs are also well separated. Cultures on primary isolation medium are routinely incubated at 25 to 30°C and examined weekly for up to 4 weeks.

The most common medium used for the isolation of dermatophytes is Sabouraud glucose agar (SGA) (original formulation with 4% glucose or Emmons’ modification with 2% glucose), amended with chloramphenicol and cycloheximide to inhibit bacterial and saprobic fungal contamination. This type of medium is available commercially as,

for example, Mycobiotic agar (Acumedia Manufacturers, Lansing, MI; Remel, Lenexa, KS; Delasco, Council Bluffs, IA), Mycosel (BD Diagnostic Systems, Sparks, MD), or Dermasel Selective Supplement (Oxoid, Basingstoke, United Kingdom; note that Remel is currently the U.S. distributor for Oxoid). An alternative medium promoting more rapid conidiation and colony pigment development is potato flake agar amended with cycloheximide and chloramphenicol (Hardy Diagnostics, Santa Maria, CA). For the isolation of cycloheximide-susceptible fungi that cause clinical infections resembling dermatophytosis, any of SGA with chloramphenicol (Remel or BD), inhibitory mould agar (BD, Remel, or Hardy), or Littman oxgall agar (BD) may be recommended (56). Inhibitory mould agar and Littman oxgall agar have the advantage of restricting contaminant colony diameters. For all media, the addition of gentamicin is recommended for specimens heavily contaminated by bacteria (62). SGA with cycloheximide, chloramphenicol, and gentamicin is routinely used as an isolation medium in some laboratories (55).

Additional and alternative media may be used in special circumstances. For example, vitamin-free Casamino Acids (BD)-erythritol-albumin agar medium plus cycloheximide, chloramphenicol, and gentamicin may be used for filament-positive skin and nail specimens, especially from body sites where Candida overgrowth may be a problem (e.g., groin and fingernails). This medium (currently not commercially available, to our knowledge) prevents the common suppression of dermatophyte outgrowth by heavy inoculum of Candida albicans, Candida parapsilosis, and related biontin-requiring yeasts (63). Dermatophyte species with vitamin requirements (very uncommon in these types of cases) may grow poorly on it, and it is always used in combination with a cycloheximide-containing SGA.

Another primary isolation medium that may be used is dermatophyte test medium (DTM; available commercially from BD, Hardy, and Remel, among others [see chapter 115]). This selective medium screens for the presence of dermatophytes in heavily contaminated material (nails, etc.). The growth of dermatophytes causes a rise in pH, thus changing the phenol red indicator from yellow to blue-green (55, 65, 66). Rapid sporulation medium, mentioned above for potato flake agar, contains a pH indicator that works on a similar principle but turns from yellow to blue-green, leaving the red reverse pigment of typical T. rubrum visible (67). DTM may uncommonly give false-negative results with some Microsporum isolates (68).

**Nucleic Acid-Based Direct Detection Techniques**

Numerous techniques have been published for directly detecting dermatophyte DNA in tissue, but as yet none is established as a routine diagnostic procedure. This is due mainly to the relatively low cost of traditional procedures. However, in terms of accuracy, traditional procedures are by no means optimal; in onychomycosis, for example, they disclose at best ~85% of true-positive cases from the initial patient specimen, and this percentage is much lower in many laboratories (60). This has given strong incentive for development of molecular detection techniques. At present, a large number of primary studies related to rapid PCR of dermatological specimens for dermatophytosis and related mycoses (e.g., nondermatophyte filamentous fungal onychomycosis) have been published. Techniques employed include PCR–enzyme-linked immunosorbent assay (69), PCR–reverse line blotting (70), PCR coupled with restriction fragment length polymorphism study (71), multiplex PCR (72), nested PCR (73), PCR based in part on a microsatellite locus permitting strain typing of T. rubrum (74), and direct PCR with sequencing (54). Also, related techniques, such as real-time PCR (75–77), have been shown to work well in trial studies but also need to prove themselves as consistently practical and cost-effective in interlaboratory study related to routine diagnosis. Many of these techniques have been extensively discussed in the excellent review by Jensen and Arendrup (78). In unusual situations, molecular direct detection methods may be invaluable: for example, in a deep dermatophytosis case in which all conventional tests had given negative results, T. rubrum was identified by means of a nested PCR study directed at amplifying a portion of the ITS region from paraffin-embedded sections (79); and real-time PCR and sequencing unambiguously identified T. rubrum from biopsy samples in a culture-negative case of tinea pedis in a chronic granulomatous disease patient (40).

**IDENTIFICATION**

At present, the great majority of dermatophytes are identified phenotypically. Identification is often based on (i) colony characteristics in pure culture on SGA and (ii) microscopic morphology. These criteria alone, however, may be insufficient, since colonial appearance may vary or be similar for different species. Characteristic pigmentation may fail to appear, and isolates, especially Trichophyton spp., may not sporulate. Special media may be required to stimulate pigment production; it may be necessary to use sporulation and physiological tests in conjunction with morphology to identify the species correctly. The majority of isolates are easily identified when visual examination is combined with any needed testing for characteristic growth factor requirements; the consequence of this is that phenotypic studies remain the least expensive option for routine identification. However, although seldom practically applicable except in high-level reference laboratories, molecular identification strategies involving PCR amplification and sequencing of ITS regions (currently the gold standard for mould identification [80]) identify unusual isolates that are misbehaving phenotypically. Moreover, several recent studies have demonstrated that rapid and robust identification of most common
dermatophytes is possible by matrix-assisted laser desorption ionization–time-of-flight mass spectrometry. Indeed, identifications with this technique correlated much more closely with the results of ITS sequencing than with identifications based on conventional phenotypic approaches (18, 81).

**Colony Characteristics**

In observing gross colony morphology, note the color of the surface and the reverse of the colony, texture of the surface (powdery, granular, woolly, cottony, velvety, or glabrous), topography (elevation, folding, margins, etc.), and rate of growth.

**Microscopic Morphology**

Microscopic morphology, especially the appearance and arrangement of the conidia (macroconidia or microconidia) and other structures, may be determined by teased mounts, sticky tape mounts, or slide culture preparations mounted in lactophenol cotton blue (LCB), in lactophenol aniline blue (phenol, an ingredient of LCB and lactophenol aniline blue, is listed as a hazardous chemical; therefore, solutions containing phenol should be prepared, stored, and used in an approved chemical safety cabinet), in lacto-fuchsin (55), or in more-permanent mounting fluids (82). Sometimes a special medium, such as cornmeal or cornmeal glucose agar, potato glucose agar, SGA plus 3 to 5% NaCl (83, 84), Palbum cereal agar (55), rapid sporulation medium (67), or lactrimel agar (85, 86 [see chapter 115]), may be required to stimulate sporulation.

**Physiological Tests**

*In Vitro Hair Perforation Test*

The in vitro hair perforation test distinguishes between atypical isolates of the *T. mentagrophytes* complex and *T. rubrum* (87). It may also be used to assist in making other distinctions such as *M. canis* versus *M. audouinii* and *Microsporum* *praecox* versus *M. gypseum* (88). Hairs exposed to *T. mentagrophytes* complex members, *M. canis*, and *M. gypseum* show wedge-shaped perforations perpendicular to the hair shaft (a positive test result), whereas *T. rubrum*, *M. audouinii*, and *M. praecox* do not form these perforating structures.

Place short strands of human hair (ideally hair from a child <18 months old) in petri dishes, and autoclave the dishes at 121°C for 10 min; add 25 ml of sterile distilled water and 2 or 3 drops of 10% sterilized yeast extract. Inoculate these plates with several fragments of the test fungus that has been grown on SGA, incubate the plates at 25°C, and examine them at regular intervals over a period of 21 days. Hairs may be examined microscopically for perforations by removing a few segments and placing them in a drop of LCB mounting fluid. Gently heating the mounts aids in the detection of the fungus. A positive control test should always be run with a known perforating species; *M. canis* is recommended. Some hair samples may prove unsuitable for unknown reasons, e.g., possible prior contact with shampoos containing antifungal inhibitors.

**Special Nutritional Requirements**

Nutritional tests aid in the routine identification of *Trichophyton* species that seldom produce conidia or that resemble each other morphologically (89). Certain species have distinctive nutritional requirements, whereas others do not. The method employs a Casamino Acids basal medium that is vitamin free (*Trichophyton* agar 1 [T1]) and to which various vitamins are added, i.e., inositol (T2), thiamine plus inositol (T3), thiamine (T4), and nicotinic acid (T5). In addition, the series includes an ammonium nitrate basal medium (T6) to which histidine is added (T7). These media are available commercially in dehydrated form from BD Biosciences and in prepared form from Remel. A small fragment (about the size of the head of a pin) from the culture to be tested is placed on the surface of the basal medium (controls) and the media containing the vitamin and amino acid additives. Care must be taken to avoid transferring agar from the fungal inoculum to the nutritional media. Cultures are incubated at room temperature (or 37°C if *T. verrucosum* is suspected) and read after 7 and 14 days. The amount of growth is graded from 0 to 4+. Commonly observed reactions are summarized in Table 4.

</table>

*Only the growth responses for organisms with growth factor requirements and the selected organisms that must be most closely compared with them are included in this table. The numbers in the table body indicate the relative degree of growth according to traditional 1+ to 4+ visually approximated scale: 0, no growth; 1, slight growth, strongly nutrient-deprived colony morphology (very sparse, subsurface colonial growth only or colony diameter strongly reduced compared to Sabouraud agar control); 2, partially stimulated growth but still significantly suppressed compared to that of the control; 4, growth comparable to that of the control (the table includes no 3+ reactions); v, variable. Blank spaces in the table indicate growth responses that are not customarily examined but that are insignificantly different from control growth responses on Sabouraud agar.*
Urea Hydrolysis
The ability to hydrolyze urea provides additional data to aid in distinguishing the typical, cosmopolitan form of *T. rubrum* (urease negative) from members of the *T. mentagrophytes* complex (typically urease positive), and from the urease-positive Afro-Asiatic or "granular" form of *T. rubrum*, formerly often called *T. raubitschekii* (90, 91). Christensen urea agar and broth may both be used; the broth appears to be the more sensitive of these alternatives (92). After the urea medium is inoculated, it is incubated at 25 to 30°C up to 7 days. The tubes should be examined every 2 to 3 days for the color change from orange or pale pink to purple-red that indicates the presence of urease, a positive test result. Negative and positive controls should always be done on new batches of these media. See Table 1.

Growth on BCPMSG
Bromocresol purple (BCP)-milk solids-glucose (BCPMSG) is available commercially as Dermatophyte Milk Agar (Hardy). Type of growth (proliferous versus restricted) and a change in the pH indicator (BCP) indicating alkalinity are especially useful for distinguishing *T. rubrum* from the *T. mentagrophytes* complex, and *T. mentagrophytes* from *Microsporum persicolor* (55, 84, 93). *T. rubrum* shows restricted growth and produces no alkaline reaction on BCPMSG, whereas members of the *T. mentagrophytes* complex typically show profuse growth and an alkaline reaction. Although *M. persicolor* shows profuse growth, it does not result in an alkaline reaction. Other tests for distinguishing *T. mentagrophytes* and close relatives from *M. persicolor* are described elsewhere (94).

 Cultures to be tested are inoculated onto slants of BCPMSG and examined for pH change and growth characteristics at the end of a 7-day incubation at 25°C. A color change from pale blue to violet-purple indicates an alkaline reaction.

Growth on Polished Rice Grains
Unlike most dermatophytes, *M. audouinii* grows poorly on rice grains and produces a brownish discoloration of the rice (55, 94). This is a useful test for differentiating this species from *M. canis* and from other dermatophytes that typically grow and sporulate on rice grains. It may be especially useful in areas where *M. audouinii* is still endemic, e.g., sub-Saharan Africa, or where immigrants or travelers from such areas are reintroducing it.

The medium is prepared in 12-ml flasks by mixing 1 part raw unfortified rice grains and 3 parts water (95) or 8.0 g of rice grains and 125 ml of distilled water. Autoclave at 15 lb/in² for 15 min. Inoculate the surface of the rice, and incubate the sample for 2 weeks at 25 to 30°C.

Temperature Tolerance and Temperature Enhancement
Tests for temperature tolerance and enhancement are useful for distinguishing the *T. mentagrophytes* complex from *T. terrestre* (96), *T. mentagrophytes* from *M. persicolor* (84), *T. verrucosum* from *T. schoenleini* (48), and *T. soudanense* from *M. ferrugineum* (97). At 37°C, members of the *T. mentagrophytes* complex show good growth, whereas *T. terrestre* does not grow and *M. persicolor* generally grows poorly or not at all (a single atypical isolate with good growth has been observed); growth of *T. verrucosum* and *T. soudanense* is enhanced, but that of *T. schoenleini* and *M. ferrugineum* is not.

Inoculate two slants of SGA with an equivalent fragment of the culture. Incubate one slant at room temperature (25 to 30°C) and one at 37°C. Compare the growth at the two temperatures when mature colonies appear at room temperature. Appropriate controls are recommended and should be compared first.

Molecular Identification Techniques
The recommendation of standard DNA barcodes (17) is in progress, with the ITS-1 region emerging as a key panfungal region for the molecular identification of moulds, including dermatophytes (80, 98). However, although PCR amplification and sequencing of ITS-1 have proven efficacy for dermatophyte identification (98), several caveats remain. First, caution is required when comparing the sequences obtained with those in public synchronized databases, which are strewn with erroneously identified fungi. Second, relatively few conserved nucleotide positions separate the different *Trichophyton* spp., principally due to the relatively slow evolution rate of the nuclear ribosomal repeat region. Many other nucleic acid-based identification techniques for dermatophytes were published in previous years but have not been widely adopted. Some recent contenders for rapid, state-of-the-art species identification include PCR using a (GACA)₄ primer (99) and restriction fragment length polymorphism of the ITS-2 gene region (100).

DESCRIPTION OF ETIOLOGIC AGENTS
Characteristic features of dermatophyte species are presented in Table 1. The table also includes data on some similar but rarely or never pathogenic *Microsporum* and *Trichophyton* species that must be distinguished from pathogenic species.

Two types of conidia may be produced on the aerial mycelium of the dermatophytes: large, multicellular, smooth or rough, thin- or thick-walled macroconidia and smaller, unicellular, smooth-walled microconidia. The three genera are classically grouped according to the presence or absence of these two types of conidia and the appearance of the surface of the macroconidia, i.e., rough versus smooth. In reality, when atypical isolates and species are taken into account, the genera show considerable overlap in morphological and physiological tests (Table 5).

It may be necessary to incubate cultures on brain heart infusion agar or BCPMSG to ensure absence of antibiotic-resistant bacterial contamination before proceeding to step 4. Procedures are adapted from Weitzman and colleagues (25) and Kane et al. (55).

Trichophyton Species

Macroconidia have smooth, thin to thick walls; are variable in shape (clavate, fusiform to cylindrical); vary in number of septa (1 to 12) and in size (8 to 86 by 6 to 25 μm); and are borne singly or in clusters. Microconidia, which are usually present and more numerous than macroconidia, may be globose, pyriform, or clavate and are borne singly along the sides of hyphae or in grape-like clusters. Though species in this genus generally produce microconidia more readily than macroconidia, two lineages producing macroconidia predominantly or exclusively have been described: (i) “Trichophyton kanei” (102), now known to be a variant of the Afro-Asiatic genotype of T. rubrum, and (ii) a variant all-macroconidial form of T. tonsurans (101). Fresh isolates of the dermatophytoid T. ajelloi may also produce many macroconidia and few or no microconidia. Some species such as T. schoenleinii rarely produce conidia of any kind in culture, and nonsporulating isolates of normally conidial species, especially T. rubrum, may also be frequently encountered, especially in primary cultures.

Microsporum Species

Microsporum species produce macroconidia and microconidia that may be rare or numerous, depending on the species and the substrate. The distinguishing characteristic is the macroconidium, which is typically rough walled (varying from minutely to conspicuously roughened). Macroconidia also vary in shape (obovate, fusiform to cylindrical), number of septa (1 to 15), size (6 to 160 by 6 to 25 μm), and width of the cell wall. Microconidia are pyriform or clavate and usually are arranged singly along the sides of the hyphae. Microsporum species invade skin, hair, and, rarely, nails. Biological (teleomorphic) species within the M. gypseum complex can be provisionally recognized on the basis of asexual and microscopic features on Takashio’s medium (103), but these species are best distinguished by mating or molecular testing.

Epidermophyton floccosum

In E. floccosum, macroconidia are lacking; only smooth-walled, broadly clavate macroconidia are produced, often with an abundance of intercalary and terminal chlamydo-spores in primary cultures. The macroconidia have one to six septa, are 20 to 40 μm long by 7 to 12 μm wide, and are borne singly or in clusters of two or three. E. floccosum is currently the only recognized Epidermophyton species; the former E. stockdaleae is now considered a synonym of Trichophyton ajelloi (14).

STRAIN TYPING SYSTEMS

Dermatophyte strains within anthropophilic species tend to be very closely related, hindering the development of useful techniques for epidemiological analysis, but strains of T. rubrum were eventually distinguished by polymorphisms in the numbers of subrepeat elements in the ribosomal nontranscribed spacer region (104–107). In addition, the Afro-Asiatic lineage of T. rubrum was distinguished from the now-cosmopolitan epidemic T. rubrum form by means of a microsatellite marker designated T1 (108). More recently, an elegant system involving multiple microsatellite markers has been developed (109). Nontranscribed spacer polymorphisms can also be applied to distinguish T. interdigitale and T. tonsurans isolates (104, 110, 111). While it is beyond the scope of this chapter to review all current molecular differentiation techniques for dermatophytes or their applications in outbreaks, the multilocus genotyping system of Abdel-Rahman et al. (112) should be cited as an example of how such methods can foster the development of epidemiological insight.

ANTIMICROBIAL SUSCEPTIBILITIES

Dermatophytes can in principle be tested for susceptibility to antifungal drugs using the Clinical and Laboratory Standards Institute M38-A2 standard procedure for moulds (113). A trial has shown that this type of methodology can be applied with good inter- and intralaboratory reproducibility to the commonly used drugs ciclopirox, fluconazole, griseofulvin, itraconazole, posaconazole, terbinafine, and voriconazole (114). However, drug resistance is very rarely encountered in dermatophytes, and treatment failures are almost always due to factors other than resistance (115). Thus, potentially burdensome requests for dermatophyte susceptibility testing should be closely screened for scientific and clinical appropriateness.
EVALUATION, INTERPRETATION, AND REPORTING OF LABORATORY RESULTS

For nonimmunocompromised patients, positive direct microscopy compatible with dermatophytosis is conventionally interpreted as presumptively indicating this condition in hair and in specimens other than those from nails, soles, and palms. The positive microscopic report itself conveys this information; it should be issued within 2 working days of specimen receipt. With soles and palms, persons who have lived in tropical areas or who are of south Asian heritage may have dermatophytosis-like infections, which are similar to dermatophytes both clinically and in direct microscopy (55); no presumptive diagnosis can be inferred until the culture result is available. The direct microscopic result, however, is still reported immediately. For patients without risk factors for Neoscytalidium, qualified physicians may make presumptive diagnoses of dermatophytosis for sole and palm skin as for other skin sites. In onychomycosis, >35 different mould species may be involved in producing conditions clinically and microscopically resembling tinea unguium (55), particularly in geriatric patients. The presence of a nondermatophyte mould may be suspected upon direct microscopic examination, which often reveals intact distorted hyphae (as opposed to arthrospores) with pronounced terminal fronding or hyphal swellings. Microscopic results are still reported promptly, but culture results are of high interest. At the same time, the outgrowth of known onychomycosis-causing nondermatophytes may or may not be significant, excepting the nail-infecting Neoscytalidium species, which are always considered significant when grown. The complexities of accurately reporting nondermatophytes from nail specimens are beyond the scope of this chapter but are discussed in light of rigorous validation studies on this topic by Summerbell et al. (60).

Isolation of a dermatophyte culture from lesional skin, hair, or nails is interpreted as diagnostic whether or not fungal elements are seen in the initial direct microscopy examination. Note that dermatophytoiids such as Microsporum cookei and T. terrestrae are presumed to be contaminants until proven otherwise; they are, however, reported along with the comment “normally nonpathogenic” when grown. These fungi have been the subjects of numerous false and questionable case reports in the literature, and there may be some confusion about their status. If such a fungus were to infect human epidermis, the gold standard for scientifically evidencing the case would be three successive, consistent repeat isolations of the organism. The fungi are observed readily when scrapings are mounted in distilled water, 480 ml. In cases in which skin scrapings are beyond the scope of this chapter but are discussed in light of rigorous validation studies on this topic by Summerbell et al. (60).

In the superficial mycoses, the causative fungi colonize the cornified layers of the epidermis or the suprafollicular portion of the hair. There is little tissue damage, and cellular response from the host generally is lacking. The diseases are largely cosmetic in impact, involving changes in the pigmentation of the skin (tinea versicolor or tinea nigra) or formation of nodules along the distal hair shaft (black piedra and white piedra).

In contrast to agents of the dermatophytoiids, the etiologic agents are diverse and unrelated.

Tinea Versicolor (Pityriasis Versicolor)

Tinea versicolor is an infection of the stratum corneum caused by a group of closely similar lipophilic yeast species of the Malassezia furfur complex. Members of this complex infecting human skin were often treated in former times as a single species but were then shown by molecular, physiological, and serotyping studies to be separate (117, 118). The complex includes M. furfur (synonyms: Pityrosporum furfur and Pityrosporum ovale pro parte), M. sympodialis, M. globosa (probable synonym: Pityrosporum orbiculare), M. restricta, M. slooffiae, M. obtusa, M. dermatis, M. japonica, and M. yamatoensis (9, 119). Some additional species have been reported for animals. In routine clinical reporting, referring to these organisms as members of the M. furfur complex is normally sufficient. Malassezia pachydermatis, which causes animal ear infections and occasional human iatrogenic fungemias, is not considered a member of the M. furfur complex and, if reported, is reported under its individual species name. It is easily distinguished from M. furfur complex members by its ability to grow on ordinary laboratory media such as Sabouraud agar (see comments on Malassezia culture below). It is insignificant when grown from human skin except where investigations of catheter-related problems are involved.

Tinea versicolor lesions appear as scaly, discrete or con- crescent, hypopigmented or hyperpigmented (fawn, yellow- brown, brown, or red) patches chiefly on the neck, torso, and limbs. The infection is largely cosmetic, becoming apparent when the skin fails to tan normally. The disease has a worldwide distribution; in tropical climates, 30 to 35% of the population may be affected, while incidence in areas of temperate climate is much lower, with only 1.0 to 4.0% of the population affected. M. furfur and related yeasts are found on the normal skin and elicit disease only under conditions, local or systemic, that favor the overgrowth of the organism.

The M. furfur complex has been associated with folliculitis (120), obstructive dacryocystitis (22), systemic infections in patients receiving intralipid therapy (121), and seborrhoeic dermatitis, especially in patients with AIDS (122). Excellent reviews are available on human infections caused by Malassezia spp. and on the characteristics of the genus (123–126). Additional information is also found in chapter 117 of this Manual.

Direct Examination

The fungi are observed readily when scrapings are mounted in 10% KOH plus ink (127), 25% NaOH plus 5% glycine, calcofluor white, or Kane’s formulation (glycerol, 10 ml; Tween 80, 10 ml; phenol, 2.5 g; methylene blue, 1.0 g; distilled water, 480 ml). In cases in which skin scrapings be assumed to be causal simply because they share a genus name with dermatophyte species.
from unspecified body sites are examined, Kane’s formulation has the advantage of vividly staining both fungi and the differential-diagnostic organisms causing erythrasma and pitted keratolysis. (These two bacterial infections, often confused with superficial mycosis, are mainly from intertriginous sites and foot soles, respectively.) Tinea versicolor is signaled in microscopy by the presence of “spaghetti and meatballs,” i.e., short, septate, occasionally branching filaments 2.5 to 4 μm in diameter and of variable lengths intermingled with clusters of small, unicellular, oval or round, budding yeast cells (Fig. 19). The yeasts show the presence of a collarette between mother and daughter cells (budding is phialidic and unipolar) and average 4 μm (up to 8 μm) in size.

**Isolation and Culture**

Culture is not essential for identification unless the findings of direct microscopic examination are atypical or unless full species identification is desired for research purposes. Also, *M. furfur* complex members are part of the normal flora of the skin, and positive culture does not indicate infection. The species require exogenous lipid and do not grow on routine mycology media. If culture is desired, scrapings may be inoculated on Leeming-Notman medium, which uses whole milk as a major lipid source (128); on Dixon agar (129); or on modified Dixon agar, consisting of malt extract (3.6%), mycological peptone (Oxoid) (0.6%), desiccated ox bile (bile salts; Oxoid) (2%), Tween 40 (1%), glycerol (0.2%), oleic acid (0.2%), and agar (1.2%). Growth of the yeasts is slow; colonies are cream colored, glossy or rough, and raised (Fig. 20), later becoming dull, dry, and tan to brownish. Only budding yeast cells generally appear in culture (Fig. 21).

**Tinea Nigra**

Tinea nigra is characterized by the appearance, primarily on the palms of the hands and less commonly on the dorsa of the feet, of flat, sharply margined, brownish black, nonscaly macules that may resemble melanoma (126).

The disease, almost always caused by *Hortaea werneckii* (*Phaeoannellomyces werneckii*, *Exophiala werneckii*, or *Cladosporium werneckii*), is most common in tropical areas (130) but has been contracted occasionally in coastal areas in and near the southeastern United States (126, 131). Cases diagnosed outside the area of endemicity have mostly resulted from travel to the American tropics or the Caribbean islands (130). *H. werneckii* is related to the ascomycetous order **Dothideales** (132).

**Direct Microscopic Examination**

Microscopic examination of skin scrapings in KOH or NaOH reveals numerous light brown, frequently branching filaments 1.5 to 5 μm in diameter (Fig. 18h); short, sinuous filaments; and budding cells, some septate.

**Isolation**

On SGA with or without antibiotics, *H. werneckii* grows slowly and usually appears within 2 to 3 weeks as moist, shiny olive to greenish black yeast-like colonies. The yeast-like cells are usually two-celled when reproductive and, instead of budding, produce new yeast cells from thick (up to 2 μm in diameter), distinctly annellated (multiply ringed

---

**FIGURE 20** Culture of Malassezia furfur on Littman oxgall agar overlaid with oil. doi:10.1128/9781555817381.ch123.f20

**FIGURE 21** Microscopic appearance of Malassezia furfur yeast cells on Littman oxgall overlaid with olive oil. Magnification, ×400. doi:10.1128/9781555817381.ch123.f21
as if wearing several bracelets) pegs. After 7 or more days, colonies may develop a fringe of thick, dark, conspicuously septate hyphae that also bear annellated fertile structures. These produce conidia that are indistinguishable from young yeast cells. The micromorphology of *H. werneckii* is described in more detail in chapter 124.

**Black Piedra**

Black piedra is a fungal infection of the scalp hair, less commonly of the beard or moustache, and rarely of axillary or pubic hairs. The disease is characterized by the presence of discrete, hard, gritty, dark brown to black nodules adhering firmly to the hair shaft (Fig. 22). It is found mostly in tropical regions in Africa, Asia, and Central and South America. Humans as well as other primates are infected (126, 130, 133).

The etiologic agent in humans is *Piedraia hortae*, an ascomycete (order *Dothideales*) forming nodules that serve as ascostromata containing locules that harbor the asci and ascospores.

**Direct Microscopic Examination**

Hair fragments containing one or more black nodules are placed in 25% KOH or NaOH with 5% glycerol. The preparation is heated gently and carefully squashed so as not to break the coverslip, as the nodules are very hard. A squashed preparation of a mature nodule should reveal compact masses of dark, septate hyphae and round or oval ascu containing two to eight hyaline, aseptate, banana-shaped (fusiform) ascospores that bear one or more appendages. The preparation should first be observed under the low-power objective to reveal the dark mass of compacted hyphae around the surface of the hair, and then examined under the high-power objective to observe the asci and ascospores.

**Isolation, Culture, and Identification**

When ascospores are seen in direct specimen microscopy, culture is unnecessary. Otherwise, SGA with chloramphenicol and SGA with chloramphenicol and cycloheximide may be used for isolation. Some reports have indicated that cycloheximide may be inhibitory; however, others have used this antibiotic successfully. SGA amended with chloramphenicol alone may be used for successful isolation.

Colonies are very slow growing; appear dark brown to black; and are glabrous at first and later covered with short, dark brown to black aerial mycelium. They tend to be heaped in the center with a flat periphery. Some colonies produce a reddish brown, diffusible pigment on the agar. Microscopic examination reveals only highly septate, dark hyphae and swollen intercalary cells. Conidia and ascospores are usually not found on routine mycological media.

**White Piedra**

White piedra is a fungal infection of the hair shaft characterized by the presence of soft white, yellowish, beige, or greenish nodules found chiefly on facial, axillary, or genital hairs (Fig. 23) and less commonly on scalp, eyebrows, and eyelashes. Nodules may be discrete or more often coalescent, forming an irregular transparent sheath.

The infection occurs sporadically in North America and Europe and more commonly in South America, Africa, and parts of Asia (130). Although white piedra is an uncommon infection, genital white piedra is occasionally but regularly seen in certain populations (126, 134).

Microscopic examination of hairs containing the adherent nodules mounted in 10% KOH or 25% NaOH-5% glycerin and squashed under a coverslip will reveal intertwined hyaline septate hyphae, hyphae breaking up into oval or rectangular arthroconidia 2 to 4 μm in diameter (Fig. 24), occasional blastoconidia, and bacteria that may surround the nodule as a zooglea (jelly-like mass).
The isolates were formerly described as Trichosporon beigelii or Trichosporon cutaneum but are now correctly identified in most cases as Trichosporon ovodites (causes scalp hair white pie-
dra). Trichosporon cutaneum (causes most cases of pubic white pie-
dra), and Trichosporon asahii (135, 136). As with the M. furfur complex, these species form a complex of difficult-to-identify
species whose distinction, except in demonstrated cases of pie-
dra, is not known to have strong clinical implications in derma-
tologic mycology. They are also very common skin contami-
nants. Ordinarily, they may be reported for skin, hair, and nails of
nonneutropenic patients simply as members of the genus
Trichosporon, based on production of budding yeast cells, arthro-
conidia, and a positive urease test, unless a research-level identi-
fication of a proven etiologic agent is attempted. The causal
agents of white piedra may be readily isolated on SGA with
chloramphenicol or other isolation media containing antibacte-
rial antibiotics. The isolation medium should not contain cyclo-
heximide, since this drug is inhibitory to some of the species.
Growth is rapid, yielding white to cream-colored colonies that
exhibit a variety of colonial morphologies depending on the
species. A description of the genus and characteristics of the
species involved in white piedra are given in papers by Guého
et al. (136, 137). More information about Trichosporon is found
in chapter 117 of this Manual.

chemical detection of interferon-gamma-producing cells in

This chapter covers most of the agents of phaeohyphomycosis, chromoblastomycosis, and sporotrichosis, as well as a number of agents of superficial and cutaneous disease. The genera discussed in this chapter belong to the ascomycetous orders Botryosphaeriales (Lasiodiplodia and Neoscytalidium), Chaetothyriales (Cladothialphora, Exophiala, Fonsecaea, Knaufia, Phialophora, Rhinocladiella, and Veronaea), Calosphaeriales (Plearostronomphora), Diaporthales (Pleurostomophora), Sordariales (Scedosporium), Microascales (Sporothrix), Ophiostomatales (Cladophialophora, Diaphorma), and Chaetothyriales (Exophiala, Lasiodiplodia). The latter two orders, together with some of the genera discussed in chapter 113, are considered in chapter 120, as these are very different from Chaetothyriales in all respects. Also, the term phaeoid indicates brown hyphae; “phaeohyphomycosis” is an umbrella term for infection caused by moulds that display brownish yeastlike cells, pseudoophyphae, or hyphae or a combination of these forms in host tissue. “Black yeasts and relatives” is preferably used to indicate members of Chaetothyriales and Dothideales only (2). The black yeasts are not a formal taxonomic group, but the term is applied to a wide range of unrelated ascomycetous and basidiomycetous fungi that are able to produce budding cells at some stage in their life cycle.

Pleomorphism (multiple morphological forms) is particularly striking in members of the black yeasts and in the genus Scedosporium. These fungi are frequently seen in the clinical laboratory to produce more than one asexual form of propagation (anamorphs). Many species still bear separate names when the connection is not known. At this moment a nomenclatural transition is taking place, which should lead to a single name for a particular fungal species. Independently propagating asexual forms, then, no longer are assigned formal names, but the former generic names are used as descriptive nouns. Only a small percentage of fungal species have the ability to produce a sexual form (teleomorph), characterized by the formation of fruiting bodies with meiotic ascospores, under routine laboratory conditions. For each organism only a single teleomorph can be produced.

**TAXONOMY AND DESCRIPTION OF THE AGENTS**

**Botryosphaeriales**

*Lasiodiplodia*

Lasiodiplodia is a coelomycete genus characterized by spherical fruit bodies filled with asexual conidia. The conidia initially are ellipsoidal and hyaline but gradually become brown and develop a median septum at maturation. *Lasiodiplodia theobromae* (Fig. 1) is the only species involved in human infection.

*Neoscytalidium*

Neoscytalidium dimidiatum (formerly known as Scytalidium dimidiatum) is a plant pathogen that produces arthroconidia in culture, and some isolates also produce pycnidia (flask-shaped structures containing conidiogenous cells) under appropriate growth conditions. The coelomycetous synanamorph had been given the separate name Nattrassia mangiferae, previously known as Hendersonula toruloidea. However, molecular studies have demonstrated that *N. dimidiatum* and *N. mangiferae* are two different species and that the latter, which is not pathogenic to humans, must be accommodated in the recently described genus Neofusicoccum (3).

Inside multilocular fruit bodies hyaline, ellipsoidal conidia develop, which in part become brownish and have one or two septa. In culture, usually only a rapidly growing, jet black, floccose anamorph with dark arthroconidia (Neoscytalidium dimidiatum [Fig. 1]) is seen; the pycnidia are only produced after 2 months’ growth on a moistened plant leaf. Melaninless mutants (4), which also show reduced conidiation, were until recently referred to as Scytalidium hyalinum. The fungus is a common plant pathogen in the tropics.

**Calosphaeriales**

Recently, some melanized phialidic fungi were segregated from *Phialophora* on molecular grounds; these now constitute small islands of clinical significance in the order

</table>
Calosphaeriales, which otherwise contains plant-associated moulds. Infections are mostly of traumatic nature and are supposed to originate directly from the woody plant material of the fungal habitat.

**Pleurostomophora**

Pleurostomophora is a genus of mainly wood-inhabiting fungi. Hyphae are dark and bear pale, tapering phialides that may be single or aggregated in dense brushes; hyaline, slimy conidia are produced through small or large collarettes. Pleurostomophora repens was occasionally reported from subcutaneous infections in humans. The second species of the genus involved also in human infections is *Pleurostomophora richardsiae* (Fig. 2) (syn. *Phialophora richardsiae*), a soft-rot fungus on wood. The recently published species *Pleurostomophora ochracea* is exceptional in producing yellow grains in mycetoma, which previously had been interpreted as being of bacterial nature (5).

**Capnodiales**

**Cladosporium**

Species of *Cladosporium*, especially *Cladosporium cladosporioides* (Fig. 3) and *C. oxysporum*, are extremely common contaminants in the clinical laboratory but have also been described as occasional human opportunists. Such cases need thorough evaluation, as infection by *Cladosporium* is highly unlikely.

**Hortaea**

Members of the genus *Hortaea* have rather wide hyphae which become profusely septate during growth of the
fungus, and they have annellidic conidiogenesis from broad scars. The halophilic species *H. werneckii* (Fig. 1) lives in evaporation ponds at the subtropical seashore and causes superficial infections. The clinical picture is known as tinea nigra.

**Chaetothyriales**

The rather small order *Chaetothyriales* is clinically highly relevant, because about half of the species known to date are able to cause infections in humans.

**Cladophialophora**

Catenate (in chains), dry conidia and an absence of differentiated conidiophores characterize *Cladophialophora*. This genus contains 10 pathogenic species (Table 1), 7 of which are almost exclusively known from humans and other warm-blooded animals. The most significant species are *Cladophialophora bantiana* and *C. carrionii*. *C. bantiana*, a remarkable neurotropic mould, is recognizable by very long, coherent, poorly branched conidial chains and by an ability to grow at 40°C (Fig. 2; see also Fig. 5). It has a characteristic 558-bp intron at position 1768 of the small-subunit (SSU) ribosomal operon (6). *C. carrionii* is a common agent of chromoblastomycosis, with small conidia in profusely branched chains.

**Cyphellophora**

*Cyphellophora* (including clinical species of *Pseudomicrodochium* [7]) is a rare group of infective agents characterized by slender, curved, mostly 1- to 3-septate conidia. Cultures are evenly melanized and show limited expansion growth; budding cells are absent. Conidia are produced from poorly developed collarettes alongside the hyphae. *Cyphellophora laoniata* and *C. phlei* (Fig. 2) are rare agents of superficial mycoses. The incidence of these fungi is probably low, but they are likely to be underdiagnosed.
Curvularia, Exophiala, Scedosporium, Sporothrix, and Other Melanized Fungi

Exophiala
Exophiala is the main genus of clinically relevant black yeasts. Strains show high degrees of morphological diversity. Most isolates initially grow in a yeast form that is succeeded by a hyphal anamorph. As a result, colonies are moist and slimy at first, becoming velvety to woolly with age. The process of conidium production is annellidic, from narrow, inconspicuous scars or extensions. Occasionally a very slowly growing, meristematic morphology (“Sarcinomyces”) is preponderant. Fresh isolates or strains cultivated on nutritionally deficient media frequently produce conidia in chains and may produce scattered or compacted phialides with huge collarettes (8). The most frequently identified species are Exophiala dermatitidis (Fig. 2) and E. jeaneselmei. The latter has been subdivided into a number of taxa, such as E. oligosperma, E. bergeri, and E. xenobiotica, on molecular grounds; they are morphologically indistinguishable (9). E. dermatitidis is recognizable morphologically by phialides without collarettes, which are wide, scar-like, very short annellated zones. In addition, growth at 40°C and the inability to assimilate nitrate are characteristic.

FIGURE 2  (a and b) Cladophialophora bantiana; (c) Phialemoniopsis curvata; (d) Exophiala dermatitidis; (e to g) Cyphellophora plurisepata; (h and i) Pleurostomophora richardsiae; (j) Phaeoacremonium parasiticum; (k) various pictures of Fonsecaea pedrosoi. Reproduced from reference 2.

doi:10.1128/9781555817381.ch124.f2
The related species *E. phaeomuriformis* differs by having a growth maximum at 38°C (11). The less frequent species *E. spinifera* can be recognized by the presence of large, stiff conidiophores. Recently, a similar species with reduced conidiogenous cells, *E. attenuata*, was described (9). Other *Exophiala* species, such as *E. asiatica* (12), have occasionally been described from severe cases in otherwise healthy individuals.

**Fonsecaea**

The four species known in the genus *Fonsecaea*, characterized by conidia produced in chains of maximally four, are all human pathogens. In culture, *Fonsecaea* species mostly have one morphological form, but they may produce additional phialides with collarettes releasing balls of one-celled conidia. No budding cells are produced on routine media. *Fonsecaea pedrosai* (Fig. 2, including the mutant *F. compacta*) is one of the etiologic agents of human chromoblastomycosis.

The other agents of this disease, *F. monophora* (13) and *F. rubica* (14), are morphologically indistinguishable. *F. multimorphosa* was described from a cerebral infection in a cat (15).

**Knufia**

Although most species of *Knufia* have been described as colonizers of rock and marble building walls, they are occasionally found as colonizers of human skin. *Knufia epidermidis* has exclusively been recovered from human skin, causing very mild infections (16).

**Phialophora**

When phialides are the only form of propagation in chaetothyrialean fungi, the generic name *Phialophora* is applied. Dematiaceous phialidic fungi belonging to other orders are now classified in genera such as *Cadophora*, *Phaeoacremonium*, and *Pleurostomophora* (17). No budding cells are produced in *Phialophora*. *Phialophora verrucosa*, with darkened, funnel-shaped collarettes (Fig. 3), is one of the commonest species of this genus. *P. americana* differs mainly by having vase-shaped collarettes (18). Given the close molecular similarity, there is no consensus as to whether *P. verrucosa* and *P. americana* comprise two species or one (18).
Rhinocladiella
Rhinocladiella is morphologically characterized by pale brown conidiophores bearing noncatenate conidia on denticles and occasionally shows exophiala-like budding cells in culture (19). It comprises three pathogenic species, Rhinocladiella mackenziei (Fig. 3), R. aquaspersa (Fig. 3), and R. baistoma, which, however, are polyphyletic within the Chaetothyriales. R. atrorubens has been reported to cause cerebral phaeohyphomycosis in an AIDS patient (20), but as this species in a modern, molecular circumscription is limited to isolates growing on conifer wood in northern countries, these cases probably concerned the sibling species R. similis (21).

The neurotropic species R. mackenziei is morphologically similar to Pleurothecium obovatum (formerly Ramichloridium obovatum) and for a long time was thought to be conspecific, but phylogenetically it does not even belong to the same order (the latter species belongs to the Sordariales) (19).

Diaporthales

Phaeoacremonium
Phaeoacremonium (22) is morphologically characterized by slender, tubular, and often tapering or inflated brown phialides. Hyaline, slimy conidia are produced through inconspicuous collarettes. Six species are known from opportunistic infections in humans (Table 1). Phaeoacremonium parasiticum (Fig. 2) being the most common. The prevalent type of infection is mycetoma.

Dothideales

The order Dothideales comprises numerous saprobes which thrive well under conditions of decreased water activity, such as on sugary leaf surfaces, rock, glass, and moist medical devices.

Aureobasidium and Hormonema

The genus Aureobasidium contains a single, ubiquitous, and highly polymorphic species, A. pullulans (Fig. 3). Colonies in vitro are often pink due to the preponderance of wide, hyaline, oligokaryotic (having 3 to 10 nuclei) hyphae bearing synchronously produced conidia and containing scattered endoconidia (conidia formed inside a hypha). Aureobasidium is often confused with Hormonema (Fig. 3), which, however, produces conidia in a basipetal succession with the youngest at the base (23). In addition, the internal transcribed spacer (ITS) ribosomal DNA (rDNA) sequences of the two species are clearly different (24).

Microasccales

The order Microasccales comprises Scoptoria similis with its Microascus teleomorphs (see chapter 120) but also Scedosporium, linked to Pseudallescheria and Petriella teleomorphs.

Pseudallescheria/Scedosporium

The genus Pseudallescheria (anamorph Scedosporium) comprises several species of clinical interest (25, 26). This fungus has become one of the most frequently misidentified organisms in medical mycology, largely due to the differential abundance of each of the phenotypes of Pseudallescheria boydii. This has led to a large number of new introductions in totally unrelated genera (2). However, it is currently accepted that P. boydii and Scedosporium apiospermum are two different species, i.e., P. boydii (anamorph Scedosporium boydii) and Pseudallescheria apiosperma (anamorph Scedosporium apiospermum) (27). The former species is homothallic, and the teleomorph (Fig. 1) is frequently found in clinical samples. The latter species is heterothallic, and the teleomorph is not present in cultures of clinical samples. The anamorphs of these two species are morphologically difficult to distinguish from each other and are characterized by hyaline, Fontana-Masson-negative hyphae from which slimy, pale brown conidia are produced in basipetal succession from inconspicuous anellides. In addition, some isolates are able to produce a Graphium synanamorph. A closely related species with a high incidence in Australia is S. aurantiacum, which is characterized by the production of a yellow to orange pigment (27). Another clinically important species that does not belong to the P. boydii species complex is S. prolificans. However, the latter fungus has flask-shaped conidiogenous cells and is monomorphic (see Fig. 6). Scedosporium species have hyaline hyphae, but conidia and synnemata are melanized; colonies are usually gray to black.

Ophiostomatales

Ophiostomatales is a large order of plant-pathogenic fungi. Most are blue-stain fungi in wood and live in association with bark beetles. Only a few species are human or animal pathogens. The main teleomorph genus is Ophiostoma.

Sporothrix

Sporothrix schenckii has colorless hyphae that bear a cluster of thin denticles with hyaline, tear-shaped conidia at their tips. Additional spherical and sessile conidia may or may not be present; this is the only melanized part of the fungus. The mould can be transformed in vitro to a stable yeast at 37°C on enriched media such as chocolate agar or brain heart infusion agar. Occasional isolates are difficult to convert and may require multiple subcultures and extended incubation. Transition is observed in environmental as well as clinical isolates.

Recent molecular studies have demonstrated that S. schenckii sensu lato is a complex of numerous phylogenetic species (28–30). The combination of phenotypic (morphology of the sessile pigmented conidia; growth at 30, 35, and 37°C; and assimilation of sucrose, raffinose, and ribitol) and genetic (analysis of the calmodulin gene sequences) approaches allows differentiation of some of these species. Apart from S. schenckii sensu stricto, the species S. brasiliensis, S. globosa, and S. lari are also involved in human infections. S. brasiliensis is a clonal species with high virulence (31) emerging from large epidemics in Brazil; transmission occurs particularly through stray cats. S. globosa is the prevalent species in Asia (32), where particularly children are infected. S. lari is a rare species that has only been reported from a single case (29).

Pleosporales

Most members of the order Pleosporales have rapidly expanding, floccose colonies, which show optimal conidium production on media poor in nutrients, such as potato carrot agar. The large conidia are then mostly visible with the aid of a stereomicroscope. Conidia are generally produced on septeate, dark brown, erect conidiophores. Conidia consist of several compartments. True septa are found in those conidia where the outer wall and septum are continuous; such conidia are euseptate (in Alternaria and Curvularia). False septa are observed in those conidia where only the inner wall layers are involved in septation and the outer wall forms a sac-like structure around the individual cells; such conidia are distoseptate (in Bipolaris and Exserohilum).

Alternaria

Since clinical strains are very likely to belong to only two species of Alternaria, Alternaria infectoria and A. alternata,
isolates are easily identified down to the species level. Available criteria comprise characteristics of growth, sporulation, and morphology, and very large differences in the ITS rDNA, which can be displayed by sequencing or by restriction fragment length polymorphisms (33). Alternaria infectoria in tissue may present with hyaline yeast cells rather than melanized hyphae. Cultures of A. infectoria, in contrast to those of A. alternata, frequently exhibit creamish patches and show reduced sporulation. Conidia of A. infectoria bear long apical beaks which serve as secondary conidiophores. A. alternata displays conidia in chains.

Bipolaris
The preponderant Bipolaris species in human infections are Bipolaris australiensis, B. hawaiiensis (Fig. 4), and B. spicifera. They are characterized by large, ellipsoidal, straight or curved conidia. Recently, these species have been transferred to Curvularia (34).

Curvularia
Most species of the genus Curvularia are easily recognizable on the basis of the characteristics of their conidia, which are ellipsoidal, often curved, and with dark and flat scars
(1). Saprobic members of Curvularia, particularly Curvularia geniculata and C. lunata (Fig. 4), have been identified as potential agents of human infections.

Exserohilum

Exserohilum (35, 36) is characterized by very long, distoseptate conidia with a distinct, protruding basal hilum. Three species have been recognized as opportunistic agents (Exserohilum longirostratum, E. magginisii, and E. rostratum [Fig. 4]), but given their close molecular similarities, they may be morphological variants of a single species (2, 37).

Sordariales

Sordariales is a large and diverse order of ascomycetes. Maderaella mycetomatis was recently proven to be another member of Sordariales (38); this species is treated in chapter 125. The genera Phialemonium, Chaetomium, and Aechactomium are treated in chapter 120. Currently, Phialemoniopsis curvata (formerly Phialemonium curvatum) is incertae sedis in the Sordariomycetes class.

Venturiales

Ochroconis (Verruconis)
The genus Ochroconis is paraphyletic (group of fungi that includes some, but not all, of the descendants from a common ancestor) to but at significant distance from the Venturiales. All species have rust brown to olivaceous colonies and produce 1- to 3-septate conidia from small, open denticles inserted in low numbers on sympodial cells. Members of Ochroconis are occasional agents of mild skin infections. Molecular distances within the Ochroconiales are remarkably large; for this reason, the neurotropic species O. gallopava (Fig. 3), with hyaline, clavate conidia and growing well at 40°C, was reallocated to a separate genus, Verruconis (39).

Epidemiology and Transmission

Phaeohyphomycoses are usually subcutaneous but can also be systemic or involving the central nervous system. Infections of the central nervous system are frequently manifested as brain abscesses or meningitis, which are usually fatal. In these infections fungi can be present usually in the cerebrospinal fluid. Most cases are produced in the invasive form. The development of either phaeohyphomycoses or chromoblastomycoses in black yeast-like fungi is species specific. The species that cause subcutaneous infections are generally uncommon in the environment and occupy hitherto-unrevealed microhabitats. Some thermotolerant species seem to be associated with environmental xenobiotics or occur in animal feces (43); others are found on slightly osmotic surfaces such as fruit (44).

Psychrophilic species that cause infections in cold-blooded vertebrates are frequent in water, either ocean water (45), municipal drinking water (46), or hospital water (47). In the indoor environment, Exophiala has been found in steam baths (44) and dishwashers (48). Members of the Pleosporales that rarely cause infections are common saprobes on decaying plant material. They may be encountered in allergic sinusitis of human and cattle (49). Many members of the Dothideales are tolerant of extreme growth conditions and are found in Antarctic or Mediterranean rock (50) or in hypersaline ponds (51). These species have the ability to transition morphologically to a tolerant, meristematic ecotype consisting of clumps of amorphous, thick-walled, highly melanized cells. Acreobasidium pullulans has a yeast phase that colonizes moist surfaces; i.e., it forms isodiametrically expanding cells that become subdivided in all directions and may eventually fall apart into small cell clumps.

Chromoblastomycosis

Chromoblastomycosis is one of the most frequently found subcutaneous mycoses. It occurs usually in the tropical and subtropical regions, affecting mainly adult males working in agriculture or related activities. The fact that males are predominantly affected has been related to a possible role of human sex hormones (52, 53). The fungus usually penetrates the cutaneous barrier through puncture wounds, usually by a thorn or a splinter. The fungal agents causing these infections are occasionally found on rotting plant material. Several reports have associated some of these fungi with palm trees and xerophyte plants, but recent sequencing data have proven that mostly other, strictly saprobic relatives are concerned. For example, cactus plant thorns carry Cladophialophora yegresii, while human cases are caused by C. carrionii (54). C. yegresii produces muriform cells in the spines morphologically similar to those known as the invasive form of C. carrionii in chromoblastomycosis. These cells may thus be regarded as an extremotolerant survival phase and are likely to play an essential role in the natural life cycle of these organisms (54). The ecology of the fungi causing chromoblastomycosis is clearly different. Fonsecaea species are isolated in the evergreen forests of tropical areas, whereas C. carrionii is identified only in desert areas under arid climatic conditions (55).

Sporotrichosis

Sporothrix schenckii can be found in soil and thorny plants. Infection is acquired through traumatic inoculation of fungi from contaminated soil or plants. Sporothrix brasiliensis, however, is primarily transmitted from bites or scratches from stray cats which are considered a primary host of this fungus (31). Occasional outbreaks occur in different populations, such as gardeners, rural workers, armadillo hunters, and persons in contact with domestic cats. In Brazil a large epidemic occurs due to expansion of S. brasiliensis (56). In the United States several outbreaks of sporotrichosis, associated with occupational or recreational exposure to sphagnum moss, have been reported; the largest occurred in 1988 and involved 84 patients (56). Most infections occur in otherwise healthy individuals, but Sporothrix infections have also been recognized as opportunistic in immunocompromised individuals.

Clinical Significance

Disorders caused by the fungi described in this chapter are mainly localized and occur in otherwise healthy hosts.
The infections arise mostly after traumatic inoculation of contaminated material from the environment; less frequently, e.g., in the case of sinusitis, otitis, or growth in the mucus of lungs of patients with cystic fibrosis, asymptomatic or mildly symptomatic colonization of cavities is observed. A number of the fungi treated in this chapter are typical opportunists, causing infections increasing in severity in individuals with impaired innate immunity and metabolic diseases such as diabetes. Such patients may have cutaneous infections by black yeasts that are otherwise found on cold-blooded animals (57), but the clinical course of such infections is usually mild (58). Infections also arise in patients with severe immunological disorders, such as neutropenic patients, solid-organ transplant recipients, or patients undergoing long-term corticosteroid therapy. This is particularly noted with Scedosporium species. Some species of Chaetothyriales (such as C. bantiana) are able to cause deep or disseminated infections in hosts with known immune disorder. If untreated, such infections may take a chronic, fatal course after a destructive disease process. The frequency of these infections is low, but given the potentially severe course of the disease, as well as the sometimes very high degrees of resistance to antifungal drugs, attentiveness to these fungi is mandatory. Chromoblastomycosis is a relatively frequent infection with significant morbidity in rural subtropical regions. Sporothrix (order Ophiostomatales) is the only agent of infection that increases in severity with defects of acquired cellular immunity, such as AIDS (59).

Among the specific disease entities caused by the melanized fungi are the following.

**Phaeohyphomycosis**

**Superficial**

**Botryosphaeriales**

*Neoscytalidium dimidiatum* is a common plant pathogen in the tropics and is regularly involved in syndromes very similar to dermatophytosis on skin and nails, usually leading to extensive hyperkeratosis (60).

**Capniodiales**

The halophilic species *Hortaea werneckii* can adhere to exceptionally salty human hands (46), causing a syndrome in the dead keratin layers known as tinea nigra.

**Chaetothyriales**

Some species of the order Chaetothyriales cause occasional superficial infections in humans. Recently described was *Knufia epidermidis*, which so far has almost exclusively been found on human skin (16). The species may cause asymptomatic infections, may be found in association with dermatophyte infections, or may cause mild cutaneous infections. *Cyphellophora lacomiata* and *C. pluriseptata* are occasionally isolated from human skin and nails (7), but their etiology has not unambiguously been proven. *Phialophora europaea* is fairly commonly involved in mild skin and nail infections (58), but due to its slow growth, it is frequently overlooked.

**Cutaneous and Corneal**

**Botryosphaeriales**

*Lasiodiplodia theobromae* is occasionally found to cause ocular infections following injury to the cornea (61, 62).

**Capniodiales**

Species of *Cladosporium*, especially *C. cladosporioides* and *C. oxyosphorum*, are associated with allergic disease in the indoor environment, with numerous (sub)cutaneous (63, 64) and even deep (65) infections, but there remains some doubt about their pathogenic role.

**Chaetothyriales**

*Cladophialophora emmossii*, *Cladophialophora boppii*, and *Cladophialophora saturnica* are rare agents of mild cutaneous infections (66, 67); also, several *Exophiala* species may cause skin infections with various degrees of severity (42).

**Pleosporales**

One of the main recognized clinical entities associated with Pleosporales is cutaneous infection in immunosuppressed patients caused by *Alternaria* and mainly affecting patients on long-term steroid usage, tacrolimus, or other immunosuppressive agents (68). Nearly all cases were caused by *Alternaria infectoria* (69, 70) and *A. alternata* (71, 72), the two main saprobic species of the genus (33). Infections attributed to *A. chlamydospora* (73, 74) probably concern meristematic segregants of *A. alternata*. Several cutaneous infections have been attributed to *A. tenuissima* (75), which is only doubtfully separate from *A. alternata* (33). *Exserohilum rostratum* can occasionally cause infections of the skin and cornea (36).

**Subcutaneous**

**Botryosphaeriales**

Rare cases of subcutaneous infection by *Lasiodiplodia theobromae* (76) and *Neoscytalidium dimidiatum* (77) have been reported.

**Calosporales**

Members of the order Calosporales are typical agents of subcutaneous infections. Most of the six pathogenic species of *Phaeoacremonium* cause this type of infection, *P. parasiticum* being the most common (78, 79). Human infections by *Pleurostomophora richardsiae* mostly involve subcutaneous cysts (80), occasionally with bone involvement (81). Most patients have some underlying condition such as diabetes or transplantation (82). A case of yellow-grain mycetoma was caused by *P. ochracea* (5).

**Chaetothyriales**

*Exophiala dermatitidis* is the most commonly encountered species in clinical settings, causing infections of cutaneous and subcutaneous tissues (83) in mostly immunocompromised patients. *E. oligosperma* is a common etiologic agent of subcutaneous infections in immunosuppressed, elderly, diabetic, or otherwise debilitated individuals (84, 85). *Exophiala jeanesi* is considered an agent of mycetoma (86), often in otherwise healthy individuals.

**Microascales**

Several species of *Scedosporium* are common causes of subcutaneous infections and mycetoma in temperate regions, especially in North America (87, 88), having a predilection for the joints.

**Pleosporales**

Members of the order Pleosporales (most commonly *Curvularia*, *Exserohilum*, and *Alternaria*) are able to cause subcutaneous infections, although more commonly they produce
allergic sinusitis with occasional cerebral involvement in otherwise healthy individuals (36, 41, 68, 89).

Systemic

**Botryosphaeriales**

Lasiodiplodia theobromae has been involved in a case of pneumonia (90). Neozygites dimidiatum caused deep infections in immunocompromised patients (91, 92).

**Calosphaeriales**

Phaeoacremonium parastictum is able to cause disseminated infections in debilitated patients (93).

**Chaetothyriales**

A disease entity that is largely confined to Chaetothyriales is primary cerebral infection in immunocompromised or immunocompetent individuals, i.e., cerebritis in which the first symptoms of disease are of a neurologic nature. Hyphal elements that show melanization either directly or after Fontana-Masson staining are observed in abscesses in the brain parenchyma. The portal of entry may be the lung, but frequently symptoms are confined to the brain. Five species account for most nontraumatic brain infections. Cladophialophora bantiana has caused about one-third of the cases in otherwise healthy individuals (40, 82, 94, 95). If untreated, the infections are fatal within 1 to 6 months. Exophiala dermatitidis is responsible for a striking number of fatal, neurotropic infections in young, healthy individuals, all in Asia (96). The other three species are Cladophialophora modesta, Fonsecaea monophora, and Rhinocladiella mackenziei. Rhinocladiella mackenziei is a remarkable fungus because it is exclusively known from fatal brain infections in the Middle East or from immigrants from that region (41). Several patients had no known immune disorder; the environmental niche of the species is unknown. Occasionally systemic dissemination is observed in patients with or without proven immune disorder; these infections are fatal if they go untreated. Secondary cutaneous lesions often lead to marked eruptions with high morbidity. The disorder has been observed repeatedly in Cladophialophora devriesii, C. modesta, C. arxii, Exophiala dermatitidis, and E. spinifera (41, 97, 98). The last two species have capsule-like extracellular polysaccharides around yeast cells (99) and have a high virulence in humans. The rare infections by E. spinifera can be localized, but in about one-half of the cases, fatal, disseminated mycoses are observed in adolescents (reviewed by de Hoog et al. [100]). Exophiala dermatitidis and, to a lesser extent, E. phaeomuriformis are regular pulmonary colonizers of patients with cystic fibrosis (101).

The etiologic agents in cases of phaeohyphomycosis published under the name F. pedrosi should be reconsidered, since it has been observed that the second species of the genus, F. monophora, has a more diverse clinical spectrum which includes brain infection (41). Occasionally, opportunistic infections including endocarditis and osteomyelitis caused by Phialophora verrucosa have been reported (102, 103). It is possible that some of these infections were attributable to P. americana.

**Dothideales**

Aureobasidium pullulans has been implicated as an agent of catheter-related septicemia, peritonitis, and disseminated infection (41, 104), and Hormonema dematioides has been implicated in a case of peritonitis (105).

**Microascales**

Relatively common deep and disseminated infections caused by Scedosporium are noted for immunosuppressed or otherwise debilitated patients. The reported clinical spectrum of S. apiospermum/P. boydii has changed over time, from prevalently chronic mycetoma in otherwise healthy patients between 1911 and 1980 to systemic opportunistic infection after 1980 (87, 88). Systemic infections after solid-organ transplantation are relatively frequent. Osteomyelitis and arthritis are also relatively common (87, 88). Fisher et al. (106) were the first to describe an association of S. apiospermum with a near-drowning syndrome, which characteristically leads to delayed, potentially fatal brain infection after the patient has recovered from the primary effects of aspiration of polluted water. In severely compromised patients, cerebral dissemination may take place from local foci. P. boydii shows a high incidence in cystic fibrosis patients (87, 88).

Despite its rather frequent occurrence in clinical settings, the history of Scedosporium prolificans, one of the most virulent species of Microascales, is remarkably short (41). Malloch and Salkin described the first clinical cases in 1984 (107). Since then, numerous strains have been recovered, mostly from clinical cases with major immunosuppression, and since no older reports of cases in immunocompetent patients are known, the species is a truly emerging opportunist (108–110). The species has been reported from bone and soft tissue infections (87, 88) as well as from (secondary) cutaneous infection, fungemia, and endocarditis (87). The fungus may disseminate to visceral organs in immunocompromised individuals (81). A nosocomial outbreak has been described (111).

**Venturiales**

Verruconis gallopava is also the cause of epizootic encephalitis in flocks of turkeys and chickens (86) and is able to cause pulmonary infections in immunocompetent individuals (112, 113).

**Pleosporales**

A wide spectrum of opportunistic infections has been attributed to Curvularia, including endocarditis, pulmonary infection, cerebral infection, and peritonitis (114–116). Exserohilum rostratum caused a large iatrogenic outbreak due to infection with contaminated methylprednisolone preparations leading to numerous fatal cases of meningitis and central nervous system vasculitis (117–120).

**Chromoblastomycosis**

Chromoblastomycosis occurs in otherwise healthy patients; it is characterized by chronic, cutaneous to subcutaneous lesions and frequently with marked hyperplasia. A primary lesion is represented by a papula at the site of inoculation that slowly enlarges over time, becoming a tumoral (cauliflower-like) lesion that can spread via the lymphatic system, although hematogenous dissemination has also been proposed. Lesions contain the typical and resistant spherical and mostly cruciately septate muriform (sclerotic) bodies, indicative of chromoblastomycosis.

Three fungal species of Chaetothyriales account for virtually all cases of chromoblastomycosis: Cladophialophora carrionii, Fonsecaea pedrosoi, and Phialophora verrucosa. Infections by C. carrionii mainly occur in arid climates (121, 122), probably acquired via traumatic inoculation of cactus spines (123). Occasionally Cladophialophora boppii (124) and, more recently, the new species Cladophialophora sa-moënsis have also been reported as causes of chromoblastomycosis (66). Infections by P. verrucosa mainly occur in
tropical climatic zones (125, 126). *Rhinocladiella aquaspersa* is a rare agent of chromoblastomycosis in South America (127–129).

**Sporotrichosis**

Sporotrichosis is a cutaneous to subcutaneous chronic infection that can undergo lymphatic spread. Musculoskeletal involvement and disseminated infection are relatively rare, as are the nasal and pulmonary infections that may arise from inhalation of conidia (46, 130, 131). Most infections originate from traumatic implantation of the fungus. Some disseminated cases were observed in AIDS patients (132, 133). In addition, infections have been described as being transmitted by animals (134, 135).

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

Collection, transport, and storage of specimens are described in chapter 114. Appropriate collection of specimens is essential for mycological study. There should be sufficient quantity for direct microscopic examination as well as for isolation.

**DIRECT EXAMINATION**

**Microscopy**

Melanization of vegetative cells or conidia, which results in colony coloration ranging from olive or gray to black, is caused by the deposition of dihydroxynaphthalene melanin in cell walls. This property occurs commonly among species classified in very different parts of the fungal kingdom. The amount of melanin expressed in host tissue may be very small and difficult to observe using traditional histologic stains. The use of the Fontana-Masson stain (136) (see chapter 115) for demonstrating the presence of melanin is therefore recommended as a routine to distinguish fungi with melanized hyphae from those causing “hyalohyphomycosis,” e.g., *Aspergillus*. This does not apply for *Sporothrix* and *Scedosporium*, which are not melanized but are able to produce melanized conidia either in vitro or in vivo or both. *Sporothrix* has a characteristic yeast form in tissue; the recognition of *Scedosporium* rests upon methods other than histopathology.

There are numerous procedures for treating the specimen to enhance fungal detection, including treatment with potassium hydroxide or calcifluor white and Giemsa, Wright, or Gram stain (see chapter 115). Histopathology procedures using periodic acid–Schiff (PAS), hematoxylin and eosin, or methenamine silver enhance observation. Fontana-Masson staining is useful to detect melanization in cells that appear hyaline with light microscopy. To summarize, some characteristic features include the following.

**Skin Infections**

Pigmented hyphal fragments, occasionally melanized yeast-like cells, are visible in infected skin tissue (Fig. 5).

**Sinusitis**

In sinusitis, the sinuses are occluded by amorphous fungus balls. Histologic examination reveals the presence of dense masses of pigmented, branched, and septate hyphae not invading the mucosa.

**Cerebral Infection**

In cases of cerebral infection, the hyphae are often poorly colored and scantily branched. In advanced cases, abscesses are formed (Fig. 5).

**Disseminated Infection**

Pigmented or poorly colored fungal elements such as hyphae or yeast-like cells can be observed in cases of disseminated infection (Fig. 6).

**Chromoblastomycosis**

The hallmark of chromoblastomycosis is the presence of muriform or sclerotic cells in tissue sections or wet preparations of pus, scrapings, or biopsy samples. Muriform cells are swollen, spherical, dark brown, thick-walled cells which often develop a septum and may finally become divided by intersecting septa in more than one plane (Fig. 6).

**Sporotrichosis**

In sporotrichosis, hyaline yeast-like cells are occasionally present, bearing slender daughter cells at very narrow bases. They are usually few in number and may easily be missed during microscopy, so Gomori methenamine-silver (GMS) or PAS staining is therefore recommended; Fontana-Masson staining is negative (Fig. 6).

**Antigen and Nucleic Acid Detection**

There are few data for detection of antigens or nucleic acids in human clinical samples for diagnosis of the mycoses included in this chapter. A panfungal PCR assay has been developed that targets the ITS1 region of the rDNA gene cluster for detecting fungal DNA in fresh and paraffin-embedded tissue specimens. This method was useful for the identifying species of *Scedosporium*, *Exophiala*, and *Exserohilum*. PCR products were sequenced and compared with sequences in the GenBank database (137). Linked to the recent outbreak of *Exserohilum rostratum* infections due to injections of contaminated steroids in United States, several molecular tests were developed for rapid identification of the fungus. Gade et al. developed a test based on the detection of free-circulating fungal DNA from human fluids and subsequent PCR amplification, using panfungal and *Exserohilum*-specific primers which target the ITS2 region, and sequencing. This test proved to be more specific than cultures (138). A very sensitive *Exserohilum rostratum*-specific real-time PCR for rapid detection and quantification of the fungus in cerebrospinal fluid or brain tissues of patients with meningitis has also been developed (139).

**ISOLATION PROCEDURES**

The use of nutritionally minimal media such as 2% water agar, moistened sterile wooden sticks, or moistened sterile filter paper stimulates the formation of conidia. In the case of infection due to more than one agent, the strain that grows in a more limited manner may pass unnoticed for a long period. Therefore, a loopful of cells suspended in 0.1% Tween and streaked onto a fresh culture plate is useful to select an individual colony for identification.

**IDENTIFICATION**

For the identification of most of the species included in this chapter, the classical method is to grow the fungi in culture and to examine the relevant morphological characteristics described above. This will mostly provide...
an identification at the generic level. Appropriate culture media are described in chapter 115. Slide culture preparations (36) using potato dextrose agar or cornmeal dextrose agar, to be handled only within a biological safety cabinet, are ideal for determining conidiogenesis. For morphological features of the fungi treated in this chapter, the reader is referred to the work of de Hoog et al. (2).

Molecular identification of most species is currently performed by sequencing of ribosomal genes and comparison with dedicated databases (140). Care should be taken when the GenBank database is used for the purpose of identification in less known fungal groups, because over 10% of the sequences may be incorrect (33). Sequences should be evaluated not only from a technical point of view but also nomenclaturally, i.e., by comparison with ex-type strains.

When ribosomal genes are used, the phylogenetic position of taxa can be established by sequencing the nuclear SSU (18S) or partial large subunit (26S) rRNA gene. This gene is mostly invariant between closely related species. In most fungal groups, species diagnostics is possible with ITS sequences. But application of this technique as a "gold standard" for melanized fungi is still in dispute. For some genera, such as Alternaria, the numerous species described on the basis of morphology prove to be invariant in the ITS region. In this case the question as to whether ITS shows insufficient polymorphism or whether simply too many species have been introduced remains. In contrast, ITS-based species distinction with black yeasts provides satisfactory results. For some genera, such as Sporothrix, sequencing of the calmodulin gene is necessary to gain resolution of species within the complex (30). In Scedosporium (26) and Phaeoa-cremonium (79), β-tubulin gene sequencing is used for this purpose.

**TYPING SYSTEMS**

A diversity of high-resolution molecular typing systems has been developed in recent years. These have been applied mainly to epidemiological tracking of fungal pathogens in the hospital and the community but also to show geographical differences among isolates and to detect cryptic species.

**Chaetothyriales**

On the basis of a multigene phylogeny, it has been demonstrated that important phenotypic features have evolved independently several times in the order Chaetothyriales and that most of the species of Cladophialophora belong to a monophyletic group comprising two main clades (carrionii and bantiana clades) (66).

In a study that investigated the molecular diversity of oligotrophic and neurotropic members of the genus Exophiala using ITS sequences and M-13 fingerprint and SSU intron data, two main groups could be distinguished within E. dermatitidis. The environmental strains were mainly placed in one of these groups, while the clinical strains were...
in the second one. Interestingly, strains from East Asia that clustered in the clinical group caused severe brain and disseminated infections, and strains of the same group recovered from outside East Asia caused only a relatively mild fungemia (11).

The natural niche of *Fonsecaea*, one of the most common agents causing chromoblastomycosis, remains uncertain. To elucidate where and how patients acquire the infection, probably through traumatic inoculation, numerous isolates with *Fonsecaea*-like morphology from environmental sources were typed using random amplified polymorphic DNA methodology. The results revealed a high degree of strain diversity and showed that most strains isolated from environments to which symptomatic human patients were exposed were found to be more closely related to species of *Cladophialophora* than to *Fonsecaea* (13).

**Dothideales**

Multilocus typing at four loci demonstrated the existence of at least five different sequence types in isolates of *Neoscytalidium dimidiatum*, of which two were detected exclusively in isolates from plants, two were found only in clinical isolates, and one was observed in isolates from humans and from a mango tree. This has been proposed as the possible source of infection in a case of mycetoma in an agricultural field worker and should be considered as a potential reservoir of pathogenic strains of the fungus (141).

**Microascales**

In numerous molecular studies there has been a high genetic diversity among isolates of *Scedosporium* from different origins (reviewed in reference 87). However, recent multilocus sequence analysis has shown that such variability could be explained by the existence of numerous cryptic species in the *Pseudallescheria boydii* complex (25, 26). In contrast, in *S. prolificans* genetic variation seems to be low to absent.

**Ophiostomatales**

With *Sporothrix*, as with *Scedosporium*, numerous molecular studies (reviewed in reference 30) have proven the existence
of a high level of intraspecific variability, with isolates mainly grouped according to their geographical origins. But recent multilocus studies have demonstrated that S. schenckii sensu lato comprises several phylogenetic species and morphospecies (28, 29) with a marked geographical distribution; i.e., S. brasiliensis isolates are mainly found in Brazil, and all the isolates from India tested molecularly belong to S. globosa. This likely correlates with the genetic and morphological diversity shown within S. schenckii by many authors.

**SEROLOGIC TESTS**

A latex agglutination test is commercially available (ImmunoMycologics Inc., Norman, OK) for detecting antibodies against S. schenckii, particularly in disseminated cases, but despite a study (142) reporting a sensitivity of 90 to 94% and a specificity of 95 to 100%, the test has not been used widely. However, the detection of antibodies was demonstrated to be useful in the diagnosis of central nervous system sporotrichosis in several patients when culture-based diagnosis had failed (143).

**ANTIFUNGAL SUSCEPTIBILITIES**

**In Vitro**

The available in vitro data for dematiaceous fungi are increasing every day, and in general the antifungal susceptibilities of the most clinically relevant species are known. However, interpretive breakpoints have not been defined, and clinical correlation data are practically nonexistent.

Amphotericin B generally has good in vitro activity against most clinically important dematiaceous fungi, such as *Exophiala* (144) and *Alternaria* (145). However, some species have been consistently resistant in vitro, including *Scedosporium* spp. and *Scopulariopsis brevipes* (88, 146–148). The azoles, in general, have demonstrated the most consistent in vitro activity against dematiaceous fungi (reviewed in reference 88) apart from *S. prolificans* (146).

The newer triazoles posaconazole and voriconazole have a broad spectrum of activity, being active against most of the fungi included in this chapter. The activities of these triazoles were similar against agents of chromoblastomycosis (149) and *Pseudallescheria boydii* complex (147). The activity of posaconazole is higher than that of voriconazole against *Alternaria* spp. (145), *Exophiala* spp. (144), and *Sporothrix* spp. (150), although against the last the activity of both drugs was very poor. Terbinafine showed a clear fungicidal activity in vitro against filamentous fungi. Studies of in vitro activity against dematiaceous fungi are emerging and fairly broad-spectrum activity is seen, including against *Alternaria* and *Curvularia* (41). Echinocandins appear to have variable and species-dependent fungistatic activities for the dematiaceous fungi (151). Micafungin has demonstrated some moderate activity against *Scedosporium* spp. (148). The in vitro activities of the available antifungal drugs against selected dematiaceous fungi have been reviewed recently (41).

**In Vivo in Animal Models**

Based on the small number of clinical cases produced by most of the fungi discussed in this chapter, the ideal treatment regimen against the infections that most of them produce is not yet known. Therefore, studies using different animal models have been designed to evaluate efficacy and/or corroborate the results obtained in vitro. Animal studies have demonstrated that posaconazole is generally the most effective against infections by less common moulds, including some of those included in this chapter (reviewed in reference 152).

**Chromoblastomycosis**

Recent studies using animal models of chromoblastomycosis testing athymic mice demonstrated that posaconazole showed higher efficacy than the recommended drugs, itraconazole and terbinafine, against infections by *F. pedrosoi* (153) and *Cladophialaphora carrionii* (154); voriconazole did not work against the former species.

**Scedosporiosis**

Voriconazole and posaconazole, but not amphotericin B, showed efficacy that correlated with in vitro MICs against *Scedosporium* boydii, *S. apiospermum*, and *S. aurantiacum*. No drug has shown efficacy against *Scedosporium prolificans* infections. The effects of double or triple antifungal drugs combinations were tested against *S. prolificans* murine infections, and micafungin plus voriconazole or amphotericin B was the most effective, being able to prolong mouse survival and to reduce fungal load in the kidneys and brain. The combination of all three mentioned drugs was ineffective (155). In a few clinical cases, the combination of terbinafine and voriconazole demonstrated synergy and favorable results (156–158).

**Phaeohyphomycosis**

Different animal studies have evaluated the most useful antifungal drugs for treating disseminated infections produced by some clinically relevant fungi. Against *Fonsecaea monophora* (159) and *Exophiala dermatitidis* (160) posaconazole was better than amphotericin B and itraconazole. In an experimental treatment of *Neoscytalidium dimidiatum* amphotericin B worked better than voriconazole and posaconazole (161). For the treatment of *Cladophialaphora bantiana* murine studies tested amphotericin B, micafungin, voriconazole, fluconazole, and posaconazole alone and in double and triple combinations. The only therapeutic regimen that was able to prolong animal survival for at least 10 months was the combination of three drugs (posaconazole, micafungin, and fluconysine) (162).

**Sporotrichosis**

Posaconazole showed excellent efficacy in experimental infections against the two most common species causing sporotrichosis, i.e., *S. schenckii* and *S. brasiliensis* (163).

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

More than 100 species of melanized fungi have caused infection in humans and animals, and many of these are relatively rare as etiologic agents. As a result, few clinicians are familiar with these fungi and they are frequently overlooked. Infections caused by dematiaceous fungi are being diagnosed increasingly among healthy as well as compromised patients. Concurrently, the expanding diversity of etiology within this group of fungi is becoming apparent. Determining whether a particular dematiaceous fungus is involved in a disease process can be difficult because most of these fungi are occasionally recovered as contaminants from clinical specimens. Repeated recovery of a suspected etiologic agent is significant, while DNA sequence identity of clinical material and the isolate is highly supportive. Isolation of a dematiaceous fungus from a normally sterile body site should not be dismissed as contamination, particu-
larly if colonies are numerous or more than one culture plate shows growth. If isolated from a nonsterile pulmonary specimen such as skin, sputum, or bronchial lavage fluid, well-documented opportunists from genera such as Cladophialophora, Fonsecaea, Verrucosis (Ochroconis), or Scedosporium, which are not seen as contaminants, also are highly indicative. Correlation between culture and histopathology results should also be determined.

Failure to order fungus culture when tissues are collected during surgical procedures is an increasing problem in the management of these infections, and clinicians should order fungus culture whenever warranted. In the future, direct identification of fungal genera from tissue blocks using immunohistochemistry, in situ DNA hybridization, or DNA sequencing will be a promising approach to rapid detection and identification of these agents.

Fungi Causing Eumycotic Mycetoma*

ABDALLA O. A. AHMED, G. SYBREN DE HOOG,
AND WENDY W. J. VAN DE SANDE

TAXONOMY AND DESCRIPTION OF THE AGENTS

All fungi known to cause eumycetoma probably belong to the phylum Ascomycota, although for many species no ascus-producing state is known (1). Ordinal relationships are hypothesized on the basis of ribosomal small subunit (2) and internal transcribed spacer (ITS) DNA sequences (3) (Tables 1 and 2; see also listing by order below). The etiologic agents described in this chapter are species that are isolated most commonly from human or lower-animal mycetoma.

Order Chaetothyriales

Exophiala jeanselmei

E. jeanselmei is one of the black yeasts, which belong to the ascomycete order Chaetothyriales. Members of this order are frequently involved in black grain mycetoma in the tropics (1, 4). E. jeanselmei (see Fig. 4) has been reported as an agent of eumycetoma in India (5, 6), Malaysia, Thailand (7), Argentina (8), and the United States (9, 10), but only a few cases (11, 12) have been confirmed by molecular data (13).

The related fungus Cladophialophora bantiana, a species that in humans is linked mainly with brain infections (14), was recently reported to cause mycetoma in humans (15, 16) and dogs (17, 18).

Order Diaporthales

Phaeoacremonium Species

Phaeoacremonium is the anamorph filamentous fungus of the teleomorph genus Togninia, which belongs to the order Diaporthales in the class Ascomycetes (19). Phaeoacremonium contains many species associated with plants and human infections (19). Members of the genus Phaeoacremonium are occasionally reported as agents of mycetoma. de Albornoz (20) described a case of infection caused by Phaeoacremonium inflatipes, Rowland and Farrar (21) and Hemashettar et al. (22) described cases of infection by Phaeoacremonium kraijenii, and Hood et al. (23) described a case of infection by Phaeoacremonium parasiticum. A mycetoma with yellow grains caused by Pleurostomophora ochracea was published by Mhmoud et al. (24).

Order Dothideales

Neotestudina rosatii

N. rosatii, which has been isolated from soil from tropical countries, is classified in the class Ascomycetes, order Dothideales (1, 2). Mycetoma caused by N. rosatii have been described in Australia, Cameroon, Guinea, Senegal, and Somalia (25, 26).

Order Hypocreales

Fusarium falciforme

F. falciforme is the filamentous fungus previously known as Acremonium falciforme (27). The genus Fusarium is classified in the order Hypocreales in the class Ascomycetes (see chapter 120). F. falciforme (see Fig. 5) is occasionally found as a cause of mycetoma in the United States and Argentina (28–30). It was also reported as the cause of an opportunistic mycetoma infection in a renal transplant recipient (31).

Order Microascales

Pseudallescheria/Scedosporium Species

The genus Scedosporium comprises a larger number of species than supposed originally (32–34). The most clinically significant species among Scedosporium species is Scedosporium apiospermum. Until recently, S. apiospermum has been considered the anamorph of Pseudallescheria boydii (the currently accepted anamorph is Scedosporium boydii). However, it becomes evident that they are phylogenetically different species (see chapter 124) (32, 33). Therefore, previously reported mycetoma cases attributed to S. boydii might actually have been caused by a different species.

S. boydii is associated with manure and polluted environments (35, 36) and has been known as an agent of human mycetoma since the 1920s (37). S. boydii is the most common agent of mycetoma in humans as well as lower animals in temperate climates (38), occurring mostly in the limbs (39).

Order Pleosporales

Biatriospora mackinnonii (Previously Known as Pyrenochema mackinnonii)

Molecular analysis of the rRNA genes also revealed that Pyrenochema mackinnonii is not similar to the type species

*Some of the material in this chapter was presented in chapter 123 by Abdalla O. A. Ahmed and G. Sybren de Hoog in the 10th edition of this Manual.
of *Pyrenochaeta* (formerly *Pyrenochaeta nobilis*) (40, 41). Furthermore, *Medicopsis romeroi* (formerly *Pyrenochaeta romeroi*) and *Pyrenochaeta mackinnonii* were found to be phylogenetically remote from each other. Therefore, *Pyrenochaeta mackinnonii* was assigned to the genus *Nigrograna* and renamed *Nigrograna mackinnonii* by de Gruyter et al. in 2012 (41). Later, after more extensive phylogenetic analyses, it was reassigned to *Biatriospora mackinnonii* by Ahmed et al. (S. A. Ahmed, W. W. J. van de Sande, D. A. Stevens, A. H. Fahal, and G. S. de Hoog, unpublished data) (41). *B. mackinnonii* has been reported as the causative agent of mycetoma in patients originating from Mexico and Venezuela.

**Curvularia** Species
Numerous species of *Curvularia* are known, mostly occurring in decaying vegetation. *Curvularia* is a hyphomycete dematiaceous mold, with some known teleomorphs belonging to the class *Euascomycetes* in the phylum *Ascomycota* (1). The ubiquitous saprobe *Curvularia lunata* (Fig. 1 and 2) has been described as an etiologic agent of mycetoma in humans in Senegal and Sudan (42, 43), and the common saprobe *Curvularia geniculata* has occasionally been reported as an etiologic agent of mycetoma in dogs in the United States (44).

**Falciformispora senegalensis** (Previously Known as *Leptosphaeria senegalensis*)
Based on the combined DNA sequence data set of the 18S small ribosomal subunit (SSU), the 26S large ribosomal subunit (LSU), RNA polymerase second largest subunit (RPB2), and translation elongation factor 1-alpha (*TEF1*) genes, it was demonstrated that *Leptosphaeria senegalensis* and *Leptosphaeria tompkinsii* were found to cluster in the pleosporalean order *Trematosphaeriaceae*, with *Falciformispora ligniutilus* as its closest relative. Therefore, *Leptosphaeria senegalensis* was renamed *Falciformispora senegalensis* and *Leptosphaeria tompkinsii* as *Falciformispora tompkinsii* (Ahmed et al., unpublished). *F. senegalensis* is a dematiaceous filamentous fungus with a known teleomorph belonging to the class *Euascomycetes* in the phylum *Ascomycota* (1). *F. senegalensis* and the related species *F. tompkinsii* cause mycetomas in the northern tropical portion of Africa, especially in Senegal and Mauritania, and in India (43, 46).

**Medicopsis romeroi** (Previously Known as *Pyrenochaeta romeroi*)
Based on sequences of the 18S ribosomal DNA (*rDNA*) and the 28S *rDNA*, it has become clear that *Pyrenochaeta romeroi* is distinctly related to the type species of *Pyrenochaeta* (40). Therefore, *Pyrenochaeta romeroi* was renamed *Medicopsis romeroi* by de Gruyter et al. in 2012 (41). M. romeroi is a coelomycete anamorphic fungus. *M. romeroi* might be misidentified as *T. grisea* when cultures are lacking pycnidia (1). Mycetoma caused by *M. romeroi* (Fig. 3) have been reported from Somalia, India, and South Africa (10, 25, 47). The color of the colonies and close resemblance of the granules produced by *M. romeroi* to those of *T. grisea* may suggest that the latter species could be a nonsporulating counterpart of *M. romeroi*.

**Trematosphaeria grisea** (Previously Known as *Madurella grisea*)
In 2004, it was demonstrated by molecular phylogeny and diagnostics that the members of the genus *Madurella* encompass a hidden diversity beyond the currently recognized species (2). An *rRNA* restriction fragment length polymorphism was used for species distinction by Ahmed et al. (48, 49), and a specific ITS PCR was used by Ahmed et al. (49). Based on the *rDNA* sequence, the taxonomic position of *M. grisea* was changed to the order Pleosporales, and therefore it should no longer be considered a sister species to *Madurella* mycetoma. Using the combined molecular data set of SSU, LSU, RPB2, and *TEF1*, it was demonstrated that *M. grisea* formed a well-supported clade with *Trematosphaeria pentus*. This finding was also confirmed with an ITS tree constructed for the family *Trematosphaeriaceae*. Therefore, it was suggested that the name of *M. grisea* should be changed to *Trematosphaeria grisea* (Ahmed et al., unpublished). *T. grisea* occurs as an etiologic agent of black grain mycetoma in South America, India, Africa, and North and Central America (42, 50–52). The fungus is a coelomycete, but

pycnidia (asexual fruiting bodies containing conidia) may remain absent. With strictly sterile cultures, molecular confirmation is required for identification.

Order Sordariales

Madurella mycetomatis

Madurella mycetomatis belongs to the ascomycete order Sordariales. The taxonomy of Madurella mycetomatis was determined by a number of phylogenetic studies in which the DNA sequences of the mitochondrial genome, rDNA ITS, beta-tubulin gene (BT2), and RNA polymerase II subunit gene (RPB2) have been determined (2, 53, 54). Madurella mycetomatis is the most common fungal causative agent of mycetoma. It is common in the arid climatic zone of Africa (Sudan, Mali, and Djibouti) and is occasionally encountered in the Middle East and India.

Madurella pseudomycetomatis, Madurella tropicana, and Madurella fahalii

Based on the ITS, BT2, and RPB2 sequences, it appeared that several other species previously misidentified as M. mycetomatis belong to different Madurella species. These new Madurella species include Madurella pseudomycetomatis, Madurella tropicana, and Madurella fahalii (54, 55). Of these species, M. fahalii seemed to be the most resistant to antifungal agents. Since these species can be differentiated only by molecular identification, it is not certain how many of the previous reported mycetoma cases attributed to M. mycetomatis might actually have been caused by a different species.

EPIDEMIOLOGY AND TRANSMISSION

The number of species involved in mycetoma is increasing, but little is known about the epidemiology and mode of transmission of these species. Case reports are indicative of the presence of certain species in particular geographical locations but do not provide a clear understanding of the environmental distribution of species and the possible ecological niches.

The causal agents of eumycetoma are largely saprobes that live on hard plant materials, such as various types of thorns and spines, associated with soil (56–59). Segretain and coworkers (26, 43), using specific isolation media and techniques, showed that F. senegalensis and F. tompkinsii could be recovered from about 50% of the dry thorns of Acacia trees that they examined, particularly those that had been stained by mud during the rainy season. N. rosatti was reportedly isolated from sandy ground (25), and M. mycetomatis was isolated from soil and ant hills (60, 61). It should be noted, however, that the identity of these fungi has not been verified with molecular methods; the possibility that environmental strains do not always belong to the same species as the clinical strains cannot be excluded. Using ITS sequencing, Badali et al. (4) reidentified a collection of E. jeanselmei clinical and environmental strains. E. jeanselmei identification was confirmed in all mycetoma or mycetoma-like infections, while other environmental strains were found to belong to other Exophiala species, suggesting some predilection for human invasion with particular species. Another example of possible human predilection is M. mycetomatis, which is a common agent of black grain mycetoma in the arid climate zones of East Africa. The direct isolation of this species from the environment is difficult (62), but its DNA could be found in both soil and thorns. Recently, phylogenetic findings even suggested dung as a possible new habitat for M. mycetomatis (63).

Borelli (64) isolated sterile fungus, reported as Madurella grisea (now known as Trematosphaeria grisea), from soil in Venezuela; the ecological niche and clinical potential of this rare species have not yet been determined.

However, in the case of other relatively common species, such as M. mycetomatis and Scedosporium species, phenotypic identification only is not enough to determine the exact epidemiology, since these apparently similar entities might hide great species diversity (see “Taxonomy and Description of the Agents”).

Mycetoma may infect all people living in areas of endemicity but develops more commonly among persons who are in contact with contaminated materials, such as field workers, farmers, and fishermen. There is no obvious immune defect in mycetoma patients; however, some studies showed some genetic association with some defects in immune genes in patients with mycetoma (65–67). It appeared that there were some associations with single nucleotide polymorphisms in genes involved in the functioning of the host immune system, such as those coding for complement receptor 1 (CR1), the CC chemokine ligand 5 (CCCR5), chemokines interleukin-8 (CXCL8) and interleukin-10 (IL-10), the interleukin receptor CXCR2, nitric oxide synthase NOS2, and trombospordin-4, and in genes involved in the sex hormone synthesis, such as those coding for cytochrome P450 subfamily 19 (CYP19) and catechol-O-methyltransferase (COMT) (65–67). The latter set could help explain the epidemiological finding that mycetoma is more common in males than in females.

Areas of endemicity are located in tropical climate zones particularly. M. mycetomatis is limited to semiarid to arid climates, while C. fimbriata species are found in the rainforest. Locally acquired mycetoma in temperate climates invariably are caused by S. boydii. Cases observed in the United States and Europe caused by species other than S. boydii are imported by immigrants from tropical countries. For example, de Hoog et al. (68) reported cases in the Netherlands originating from Indonesia and Suriname, and Ahmed et al. (48) reported M. mycetomatis mycetoma cases seen in France but originating in Mali.

Climate has a definite influence on the prevalence and distribution of mycetoma. Rivers that flood each year during the wet season in many countries of Africa and Asia influence the distribution of the causal agents. Rainfall also aids the spread of the etiologic agents on organic matter (69).

CLINICAL SIGNIFICANCE

A mycetoma (plural, mycetomata) (70) is a localized, chronic, noncontiguous, granulomatous infection involving cutaneous and subcutaneous tissues and eventually, in some cases, bones. Mycetoma are generally confined to either the feet or the hands but occasionally affect sites such as the back, shoulders, and buttocks. Rarely, other body sites can be involved such as scalp, eye, jaw, and oral cavity (53, 71–73). The characteristic triad of a painless subcutaneous mass, sinuses, and discharge containing grains (masses of fungal organisms) is characteristic of mycetoma; however, a similar condition (actinomycetoma) may be caused by aerobic actinomycetes bacteria.

The disease is more commonly seen in humans than in lower animals. Only a few cases of mycetoma involving such animals as cats, dogs, horses, and goats have been described in the literature (18, 42, 44, 74–76). Most cases occur in otherwise healthy patients. Cases of development of
mycetoma after an accidental implantation of the etiologic agent following surgery (77) and in a renal transplant recipient (31) have been reported.

A mycetoma develops after a traumatic injury by microbe-contaminated thorns, splinters, fish scales or fins, snake bites, insect bites, farm implements, and knives. The initial lesion is often characterized by a feeling of discomfort and pain at the point of inoculation. Weeks or months later, the subcutaneous tissue at the site of inoculation becomes indurated, abscesses develop, and fistulae may drain to the surface. As described above, mycetomata are characterized by swelling, granulomas, abscesses, and sinuses from which serosanguinous fluid containing fungal grains are discharged. Grains, which are not seen with other subcutaneous mycoses, can vary from approximately 0.2 to over 5 mm in diameter. The size, color, shape, and internal architecture of the grains vary depending on the species of the etiologic agent. Some of the host material, especially at the periphery of the grain, provides a protective barrier for the fungus against antifungal agents and humoral immune responses such as antibodies. In mycetoma due to S. boydii, subcutaneous infections frequently lack the formation of grains when the patient’s immunity is impaired (78).

A mycetoma develops slowly beneath thick fibrosclerous tissue. The subsequent phase of proliferation involves the invasion of muscles and intramuscular layers by portions of the sclerotium that break free from their parent structure. The granulomatous lesions can extend as deep as bone, where severe bone destruction, formation of small cavities, and complete remodeling may occur. Early osteolytic damage includes loss of the cortical margin and external erosion of the bone. As the infection progresses, blood, lymphatic vessels, and nerves may be damaged. Frequently, secondary bacterial infections and osteomyelitis producing total bone destruction occur. Pain in mycetoma is often associated with bone involvement and secondary bacterial infection. In mycetoma caused by S. boydii, arthritis is frequently observed, due to the predilection of this species for cartilaginous tissues (79–82).

Fungus balls in preexisting lung cavities are sometimes inappropriately called mycetomata (83, 84). In the absence of well-organized grains, they should be referred to as aspergillosas, or simply as fungus balls, depending on the etiologic agent (85). Similarly, mycelial aggregates formed by dermatophytes in cutaneous or subcutaneous tissues differ from grains of mycetoma by lacking granule ontogeny, a distinct Splendore-Höeppli reaction (see “Microscopy” below) surrounding the mycelial aggregates, and the entry of the fungus from the hair follicles into deeper tissue following the rupture of the follicular epithelium. Such infections caused by dermatophytes have been referred to as pseudomycetomata (86).

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

Methods of collection, transport, and storage of specimens are described in detail in chapter 114. Different specimens can be obtained from patients with eumycetoma, but direct examination and culture of fungi causing mycetoma always require surgical tissue biopsies and/or bone curettage. Tissue materials should be divided and submitted for both microbiology and histopathology examination. It should be noted that tissue biopsy specimens without visible grains usually result in negative cultures. The best specimen for fungal cultures is usually collected during surgery as excisional or incisional biopsy. Grains are not always present in tissue specimens obtained by a cutaneous biopsy procedure with local anesthesia. However, incisional biopsy specimens obtained under local anesthesia, when containing grains, can also result in positive cultures. Grains collected with cotton swabs from the sinus tracts are not recommended, because such grains can be contaminated or dead.

Several grains are usually needed for direct examination and culture, and therefore, as much tissue as possible should be obtained. Tissue should be collected in sterile, dry, leak-proof containers and transported to the laboratory as soon as possible at room temperature. If transport is delayed for more than 2 h, specimens can be refrigerated. Small biopsy samples can be covered with 2 to 3 ml of sterile saline to prevent drying during transportation to the laboratory.

**DIRECT EXAMINATION**

**Microscopy**

The grains of eumycetomata are composed of septate mycelial filaments at least 2 to 5 μm in diameter. The mycelium may be distorted and unusual in form and size, and the cell walls of the fungi, especially toward the periphery of the grains, are thickened. Vesicles are frequently present, especially at the periphery of the grain. The mycelium of the grains may be embedded in a cementlike substance, depending on the species involved. Wethered et al. (87) described the cement surrounding grains of M. mycetomatis as being an amorphous, electron-dense material with areas containing different-sized membrane-bound vesicular inclusions. Recently, Ibrahim et al. studied the composition of M. mycetomatis grains, which were found to contain melanin, heavy metals, proteins, and lipids (88). It was suggested that the elements composing the grains in mycetoma may play a role in pathogenicity and resistance to antifungal agents (88, 89). Often, the sclerota elicit an immune response, known as the Splendore-Höeppli reaction (70, 86), seen histologically in the form of an eosinophilic deposit of amorphous material around the grain. A similar tissue reaction in experimental eumycetoma in mice has been described (90).

Grains are white or yellow-brown (“white grain mycetoma”) when the agent is producing mostly hyaline mycelia, and they are black (“black grain mycetoma”) in the case of melanized fungi. A single proven yellow-grain fungal mycetoma has been reported thus far, but earlier cases may have been incorrectly diagnosed as bacterial mycetoma (24). Melanin is a high-molecular-weight compound that is anchored to extracellular proteins. A precursor for production of melanin in ascomycetous fungi is 1,8-dihydroxynaphthalene (DHN-melanin) (70, 91). In Madurella mycetomatis, melanin was shown to be produced through the DHN pathway and offers the fungus protection against strong oxidants and antifungal drugs (89). Reports of hyaline fungi such as Sarocladium kiliense (formerly Acremonium kiliense) and Fusarium solani var. coeruleum forming black grains (92) are probably erroneous. Etiologic agents with melanized hyphae or conidia such as P. inflatipes and S. boydii produce whitish grains in tissue (8, 20, 59, 93). Melanin production in Phaeoacremonium species is facultative, while in S. boydii dark pigmentation is limited to the conidia.

**Curvularia geniculata**

C. geniculata grains are black to dark brown, firm, and 0.5 to 1.0 mm or more in size. In tissue sections, grains are spherical, ovoid, or irregularly shaped and are often surrounded by a zone of epithelioid cells. The periphery of the
grain is a dense, interwoven mass of dematiaceous mycelium and thick-walled, chlamydosporelike cells embedded in a cementlike substance. The interior of the grains is vacuolar and consists of a loose network of septate, hyphal filaments.

Curvularia lunata
The grains of C. lunata resemble those of C. geniculata in their morphologic characteristics.

Falciformispora Species
The grains of the two Falciformispora species that cause mycetoma are indistinguishable from each other. They are black, 0.5 to 2 mm in size, and firm to hard. In tissue sections, the grains are round to polylobulated, with large vesicles. At the periphery, the mycelium is embedded in a black, cementlike substance. The central portion of each grain consists of a loose network of hyphae.

T. grisea
Grains of T. grisea are black, 0.3 to 0.6 mm in diameter, and soft to firm. In tissue sections, the grains are oval, lobulated, or reniform (kidney shaped), and sometimes vermiform (worm shaped). They are composed of a dense network of hyphae weakly pigmented in the center and brown to blackish brown in the peripheral region as the result of the presence of a brown, cementlike interstitial material.

M. romeroi
M. romeroi produces soft to firm black sclerotia that are oval, lobulated, sometimes vermiform, and about 1.0 mm in diameter. They resemble those of T. grisea (94).

E. jeanselmei
In host tissue, E. jeanselmei produces dark sclerotia that are brown to black, irregular in shape, and fragile. Detached portions or fragments of the sclerotia often are found within giant cells. When extruded through fistulae, the grains often look like worms (vermiform) because of their elongated shapes and irregular surfaces. In tissue sections, grains appear as hollow structures or as sinuous bands that are vermiform. The external surface is composed of brown, thick-walled hyphae and thick-walled chlamydosporelike cells. The grains are cement free. Within the hollow grains, smaller, degenerated hyphal fragments with leukocytes and giant cells may be seen.

M. mycetomatis
The grains produced by M. mycetomatis are reddish brown to black. They may reach 5 mm or more in diameter and are firm to hard. In tissue sections, the sclerotia are compact, variable in size and shape, and frequently multitubulated. They are composed of hyphae 1.2 to 5 μm in diameter that terminate in enlarged hyphal cells at the periphery of the grains, which measure 12 to 15 μm in diameter. The cell wall pigment is minimal, but hyphal cells contain brown particles. The hyphae are embedded in a conspicuous brown matrix that is characteristic of M. mycetomatis. Some grains are vesicular and more regular in size and shape. The vesicles are predominantly visible in the peripheral zone in a dense, brown, cementlike matrix.

N. rosatii
The sclerotia of N. rosatii are white to brownish white, 0.5 to 1.0 mm in diameter, and soft. In tissue sections, the sclerotia appear to be polyhedral to subregular and consist of hyphae that are embedded in the peripheral cementing material. The sclerotia demonstrate an eosinophilic border. The central portion of each sclerotium consists of more or less disintegrated mycelium and chlamydospores.

Phaeoacremonium Species
Although Phaeoacremonium is a dematiaceous fungus and the well-known agent of phaeohyphomycosis, it seems that melanin production is facultative in eumycetoma. White grain mycetoma caused by P. kraijdenii has been reported by Hemashettar et al. (22).

F. falciforme
The grains of F. falciforme are white to pale yellow, soft, and 0.2 to 0.5 mm in diameter. They are composed of slender, polymorphic, septate hyphae 1.5 to 2.0 μm in diameter with irregular bulbous swellings and peripheral cementing material.

Pseudallescheria/Scedosporium
Grains of Pseudallescheria/Scedosporium species in tissue are white to yellowish white and soft to firm; they vary from globose to subglobose or lobulated and are 0.2 to 2.0 mm in diameter. They are composed of hyaline hyphae 1.5 to 5.0 μm in diameter that radiate from the center into terminal thick-walled cells 15 to 20 μm in diameter at the peripheries. The central portion of each grain consists of loosely interwoven hyaline mycelium.

Antigen Detection
Serological techniques are important noninvasive, non-culture-based tools for diagnosis of infectious diseases. Since obtaining a pure culture of fungi that cause mycetoma is not always easy, the availability of good antigen or antibody tests (see “Serologic Tests”) would be helpful in the diagnosis and follow-up of patients under treatment. Unfortunately, there are no commercially available antigen tests for these agents.

Nucleic Acid Detection Techniques
Molecular diagnostics have been developed for selected agents. However, most of these molecular assays have been used for culture identification (see below) and have not been validated for direct detection from clinical specimens. PCR-based assays for rapid diagnosis of Scedosporium apiospermum infections from infected tissue are useful (95, 96). Willinger et al. (97) used molecular techniques for detection of S. apiospermum and similar organisms from fungus balls in the maxillary sinus. A multiplex PCR for direct detection of Scedosporium species in respiratory specimens has also been developed (98).

ISOLATION PROCEDURES
To maximize the chances of obtaining pure cultures of the etiologic agents, grains from the eumycotic mycetoma should be washed several times with saline containing antibacterial antibiotics such as penicillin and streptomycin. The grains are then cultured on Sabouraud dextrose agar (SDA) containing chloramphenicol (50 mg/liter) and SDA containing chloramphenicol and cycloheximide (500 mg/liter) in petri dishes. Plates should be incubated at 25 and 37°C. Because many of the fungi that cause mycetoma grow slowly, culture plates should be incubated for 4 weeks before being discarded as negative. Identification of the isolated fungus is based on gross morphology of fruit bodies and conidia, if present.
IDENTIFICATION

Morphological Identification

The mycological identification of most fungi causing mycetoma can be achieved by studying the morphological characteristics described below. For additional morphological features and simplified identification keys, readers are referred to specialized references such as the Atlas of Clinical Fungi (1).

C. geniculata
In culture, C. geniculata develops a rapidly growing, floccose to downy, olive gray to black colony. Microscopically, the melanized, septate hyphae bear solitary, geniculate (bent like a knee) conidiogenous cells. The conidia are without protruding hila. They are smooth walled, predominantly five celled, curved, with the swollen median cell pale to dark brown, in contrast to the lighter end cells.

Falciformispora Species
In culture, F. senegalensis and F. tompkinsii grow rapidly and produce gray-brown colonies. On cornmeal agar, both species produce ascosporastoma that are nonostiolate (without a natural opening), scattered, immersed or superficial, globose to subglobose, black, and covered with brown, smoothly bent hyphae. The asci, produced after prolonged incubation on plant stems, are eight spored, clavate to cylindrical, and double walled. The major difference between the two species is found in the ascospores, which differ in size, shape, septation, and the nature of the gelatinous sheath that surrounds them (46, 99).

T. grisea
In culture, T. grisea forms slow-growing, velvety colonies that are cerebriform, radially furrowed or smooth, and dark gray to olive brown to black. The reverses of the colonies are black. Microscopically, the hyphae are septate, light to dark brown, 1 to 3 μm in diameter, and nonsporulating. Chlamydospores are rare. Large moniliiform hyphae, 3 to 5 μm in diameter, are often present. Some isolates of T. grisea have been described as producing abortive or fertile pycnidia (94, 100). Such isolates are morphologically indistinguishable from B. mackinnonii (101, 102), but rRNA ITS sequence data (2) show large differences between these species.

M. romeroi
In culture, colonies of M. romeroi are fast growing and floccose to velvety, with a gray surface and whitish margin. The reverse of the colony is black, with no diffusible pigment. On nutritionally deficient media such as oatmeal agar incubated at 30°C, most of the ascomata are submerged. The ascosporastoma walls are smooth and are surrounded by interwoven brown to hyaline hyphae. The eight-spored asci, 12 to 35 by 10 to 25 μm, are scattered in the central part of the ascospora (Fig. 7) and are globose to subglobose, thick walled, and bitunicate, becoming evanescent as the ascospores mature. The ascospores vary in size (9 to 12.5 by 4.5 to 8.0 μm) and shape, ranging from ellipsoidal to rhomboidal, asymmetrical, or slightly curved; they are constricted at the median transverse septum and have brown smooth walls.

E. jeanselmei
Initially, the colonies of E. jeanselmei may be yeastlike and black, gradually spreading, becoming raised or dome shaped, with limited expansion growth. After 2 weeks on SDA, the colonies are covered with short aerial hyphae and appear olive gray with an olive black reverse. Microscopically, annellidic, rocket-shaped conidiogenous cells are inserted at right angles on undifferentiated hyphae. The septate mycelium is sometimes toruloid, branched, and pale brown. The conidia, which aggregate in masses at the tips of annelides, tend to slide down the conidiophore or along the hyphae. The smooth conidia are exogenous, nonseptate, subsphe- rical, and ellipsoidal to cylindrical, measuring 1.5 to 2.8 μm.

M. mycetomatis
In culture, M. mycetomatis shows wide variation. Colonies are slow growing and white at first, becoming olivaceous, yellow, or brown; they are flat or dome shaped and velvety to glabrous, often with a rust brown diffusible pigment. On nutritionally deficient media, sclerotial bodies 750 μm in diameter develop. These are black and consist of undifferentiated polygonal cells. On SDA, the mycelium is sterile. On nutritionally poor media, such as soil extract or hay infusion agar, about 50% of the isolates produce round to pyriform conidia 3 to 4 μm in diameter at the tips of phialides. The phialides are tapering, ranging from 3 to 15 μm in length, often with an inconspicuous collarette (Fig. 6).

N. rosatii
In culture, colonies of N. rosatii are slow growing, attaining diameters of 25 to 28 mm in 2 weeks, and have an aerial mycelium that is grayish black to brownish black. On potato-carrot or cornmeal agar incubated at 30°C, most of the ascomata are submersed. The ascosporastoma walls are smooth and are surrounded by interwoven brown to hyaline hyphae. The eight-spored asci, 12 to 35 by 10 to 25 μm, are scattered in the central part of the ascospora (Fig. 7) and are globose to subglobose, thick walled, and bitunicate, becoming evanescent as the ascospores mature. The ascospores vary in size (9 to 12.5 by 4.5 to 8.0 μm) and shape, ranging from ellipsoidal to rhomboidal, asymmetrical, or slightly curved; they are constricted at the median transverse septum and have brown smooth walls.

Phaeoacremonium Species
Members of the genus Phaeoacremonium are morphologically characterized by slender, gradually tapering, melanized conidiophores with narrow phialide openings producing ellipsoidal to reniform conidia.

F. falciforme
Colonies of F. falciforme on SDA are slow growing, reaching 60 to 65 mm in diameter in 2 weeks. They are downy and gray-brown, becoming gray-violet. The reverse of the colony develops a violet-purple pigment. The hyphae are hyaline, septate, smooth, branched, and 1.5 to 2.5 μm in diameter. They bear erect, undifferentiated, unbranched, repeatedly septate conidiophores. The conidia are borne at the tip of
Pseudallescheria/Scedosporium

Pseudallescheria/Scedosporium colonies grow rapidly and are floccose and white at first, becoming gray as conidia are produced. With age, the colonies become dark grayish brown. Submerged ascocarps (cleistothecia) (Fig. 8) may be produced when isolates are grown on cornmeal agar and are visible macroscopically as small black dots. They are globose, nonostiolate, 140 to 200 μm in diameter, and often covered with brown, thick-walled, septate hyphae 2 to 3 μm wide. They have a wall 4 to 6 μm thick that is composed of two or three layers of interwoven, flattened, dark brown cells, each 2 to 6 μm wide. The cleistothecia open at maturity by an irregular rupture of the wall. The eight-spored asci are ellipsoidal to nearly spherical and 12 to 18 by 9 to 13 μm. The ascospores are ellipsoidal to oblate, symmetrical or slightly flattened, measure 6 to 7 by 3.5 to 4.0 μm, are straw colored, and have two germ pores.

The anamorph Scedosporium boydii (Fig. 9) produces co- nidia that are oval to clavate, truncate, and subhyaline, becoming pale gray to pale brown in mass. Conidia are produced singly. They remain attached at the tips of annellides. Annellations can be detected at the tips of conidiogenous cells as swollen rings. Some isolates also produce a Graphium synanamorph of S. boydii (Fig. 10), which is characterized by ropelike bundles of hyphae with annellidic conidiogenesis. The hyphae are fused into long stalks known as synnemata. The conidia produced are hyaline, cylindric to clavate, and truncate at the base. A fungus consisting of elongate, multicellular conidia and described as Polycyrtella hominis (103) was recently proven to be a degenerate anamorph of S. boydii (104).

Molecular Identification

Certain species (T. grisea, M. mycetomatis, N. rosatii, B. mackinnonii, and M. romeroi) do not sporulate readily but...
can be recognized by molecular techniques (49, 105). Borneman and coworkers developed a rapid protocol for identifying agents of black grain mycetoma by sequence data of the rRNA ITS region (106). The black yeast *E. jeanselmei* (4), *M. mycetomatis* (48), *C. lunata*, *M. romeroi*, *B. mackinnonii* (107), and agents of the genus *Phaeoacremonium* can be identified by using the same marker (107), and agents of the genus *Phaeoacremonium* can be recognized by molecular techniques (49, 105). Boversee et al. (109) also developed specific primers based on rRNA ITS sequences for the identification of *Psuedallescheria* and *Scedosporium* species. Given the large intra- and interspecific variability of the species, a less variable region, such as the 26S rRNA operon (109), might also provide successful detection of *A. apispermum*-like genotypes. Recently, Lu et al. developed and evaluated three molecular methods targeting partial beta-tubulin gene for the identification of *S. apiospermum* and *Psuedallescheria* (111, 112).

## TYPING SYSTEMS

Over the years, many molecular typing techniques have been established for a number of fungal species, including those causing mycetoma. Such techniques are useful not only in genotyping but also in accurate species identification (49). Genotyping enables differentiation of environmental and clinical isolates, and therefore it is an important tool in understanding the environmental distribution of species and source of infection. Harun et al. (113) provided a comprehensive review of the methods used in the genotyping of *Scedosporium* and *Psuedallescheria* (111, 112).

## SEROLOGIC TESTS

Currently, there are no commercially available assays for antibody detection of these agents, but some in-house-developed antibody detection tests have been used in some areas of endemicity. The clinical value of these tests is hampered by a lack of standardized antigen preparation, sensitivity, and specificity. The most widely used assays for antibody detection in the area of endemicity are immunodiffusion and counter-immunoelectrophoresis (CIE) using crude antigens prepared from fungal hyphae (118). Using immunodiffusion and CIE, it was possible to differentiate patients with eumycetoma due to *M. mycetomatis* from patients with actinomycetoma, but negative results in confirmed cases were frequent (118–120). Next to immunodiffusion and CIE, several enzyme-linked immunosorbent assays (ELISAs)

have been developed. The antigens used were either whole fungus cytoplasmatic extracts or recombinant proteins such as the *M. mycetomatis* translationally controlled tumor protein, fructose bisphosphate aldolase or pyruvate kinase (102, 121–123). For most of the ELISAs, no clear distinction between patients and healthy controls could be demonstrated (121–123). Furthermore, sera from patients infected with *M. mycetomatis* also cross-reacted with antigens prepared from *S. boydii* (123). Only the ELISA developed by Wethered et al. in 1988 for *M. mycetomatis* cytoplasmatic antigens could clearly differentiate between patients and healthy controls based on IgM antibody responses, but when this ELISA was repeated by Zaini et al., no differentiation between patients and healthy controls was obtained (123, 124).

## ANTIMICROBIAL SUSCEPTIBILITIES

Limited antifungal susceptibility data are available for most fungi causing eumycotic mycetoma. However, for some species such as *M. mycetomatis*, *S. boydii*, and *E. jeanselmei*, a reasonable number of strains have been tested. With the exception of *S. boydii* and *Fusarium* species, most fungi causing eumycotic mycetoma are susceptible in vitro to ketoconazole, itraconazole, voriconazole, and posaconazole. However, it should be noted that in vitro activities and clinical responses to these agents are variable (4, 125–130). Ketoconazole and itraconazole are the most common agents used for the treatment of mycetoma, but their clinical response is poor (125, 126, 131, 132). The newer triazoles, such as voriconazole and posaconazole, have the highest in vitro and in vivo efficacy (126); however, treatment failure has also been reported, especially with voriconazole (130). As shown in Table 3, most of the mycetoma-causative agents have relatively high MICs for amphotericin B, fluconazole, terbinafine, flucytosine, caspofungin, anidulafungin, and micafungin. In contrast, most species have relatively lower MICs for the azoles, with the lowest MICs for all species for posaconazole. However, it should be noted that antifungal susceptibilities of different azoles vary among different causative agents (Table 3), which makes species identification essential for the proper selection of an antifungal agent.

Only limited patient-based studies have been performed to determine the outcome of antifungal treatment, and studies comparing different antifungal agents with clinical outcome are missing. Nevertheless, as a summary of the few available studies, we can draw some conclusions. In the case of *M. mycetomatis* mycetoma, treatment with ketoconazole resulted in the cure of only 5 of 13 patients (131), while treatment with itraconazole resulted in the cure of only 1 of 13 patients (132). Although the cure rates were not promising, all patients receiving regular treatments were partially improved or had stable lesions. However, with the newer azoles, such as posaconazole, a better outcome has been achieved (133). Negroni and his group treated 6 mycetoma patients with posaconazole and were able to cure 4 patients, and the two other patients were either clinically improved or had stable mycetoma lesions (133). The only nonazole drug that was evaluated clinically for treatment of mycetoma is terbinafine. In the study of N’diaye et al., 20 patients were treated with terbinafine, of which 4 were cured, 12 showed clinical improvement, and 4 showed no effect (134). Based on these limited observations and the in vitro data summarized in Table 3, posaconazole seems to be a promising choice for the treatment of mycetoma, but properly designed clinical trials are needed to confirm this assumption.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Because agents of eumycotic mycetoma are soil or plant saprobes, their etiologic role in mycetoma must be carefully established. A definitive diagnosis is based on the demonstration of grains in tissue, which are expelled through draining sinuses. Grains may become entangled on gauze bandages placed over fistulae. Fus, exudate, or biopsy material should be examined for the presence of grains that are detectable with the naked eye. Their color, internal architecture, size, and shape give a fair indication of the identity of the possible etiologic agents.

Actinomycotic mycetomata are differentiated from eumycotic mycetomata by the examination of crushed, Gram-stained grains. Actinomycotic grains, as well as coccoid and bacilliform forms, are composed of Gram-positive, interwoven, thin filaments, 0.5 to 1.0 μm in diameter. Grains of the eumycotic agents, on the other hand, are composed of broader, interwoven, septate hyphae, 2 to 5 μm in diameter, with many unusually shaped, swollen cells up to 15 μm in diameter, especially at the periphery of the grains. In many species, the grains are embedded in cementlike material.

Although the gross and microscopic characteristics of the grains provide insight into the identity of the etiologic agent or a particular group to which it belongs (135), definitive identification of the etiologic agent should be based on isolation of the same fungus from several grains. Clinical microbiology laboratories should avoid reporting patients’ specimens as “black grain mycetoma” or “black grain mycetoma,” and isolation and identification of species involved should be attempted. Careful evaluation of culture results is important, especially when new or uncommon fast-growing species are reported, since some of these species might represent contamination during collection of specimens or isolation. On the other hand, physicians should avoid planning a patient’s therapy based on grain morphology in clinical materials alone; rather, results of laboratory diagnosis with species identification should be awaited.

Mycotoxins

KURT THROCKMORTON, NANCY C. ISHAM, MAHMOUD A. GHANNOUM, AND NANCY KELLER

Mycotoxins are secondary metabolites produced by many different species of ubiquitous fungi having adverse effects on humans and animals. Secondary metabolites, also referred to as natural products, are not required for growth under laboratory conditions but afford protective roles for the producing fungi. These roles range from protection from predators to exclusion of other microbes for niche securement (1, 2). Accordingly, many secondary metabolites are bioactive and cause damage when ingested by humans and animals. Not all toxic compounds produced by fungi are referred to as mycotoxins; for example, yeast and mushroom poisons are excluded by convention, compounds inhibitory mainly to bacteria are termed antibiotics, and those toxic to plants are called phytotoxins, although there can be overlap in toxicity to several kingdoms (3). In this chapter, we review the most common mycotoxins and their relevance to sick building syndrome (SBS), bioterrorism, and food safety. We do not describe the impacts of mycotoxins on health, health costs, or the economy, as these topics have been reviewed extensively elsewhere (4–7). The reader is referred to other recent reviews on mycotoxins (3, 8).

CHEMICAL CLASSIFICATION AND BIOSYNTHESIS OF MYCOTOXINS

The vast majority of mycotoxins, and indeed all fungal secondary metabolites, arise from a few well-known chemical precursors. Polyketides, like fatty acids, are synthesized from acyl coenzyme A (acyl-CoA), nonribosomal peptides from amino acids, alkaloids from prenylated aromatic amino acids, and terpenes from isoprene. Figure 1 provides a list of some of the most commonly encountered mycotoxins, their chemical class and structure, and the fungi that produce them.

The structure and in some cases the biochemistry of the most common mycotoxins were elucidated earlier than the genetics. However, within the last decade, the genes encoding the enzymes required to synthesize many common mycotoxins have been found (8). The first mycotoxin gene clusters to be characterized were the aflatoxin cluster in both Aspergillus flavus and Aspergillus parasiticus (9, 10) and the sterigmatocystin cluster in Aspergillus nidulans (11). The finding that the genes were clustered in a single genetic locus has turned out to be a hallmark of fungal secondary metabolites (12). The molecular genetics of fungal secondary metabolite clusters has been the subject of many recent reviews (13).

Aflatoxins

The aflatoxin class of mycotoxins was the first to be discovered and studied. Some of the most common aflatoxins (Fig. 1) are aflatoxins B1, B2, G1, and G2, named for their blue or green fluorescence under UV light (14), with aflatoxin B1 being the most potent natural carcinogen known (15). There have been several recent reviews of aflatoxins and the fungi producing them (16).

Aflatoxins are produced by several species of Aspergillus, in particular, A. flavus and A. parasiticus. A. flavus is the most common contaminant of agricultural products, including cereals, rice, figs, nuts, and tobacco (17, 18). Contamination of crops can occur in the fields before harvest, especially in times of drought (18, 19), or during storage, depending upon the moisture content of the substrate and the humidity of the storage conditions (17, 20). Aflatoxin contamination can be the cause of a variety of economic and health problems and is particularly problematic in developing countries (21). For instance, the presence of aflatoxin in grain significantly lowers the grain’s value, as feed or an export commodity, because of the toxin’s link to increased mortality in farm animals (22). Further, ingestion of aflatoxin by dairy cows can lead to the presence of aflatoxin M1, a hydroxylated form of B1, in their milk (23).

There are substantial differences in the susceptibilities of vertebrate species to aflatoxin exposure. One of the first indications of the effects of aflatoxins was observed in 1960, when more than 100,000 turkey poults died from aflatoxin-contaminated feed, an outbreak named “turkey X disease” (24). Other outbreaks have occurred in ducklings and chickens (25), swine (26), and calves (27), due mostly to contaminated Brazilian peanut meal used as feed. The most recent notable outbreak of acute aflatoxicosis in humans was in Kenya in 2004 (28), followed by lesser yet significant outbreaks in 2005 and 2006 (29). These outbreaks illustrate the need for monitoring and regulation of the amount of mycotoxins in foods meant for human consumption, a luxury not normally available to developing countries. Aflatoxin contamination of pet food, particularly dog food, is a recurring problem in the United States and other countries (30).

This chapter contains information presented by Nancy C. Isham, William J. Halsall, and Mahmoud A. Ghannoum in chapter 124 of the 10th edition of this Manual.
Citrinin

Citrinin (Fig. 1) is a simple, low-molecular-weight compound that crystallizes as lemon-colored needles. It was tested as an antibiotic and a treatment for ulcers (31) before the discovery of its mycotoxic effects. The most common organisms producing citrinin are the *Penicillium* species *P. citrinum*, *P. expansum*, *P. aurantiogriseum*, and *P. camemberti* (used to produce cheese), *Aspergillus neonitves* and *Aspergillus oryzae* (used to produce sake and soy sauce), *Aspergillus terreus*, and *Monascus* spp., used to produce red food dyes (32).

Citrinin, first isolated from *P. citrinum*, has been associated with Japanese yellow rice disease (33). It has also been found in various grains, peanuts, and fruits, and there is limited evidence of its surviving unchanged in cereal products (3). Citrinin has demonstrated nephrotoxic effects on all animal species tested (34) and was shown to inhibit dehydrogenase activity in rats' kidneys, liver, and brain (35). However, there have been no reported outbreaks of human citrinin poisoning, and its relevance to human health is unknown.

Cyclopiazonic Acid

Cyclopiazonic acid (CPA) (Fig. 1) is an indole-tetramic acid mycotoxin produced by several species of *Penicillium* and *Aspergillus* (36, 37). It has demonstrated severe toxicity on all species tested, including rats (38), chickens (39), dogs (40), and pigs (41). Contamination of various food products, including grains, meats, and cheese, with CPA is sometimes coincident with aflatoxin contamination (42). As such, it is suspected that some of the symptoms of turkey X disease may have been due to the toxicity of cocontaminant CPA (43).

Interestingly, the CPA gene cluster is present in *A. flavus* but truncated in its close relative *A. oryzae* (44); this is reminiscent of repeated findings of truncated or mutated aflatoxin clusters in this species (45). *A. oryzae*, a species used in the manufacture of fermented rice products, does not produce CPA due to a deletion in the backbone gene of the cluster; or, in some *A. oryzae* strains where the backbone gene is present, CPA is converted to a less toxic compound, 2-oxoCPA, by an enzyme not present in *A. flavus* (46). Little is known about its toxicity to humans, but it may affect the heart (47) and liver and is thought to cause "kodo poisoning" (48).
Ergot Alkaloids

Ergot alkaloids, produced by the ergot fungus Claviceps purpurea, are the causative agent of ergotism, or St. Anthony’s fire, which can manifest either as a gangrenous or convulsive condition following ingestion of contaminated grains, especially rye (49). Two main classes of ergot alkaloids exist: lysergic acid derivatives and clavines. Both are indole alkaloids derived from tetracyclic ergoline. Lysergic acid, common to all ergot alkaloids, often forms amide, amino acid, or peptide derivatives, e.g., ergine, ergonovine, lysergic acid diethylamide (LSD), and ergovaline. The clavines contain the ergoline structure but do not have amino acid or peptide components, e.g., pergolide and lisuride (49). Semisynthetic ergot alkaloids have been investigated for their anticancer potential (51) and their effect on serotonin (51). By 2002, there were 28 known fumonisins found in grain, including barley, oats, rye, and wheat. DON can also suppress bovine and porcine neutrophil function in vitro (77). Stachybotrys chartarum produces several trichothece, including verrucarsins B and J, roridin E, satratoxins F, G, and H, and isosatratoxins F, G, and H (78, 79). Stachybotrys-contaminated straw was first described as causing a highly fatal equine disease (80) and has since become better known as a factor in SBS, discussed below.

Fumonisins

Fumonisins (Fig. 1) are among the most recently discovered mycotoxins. In the late 1970s and early 1980s, it was determined that fumonisins produced by Gibberella fujikuroi were the cause of leukoencephalomalacia in horses (56) and hepatocarcinoma in rats (57). By 2002, there were 28 known fumonisins analogs, separated into groups A, B, C, and P (58). Fusarium proliferatum, Gibberella nivagamae, Aspergillus niger, and Alternaria alternata also produce these mycotoxins (59, 60). Besides the syndromes mentioned above, fumonisins have been shown to cause pulmonary edema and hydrothorax in swine (61). G. fujikuroi, the major producer of fumonisins, can have an important effect on the supply of corn, as it causes a variety of blights and rots depending on environmental conditions (62). There is considerable concern and evidence that fumonisins cause several human diseases, particularly esophageal cancer (63). Likely due to these concerns, international monitoring systems are now in place for its antibiotic effects (72). However, patulin was reclassified as a mycotoxin in the 1960s following discovery of its toxic effect to humans (52, 53). A representative compound, ergotone, is shown in Fig. 1.

Aspergillus, Balansia, Claviceps, Epichloë, and Neotyphodium spp. have been found to produce ergot alkaloids. A. fumigatus has been shown to produce fumigacinines A, B, and C and fucatlavine, first described for C. purpurea and later for Neotyphodium (54). Modern methods of cleaning grains have all but eliminated the threat to the human food chain. However, ergotism remains an important veterinary concern, as symptoms of gastrenteritis, convulsions, and abortion in cattle, sheep, pigs, and chickens mimic those in humans (55).

Ochratoxins

Ochratoxins A and B (Fig. 1) are produced by Penicillium verrucosum and Aspergillus spp., especially A. ochraceus. These toxins can be carcinogenic, immunosuppressive, and nephrotoxic (22, 66). Ochratoxin A, first discovered to be toxic to animals in 1965 (67), is more common than ochratoxin B and can be metabolized by cytochrome P450 in the liver (68). Ochratoxins are most often found contaminating barley but may be present in oats, rye, wheat, and coffee beans (3, 67). They are of particular concern because they can be carried through the food chain, especially in milk and pork (69). Scandinavian countries, particularly Denmark, have had high incidence of porcine nephropathy and high levels of ochratoxin A contamination (70). Some studies speculate that ochratoxin A may contribute to Parkinson’s disease (71).

Patulin

Patulin (Fig. 1) was first isolated in the 1940s from Penicillium griseofulvum, and efforts were made to mass-produce it for its antibiotic effects (72). However, patulin was reclassified as a mycotoxin in the 1960s following discovery of its toxicity to plants and animals (3). Patulin occurs commonly in unfermented fruit made from P. expansum-contaminated fruit (73). Though toxic at high concentrations in vitro, natural patulin poisoning in humans has yet to be proven (3). Nevertheless, due to concern of its prevalence in apple juice and other items preferentially consumed by children, several countries limit patulin levels in certain foods and beverages (74). The reader is referred to a recent review on the biosynthesis and toxicity of patulin (75).

Trichothece

Trichothece mycotoxins are secondary metabolites of a variety of Fusarium, Myrothecium, Phomopsis, Stachybotrys, Trichoderma, and Trichothecium spp., among others. Some of the most common and well-studied Fusarium trichothecenes (Fig. 1) are T-2 toxin, HT-2 toxin, diacetoxyscirpenol, nivalenol, and deoxynivalenol, also called DON or vomitoxin. DON is one of the most common mycotoxins found in grain, including barley, oats, rye, and wheat. When ingested in large quantities by livestock, it can cause nausea, vomiting, and diarrhea. Ingestion of smaller quantities results in weight loss and feed refusal (76). DON can also suppress bovine and porcine neutrophil function in vitro (77). Stachybotrys chartarum produces several trichothece, including verrucarsins B and J, roridin E, satratoxins F, G, and H, and isosatratoxins F, G, and H (78, 79). Stachybotrys-contaminated straw was first described as causing a highly fatal equine disease (80) and has since become better known as a factor in SBS, discussed below.

Zearalenone

Zearalenone (Fig. 1) is a nonsteroidal estrogen or phytoestrogen produced by various species of Gibberella, including G. pulicaris and G. tricincta (81). Zearalenone is a common contaminant of cereal crops worldwide and has been implicated in hyperestrogenism of farm animals as a result of digestion of moldy corn and grains (82). Some of the symptoms of hyperestrogenism are enlargement of the uterus and nipples, vaginal prolapse, and infertility (83). Several outbreaks of zearalenone poisoning of swine have been reported (84).

FOOD SAFETY

Consumption of moldy food products is the leading cause of mycotoxicoses in agricultural animals and humans alike. Contamination can occur at any point, ranging from the crop field through storage and shipping. The economic consequences of mycotoxin contamination are immense, and mycotoxins pose a higher chronic dietary risk than synthetic contaminants, plant toxins, food additives, or...
pesticide residues (85). Tables 1 and 2 list the mycotoxins discussed in this chapter and their common substrates. The reader should note that neither table is exhaustive, and other fungi and substrates can be involved in mycotoxin poisonings.

**Detection**

Since it would be impossible to prevent all mycotoxin contamination, methods of monitoring food and feed must be established. The regulatory guidelines for limiting mycotoxins differ between countries but have been summarized in compendia published by the Food and Agriculture Organization of the United Nations and more recently reviewed (74, 86). Mycotoxins as a group are comprised of diverse chemical structures, which are often present in smaller amounts than other interfering substances, requiring that each be separated from its substrate and studied by a unique assay. Generally, sample preparation consists of an extraction step and a purification step. Though this method is the most definitive, it is very expensive and time-consuming. Thus, newer screening methods for the presence of mycotoxins have been developed over the past decade. On the other hand, many of these screening methods are still plagued by cross-reactivity and require confirmation with more-selective validated methods.

Several reviews on current detection methodologies exist (87). Confirmatory tests and novel screening techniques include immunoassays such as enzyme-linked immunosorbent assay, fluorescence polarization immunoassay, surface plasmon resonance, and other conductometric measurements (88). High-performance liquid chromatography (HPLC) and gas chromatography (GC) are widely used, and since the introduction of atmospheric pressure ionization, liquid chromatography-mass spectrometry has become a routine technique for detecting the presence of mycotoxins, including tricothecenes, ochratoxins, zearalenone, fumonisins, and aflatoxins (89). The latest official methods, validated by the Association of Official Analytical Chemists International, are based on immunoaffinity column cleanup of conventional extracts, followed by fluorescently labeled HPLC (22). The reader is referred to comprehensive reviews of recent developments in analytical protocols (88, 90).

**Effects of Climate Change**

It is estimated that one-quarter of the world’s crops are contaminated to some extent with mycotoxins (91). This proportion varies from year to year based on environmental factors. There is much evidence of the influence of environmental factors, mainly temperature, humidity, drought, insect attack, and other plant stressors, on mycotoxin production by molds. Further, the pathogenicity of different molds may be additive, and competition between mold species may be temperature dependent (83). Each species and its ability to produce mycotoxins must be evaluated independently under its optimum growth conditions. For wheat species, infection of the cereal ears by Gibberella spp., particularly G. zeae, a predominant producer of DON, is enhanced by warm, humid weather (92). At the other extreme, production of fumonisins and aflatoxins is greater under drought conditions. Warmer temperatures and fewer frost days result in more insect and plant pathogens surviving the winter and causing plants to be more susceptible to mold infestation. Recent studies have shown increases in mycotoxin contamination of multiple crops (93). In summary, climate changes in any particular region may result in radical changes in the amount and type of crop damage and mycotoxin contamination.

Current Practices and the Future of Prevention Amelioration of Mycotoxin Contamination

Several different approaches are currently being developed to protect the food supply from mycotoxin contamination, including measures taken before, during, and after cultivation of crops, yet the most reliable preventative treatments are still cultural practices and humidity control in postharvest facilities. Though most breeding successes have been reported for wheat and barley, it is also essential to breed for resistance in other crops, such as corn and oats (94).

Several labs have attempted to create transgenic lines resistant to various mycotoxicogenic fungi, but none are in production. However, several reports suggest that Bt crops, i.e., those transgenically expressing insecticidal Bacillus thuringiensis toxins, are less susceptible to mycotoxin contamination due to decreased insect infestation (95). Indeed, insecticides have been shown to reduce the growth of Aspergillus and the resultant accumulation of ochratoxin A (96).

One biological control discussed but not implemented to any degree is the application of mycoviruses, which are typically easily spread through asexual fungal spores. Though many mycoviruses have minimal effects on their host fungi, they have the potential to be used as vectors for resistance genes. This approach may expand with the increasing availability of virus-specific molecular detection methods (5). Additionally, a recent study shows that the application of non-toxicogenic strains of A. flavus to corn plant whorls prior to tasseling significantly reduced aflatoxin accumulation, presumably through competition with toxigenic strains (97). This method appears promising and is being assessed in many different climates worldwide (98).

Finally, recent studies have concentrated on degradation of mycotoxins following crop harvest. Many microorganisms, such as soil and water bacteria, fungi, protozoa, and specific enzymes isolated from microbial systems, degrade mycotoxins, specifically aflatoxins (99). The addition of sodium carbonate and other feed additives has demonstrated success, lowering mortality and reducing adverse effects of mycotoxin-contaminated feed in livestock (58, 100).

BIOTERRORISM

In response to concerns about the possible use of mycotoxins in bioterrorism, the Committee on Protection from Myco-toxins was formed by the National Research Council in 1982 (101). Following years of research, Ciegler addressed the possibility of use of mycotoxins as chemical weapons in 1986 (102). However, the choice of aflatoxin as a weapon of mass destruction is odd at best; the effects of aflatoxicosis, such as liver cancer, are too slow-acting to be effective during war.

Trichothecenes are much more suited for warfare than aflatoxins; they act immediately upon contact, and several milligrams can be lethal. Of historical note is the “yellow rain” incident of 1981 (103). The United States accused the Soviet Union of using nivalenol, DON, and T-2 toxin against Hmong tribespeople in Cambodina and Laos. However, it was later concluded that this “yellow rain” was not a weapon but the excreta of swarms of wild Asian honeybees (104).

The use of mycotoxins in bioterrorism has been assessed by several investigators in recent years (3, 105, 106). Aflatoxins and trichothecenes have been tested for combined toxicity and were found to have additive effects in most cases. The combination of these mycotoxins resulted in a synergistic effect in human bronchial epithelial cells (107).

Interestingly, chlorine dioxide may be effective in the detoxification of trichothecenes, rodirin A, and verrucarin A (108) in the case of widespread exposure. T-2 toxin, along with aflatoxin, received some notoriety as a possible biological weapon used in the Gulf War (109). However, there is no clear data to support a role for either mycotoxin in ensuing illnesses afflicting veterans of this war (110). Much of the information addressing mycotoxins in biological warfare remains classified, and thus the question remains unresolved. In general, it is accepted that while the presence of mycotoxin weapons may cause terror, the actual use of such weapons would not be effective or reliable in a time of war.

SICK BUILDING SYNDROME

SBS is a loosely defined term that applies to indoor environments suspected of causing a variety of health problems for occupants. The buildings usually have many issues, including water damage, improper heating, ventilation, and air conditioning systems, poor construction, and bacterial, fungal, and/or insect infestation. Symptoms may include eye, nose, and throat irritation, fatigue, headache lack of concentration, frequent respiratory tract infections, shortness of breath, dizziness, and nausea (111). Mycotoxins are just one of many factors considered to be possible contributors to SBS. Several mycotoxin-producing fungi have been implicated, including Alternaria, Aspergillus, Cladosporium, Chaetomium, and Penicillium spp. One of the most widely investigated species is S. chartarum. For comprehensive reviews, see references 4 and 112.

It has not, however, been proven that occupants develop illnesses either from “sick” buildings or the molds inside them. Recent reviews of SBS conclude that there is no evidence that mold presents a threat to life for healthy members of the general population in typical exposures; indoor airborne microorganisms are only weakly correlated with human disease, and a causal relationship has not been established; and the concentration of mold required to create infective doses is inconsistent with the reported spore concentrations in buildings (4, 111).

A further argument against mycotoxins as the cause of SBS symptoms is that most mycotoxins are not volatile, and therefore, widespread exposure is unlikely. Moreover, the conditions conducive for mold growth are not necessarily optimal for mycotoxin production, and fungi differ in their abilities to produce mycotoxins. To conclude that mold found within a sick building is associated with occupants’ symptoms, the existence of the mold indoors, the mode of transmission, either by contact or proximity to spores and related byproducts, and the portal of entry, whether by inhalation, ingestion, or skin absorption, must be established. The mere presence of fungi in an indoor environment is insufficient evidence to establish a causative relationship and does not prove that mycotoxin is also present.

CONCLUSIONS

There are several classes of mycotoxins, produced by a wide range of fungal species, that have been linked to various environmental issues such as SBS, veterinary problems, bioterrorism, and food safety. Over the past decade, there have been many developments in the processes for identifying mycotoxin contamination and advances in methods to control its production. Much research is yet needed to reduce the threat of mycotoxin-producing fungal species to the health of human, livestock, and plant populations and its resultant effects on the international economy.

Lacazia, Lagenidium, Pythium, and Rhinosporidium
RAQUEL VILELA AND LEONEL MENDOZA

In the past 100 years the microbial pathogens described in this chapter have been classified as fungal and/or parasitic protistan pathogens (1–4). Based on their apparent epidemiological connection with water, they were at one point also placed in a new category of hydrophilic infectious agents (1). However, based on taxonomic and other morphological characteristics, these three anomalous species were not well understood (1, 4). This frustrating situation fueled a strong controversy that has only recently been solved with the advent of molecular methodologies (5, 6). Despite the recent finding that both Pythium insidiosum and Rhinosporidium seeberi are parasitic pathogens, they are still studied by medical mycologists, continuing a historical tradition. More recently, the finding of an oomycete in the genus Lagenidium afflicting mammalian hosts alerted the medical community to the presence of a novel pathogen phenotypically similar to the fungi and indistinguishable from the clinical and pathological features displayed by P. insidiosum during infection. Based on rDNA phylogenetic analysis, the evolutionary location of the microbial pathogens discussed in this chapter have been classified as fungal and/or parasitic agents (1). However, based on taxonomic and other morphological characteristics, these three anomalous species were not well understood (1, 4). This frustrating situation fueled a strong controversy that has only recently been solved with the advent of molecular methodologies (5, 6).

Based on their apparent evolutionary location of the microbial pathogens discussed in this chapter have been classified as fungal and/or parasitic agents. The proposed name Lacazia loboi is based on the morphological features observed in vivo in its parasitic stage. Its in vivo phenotype is characterized by the development of unicellular, thick-walled, lemon-shaped, yeast-like cells that can be found forming one, two, or more cells in chains with occasional branching and characterized by short tubules (Fig. 2). The yeast-like cells of L. loboi measure ~5 to 12 μm in diameter and can be easily observed with most stains. Interestingly, L. loboi's in vivo phenotype is very similar to the parasitic stage of P. brasiliensis. The morphological features of L. loboi and the cross-reaction observed in serological tests of patient sera with lacaziosis and the antigens of P. brasiliensis led Almeida and Lacaz (4) to classify this pathogen in the genus Paracoccidioides. Electron microscopic analysis of L. loboi showed thick chitinous yeast-like cell walls and an amorphous cytoplasmic content. Approximately 60% of the yeast-like cells observed lacked a defined cytoplasmic region, a finding in agreement with the result of viability studies.

**Description of the Agent**

Because L. loboi cannot be cultured, our knowledge of this pathogen is based on the morphological features observed in its parasitic stage. Its in vivo phenotype is characterized by the development of unicellular, thick-walled, lemon-shaped, yeast-like cells that can be found forming one, two, or more cells in chains with occasional branching and characterized by short tubules. The yeast-like cells of L. loboi measure ~5 to 12 μm in diameter and can be easily observed with most stains. Interestingly, L. loboi's in vivo phenotype is very similar to the parasitic stage of P. brasiliensis. The morphological features of L. loboi and the cross-reaction observed in serological tests of patient sera with lacaziosis and the antigens of P. brasiliensis led Almeida and Lacaz (4) to classify this pathogen in the genus Paracoccidioides. Electron microscopic analysis of L. loboi showed thick chitinous yeast-like cell walls and an amorphous cytoplasmic content. Approximately 60% of the yeast-like cells observed lacked a defined cytoplasmic region, a finding in agreement with the result of viability studies.

**Epidemiology and Transmission**

Lacaziosis (Jorge Lobo's disease) is known to occur only in patients inhabiting the tropical areas of the Americas (7). In addition to the many human cases, reports of the disease in species of dolphins around the coasts of South America, Florida, and the Gulf of Mexico have also been found (6). Although the majority of patients with lacaziosis have been from Brazil, cases from Mexico, Central America, Colombia, Suriname, Venezuela, and other nearby countries have also been reported (4). Two European human patients apparently acquired the infection after contact with an infected bottle-nosed dolphin in an aquarium. In addition, American and Canadian patients were reported with the infection after visiting or working in the areas of endemicity (14, 15).
Lacazia, Lagenidium, Pythium, and Rhinosporidium

FIGURE 1 Phylogenetic location of the four microbial pathogens studied in this chapter using small-subunit ribosomal DNA sequences. Forming a sister group, the algae and stramenopilans are placed basal to the plants. The latter includes the mammalian pathogenic Oomycetes Pythium spp. and Lagenidium spp. They develop hyphal-like elements, vesicles with biflagellate zoospores, and oogonia. R. seeberi is placed at the point where the animals and fungi diverge (red circle). This uncultivated protist is characterized by the development of spherical phenotypes with endoconidia. L. loboi is an anomalous, uncultivated, ascomycetous fungus developing yeast-like cells in chains. doi:10.1128/9781555817381.ch127.f1

Interestingly, an apparent lacaziosis case in a Greek woman with no history of traveling to the Americas was recently reported (16). The diagnosis was based on histological morphology. However, the yeast-like cells depicted in this particular patient lacked some of the morphological features observed in Fig. 2B and C. Moreover, no molecular testing was conducted to further authenticate the case.

It is believed that the infection is acquired through small traumatic skin lesions after contact with the pathogen near aquatic ecological niches. The report of dolphins with lacaziosis tends to support this assumption. However, the real ecological niche of this pathogen is unknown. The disease seems to occur in apparently healthy hosts. It is quite possible that L. loboi cells possess hyphae with propagules (perhaps conidia) similar to those in P. brasiliensis that may make contact with hosts through trauma, thus causing lacaziosis. Transmission of the disease from one patient to another is rare, but some cases have been reported of autoinoculation and accidental infection by physicians in contact with infected patients (4, 17) or with infected dolphins (18). In addition, the disease can be experimentally reproduced in mice (19).

Clinical Significance
Infections caused by L. loboi are rarely observed in the endemic tropical areas of the Americas. Recent reports indicate that human cases of the disease are sporadic in the areas of endemicity and occur mainly in males. The number of cases so far reported is around 600, but its real occurrence could be higher. The disease is diagnosed in apparently healthy hosts inhabiting such areas. A genetic predisposition theory was abandoned after the finding that the number of cases in a Brazilian tribe with a high occurrence of the disease dramatically decreased when the tribe was moved to a new location. One common problem in the areas of endemicity is that patients with the disease do not seek medical attention until years after infection, when the lesions have increased in size and spread to other skin areas. One explanation may be that the affected population is usually poor with no access to health care and that the lesions are rarely painful. The disease has been also reported in dolphins inhabiting coastal areas of regions of endemicity as well as areas of nonendemicity (18, 20).

Frequently affected anatomical areas are the arms, ears, back, chest, face, and lower limbs. Some investigators believe that the distribution of lesions on cooler areas of skin in humans and in dolphins may indicate that the pathogen does not tolerate well a temperature of 37°C. Initially, a single small (0.5 to 1.0 cm in diameter), smooth, parakeriolar skin lesion develops. Some patients complain of slight pruritus at this stage. The infection is not life-threatening and usually evolves very slowly, sometimes over 20 or more years. Usually, when patients seek medical attention they have already developed more than one lesion. In the chronic phase, the lesions are polymorphic. At least five clinical manifestations are recognized, including the typical parakeriolar type and the infiltrative, gummatous, ulcerated, and verrucous forms. However, Lacaz et al. (4) pointed out that

Collection, Transport, and Storage of Specimens

The guidelines for the collection, processing, storage, and examination of specimens are provided in chapter 114. Clinical specimens collected in cases of lacaziosis are mostly biopsied tissues from the infected sites. L. loboi cannot be cultured; thus, clinical specimens from the infected areas are usually fixed in formaldehyde for histopathologic evaluation.

Direct Examination

Microscopy

In contrast to the systemic spread of P. brasiliensis infections, L. loboi is typically confined to cutaneous and subcutaneous tissues. The lesions are characterized by fibrosis and granulomatous reaction with numerous histiocytes and giant cells containing numerous yeast-like cells of L. loboi. Areas of necrosis and the presence of other inflammatory cells have been reported. When tissue is stained with hematoxylin and eosin (H&E), the typical yeast-like cell arrangement in chains is not observed. Instead, L. loboi appears as oval to spherical, poorly stained cells or as round empty spaces with thick cell walls (Fig. 2A). Special fungal stains such as Gomori methenamine silver (GMS) and periodic acid-Schiff (PAS) should be used for the histopathological diagnosis of lacaziosis. With GMS, L. loboi yeast-like cells are dark or have the appearance of empty cells (Fig. 2B). The yeast-like cells are in chains of two or more cells and form branches, similar to the yeast cells observed in the infected tissue of patients with paracoccidioidomycosis. The cells are typically connected with small tubules, a feature also observed with other fungal stains such as PAS (Fig. 2B and C).

For the diagnosis of lacaziosis using direct microscopy, biopsy specimens should be cut into pieces of 2 to 5 mm in diameter. One or more pieces are then placed with 1 or 2 drops of 10% potassium hydroxide (KOH) on a glass slide with a coverslip. The slide should be heated without boiling and then held for about 15 min at room temperature before microscopic evaluation. In 10% KOH, L. loboi yeast-like cells appear in great quantities (Fig. 2C). Cells 2–12 μm in diameter and uniform in size can be found as single yeast cells or as chains connected by tubules of three or more cells. In wet mounts, moving protoplasmic granules can also be detected within some of the yeast-like cells (Fig. 2C).

Nucleic Acid Detection Techniques

So far, there are no commercially available nucleic acid probes for the detection of this pathogen in clinical samples.

Isolation Procedures, Identification, and Typing Systems

Claims that L. loboi has been isolated in pure culture have not yet been validated. Most of the recovered organisms were fungal contaminants or P. brasiliensis (4, 8). The identi-
L. loboi is well known for its resistance to antimicrobial drugs, including most antifungals (4). This fact has left clinicians with only one choice: surgery. Due to the intractability of this organism to culture, susceptibility testing is not possible.

Evaluation, Interpretation, and Reporting of Results
Clinical samples from patients suspected of lacaziosis submitted to the laboratory comprise deep skin scrapings and tissue biopsies. The samples have to be processed as described above ("Direct Examination" and "Microscopy") and evaluated for the presence of uniform yeast-like cells connected by small tubules forming short chains. Because P. brasiliensis in the parasitic phase can also form yeast cells connected by tubules, the significant variation in size could be used to separate L. loboi from P. brasiliensis. The latter pathogen tends to develop large and small yeast cells in the infected tissues, whereas L. loboi yeast-like cells have uniform size. In addition, the lack of fungal growth in culture could also be used as an aid in the diagnosis of this uncultivated pathogen. After laboratory evaluation of the clinical material, the presence of uniform yeast-like cells that yielded no fungal growth in culture is used to confirm lacaziosis. This is particularly important for patients who have visited areas where the disease is endemic. The report of the results should include the finding of uniform yeast-like cells connected by tubules, the lack of fungal growth in culture, and the histopathological results of the evaluated tissue samples.

**PYTHIUM INSIDIOSUM**

**Taxonomy**

P. insidiosum was first reported more than 150 years ago in Indonesian equines (3), but successful isolation of this organism in pure culture was not possible until the beginning of the 20th century. Later, a similar organism was isolated again from horses and the name Hyphomycetes destruens was introduced. The finding that a strain from New Guinea (22) developed zoospores suggested that this pathogen was an organism in the genus Pythium. De Cock et al. (3) introduced the binomial P. insidiosum, placing this pathogen within the protist...
**Description of the Agent**

*P. insidiosum* can be readily isolated on most mycological media (3). This pathogen develops white submerged colonies with a characteristic radiate pattern and few to no aerial hyphae, very similar to that in the mammalian pathogenic *Lagenidium* spp. (Fig. 3A). The hyphae have perpendicular lateral branches measuring 4 to 10 μm in diameter and possess few cross-septa (Fig. 3B). Zoosporogenesis (development of zoospores) is only possible in water cultures containing various ions, including Ca\(^{2+}\) (3, 26, 27). The structures in which the zoospores develop are termed vesicles (Fig. 3C).

Zoospores form by progressive cleavage and mature inside large vesicles (20 to 60 μm in diameter) (Fig. 3C). Once fully formed, the biflagellate zoospores mechanically break the sporangial wall, swim, and then encyst. It has been proposed that the zoospores may be the infectious units due to their motility. Zoospores are kidney-like in shape, and two unequal flagella arise from inside a lateral groove. Upon encystment, the zoospores lose their flagella and become spherical. Under the right conditions, the encysted zoospores develop a germ tube and form long filaments (26). *P. insidiosum* oogonia (sexual stage) have been rarely observed and are believed to represent a resistant stage in nature.

**Epidemiology and Transmission**

Infections caused by this hydrophilic pathogen have been recorded in tropical, subtropical, and some temperate areas of the world. In the Americas, pythiosis is common in tropical Central, North, and South America, with most cases reported in Brazil, Colombia, Costa Rica, the United States, and Venezuela (3, 26). In the United States, infections are more prevalent in animals and humans inhabiting southern states such as Alabama, Georgia, Florida, Louisiana, Mississippi, North Carolina, South Carolina, and Texas. However, cases of the disease have also been reported in other states, including California, Illinois, Indiana, Kansas, New Jersey, Missouri, Tennessee, Virginia, and as far north as...
as Wisconsin and New York. In Asia, pythiosis has been reported in Japan, India, Indonesia, Pacific islands, South Korea, and Thailand and also in nearby areas such as Australia, New Guinea, and New Zealand. Tropical Africa is ideal for pythiosis; however, only one case in a dog with the cutaneous form was reported in the northwest African country of Mali. This might suggest that the disease has been misdiagnosed in this geographic region (23).

Until recently, infections caused by *P. insidiosum* were considered exotic. The disease was believed to be restricted to animals in tropical regions with few or no occurrences in other geographical areas. Interestingly, in the last 10 years the number of pythiosis cases has increased on all continents (3, 28). The finding that humans (28–31), dogs (32, 33), and other animals can be infected indicates that previously pythiosis was erroneously diagnosed as a fungal infection. Most cases of pythiosis occur in apparently healthy humans and animals. In Thailand, however, the disease in humans is associated with thalassemia or similar blood disorders (29).

The infection is acquired after *P. insidiosum* propagules enter the skin or the intestinal tract through traumatic lesions (26, 33). The infection is believed to be acquired from wet environments. Supabandhu et al. (34) cultured and identified *P. insidiosum* from environmental samples, confirming the presence of this oomycete in wet agricultural environments in Thailand. In addition, cases of pythiosis in the absence of water suggest that *P. insidiosum* can cause infection after contact with resting spores from terrestrial environments.

The transmission of *P. insidiosum* from one individual to another (human or animal or vice versa) has not been recorded. Only rabbits seem to be susceptible to experimental inoculation (35).

**Clinical Significance**

The clinical manifestations of pythiosis vary according to the infection site. Most patients with the disease state that they had a skin injury prior to the infection. The lesions caused by *P. insidiosum* in humans can be classified into superficial infections (keratitis); cutaneous and subcutaneous forms, including orbital pythiosis; and vascular forms that usually lead to systemic infection and death. Keratitis caused by *P. insidiosum* is similar to that caused by fungi and other etiologic agents (36–38). It begins with trauma to the superficial layers of the eye, followed by the development of conjunctivitis, photophobia, corneal ulcers, and hypopyon (pus in the interior chamber of the eye). Cutaneous and subcutaneous infection is characterized by the formation of granulomatous plaques and/or ulcerated swellings that remain localized. Once the pathogen has reached the subcutaneous tissues, itchy papules may develop. The orbital form of subcutaneous pythiosis is rare and has been observed mainly in children in Australia and the United States (39). Vascular pythiosis starts with a traumatic lesion, usually on the lower limbs, followed by dissemination of the pathogen to the nearby arteries (37, 46). Initially, the infected skin shows signs of dry gangrene, and the formation of painful necrotic ulcers in some patients has also been reported (28).

Clinical symptoms are claudication (limping) of the affected limb, local ischemia, swelling, pain, and the absence of the dorsalis pedis pulse. As the infection progresses, an ascending arteritis, with the formation of thrombi and aneurysms of the large arteries, is the main feature. If not treated, *P. insidiosum* may spread through the arteries and reach the iliac and renal arteries and abdominal aorta, causing disseminated pythiosis. This form of pythiosis is more common in Thailand among patients with thalassemia, and it is usually life-threatening (28, 30, 31). Human pythiosis should be differentiated from arteriosclerosis, diabetes mellitus, *Lagenidium* spp. cutaneous leishmaniasis, mycotic keratitis, subcutaneous tuberculosis, subcutaneous mucormycosis, and other mycoses associated with filamentous fungi.

**Collection, Transport, and Storage of Specimens**

The clinical specimens required for diagnosis of pythiosis vary according to the infected host and the clinical form (25, 28). The infections caused by *P. insidiosum* share identical methodologies for the collection, transport, and storage of the clinical samples with that in *Lagenidium* spp. A portion of the small tissue samples used for microscopy also can be used to inoculate Sabouraud dextrose agar (SDA) plates. The pieces have to be submerged into the agar and incubated at 37°C for 24 to 48 hours. *Lagenidium* spp. that are pathogenic for dogs, cats, and humans develop white-yellowish, flat, glabrous colonies (Fig. 4A), similar to that recovered in cases of pythiosis. The presence of broad, 9- to 18-μm, coenocytic hyphae displaying large spherical structures connected by short strands of hyphae is the main feature of strains recovered from dogs (Fig. 4B). An strain of *Lagenidium* sp. recovered recently in a case of human keratitis showed only broad, sparsely septate hyphae (40). Strains of *Lagenidium* displaying spherical structures connected by short strands of hyphae can be used to differentiate *P. insidiosum* from *Lagenidium* sp. (Fig. 4B); however, some mammalian pathogenic *Lagenidium* spp. could develop only hyphae. Those cases have to be investigated using molecular methodologies (see below). So far, there is no typing system available for *Lagenidium* sp.

For patients with keratitis, swabs or scrapings of the affected eyes should be collected. Dryness of clinical specimens from keratitis patients could prevent the microscopic detection of the hyphal elements and subsequent culture of *Lagenidium* spp. Swabs must be immediately transported at room temperature in tubes with high humidity (or containing small quantities of sterile distilled water) to the laboratory and should be processed upon arrival. The collected eye scrapings should be placed in small aseptic petri dishes and immediately transported at room temperature to room humidity to room temperature to the laboratory. Biopsy or necropsy samples are usually collected in sterile distilled water and transported at room temperature to the laboratory. Specimens collected from patients with cutaneous, subcutaneous, vascular, and disseminated lagenidiosis can also be placed in tubes containing sterile distilled water plus 100 U of penicillin/ml and 0.25 mg of streptomycin or 0.4 mg of chloramphenicol per ml. If these antibiotics are not available, the use of sterile distilled water is encouraged. Although some studies indicate that transportation or storage at 4°C of specimens from patients suspected of lagenidiosis did not interfere with the isolation of the pathogen in the laboratory, others report a considerable reduction in the number of positive cultures from samples stored at 4°C (26). The reader should consult Chapter 114 for more information on collection.

**Direct Examination**

**Microscopy**

Clinical specimens of *P. insidiosum* in 10% KOH characteristically show the presence of long (4.0 to 9.0 μm diameter), hyaline, sparsely septe hyphal structures (Fig. 3B). Some hyphal elements may reach more than 15-μm lateral branches at a 90° angle, a typical feature of this oomycete.
In histopathological preparations stained with H&E, *P. insidiosum* appears as short or long, hyaline, coenocytic (without septa) hyphae 6 to 10 μm in diameter (Fig. 3D). The fact that in vivo structures of *P. insidiosum* are detectable in H&E has been used to differentiate this oomycete from the hyphal elements developed by members of the order Entomophthorales (genera *Basidiobolus* and *Conidiobolus*). In infected tissues *P. insidiosum* triggers eosinophilic granulomata with giant cells, mast cells, and other inflammatory cells (Fig. 3D). The hyphal elements of *P. insidiosum* are found in the center of microabscesses with numerous eosinophils that usually degranulate over the organism’s hyphae (Splendore-Hoeppli phenomenon) (Fig. 3D, arrow). The activation of an eosinophilic inflammatory response with the Splendore-Hoeppli phenomenon is a feature in common with the order Entomophthorales, from which it must be differentiated. Although most experts in the diagnosis of pythiosis agree that it is difficult to distinguish between the hyphal structures of *P. insidiosum* and those features of the Entomophthorales such as the poor staining capabilities in H&E, the ribbon-type morphology and the bigger size of the zygomycetes hyphal filament structures sometimes help to distinguish these fungi from *P. insidiosum*. *P. insidiosum*’s hyphal elements are well stained by GMS and appear as short or long, sparsely septate, tubular dark structures (Fig. 3E). Transversely sectioned, poorly stained (with GMS or PAS) hyphae can also be found as ring-shaped bodies.

The most important immunohistological tests for the specific identification of the hyphal elements of *P. insidiosum* in infected tissues have been the peroxidase and the immunofluorescence tests (41). Because the hyphal structures of *P. insidiosum* are difficult to differentiate from those in the fungi, especially the mucormycetes and entomophthorales (formerly zygomycetes), these assays have been of paramount importance for the accurate identification of this oomycete in the absence of culture. Most of these assays are available through reference laboratories for pythiosis in the United States at Michigan State University (https://bld.natsci.msu.edu/research/pythium-insidiosum/) and Pan American Veterinary Laboratories (http://pavlab.com) and in other countries such as Brazil and Thailand.

**Nucleic Acid Detection Techniques**

The first molecular approach for the diagnosis of *P. insidiosum* from clinical specimens was carried out on a patient with keratitis (36). The hyphal elements present in the specimen were identified by sequencing part of the 18S ribosomal DNA region using the NS1 and NS2 and ITS universal primers. This approach has been successful on clinical specimens (36, 30). Grooters and Gee (42) introduced a PCR technique for the identification of *P. insidiosum* from cultures and from clinical specimens. A set of primers (PI-1 and PI-2) that amplified 105 bp of the ITS-1 region of *P. insidiosum* were tested. These primers have been used by several laboratories (30) and were entirely specific when tested against several filamentous fungi. Schurko et al. (43) introduced a dot-blot hybridization technique by constructing a 530-bp species-specific DNA probe for the detection of *P. insidiosum*. This DNA probe specifically binds to the intergenic spacer 1 (IGS1) of this pathogen, and it did not hybridize with the genomic DNA from 23 other *Pythium* species, *Lagenidium gigantium*, or several pathogenic fungi, including the entomophthoramycetes fungi *Conidiobolus coronatus* and *Basidiobolus ranarum*. This probe may be ideal for the detection of *P. insidiosum* from environmental samples and for the specific diagnosis of pythiosis from clinical specimens from susceptible hosts. Other similar in-house molecular assays have been suggested, but they have limited availability.

**Isolation Procedures, Identification, and Typing Systems**

In contrast with the other hydrophilic pathogens covered in this chapter, *Lagenidium* spp. (see below) and *P. insidiosum* can be cultured on various media. The most common media used for the isolation of *P. insidiosum* are 2% SDA or broth with or without antibiotics (see "Collection, Transport, and Storage of Specimens"), blood agar, cornmeal agar (Difco), potato dextrose agar, and nutritive agar (Difco). Biopsy or necropsy tissues and kunkers (stony hard masses found only in horses with pythiosis) from patients suspected of pythiosis are usually cut into small fragments 2 to 5 mm in diameter, placed into tubes containing sterile distilled water, and vigorously washed two to three times before plating. The small fragments are then physically pushed into the agar and the plates are incubated at 25 and 37°C for 2 or more days. The relative humidity of the incubator should be enhanced by placing a beaker of water inside the chamber. Specimens that have been transported for more than 24 h can also be
inoculated into tubes containing broth and then incubated at 37°C. Usually, cottony colonies surrounding the clinical specimens are detectable after 24 to 48 h of incubation (25). On solid medium, \textit{P. insidiosum} develops only sparsely septate hyphae (Fig. 3B). The appearance of \textit{P. insidiosum} on solid medium was previously described.

\textit{P. insidiosum} can be identified definitively only if the isolate develops the characteristic oogonia (sexual stage) on culture plates. The formation of oogonia, however, is extremely rare, which further complicates the final identification of this pathogen in the clinical setting. Given that \textit{Lagenidium} spp. and \textit{P. insidiosum} display identical lesions in infected mammals, the development of zoospores in water as a definitive characteristic for the identification of \textit{P. insidiosum} needs to be revisited. The identification of \textit{P. insidiosum} using molecular methods with isolates and clinical specimens as described above is recommended (see “Nucleic Acid Detection Techniques,” above). A drawback to this approach is that only a few laboratories possess these capabilities. Currently, there are no typing systems available for \textit{P. insidiosum}.

Serologic Tests
Early serological tests showed that anti-\textit{P. insidiosum} antibodies could be detected in the sera of infected hosts and, thus, could be used for the diagnosis of pythiosis. The most common assays for pythiosis are agglutination, enzyme-linked immunosorbent assay (ELISA), immunodiffusion, and Western blotting. Immunodiffusion has proven to be a very specific test, with several precipitin bands, but it is too insensitive and yields many false negatives, especially when performed with sera from humans and dogs with pythiosis (44). To overcome this drawback, an ELISA and a Western blot assay were later introduced (30, 32, 44–46). These assays are extremely sensitive in detecting anti-\textit{P. insidiosum} IgG. However, it may cross-react with anti-\textit{Lagenidium} spp. antibodies (47). Recently, an agglutination test was used for the rapid diagnosis of pythiosis. Although it proved to be a good screening test, it had a high rate of false positives and false negatives (48). The finding that antibodies in the sera of different hosts recognize different antigenic proteins when evaluated with several geographically divergent strains of \textit{P. insidiosum} suggests frequent subclinical infections with multiple \textit{P. insidiosum} strains (49).

Antimicrobial Susceptibility
\textit{Pythium insidiosum}, like the other oomycetes (including \textit{Lagenidium} spp.), does not possess ergosterol in its cytoplasmic membrane. Despite this obvious contraindication, amphoterocin B and other antifungal drugs that target ergosterol have been used with mixed results. For instance, two children with orbital pythiosis were successfully treated with amphoterocin B in Australia (39). However, this antifungal did not have an effect in humans from Thailand with the disease (29, 31). Recently, susceptibility testing on a strain isolated from a child in Tennessee with orbital pythiosis showed the strain to have low MICs of terbinafine anditraconazole (50). Although this combination of drugs was successfully used in this case, the same combination was less effective when tested in other humans and animals. One explanation for this contradiction is the possibility that these antifungal drugs may be affecting pathways other than sterols. The inconsistent results with most antifungal drugs for the treatment of pythiosis have led to the use of unconventional treatments such as immunotherapy (31). Immunotherapy has been found effective in 55% of humans and dogs and in 70% of equines with the disease (48). In addition, some investigators have evaluated in vitro combinations of several antifungals against \textit{P. insidiosum} with promising results (41, 51–53). These studies indicate that terbinafine plus fluconazole or ketoconazole (52), or terbinafine plus amphotericin B (53), substantially reduced the in vitro growth of \textit{P. insidiosum}. However, these combinations of antifungal drugs have yet to be tested in clinical cases.

Evaluation, Interpretation, and Reporting of Results
Culture is the gold-standard test for pythiosis. Because \textit{P. insidiosum} morphological features in infected tissues are identical to those displayed by the fungal entomophthoromycetes \textit{Conidiotheca} and \textit{Basidiotheca}, wet mounts, histopathological examination of tissue sections, serological assays, and culture have to be evaluated as a whole for a proper interpretation and identification of this pathogen in the laboratory. For instance, the finding of sparsely septated hyaline hyphae in a wet mount preparation must be confirmed by culture. Moreover, serological assays such as ELISA and Western blot could detect anti-\textit{P. insidiosum} antibodies in hosts with putative clinical diagnosis of pythiosis, but they should be interpreted with caution. \textit{P. insidiosum} can cause subclinical infections in human and animals inhabiting areas of endemicity. Thus, false positives have been found in apparently healthy individuals (48). When culture is not possible, the use of molecular approaches and/or immunohistochemical (peroxidase and immunofluorescence) tests could be of help. The presence of hyaline hyphae in wet mount preparations and in histopathology should be reported as suggestive of pythiosis, whereas positive results in culture (development of zoospores in water cultures) or positive reactions in molecular assays and/or in immunohistochemical staining tests are reported as confirmatory tests of disease. In such cases the report of results should include the following: “pythiosis caused by \textit{P. insidiosum} confirmed by culture and supported by serological and/or molecular assays.”

\textbf{LAGENIDIUM SPP.}

Taxonomy
Until recently, \textit{P. insidiosum} was considered the only oomycete causing disease in mammalian hosts (3, 25). However, in 1996 several cases of novel mammalian pathogenic oomycete species causing skin infections with dissemination to blood vessels were reported (47). Although a complete description of the species causing lagenidiosis in mammalian hosts was still pending, unpublished molecular data indicated that at least two \textit{Lagenidium} species were involved (51, 54). The genus \textit{Lagenidium} comprises oomycete species affecting lower animals such as crabs, mosquito larvae, nematodes, and others (55). Because members of the oomycetes develop hyphal-like elements, they were for a long time known as the “aquatic fungi” (water molds). However, they are not true fungi. They are currently classified within the kingdom Stramenopila, phylum Heterokonta, class Oomycota, order Lagenidiales, and family Lagenidiaceae (Fig. 1). Although Dick (56), using phenotypic characteristics, recently questioned the validity of this genus, current phylogenetic studies have found \textit{Lagenidium} species clustered with \textit{L. giganteum}, a mosquito larval pathogen with strong statistical support (R. Vilela and L. Mendoza, unpublished data). This finding suggests that the classification of \textit{Lagenidium} species based on morphology alone is problematic.

Description of the Agent
\textit{Lagenidium} species can be readily isolated in media used to recover fungi in the clinical laboratory (47, 55). This is in contrast with some of the other pathogens covered in this...
chapter. On SDA, Lagenidium species develop well at 37°C and slower at 25°C. At 37°C they develop white-yellow submerged colonies without aerial mycelia in less than 24 hours (Fig. 4A). Based on cases studied at Michigan State University, Lagenidium spp. developed 8- to 15-μm ribbon-type hyphae and spherical structures 20 to 45 μm in diameter (unpublished data) (Fig. 4B). In liquid media, undifferentiated hyphae can develop vesicles at the tip of these structures. The vesicle increases in size as more protoplasmic material enters the vesicle, and zoosporangia are formed within the following 20 minutes. The presence of sexual structures (oogonia) has not yet been reported. The two species mentioned so far in the literature, L. caninum and L. karlingii, were introduced without a formal description. Thus, the microscopic and phylogenetic features of these two novel species are still awaiting description.

**Epidemiology and Transmission**

So far, most cases of lagenidiosis in mammalian hosts have been reported in the United States (54, 55). A case of keratitis caused by a Lagenidium sp. in a Thai human patient was recently reported (40). In addition, an Australian dog case of lagenidiosis was also studied by us (unpublished data). In the U.S., lagenidiosis occurred in the same areas reporting P. insidiosum infection (see below) (51, 54, 55). This includes the states bordering the Gulf of Mexico and Arkansas, Georgia, Illinois, Indiana, Maryland, North Carolina, South Carolina, Tennessee, and Virginia, among others. Lagenidium spp. complete their life cycle in wet environments, possibly using lower animal hosts or plants. Mammals with open skin injuries entering contaminated environments can be exposed to the zoosporangia developed by these species and could develop lagenidiosis. Transmission from one infected host to another has not been observed. Experimental infection in mice has been unsuccessful (47).

**Clinical Significance**

The genus Lagenidium and P. insidiosum have been recognized as emerging pathogenic oomycetes causing invasive superficial, cutaneous, subcutaneous, and arterial infections (25). These pathogens are rarely observed causing systemic infection. The common sites of infection in humans and animals are cornea, gastrointestinal tract, limbs, and other anatomical areas (40, 55). Mammalian-pathogenic Lagenidium species have been reported in only three geographical areas (see above), but other tropical and subtropical regions may contain these pathogenic species as well.

**Collection, Transport, and Storage of Specimens**

See the corresponding text in the section on Pythium insidiosum.

**Direct Examination**

**Microscopy**

Small pieces of biopsied tissue cut in 5-mm blocks, scrapings of lesions in wet mounts, and cytological samples stained with Giemsa reveal the hyphal structures of Lagenidium spp. in infected tissues. In wet mount, broad 9- to 18-μm, branched, sparsely septate hyphae (broader than those in P. insidiosum) are observed in cases of lagenidiosis (Fig. 4C). Differentiation in histopathological sections between Lagenidium and P. insidiosum hyphae is difficult. Both trigger an eosinophilic granuloma, and although Lagenidium hyphae are larger than P. insidiosum, a definitive diagnosis can only be made by culture (see the section on P. insidiosum) or by using molecular tools. The microscopic features of some Lagenidium sp. causing lagenidiosis in dogs in culture display the presence of oval and spherical structures, a morphological feature that could be used to separate these mammalian-pathogenic oomycetes in the laboratory (Fig. 4B). However, there are other Lagenidium strains pathogenic for mammals that lack these features and, thus, morphology alone would not provide an unequivocal distinction between these two organisms.

**Isolation Procedures, Identification, and Typing Systems**

See the corresponding text in the section on Pythium insidiosum.

**Serologic and DNA Tests**

ELISA and Western blot assays have been tested in cases of lagenidiosis in both humans and lower animals (15, 47). Although both assays detected the presence of antibodies in cases of lagenidiosis, the antigenic banding patterns observed in Western blot were very difficult to interpret and ELISA had a strong cross-reaction with P. insidiosum antigens. Despite this limitation, the ELISA has been suggested to monitor the response to treatment used to demonstrate in cured cases (47.). Specific primers for the identification of isolates and Lagenidium hyphae in biopsied tissue section have been described (47). However, their specificity is not known.

**Antimicrobial Susceptibilities**

As previously mentioned, the oomycetes differ from the true fungi in several aspects, one of which is that oomycetes lack sterols in their cytoplasmic membranes. Thus, Pythium spp. and Lagenidium spp. are intrinsically resistant to most antifungal drugs targeting this pathway. Thus, an early and accurate diagnosis is essential for a good response in infected hosts. Several antifungals have been tested in vitro using Lagenidium isolated from humans and lower animals (51). Sadly, the in vitro response has shown contradictory results.

**Evaluation, Interpretation, and Reporting of Results**

Cases of lagenidiosis with positive culture have to be evaluated by microscopy looking for the typical structures encountered in some strains (Fig. 4B). If the strain does not display fruiting bodies, the induction of zoospores must be performed (25, 27). The development of sporangia and biflagellate zoosporangia could be interpreted as proof that the isolate is an oomycete. So far, there are no reports of oomycetes as normal laboratory contaminants or normal microbiota of humans or lower animals. In addition, genomic DNA from the strain isolated from biopsies could be used to identify the strain. The report of the case should include the following: (i) the presence of pigment, (ii) the development of zoospores from positive cultures, and (iii) the identification of the strain by morphology and DNA tools.

**RHINOSPORIDIUM SEEBERI**

**Taxonomy**

The first two cases of rhinosporidiosis were reported in 1900 by Guillermo Rodolfo Seeber in his M.D. thesis in Argentina (1, 2). He stated that in 1896 he had found two patients with nasal polyps containing an organism similar to that reported by Posadas in 1892 (occidiodidomykosis). He also mentioned that, in 1892, Malbran had studied a case of a nasal polyp showing a spherical microbe with identical morphological
more than 450 μ and then the in vivo μ The endospores increase in size and progressively develop diameter, from a pore developed only in mature sporangia. Seeber in 1912 introduced the name Rhinosporidium seeberi and called attention to its priority over R. kinearlyi. Ashworth in 1923 (2) stated that the genus Rhinosporidium proposed by Minchin and Fanthan should be adopted and that, based on the description of Seeber (2) and the name Coccosidioidea seebeoriae reintroduced by Belou, the binomial R. seeberi has priority. The fact that this pathogen has not been cultured led some investigators to extreme hypotheses that were critically reviewed by Vilela and Mendoza (57). The suggestion that R. seeberi is a cyanobacterium in the genus Microcystis is the most recent in a long list of similar views. This and other views have been challenged by several groups showing that morphological, cell cycle, and phylogenetic analyses all linked this pathogen with the protistal eukaryotes (57). The placement of R. seeberi within the Mesomycetozoa came as a surprise. This group comprises orphan aquatic fish and amphibian parasites with spherical forms and endospores strikingly similar to those of R. seeberi (5, 6). Using the ribosomal DNA internal transcriber spacer region (ITS), it was recently found that R. seeberi may include several species-specific strains that could represent new species (58).

Description of the Agent
This anomalous pathogen has resisted culture; thus, its morphological features are only known through in vivo microscopic and ultramicroscopic studies (1, 2). In infected tissues, R. seeberi has a complex parasitic cell cycle. It appears as multiple spherical structures known as sporangia (cysts in most mesomycetozoa) in different stages of development (Fig. 5A and B). The in vivo life cycle starts with the release of hundreds of oval or spherical endospores, 7 to 15 μ in diameter, from a pore developed only in mature sporangia. The endospores increase in size and progressively develop from juvenile (JS) (10 to 100 μ), to intermediate (IS) (100 to 150 μ), then to mature sporangia (MS) (150 to more than 450 μ). The endospores are released from MS and then the in vivo cycle is somehow reinitiated (Fig. 5C). Although the diameter of the sporangium has been used to identify the in vivo stages, the mature sporangium differs from other stages by the presence of well-developed endospores (Fig. 5D). The finding of mitotic figures within some sporangia in histological preparations has been mentioned (59). These authors found that the nuclei within IS sporangia synchronously divide without cytokinesis. A cell wall is developed around each endospore in large sporangia with thousands of nuclei, becoming an MS.

Epidemiology and Transmission
Rhinosporidiosis usually occurs in most tropical and subtropical areas of the world except Australia (1). Although the infection was first recognized in Argentina, India and Sri Lanka, show the highest occurrence of the disease (54). Rhinosporidiosis occurs sporadically in other geographical areas such as the Americas, Africa, Europe, and Asian countries including the Middle East. Because some cases of rhinosporidiosis occur in dry areas, especially after sand storms, the hydrophilic nature of this pathogen has been long questioned (1, 2, 60). Based on accounts from patients with the disease, it is believed that rhinosporidiosis is acquired through contact with aquatic environments contaminated with R. seeberi, but the precise mechanism of infection from natural sources is unknown.

The finding linking R. seeberi to aquatic pathogens of fish and amphibians (5, 6, 61), tends to confirm its hydrophilic nature. Most probably, this pathogen evolved from an aquatic niche, in which it still can be found, to terrestrial environments by the development of resistant spores. This is a very likely scenario since the formation of zoospores, as in the other members of the Dermocystida among which R. seeberi is phylogenetically located, has not been found (1, 2, 6, 60). The disease tends to occur as single cases, but two outbreaks of rhinosporidiosis in humans in Serbia (62) and in swans from Florida, United States (63), have also been recorded. The resistant spores present in water and soil may gain entry through small cutaneous or mucocutaneous wounds and establish infection. Although the disease occurs in apparently normal hosts, some investigators have suggested associations with particular occupational and social conditions (1, 60). Little is known about the predisposing factors leading to the disease. The disease has not been induced in experimental animals, and transmission from one host to another has yet to be reported.

Clinical Significance
In addition to humans, rhinosporidiosis around the facial areas has been also reported in several animal species including cattle, cats, dogs, goats, horses, river dolphins, and birds (1, 6). In humans, the most common clinical manifestation is the formation of painless polyps usually located on mucosal areas of the nose, eye, larynx, genitalia, and rectum. Multicentric skin lesions have also been recorded (60). The disease is not life-threatening, but it can cause breathing difficulties when the polyps obstruct the nose or laryngeal passages. Rhinorrhea and bleeding are common with polyps located in the nose. The slow-growing polypoidal masses are usually found as single or multiple, pedunculate (attached to the skin), sessile, red lesions that bleed easily. Pruritus of the affected areas is also common. The differential diagnosis includes bacterial and fungal infection, neoplasia, and other similar mucosal and skin conditions.

Collection, Transport, and Storage of Specimens
The guidelines for the collection, processing, storage, and examination of specimens are provided in chapter 114. Clinical specimens collected in cases of rhinosporidiosis are usually biopsy tissues from infected sites. Since R. seeberi cannot be cultured, clinical specimens are usually fixed in formaldehyde upon collection to be histopathologically evaluated later. Nonetheless, fresh samples should also be examined in the laboratory to rule out other etiologic agents and to confirm the histopathological findings. In these cases, biopsy specimens should be aseptically collected and transported immediately to the laboratory. For samples collected far from the laboratory, cooling (−80 to 4°C) of collected specimens for shipping or storage purposes may be necessary.

Direct Examination
Microscopy
Wet mount preparations from clinical specimens from cases of rhinosporidiosis usually show the presence of mature and immature spherical sporangia and numerous endospores. Mature sporangia with endospores have thin cell walls and measure more than 400 μ in diameter. JS and IS sporangia are smaller and may have thicker cell walls. In fresh specimens treated only with water, the release of endospores from MS sporangia has been reported (6). A purification system to study R. seeberi phenotypes was recently proposed (1). The presence of R. seeberi sporangia and endospores can also be
FIGURE 5  *R. seeberi*. (A) H&E-stained mature sporangia with endospores and numerous juvenile sporangia of different sizes. Magnification, ×10. (B) A collapsed sporangium in U-shaped and juvenile sporangia with prominent nuclei and nucleoli (long and short arrows, respectively). Magnification, ×30. (C) Mature sporangium releasing endospores through a cell wall pore. Magnification, ×30. (D) Wright-Giemsa impression smear from a dog with nasal rhinosporidiosis. An immature collapsed sporangium may be observed in the lower section. Numerous endospores surrounded by a clear halo are shown near the top. Magnification, ×70. Panel D is courtesy of W. A. Meier. doi:10.1128/9781555817381.ch127.f5

found on smears stained with Giemsa or Gram stain (Fig. 5D). The spherical unstained elements of *R. seeberi* develop autofluorescence when viewed with a fluorescence microscope.

The parasitic spherical structures of this mesomycetozoa pathogen stain very well with H&E, but they also stain with GMS and PAS, a feature used by many in the past to suggest a link with the members of the kingdom Fungi. Biopsy tissue from polypoidal lesions stained with H&E is characterized by the presence of numerous sporangia at different stages of development (Fig. 5A and B). Hyperplasia of the mucous membranes and/or skin with fibrovascular and fibromyxomatous connective tissue containing numerous sporangia is the main feature of the infection. Inflammatory infiltrates of lymphocytes, neutrophils, plasma cells, and more rarely giant cells and eosinophils are usually observed in cases of nasal, ocular, and skin infections. JS and IS possess a central nucleus with a prominent nucleolus (Fig. 5B). The collapse of defective sporangia may cause the formation of U-shaped structures. Mature sporangia possessing several thousand endospores are usually found near the mucosal epithelium, where they are transported from the internal infected areas by a transepidermal elimination phenomenon (Fig. 5A and C) (60). The cell wall of the mature sporangia is usually thin and the enclosed endospores may contain clusters of 1- to 3-μm reddish spherical vesicles. Endospores have a mucoid capsule that does not stain in H&E preparations. The presence of a pore on the sporangial wall is also observed, depending on the plane of the sectioned tissue (Fig. 5C).

Nucleic Acid Detection in Clinical Materials
Currently there are no available DNA-based techniques for the diagnosis of *R. seeberi*.

Isolation Procedures, Identification, and Typing Systems
Despite numerous reports claiming that *R. seeberi* has been isolated in pure culture, such claims have not yet been validated. Most of the organisms recovered from cases of rhinosporidiosis have proven to be fungal or bacterial contaminants (1, 60). Because *R. seeberi* has not yet been cultured,
the identification of this pathogen is based on its phenotypic characteristics. The wet mount preparations and/or histopathological analyses. The morphological characteristics of R. seeberi in infected tissues are almost pathognomonic. Nonetheless, the organism’s epidemiological features and the clinical signs of disease should be taken into consideration for a final diagnosis. Morphologically, the parasitic (spherule) stages of Coccidioides immitis and C. posadasii mimic the R. seeberi sporangia with endospores. However, the sporangia size range of R. seeberi (<400 to 4 μm), the epidemiological, clinical, and phylogenetic features of coccidiomycosis, and the fact that Coccidioides species can be readily cultured categorically separate this pathogen from R. seeberi.

Serologic Tests
Although early investigators did not detect R. seeberi antibodies in the sera of infected hosts using endospores or sporangia as antigens, others suggested that the reason for the failure was the use of insensitive assays such as immunodiffusion. Using an immunoelectronmicroscopic approach, it was shown for the first time that anti-R. seeberi antibodies reacted against a specific antigen in mature sporangia in the sera of patients with rhinosporidiosis (60). Despite these efforts, there are no available serological diagnostic assays for rhinosporidiosis in the clinical setting.

Antimicrobial Susceptibility
R. seeberi is resistant to most antifungal drugs (1, 60); however, the use of dapson was found helpful to control some cases (1). Because this pathogen cannot be isolated in culture, susceptibility testing is not possible. Treatment is carried out by surgical removal of the infected tissues.

Evaluation, Interpretation, and Reporting of Results
The finding of spherical structures at different stages of development, some of them containing numerous endospores on histopathology, in cytological samples stained with Giemsa, Gram, and wet mount preparations, is suggestive of rhinosporidiosis. Since the R. seeberi spherical structures with endospores mimic the parasitic stage of Coccidioides species, a differential diagnosis is required, especially in the endemic areas of coccidioidomycosis. The finding of >300-μm spherical sporangia with endospores and negative cultures could be confirmatory of rhinosporidiosis. The report of the results should contain the finding of typical spherical structures that resisted culture.

Microsporidia
RAINER WEBER, PETER DEPLAZES, AND ALEXANDER MATHIS

TAXONOMY
Microsporidia are obligate intracellular, unicellular, spore-forming eukaryotes. More than 160 microsporidial genera and 1,300 species that are pathogenic in every major animal group have been identified (1–5). To date, nine genera (Anncaliia, Encephalitozoon, Endoreticulatus, Enterocytozoon, Nosema, Pleistophora, Vittaforma, Tubulinosema, and Trachipleistophora), as well as unclassified microsporidia, assigned to the collective group Microsporidium, have been implicated in human infections (Table 1).

Microsporidium develop intracellularly exclusively and have no metabolically active stages outside the host cell. A life cycle (Fig. 1) involving a proliferative merogonic sequence followed by a sporogonic sequence results in environmentally resistant spores of unique structure. Mature spores contain a tubular extrusion apparatus (polar tube) for injecting infective spore contents (sporoplasm) into the host cell.

Microsporidia are true eukaryotes because they have a membrane-bound nucleus, an intracytoplasmic membrane system, and chromosome separation on mitotic spindles, but they are unusual eukaryotes in that they have bacterium-like ribosomes, no recognizable mitochondrion, no peroxisomes, and simple vesicular Golgi membranes. Compared with those of other eukaryotes, the genomes of microsporidia are reduced in size and complexity (6, 7). The genome sizes of different microsporidia vary between 2.3 and 19.5 Mbp, and the numbers of chromosomes range from 7 to 16 (8).

The compactness of the microsporidial genomes results from the loss of genes and from the reduction of coding and noncoding elements. The small-subunit rRNA genes of microsporidia, for example, are significantly shorter than those of other eukaryotes.

Due to the absence of mitochondria in microsporidial studies, it had been postulated that microsporidia are ancient protists that diverged before the mitochondrial endosymbiosis (9). However, genes related to mitochondrial functions were identified in Encephalitozoon cuniculi (6), and immunolocalization of the mitochondrial heat shock protein 70 in the microsporidian Trachipleistophora hominis revealed tiny organelles with double membranes, named mitosomes (10, 11). Recent genome-wide sequence and synteny analyses indicate that the organisms of the phylum Microsporidia belong to the kingdom of the Fungi (12), being derived from an endoparasitic chytrid ancestor on the earliest diverging branch of the fungal phylogenetic tree (13, 14). Also, structural features of the organisms such as the presence of chitin in the spore wall, diplokaryotic nuclei, and electron-dense spindle plaques associated with the nuclear envelope suggest a possible relationship between fungi and microsporidia, whereas the life cycle of microsporidia is unique and dissimilar to that of other fungal species.

DESCRIPTION OF THE GENERA AND SPECIES
The species are illustrated in Fig. 1 and listed in Table 1. Anncaliia spp. have diplokaryotic nuclei and develop in direct contact with host cell cytoplasm. Additionally, the organisms produce electron-dense extracellular secretions and vesiculotubular appendages. Three former members of the microsporidial genus Brachiola that are pathogenic in humans were transferred to the genus Anncaliia based on novel ultrastructural and molecular data (15). Disporoblastic sporogony of Anncaliia vesicularum (formerly Brachiola vesicularum) produces 2.5- by 2-μm diplokaryotic spores containing 7 to 10 anisofilar coils of the polar filament arranged in one to three rows, usually two (16). On the basis of diplokaryotic nuclei, disporoblastic sporogony, and the formation of vesiculotubular secretions, Nosema connori and Nosema algerae, also discovered in human infections, have been reclassified as species of Anncaliia. Spores of Anncaliia connori measure 2.0 to 2.5 by 4.0 to 4.5 μm and contain polar tubes with 10 to 12 coils (17). Spores of Anncaliia algerae measure 3.7 to 5.4 by 2.3 to 3.9 μm and have 8 to 11 coils of the polar tube (18).

Encephalitozoon spp. develop intracellularly in parasitophorous vacuoles bounded by a membrane of presumed host cell origin. Nuclei of all stages are unpaired. Meronts divide repeatedly by binary fission and lie close to the vacuolar membrane. Sporonts appear free in the center of the vacuole and divide into two or four sporoblasts, which mature into spores. The spores measure 1.0 to 1.5 by 2.0 to 3.0 μm, and the polar tube has four to eight isofilar coils.

Encephalitozoon cuniculi was isolated from a range of animals before human infections were identified. Human isolates of three Encephalitozoon spp. and animal isolates of E. cuniculi are morphologically identical. In 1991, Encephalitozoon hellem was distinguished from E. cuniculi on the basis of different protein patterns (19). In 1993, Septata intestinalis was described and named on the basis of the unique morphological findings that the organisms are contained in intracellular vacuoles and that a pathogen-secreted fibrillar network...
surrounds the developing organisms, giving the vacuoles a septate appearance (20). Subsequently, on the basis of phylogenetic analyses, S. intestinalis was reclassified as Encephalitozoon intestinalis. Finally, so far four genotypes of E. cuniculi have been identified that partially differ in animal-host preferences and geographic distributions (21, 22).

Endoreticulatus spp. was proposed in a single case based on genetic findings; ultrastructural results are not available (23).

Enterocytozoon bienesi develops in direct contact with host-cell cytoplasm (Fig. 2). The proliferative and sporogonic forms are rounded multinucleate plasmodia with unpaired nuclei measuring up to 6 μm in diameter. The oval spores measure 0.7 to 1.0 by 1.1 to 1.6 μm. The polar tube, derived from electron-dense disks in sporonts, has five to seven isofilar coils that appear in two rows when seen in transverse section by transmission electron microscopy (24).

Nozema spp. develop in direct contact with host-cell cytoplasm, nuclei are paired (diplokaryotic), divisions are by binary fission, and sporonts are disporoblastic. Only one species of human origin, Nozema ocularum, has been retained in this genus. It will probably require reclassification, but insufficient information is currently available for a new generic assignment. Spores measure 3 by 5 μm and have polar tubes with 9 to 12 coils.

Pleistophora spp., including P. ronneafiei, which is pathogenic in humans, have unpaired nuclei, and all stages are multinucleate plasmodia, which divide into smaller multineculeate segments. Meronts have a thick, amorphous coat, which separates from the surface in sporogony to form a sporophorous vesicle. Sporogonic divisions give rise to a large and variable number of spores, packaged in the persistent sporophorous vesicle. The spores contain polar tubes with 9 to 12 coils and measure 2 to 2.8 by 3.3 to 4.0 μm (25).

Trachipleistophora hominis forms spores in sporophorous vesicles; these arise from repeated binary fissions and not from multinucleate plasmodia. The vesicles, which contain 2 to more than 32 spores, enlarge as the number of spores increases. The nuclei are unpaired in all stages of development. The pear-shaped spores measure 2.4 by 4.0 μm and have about 11 isofilar coils (26). Trachipleistophora anthropophthera is similar to T. hominis but appears to be dimorphic, as two different forms of sporophorous vesicles and spores have been observed (27).

Tubulinosome acidophagus was proposed based on genetic analyses. Ultrastructurally, all developing stages are in direct contact with host-cell cytoplasm, spores are unpaired, and sporonts develop into disporoblastic sporonts (28). The sporonts contain a large, amorphous polar tube, which separates from the sporogonial plasmodium to form a sporophorous vesicle. The spores measure 3 by 5 μm and have polar tubes with 9 to 12 coils (29).

*f Formerly Nosema coreum.

generic assignment. Spores measure 3 by 5 μm and have polar tubes with 9 to 12 coils.

Pleistophora spp., including P. ronneafiei, which is pathogenic in humans, have unpaired nuclei, and all stages are multinucleate plasmodia, which divide into smaller multineculeate segments. Meronts have a thick, amorphous coat, which separates from the surface in sporogony to form a sporophorous vesicle. Sporogonic divisions give rise to a large and variable number of spores, packaged in the persistent sporophorous vesicle. The spores contain polar tubes with 9 to 12 coils and measure 2 to 2.8 by 3.3 to 4.0 μm (25).

Trachipleistophora hominis forms spores in sporophorous vesicles; these arise from repeated binary fissions and not from multinucleate plasmodia. The vesicles, which contain 2 to more than 32 spores, enlarge as the number of spores increases. The nuclei are unpaired in all stages of development. The pear-shaped spores measure 2.4 by 4.0 μm and have about 11 isofilar coils (26). Trachipleistophora anthropophthera is similar to T. hominis but appears to be dimorphic, as two different forms of sporophorous vesicles and spores have been observed (27).
FIGURE 1  Generalized life cycle of microsporidia and identifying characteristics of the genera known to infect humans. Light stippling indicates merogonic stages; heavy stippling indicates sporogonic stages; no stippling indicates spores and sporoplasm. (A) Basic life cycle, illustrated by Nosema. Development may occur in direct contact with host-cell cytoplasm (Nosema, Anncaliia, and Enterocytozoon) or in isolation by host cell membranes (Vittaforma and Encephalitozoon) or a cyst-like sporophorous vesicle of pathogen origin (Pleistophora and Trachipleistophora). 1, Sporoplasm: the infective stage emergent from the spore. It may have unpaired nuclei (monokaryotic) or two nuclei in close apposition (diplokaryotic), depending on the genus. 2, Merogony: proliferative stage. It may have a simple plasma membrane, but a surface coat is present in Anncaliia, Pleistophora, and Trachipleistophora. Division can be by binary or multiple fission into two or more individuals. 3, Sporont: the first stage of sporogony. If not already present, a surface coat is added (this step is delayed in Enterocytozoon). 4, Sporogony: divisions culminating in spore production. Binary or multiple fissions give rise to sporoblasts. 5, Sporoblasts: end products of sporogony, which mature into spores. 6, Spores: resistant stages for transmission. Spores are characterized by an extrusion apparatus (polar tube), which serves to conduct the sporoplasm into a host cell. The polar tube may be of uniform diameter (isofilar) or show a sharp decrease in diameter in the most posterior coils (anisofilar). (B to G) Identifying characteristics of genera. (B) Anncaliia. Members of this genus are monokaryotic and di- or tetrasporoblastic; the life cycle is like that of Nosema, but meronts are of bizarre shapes and possess a surface coat with vesiculotubular structures (vt) embedded in it and extended from it. (C) Vittaforma. Members of this genus are diplokaryotic and polysporoblastic; all stages, including spores, are isolated in a close-fitting, ribosome-studded cisterna of host endoplasmic reticulum (er). (D) Pleistophora. Members of this genus are monokaryotic and polysporoblastic; meronts and sporonts are multinucleate stages called plasmodia; a thick surface coat is already present on meronts and sporonts (1); this coat separates from the sporogonial plasmodium to form a cyst-like vesicle, the sporophorous vesicle; the plasmodium divides within it to produce numerous spores (2). (E) Trachipleistophora. Members of this genus are monokaryotic and polysporoblastic. The meront surface coat has branched extensions (1); these are withdrawn when the coat separates to form the sporophorous vesicle around a uninucleate sporont; the sporont undergoes a series of binary fissions (2 and 3) and finally encloses numerous spores (4). (F) Encephalitozoon. Members of this genus are monokaryotic and di- or tetrasporoblastic; all stages of the life cycle, developing from the sporoplasm, occur concurrently within a host cell vacuole (parasitophorous vacuole); merontic stages are appressed against the vacuole wall; sporogonic stages are free; the vacuole is finally packed with spores, so that it superficially resembles a sporophorous vesicle. (G) Enterocytozoon. Members of this genus are monokaryotic and polysporoblastic; meronts (1) have irregular nuclei and lucent clefts; sporonts (2) are multinucleate with rounded nuclei and have highly characteristic electron-dense disks, which are polar tube precursors; all spore organelles are formed prematurely, so that constriction around the sets of organelles and a nucleus (3) gives rise directly to almost mature spores. The surface coat is deposited only during constriction. doi:10.1128/9781555817381.ch128.f1
FIGURE 2  Transmission electron micrograph showing the duodenal epithelium of a HIV-infected patient infected with *Enterocytozoon bieneusi*. The different developmental stages between the enterocyte nuclei and the microvillus border include a proliferative plasmodium (1), late sporogonial plasmodia (2), and mature spores (arrow). contact with the host-cell cytoplasm. Spore size ranges from 1.4 to 2.4 μm in length, nuclei are diplokaryotic, and polar filaments are anisofilar and contain 11 coils arranged mostly in single rows, although in some spores double rows are present (28, 29).

*Vittaforma corneae*, originally classified as *Nosema corneum*, was transferred to a new genus on the basis of ultrastructural features (30). Nuclei are diplokaryotic, sporogony is polysporoblastic, sporonts are ribbon-shaped, and all stages, including spores, are individually enveloped by a cisterna of host endoplasmic reticulum studded with ribosomes. The spores contain polar tubes with five to seven coils and measure 1.2 by 3.8 μm.

*Microsporidium* is a collective generic name for microsporidia that cannot be classified because available information is not sufficient. *Microsporidium ceylonensis* and *Microsporidium africanum* have been assigned to the group name (31).

EPIDEMIOLOGY AND TRANSMISSION

Human microsporidial infections have been documented globally. The sources of microsporidia infecting humans and their modes of transmission are uncertain but ingestion of the environmentally highly resistant spores is probably the most important mode of transmission. Transmission by dust or aerosol has also been considered based on respiratory or ocular infections (32, 33). Direct contact with water during bathing in hot spring spas was associated with microsporidial keratitis (34). Water contact was found to be a risk factor for microsporidiosis. *E. bieneusi*, *E. intestinalis*, and *V. corneae* homologous DNA has been detected in sewage effluent, groundwater, and surface water (35, 36), also suggesting anthropogenic transmission. Furthermore, foodborne outbreaks associated with microsporidia have been reported (37), and microsporidia pathogenic in humans have been detected in fresh food produce (38) and in milk specimens from dairy cows (39). Studies with mammals suggest that *Encephalitozoon* spp. can be transmitted transplacentally from mother to offspring, but no congenitally acquired human infections have been reported.

Direct zoonotic transmission of microsporidia has not been verified but appears likely because many microsporidial species can infect both humans and animals (3). *E. cuniculi* is considered to be a zoonotic pathogen; two of its four genotypes that were detected in natural infections in rabbits, dogs, and tamarins have been isolated from human immunodeficiency virus (HIV)-infected patients (21, 40). In addition to documentation in humans, *Encephalitozoon* spp. have been detected in psittacines kept in aviaries, in a variety of wild birds, including in feces of urban feral pigeons (41), in domestic animals in Mexico (42), and in gorillas in Uganda. *E. bieneusi*, discovered in humans, is increasingly being recognized in animals (wildlife, livestock, and companion animals). Genetic analyses of this pathogen revealed two major groups, one comprising anthropogenic genotypes,
and the other containing multiple genotypes with zoonotic potential (43). Also, an insect-pathogenic microsporidian, A. algerae, was isolated from three patients (44, 45).

**CLINICAL SIGNIFICANCE**

Although microsporidiosis appears to occur most frequently in persons infected with HIV, it is emerging in otherwise immunocompromised but also in immunocompetent persons (Table 1) (1, 4). In the non-HIV-infected immunocompromised host, microsporidial infections were described in organ transplant recipients (46), in patients with hematologic malignancies receiving monoclonal antibody therapy (47), in patients with rheumatic disease undergoing antitumor necrosis factor therapy (48), in the elderly (49), and in malnourished children (50). In immunocompetent persons, microsporidia have been associated with keratoconjunctivitis (51), self-limiting diarrhea (52), and rarely cerebral infection (53–55). Microsporidia are also found in asymptomatic persons (56).

Microsporidia has been associated with abnormalities in structures and functions of infected organs, but the mechanisms of pathogenicity of the different microsporidial species are not sufficiently understood. Patients with severe cellular immunodeficiency appear to be at the highest risk for developing microsporidial disease. Unfortunately, little is known about immunity to this infection, although the importance of T cells has been demonstrated in experiments with athymic mice (57). It is not understood whether microsporidiosis in immunocompromised patients is primarily a reactivation of latent infection acquired prior to the state of suppressed immunity or whether microsporidial disease is caused by recently acquired infection.

**Enterocytozoon bieneusi**

*E. bieneusi* infects the enterocytes of the small intestine and epithelial cells of the biliary tree and respiratory tract. Clinical disease is probably caused by the continuous excess loss of epithelial cells. *Enterocytozoon* infection may be accompanied by alterations in small bowel physiology such as decreased brush border sucrase, lactase, and maltase activities, as well as malabsorption.

*E. bieneusi* is estimated to be one of the most important HIV-associated intestinal pathogens, present in 5 to 30% of patients with chronic diarrhea, weight loss, or cholangiopathy, particularly when CD4 lymphocyte counts are below 100/μl (58). Upper or lower respiratory tract infections have been detected in a few patients (59), but systemic infection due to *E. bieneusi* has not been documented. Case reports have documented that the organisms are also a cause of diarrhea in organ transplant recipients (46).

In immunocompetent adults and in children, *E. bieneusi* is associated with self-limiting watery diarrhea (lasting up to 2 to 3 weeks), particularly among persons who reside or have traveled in tropical areas (60). Furthermore, the organisms have been identified among malnourished children in tropical areas (50), and elderly persons (residing in resource-rich countries) with acute or chronic diarrhea (49).

**Encephalitozoon spp.**

*Encephalitozoon* spp. infect epithelial and endothelial cells, fibroblasts, macrophages, and possibly other cell types, as reported for humans and mammals. Human encephalitozoonosis was first described in two children with a seizure disorder (53, 54). Cerebral infections have subsequently been substantiated (55, 61, 62). Unexpectedly, *E. cuniculi* endocarditis was diagnosed in a non-immunocompromised patient with a dual-chamber pacemaker (63).

The spectrum of recognized *E. cuniculi* - and *E. hellem*-associated disease in patients with AIDS, organ transplant recipients, and otherwise immunocompromised patients includes keratoconjunctivitis, intraocular infection, sinusitis, broncholitis, pneumonitis, nephritis, ureteritis, cystitis, prostatitis, urethritis, hepatitis, sclerosing cholangitis, peritonitis, diarrhea, and encephalitis (1, 19, 40, 61). Clinical manifestations may vary substantially, ranging from an asymptomatic carrier state to organ failure.

*E. intestinalis* infects primarily enterocytes, but the organism is also found in intestinal lamina propria, and dissemination to the kidneys, airways, and biliary tract appears to occur via infected macrophages (20). Chronic diarrhea and disseminated disease due to *E. intestinalis* have been diagnosed mainly in immunodeficient patients. A case of nodular cutaneous *E. intestinalis* infection was observed in a patient with AIDS (64). Furthermore, *E. intestinalis* has been detected in stool specimens from healthy children and adults, with or without diarrhea, living in Mexico (65), and among travelers with diarrhea returning from tropical countries (66).

**Other Microsporidia**

Different microsporidial species have been isolated from immunocompetent persons (1, 30, 67) and from immunodeficient persons (68) with keratoconjunctivitis, severe keratitis, or corneal ulcers. Also, keratoconjunctivitis due to microsporidia has been diagnosed in immunocompetent contact lens wearers (Table 1).

In immunocompromised patients, disseminated infections and myositis have been linked to infections with different microsporidia (Table 1), including Pleistophora sp. (69), *P. romaei* sp. (25), *T. hominis* (70), *A. vesiculatum* (16), *A. algerae* (44), and *T. acridophagus* (28, 29). *A. algerae* has also been isolated from erythematous skin nodules from a boy with acute lymphocytic leukemia (71). Myositis due to *Endoreticulatus* spp. was diagnosed in an otherwise healthy man in Thailand (23).

Trachipleistophora anthropophthera has been identified at autopsy in cerebral, cardiac, renal, pancreatic, thyroid, hepatic, splenic, lymphoid, and bone marrow tissue of patients with AIDS who initially presented with seizures (72). Disseminated infection due to *A. comorni* was found at autopsy in a 4-month-old athymic male infant (17).

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

Spores of enteropathogenic microsporidia can be detected in stool specimens or duodenal aspirates that have been fixed in 10% formalin or in sodium acetate-acid-formalin, fresh stool samples, or biopsy specimens. The spores of microsporidia causing disseminated infection can usually be detected in fresh or fixed urine sediments, other body fluids (including sputum, bronchoalveolar lavage fluid, nasal secretions, cerebrospinal fluid, and conjunctival smears), corneal scrapings, or tissue. For histologic examination, tissue specimens are fixed in formalin. For electron microscopy, fixation of tissue with glutaraldehyde is preferred. Collection of fresh material (without fixative) may be useful for cell culture and for molecular identification. Microsporidial spores are environmentally resistant and, if prevented from drying, can remain infectious for periods of up to several years (73).
DETECTION PROCEDURES

The most robust technique for the diagnosis of microsporidial infection is light-microscopic detection of the organisms themselves. Spores, the stages of microsporidia pathogenic in humans that are usually identified, are small, ranging in size from 1 to 4 μm. Evaluation of patients with suspected intestinal microsporidiosis should begin with light-microscopic examination of stool specimens, and microsporidia which cause systemic infection are best detected in urine sediments or other body fluids. Definitive species identification of microsporidia is made by electron microscopy and, preferably, genetic analysis (73).

Examination of Stool Specimens

Preparation of Smears, Staining, and Microscopic Examination

Smears are prepared using 10 to 20 μl of unconcentrated stool that is very thinly spread onto slides. Most of the coprological procedures that have been adapted for the concentration of ova and parasites fail to concentrate microsporidial spores. The formalin-ethyl acetate concentration of the specimen is adjusted to the extent that the stool can be made to spread evenly over the slide without forming puddles. Examination of stool specimens, and microsporidia in stool that is very thinly spread onto slides. Most of the coprological procedures that have been adapted for the concentration of ova and parasites fail to concentrate microsporidial spores. The formalin-ethyl acetate concentration of the specimen is adjusted to the extent that the stool can be made to spread evenly over the slide without forming puddles.

The most commonly used stains are chromotrope-based stains (74) and chemofluorescent optical brightening agents (75, 76), including calcofluor white and other chemofluorescent stains. Regardless of which staining technique is utilized, the use of positive-control material is essential. The detection of microsporidial spores requires adequate illumination and magnification, i.e., magnification of ×630 or ×1,000 (oil immersion). The differences in the sizes of spores, the stages of microsporidia pathogenic in humans that are usually identified, are small, ranging in size from 1 to 4 μm. Evaluation of patients with suspected intestinal microsporidiosis should begin with light-microscopic examination of stool specimens, and microsporidia which cause systemic infection are best detected in urine sediments or other body fluids. Definitive species identification of microsporidia is made by electron microscopy and, preferably, genetic analysis (73).

Chromotrope-based staining procedures

Microsporidial spores are ovoid and have a specific appearance when stained with chromotrope stains (Fig. 3 and 4, right panel) (74). The spore wall stains bright pinkish red, some spores appear transparent, and other spores show a distinct pinkish red-stained belt-like stripe that girds the spores diagonally or equatorially. Most background debris in stool specimens counterstains a faint green (or blue, depending on the staining technique). Some other fecal elements, such as parasite cysts (e.g.,Cyclospora), yeasts, and some bacteria, may also stain reddish, but they are distinguished from microsporidial spores by their sizes, shapes, and staining patterns.

Several modifications of the original chromotrope-staining solution (74) have been proposed, including modifications of the counterstain and changes in the temperature of the standard chromotrope-staining solution and in the staining time (77). An acid-fast trichrome stain (78), that permits visualization of acid-fast cryptosporidial oocysts as well as microsporidial spores on the same slide, and a “quick-hot” Gram-chromotrope-staining technique (79) have also been developed.

Chemofluorescent Agents

Chemofluorescent optical brightening agents are chitin stains, which require examination with a fluorescent microscope. With the correct wavelength illumination, the chitinous wall of the microsporidial spores fluoresces brightly, facilitating the detection of spores. However, staining is not specific because small yeast cells, which may be present in fecal material, and other fecal elements may also be brightened. Some experience is necessary to distinguish the microsporidia.

Epidemiological comparisons of the chromotrope staining technique with methods that use chemofluorescent optical brighteners indicate that these tests are robust for routine use and that the sensitivities of both methods are similarly high. Some laboratories use both staining techniques because the chromotrope stains result in a highly specific visualization of spores, whereas the chemofluorescent agents may be more sensitive but may produce false-positive results.

Immunofluorescent-Antibody Tests

Monoclonal antibodies against Encephalitozoon spp. (80) and E. bieneusi (81) have been generated, of which some have been evaluated for diagnostic purposes with stool specimens. However, immunofluorescence procedures for the detection of Encephalitozoon or Enterocytozoon microsporidial spores are not commercially available.

Cytological Diagnosis

Microsporidial spores have been detected in sediments obtained by centrifugation of body fluids for 10 min at 500 × g, including duodenal aspirates, bile, biliary aspirates, urine (Fig. 4, right panel), bronchoalveolar lavage fluid (Fig. 4, middle panel), and cerebrospinal fluid, and in smears of conjunctival swabs, sputum, and nasal discharge. Microscopic examination of stained smears of centrifuged duodenal aspirate obtained during endoscopy is a highly sensitive technique for the diagnosis of intestinal microsporidiosis. Because microsporidial infection often involves multiple organs, the detection of microsporidia in virtually any tissue or body fluid should prompt a thorough search of other sites. Particularly...
for patients with suspected disseminated microsporidiosis, urine specimens should be examined (1, 73).

**Examination of Biopsy Specimens and Corneal Scrapings**

Examination of duodenal and terminal ileal tissue has resulted in the detection of intestinal microsporidia, but the pathogens are rarely found in colonic tissue sections. Microsporidial species causing disseminated infection have been found in almost every organ system (1).

Only highly experienced pathologists have reliably and consistently identified microsporidia in tissue sections by using routine techniques such as hematoxylin and eosin staining. Ultrathin plastic sections stained with methylene blue-azure II-basic fuchsin or with toluidine blue may facilitate detection. In our experience, tissue Gram stains (Brown-Brenn or Brown-Hopps) have proved to be the most useful for the rapid and reliable identification of HIV-associated microsporidia in routine paraffin-embedded tissue sections (Fig. 4, left panel) and corneal scrapings (1, 32). The microsporidial spores are Gram variable, and they are readily identified because of the contrasting dark blue or reddish staining against a faint brown-yellow background. Others prefer a silver stain (Warthin-Starry stain) (82), the chromotrope-based staining technique, or chemofluorescent agents.

**Molecular Techniques**

Universal panmicrosporidian and genus- or species-specific primer pairs that target the rRNA genes and their application in the diagnosis of intestinal microsporidial infection have been described (5). The detection and identification of *E. bieneusi* and the different *Encephalitozoon* spp. have been successfully performed with fresh stool specimens, formalin-fixed stool specimens, intestinal tissue obtained by endoscopic biopsy, urine specimens, and other body fluids. A real-time PCR method was developed for quantitation of *E. bieneusi* DNA (83) and *E. intestinalis* DNA (84) in stool specimens. Furthermore, *in situ* hybridization to visualize *E. bieneusi* in tissue sections has been developed (85).

**ISOLATION OF MICROSPORIDIA**

Microsporidia cannot be grown axenically. *Encephalitozoon* spp., *T. hominis*, *V. corneae*, and *A. algerae* have been isolated with different cell culture systems, including RK-13 (rabbit kidney), MDCK (Madin-Darby canine kidney), MRC-5 (human embryonic lung fibroblast) cells, and other cells (31, 40, 86). Only short-term *in vitro* propagation has been accomplished with *E. bieneusi*. The isolation of microsporidia has no relevance for diagnostic purposes but is an important research tool.

**IDENTIFICATION**

The identification of microsporidia and their taxonomy have been based primarily upon ultrastructural characteristics. Microsporidial ultrastructure is unique and taxonomonic for the phylum, and ultrastructural features can distinguish all microsporidial genera (Fig. 1) (31). Nevertheless, morphologic features alone do not sufficiently characterize all microsporidial species pathogenic for humans. The characterization of the three *Encephalitozoon* spp., which share most of their morphologic features, requires antigenic or genetic analyses, which may also reveal subtype-specific variation (19, 21). Identification of novel microsporidial
species can be achieved by phylogenetic analyses of gene sequences derived from PCRs using panmicrosporidian primers.

**SEROLOGIC TESTS**

Serologic assays (including the carbon immunocassay, indirect immunofluorescence test, enzyme-linked immunosorbent assay, and Western blot immunodetection) have been useful in detecting specific antibodies to *E. cuniculi* in several species of animals. However, the value of such tests for humans has controversially been discussed because of possible cross-reactivity of the spore wall antigens of the *Encephalitozoon* species. Furthermore, results of serologic studies with humans were not substantiated by the detection of organisms in individuals with antibody responses. By employing recombinant antigens of the polar tube of *E. cuniculi*, improved specificity was demonstrated, and the development of serodiagnostic tests seems feasible (87).

**ANTIMICROBIAL SUSCEPTIBILITIES**

Albendazole has been found to cause growth deformities of *Encephalitozoon* and *Vittaforma* and to reduce or eradicate the organisms propagated in cell cultures but does not destroy mature microsporidial spores; thus, these may sustain infection (88). Fumagillin, its analog TNP-470, nikkomycin Z, and fluoroquinolones have been shown in *vitro* to inhibit completely or partially the replication or spore germination of *Encephalitozoon* and *Vittaforma* (88, 89). In *vitro* systems to investigate *E. bieneusi* are not available.

Treatment studies with humans are limited, and only two randomized controlled trials have been conducted. Albendazole can result in clinical cure of HIV-associated encephalitozoonosis in parallel with the cessation of spore excretion (90). In contrast, albendazole is not effective against *Enterocytozoon* infection and does not reduce pathogen load, although previous observations had suggested that clinical improvement may occur in some patients. Orally applied fumagillin appeared to eradicate *E. bieneusi* in severely immunodeficient HIV-infected patients (91) and in renal transplant recipients (92), but serious adverse events have also been reported (91, 93).

*Enterocytozoon bieneusi*-associated diarrhea as well as systemic infection due to *Encephalitozoon* spp. is mainly observed in severely immunodeficient patients. Improvement of immune functions by antiretroviral therapy results in complete clinical response and normalization of intestinal architecture, which parallel the clearance of intestinal microsporidia (94). Microsporidial keratoconjunctivitis may be a self-limiting disease (95, 96), or may be cleared by repeated corneal swabbing (97). Successful systemic albendazole treatment (98) or response to topical voriconazole application (99) have been reported.

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

Microsporidia are predominantly opportunistic pathogens capable of causing disease in severely immunodeficient HIV-infected persons (with CD4 cell counts below 200/μl) and otherwise immunocompromised patients, including organ transplant recipients. Therefore, stool examination or examination of other specimens is particularly indicated for these patient groups, and it is prudent to consider microsporidia as the etiologic agents when they are detected in clinical specimens from such patients. Furthermore, various microsporidial species may cause self-limited diarrhea or keratoconjunctivitis in immunocompetent and otherwise healthy persons.

Routine diagnosis of microsporidiosis is based upon microscopic detection of microsporidial spores. Although sensitive and specific, light-microscopic examination does not allow the identification of the organisms to the genus and species level. This can be achieved in most cases by electron microscopy, which is relatively insensitive for the detection of microsporidia because only small samples are examined and sampling errors may occur, or by PCR assays and further sequence analyses. Immunocompetent patients may excrete lower numbers of microsporidial spores in feces or urine, and therefore, the threshold of the current light-microscopic detection procedures may not be sufficient for the reliable detection of microsporidia in this group.

After a long period of slow development, the past decade has seen the introduction of an important new class of antifungal agents (the echinocandins), expansion of the spectrum of an established class of agents through chemical modification (the triazoles), and the development of novel methods for delivering established agents (lipid-based formulations of amphotericin B). These developments have changed the standards of care for the treatment of many invasive fungal infections, particularly aspergillosis and candidiasis. This chapter reviews the four major families of antifungal drugs that are currently available for systemic administration: the allylamines, the azoles, the echinocandins, and the polyenes. The comparative activities of the major systemic antifungal agents against important groups of fungi are summarized in Table 1. This chapter also discusses the characteristics of several other agents that can be used for the oral or parenteral treatment of superficial, subcutaneous, or systemic fungal infections. Novel agents that are currently in clinical trials are briefly reviewed.

### ALLYLAMINES

The allylamines are a group of synthetic antifungal compounds effective in the topical and oral treatment of dermatophytes. Two drugs, terbinafine and naftifine, are licensed for clinical use. Naftifine is only available as a topical preparation.

#### Mechanism of Action

The allylamines inhibit squalene epoxidase, a critical enzyme in the formation of ergosterol, the principal sterol in the membrane of susceptible fungal cells. The consequent accumulation of squalene leads to membrane disruption and cell death (1).

#### Terbinafine

Terbinafine (Lamisil; Novartis Pharmaceuticals) is a lipophilic drug that is available for oral or topical administration. It is widely used for the treatment of superficial fungal infections caused by dermatophytes.

#### Spectrum of activity

Terbinafine is effective against several groups of pathogenic fungi, including dermatophytes (Epidermophyton, Microsporum, and Trichophyton spp.) (2–4) and dematiaceous fungi (5). It also has some activity against Aspergillus spp. (6), Candida spp. (6), Blastomyces dermatitidis and Histoplasma capsulatum (7), Paracoccidioides brasiliensis (8), Talaromyces (Penicillium) marneffei (9), and Sporothrix schenckii (6, 8).

#### Acquired Resistance

The development of resistance to terbinafine among dermatophytes, even after prolonged exposure, is rare.

#### Pharmacokinetics

Terbinafine is well absorbed after oral administration and is then rapidly and extensively distributed to body tissues (10). It reaches the stratum corneum as a result of diffusion through the dermis and epidermis, and secretion in sebum. Diffusion from the nail bed is the major factor in its rapid penetration of nails. Terbinafine has been found to persist in nails for long periods after cessation of treatment. It is extensively metabolized by the human hepatic cytochrome P-450 enzyme system, and the inactive metabolites are mostly excreted in the urine (11).

#### Clinical Use

Terbinafine is the drug of choice for dermatophyte infections of the skin and nails where topical treatment is considered inappropriate or has failed (12, 13). It is not as effective as itraconazole for treatment of fungal nail infections (onychomycosis) involving nondermatophytes. Terbinafine has also proven effective in some patients with aspergillosis, chromoblastomycosis, and sporotrichosis (14), but it is not licensed for these indications. Anecdotal evidence suggests that the use of terbinafine in combination with voriconazole may be beneficial in the treatment of infections with Scedosporium prolificans (15).

#### Drug Interactions

Although terbinafine is metabolized by the human hepatic cytochrome P-450 enzyme system, it does not inhibit most CYP enzymes at clinically relevant concentrations (11). Blood concentrations of terbinafine are reduced when it is given together with drugs, such as rifampin, that induce the hepatic cytochrome P-450 system.

#### Toxicity and Adverse Effects

Terbinafine produces few adverse reactions. These include abdominal discomfort, nausea, diarrhea, impairment of taste,

This table is a general overview for comparison of the activities of some systemic drugs against various fungi. Readers are recommended to refer to the text for more detailed information.

- a, no meaningful activity; +, occasional activity; ++, moderate activity but resistance is noted; ++++, reliable activity with occasional resistance

AZOLES

This large group of synthetic agents contains many compounds that are effective in the topical treatment of dermatophyte infections and superficial forms of candidiasis; a number are suitable for systemic administration. Members of this group have in common an imidazole or triazole ring with N-carbon substitution. The systemic-use antifungals are the triazoles.

Mechanism of Action

Azole compounds inhibit a fungal cytochrome P-450-dependent enzyme, lanosterol 14 α-demethylase, which is responsible for the conversion of lanosterol to ergosterol, the principal sterol in the membrane of susceptible fungal cells. This results in the accumulation of various toxic methylated sterols and the depletion of ergosterol with subsequent disruption of membrane structure and function. The activity is essentially fungistatic, although voriconazole and itraconazole can exert fungicidal effects against Aspergillus and some other mold species at concentrations achieved with recommended dosages (17).

Several mechanisms of resistance have been described (see chapter 130). These include upregulation of multidrug efflux-transporter genes, upregulation of the ERG11 gene that encodes the target enzyme, lanosterol 14 α-demethylase, and decreased affinity of this enzyme forazole agents due to either intrinsic or acquired amino acid substitutions (18). Changes in other enzymes involved in the ergosterol biosynthesis pathway, such as loss of Δ5,6 sterol desaturase activity, may also contribute to azole resistance (18).

Pharmacokinetics

With the exception of fluconazole, food has a significant effect on the absorption of azole antifungals. Administration with lipid-rich food improves the absorption of ketoconazole, posaconazole, and the capsule formulation of itraconazole (19–22). In contrast, absorption of voriconazole and the oral solution formulation of itraconazole is reduced when given with a high-fat meal (23, 24).

Peak blood concentrations of azoles are typically reached within 2 to 3 h after oral administration. With fluconazole and posaconazole, blood levels increase in proportion to dosage (25). In contrast, increases in itraconazole dosage produce disproportionate changes in peak blood concentrations due to saturable first-pass metabolism in the liver (26). In adults, there is a disproportionate increase in blood levels of voriconazole with increasing oral and parenteral dosage (27). In children, however, increases in dosage produce proportional changes in drug levels, and clearance of the drug is more rapid (28).

Due to its low protein binding (about 12%), fluconazole attains high concentrations in most tissues and body fluids. Levels of the drug in cerebrospinal fluid (CSF) usually exceed 50% of the simultaneous blood concentration (29). Likewise, voriconazole is extensively distributed into tissues (29), with CSF levels that are around 30 to 60% of the simultaneous blood concentration (30). Voriconazole and fluconazole concentrations in vitreous and aqueous fluids are around 40 to 50% of the simultaneous blood level, which makes them useful for treating endophthalmitis (31). Levels of itraconazole in the CSF are minimal (22).

Levels of itraconazole in tissues such as lung, liver, brain, and bone are two to three times higher than in serum. High concentrations are also found in the stratum corneum as a result of drug secretion in sebum (32). Itraconazole has been found to persist in the skin and nails for weeks to months after the end of a course of treatment, thereby allowing intermittent pulse regimens for dermatophyte infections and onychomycosis (32, 33).

With the exception of fluconazole and posaconazole, the azoles are extensively metabolized by the human hepatic cytochrome P-450 enzyme system, and are eliminated as inactive metabolites in the bile or urine. More than 90% of a dose of fluconazole is eliminated in the urine, predominantly as unchanged drug, which makes it useful for treating urinary tract infections caused by susceptible species (34). More than 75% of a dose of posaconazole is eliminated in the feces, predominantly as unchanged drug, with the remainder being excreted as glucuronidated derivatives in
the urine (35). Itraconazole is unusual because its major metabolite, hydroxyitraconazole, is bioactive and has a similar spectrum of activity as the parent compound (36). This metabolite is found at serum concentrations about 2-fold higher than those of the parent drug (22).

Itraconazole is metabolized by several different hepatic cytochrome P-450 enzymes, primarily CYP-2C19, with more than 80% of a dose being eliminated as inactive metabolites in the urine (34). However, as a result of a point mutation in the gene encoding this enzyme, some persons are poor metabolizers while others are extensive metabolizers. About 3 to 5% of Caucasians and 15 to 20% of non-Indian Asians are poor metabolizers (29). Voriconazole blood concentrations are as much as 4-fold lower in individuals who metabolize the drug more extensively and can reach toxic levels in poor metabolizers.

**Drug Interactions**
Most azole antifungal agents are extensively metabolized by the human hepatic cytochrome P-450 enzyme system and are potent inhibitors of CYP-3A4; some also inhibit CYP-2C9 and CYP-2C19. Their coadministration with other drugs that are metabolized by these enzymes can result in increased blood concentrations of theazole, the interacting drug, or both (37). When an azole agent is discontinued, the change in metabolism that occurs may necessitate upward or downward adjustment of the dosage of the other drugs. Administration of azoles with drugs that are potent inducers of the human cytochrome P-450 enzyme system, such as rifampin, results in a marked reduction in blood concentrations, especially with itraconazole and ketoconazole (37).

**Fluconazole**
Fluconazole (Diflucan; Pfizer) is a water-soluble bis-triazole available in both oral and parenteral formulations. It is extensively used as prophylaxis and in treating yeast infections, particularly in the treatment of candidiasis and cryptococcosis.

**Spectrum of Activity**
Fluconazole possesses the narrowest spectrum of all the azole antifungals currently available for systemic use. It is active against most Candida spp. and Cryptococcus neoformans (38, 39). However, isolates of Candida krusei are intrinsically resistant and Candida glabrata has decreased susceptibility (39, 40). The spectrum of activity also includes several dimorphic fungi (B. dermatitidis, Coccidioides spp., and H. capsulatum) (41). Fluconazole has no activity against Aspergillus spp., Fusarium spp. (42), or mucoraceous moulds (43).

**Acquired Resistance**
There have been few reports of resistance developing in C. albicans during short-term fluconazole treatment in patients with mucosal or deep-seated forms of candidiasis (18). In contrast, many strains of C. glabrata rapidly become resistant to fluconazole during treatment (44). In persons with AIDS, resistant strains of C. albicans have appeared following repeated courses of low-dose fluconazole treatment for oral or esophageal infection. However, with the widespread use of highly active antiretroviral treatment for HIV infection, resistant strains are now rarely encountered (45). There are a few reports of resistant strains of C. neoformans from AIDS patients with relapsed infection following long-term maintenance treatment with fluconazole, but these cases are thought to be rare (46, 47).

**Clinical Use**
Fluconazole is widely used in the treatment of mucosal and systemic candidiasis (48), coccidioidomycosis (49), and cryptococcosis (50). It is also widely used for the prevention of candidiasis in neutropenic patients (48), as well as for the prevention of relapse of cryptococcal meningitis in persons with AIDS (50). Fluconazole is an alternative for the treatment of histoplasmosis and sporotrichosis, but is less effective than itraconazole (51, 52).

**Therapeutic Drug Monitoring**
Serum concentrations of fluconazole are predictable from dosing and organ function, and routine monitoring of drug levels is not required (53–55).

**Toxicity and Adverse Effects**
Fluconazole is one of the least toxic and best-tolerated azole drugs and side effects during treatment are rare. The most common patient complaints include headache, hair loss, and loss of appetite. Transient abnormalities of liver enzymes and rare serious skin reactions, including Stevens-Johnson syndrome, have been reported.

**Itraconazole**
Itraconazole (Sporanox; Ortho-McNeil-Janssen Pharmaceuticals) is a lipophilic triazole drug available for oral or parenteral administration. It is extensively used, particularly in the treatment of superficial fungal infections, as well as in a range of subcutaneous and systemic infections.

**Spectrum of Activity**
Itraconazole has good activity against a broad spectrum of pathogenic fungi, including Aspergillus spp. (56–60), Candida spp. (39, 56, 59), many dematiaceous moulds (5, 61), dermatophytes (2–4), and dimorphic fungi (B. dermatitidis, Coccidioides spp., H. capsulatum, P. brasiliensis, T. mentefei, and S. schenckii) (8, 9, 41, 62–64). Itraconazole has modest activity against C. neoformans (39, 59), but is ineffective against Pseudallescheria boydii (65) and most mucoraceous moulds (43).

**Acquired Resistance**
Itraconazole-resistant strains of A. fumigatus have been reported following treatment (66, 67). Of more concern are increasing reports of itraconazole resistance due to an environmentally acquired mutation in cyp51a, TR/L94H (68). This mutation has now been identified in isolates from Europe, China, and India and has become a serious problem in parts of Europe (66, 69–72).

**Clinical Use**
Itraconazole has been widely used to treat various superficial fungal infections, including the dermatophytes, onychomycosis, pityriasis versicolor, and mucosal and cutaneous forms of candidiasis. It is also effective in patients with paracoccidioidomycosis, chromoblastomycosis, sporotrichosis, and certain forms of phaeohyphomycosis (51, 73, 74). Despite its limitations, itraconazole continues to be a drug of choice in the management of mild to moderate forms of blastomycosis and histoplasmosis (52, 75). It was the first orally active drug for aspergillosis, but its use in seriously ill patients with life-threatening forms of this disease is not recommended (76). Itraconazole is the drug of choice for long-term maintenance treatment to prevent relapse in AIDS patients with histoplasmosis (52), but it is less effective than fluconazole as maintenance treatment in AIDS patients with cryptococcosis (50).
Therapeutic Drug Monitoring
Absorption of the capsule formulation of itraconazole after oral administration shows marked variation between individuals. Because low serum concentrations are often predictive of treatment failure, measurement of blood levels is advisable in situations where the drug is used to treat or prevent serious invasive fungal infections (53–55). For prophylaxis, a target trough concentration of >0.5 μg/ml has been proposed; for treatment, a trough of >1 to 2 μg/ml has been recommended (53).

Toxicity and Adverse Effects
Most side effects associated with itraconazole are mild and reversible. The most frequently reported adverse events are headache, loss of appetite, nausea, abdominal discomfort, diarrhea, skin rashes, and transient elevations of liver enzymes. Gastrointestinal intolerance is more common with itraconazole oral solution and is sometimes severe enough to necessitate discontinuation of treatment (77, 78). Rare, but serious, side effects include Stevens-Johnson syndrome, hepatitis, and congestive heart failure.

Ketoconazole
Ketoconazole (Nizoral; Ortho-McNeil-Janssen Pharmaceuticals) is a lipophilic drug formulated for oral or topical use. It is the only antifungal imidazole still available for systemic administration, but its main use is now as a topical agent.

Spectrum of Activity
Ketoconazole has useful activity against dermatophytes (2–4) and dimorphic fungi (B. dermatitidis, Coccidioides spp., H. capsulatum, P. brasiliensis, and S. schenckii) (62, 79). It is also active against Candida spp. and C. neoformans, although it is less effective than the newer triazoles.

Acquired Resistance
This is rare, but several instances were documented in the 1980s among patients given long-term treatment for chronic mucocutaneous candidiasis due to C. albicans.

Clinical Use
Due to the availability of less toxic, more efficacious alternatives, ketoconazole is now little used, except in resource-limited environments. Ketoconazole remains a useful topical agent for dermatophytosis, cutaneous candidiasis, pityriasis versicolor, and seborrheic dermatitis (80).

Toxicity and Adverse Effects
Unwanted effects include loss of appetite, abdominal pain, nausea, and vomiting. Transient elevations of liver enzymes are common with oral ketoconazole, and fatal hepatitis is a rare but well-recognized adverse event. High doses of ketoconazole inhibit human adrenal and testicular steroid synthesis, with clinical consequences such as alopecia, gynecomastia, and impotence.

Posaconazole
Posaconazole (Noxafil; Merck) is a second-generation, broad-spectrum triazole compound which is currently only available as an oral suspension. An intravenous formulation has passed a phase I clinical trial. A new tablet with better bioavailability, release in the small bowel, and absorption is also in development. Posaconazole is highly lipophilic and has a chemical structure similar to that of itraconazole.

Spectrum of Activity
Posaconazole is highly active against most Aspergillus spp. (56, 58, 60), as well as Candida spp., C. neoformans, and Trichosporon spp. (39, 56, 64, 81). It has potent activity against a number of dimorphic fungi, including B. dermatitidis, Coccidioides spp., H. capsulatum, T. marneffei, and S. schenckii (41, 64). It is less active against Fusarium spp. and P. boydii, but appears to be effective against dematiaceous fungi (41, 42, 64, 65). Unlike other azole antifungals, posaconazole has significant activity against some mucoraceous moulds (43, 56, 64, 82).

Acquired Resistance
Posaconazole sometimes has activity against strains of Aspergillus and Candida spp. that show resistance to itraconazole, fluconazole, and/or voriconazole (64, 68). Posaconazole resistance in A. fumigatus isolates harboring the TR/L98H mutation has been shown (66, 69, 72).

Clinical Use
The lack of an intravenous formulation of posaconazole is a major disadvantage when treating seriously ill patients. In the United States, the drug has been approved for the treatment of oropharyngeal candidiasis (including infections refractory to itraconazole and/or fluconazole), as well as for prophylaxis of invasive aspergillosis and candidiasis in high-risk patients, such as hematopoietic stem cell transplant (HSCT) recipients with graft-versus-host disease and neutropenic cancer patients. In the European Union, posaconazole has been licensed for similar indications, as well as for salvage treatment of invasive aspergillosis, coccidiodomycosis, chromoblastomycosis, Fusarium infections, and mycetoma. Other indications for which posaconazole has proved effective but is not currently licensed include histoplasmosis (83), coccidiodomycosis (84), and infections caused by mucoraceous moulds (82, 85).

Therapeutic Drug Monitoring
Similarly to itraconazole and voriconazole, there appears to be a relationship between posaconazole trough serum concentrations and clinical response, and measurement of drug levels may therefore be useful (86). For prophylaxis, a target trough concentration of >0.5 μg/ml has been proposed; for treatment, a trough of >0.5 to 1.5 μg/ml has been suggested (53).

Toxicity and Adverse Effects
Posaconazole is well tolerated, even among patients receiving the drug for longer than 6 months (87). The most frequently reported side effects have been gastrointestinal symptoms and headache. Transient transaminase abnormalities have also been reported. Rare cases of cholestasis or hepatic failure have occurred during treatment with posaconazole.

Voriconazole
Voriconazole (Vfend; Pfizer) is a second-generation broad-spectrum triazole compound available for oral or intravenous administration. Its chemical structure is similar to that of fluconazole.

Spectrum of Activity
Voriconazole is highly active against most Aspergillus spp., Fusarium spp., and P. boydii (42, 56, 58, 60, 61, 63), as well as Candida spp., C. neoformans, and Trichosporon spp. (64, 81). Voriconazole has potent activity against a number of dimorphic fungi, including B. dermatitidis, Coccidioides spp., H. capsulatum, and T. marneffei (41, 63), as well as dematiaceous moulds (61). Voriconazole is ineffective against mucoraceous moulds (43, 61, 64).
Acquired Resistance
Some fluconazole-resistant strains of Candida spp. have shown reduced susceptibility to voriconazole, and essentially all C. glabrata isolates that are resistant to fluconazole are nonsusceptible to voriconazole (64). Aspergillus isolates may acquire voriconazole resistance during long-term azole therapy (66, 88). Environmentally acquired resistance to voriconazole in A. fumigatus due to a TR/L98H mutation, as well as a newly described cyp51a mutation, is occurring more frequently (69–71, 88, 89).

Clinical Use
The availability of both an intravenous formulation and a well-absorbed oral formulation of voriconazole is a distinct advantage when treating seriously ill patients. In the U.S., the drug has been approved for the treatment of invasive aspergillosis and has become the drug of choice for these infections (76). It is also licensed for the treatment of candidemia in nonneutropenic patients, for disseminated infections caused by Candida spp., and for esophageal candidiasis, as well as for salvage treatment of Fusarium and Scedosporium infections. In the European Union, voriconazole has been approved for similar indications. Voriconazole has no activity against mucoraceous moulds, and its use in immunocompromised patients has sometimes been associated with breakthrough infections caused by these organisms.

Therapeutic Drug Monitoring
Voriconazole serum concentrations are highly variable, largely due to differences in the rate of metabolism between individuals, and it may be beneficial to monitor drug levels (53–55). For prophylaxis, a target trough concentration of >0.5 μg/ml has been proposed; for treatment, a trough of >1 to 2 μg/ml has been recommended (53). To avoid toxicity, trough concentrations of 6 μg/ml of voriconazole should not be exceeded.

Toxicity and Adverse Effects
Voriconazole is generally well tolerated. About 30% of patients experience transient visual disturbances and hallucinations, usually during the first week of treatment (29). Other side effects include skin rashes and transient abnormalities of liver enzymes. Rare, but serious, adverse effects include Stevens-Johnson syndrome, hepatic failure, and cardiovascular events.

Echinocandins
The echinocandins are a new class of semisynthetic lipopeptide antifungal agents that target the fungal cell wall. Three echinocandins have been approved for the treatment of serious fungal infections: anidulafungin, caspofungin, and micafungin. Due to their high molecular weight and low oral bioavailability, these drugs are only available as intravenous preparations. They are now widely used, particularly in the treatment of candidiasis.

Mechanism of Action
The echinocandins disrupt fungal cell-wall synthesis by inhibiting the enzyme 1,3-β-D-glucan synthase. This results in inhibition of the formation of 1,3-β-D-glucan, an essential polysaccharide component of the cell wall of susceptible fungi. Inhibition leads to osmotic lysis of the cell and eventual cell death. Echinocandin drugs bind to Fksp, the major subunit of 1,3-β-D-glucan synthase, which is encoded by three FKS genes in Candida spp. (90). The echinocandins are fungicidal for Candida spp., but fungistatic for Aspergillus spp. (91), where they block the growth of the apical tips of the hyphae.

Resistance to echinocandin drugs among clinical isolates has been associated with mutations in the Candida spp. FKS1 gene that lead to amino acid substitutions in the Fks1p subunit of 1,3-β-D-glucan synthase (90, 92). These changes result in altered drug binding and confer cross-resistance to all echinocandin drugs. Mutations in the FKS1 and FKS2 genes are responsible for reduced susceptibility to caspofungin, micafungin, and anidulafungin in C. glabrata (93, 94).

Spectrum of Activity
The echinocandins have a limited spectrum of activity. They are highly active against a broad range of Candida spp., including fluconazole-resistant strains (91, 95–98). C. parapsilosis, C. lusitaniae, and C. guilliermondii have higher MIC values to the echinocandins, but the clinical implications of these values are not yet clear (95–98). The echinocandins are also active against Aspergillus spp., including those that are intrinsically resistant to amphotericin B (58, 91, 96, 99, 100).

The echinocandins are ineffective against fungi that lack a significant amount of 1,3-β-D-glucan in their cell wall, including C. neoforms and Trichosporon spp., as well as Fusarium spp. and the mucoraceous moulds (43, 56, 58, 91, 96, 99, 101). Micafungin has been reported to be active against the mycelial forms of several dimorphic fungi, including B. dermatitidis and H. capsulatum, but is ineffective against the tissue forms of these pathogens (102).

Acquired Resistance
This is rare at present, but resistant strains of several Candida spp. have been recovered from patients failing echinocandin treatment (103–106). Resistance has been associated with acquisition of mutations in the FKS1 and/or FKS2 genes that led to amino acid substitutions within the FKS1p and FKS2p subunits of 1,3-β-D-glucan synthase (93, 94, 103–105). The highest rates of resistance have been detected in C. glabrata, especially in strains already resistant to fluconazole (103, 107).

Pharmacokinetics
Blood concentrations of all three echinocandins increase in proportion to dosage (108–110). These drugs are extensively distributed to body tissues, but levels in the CSF are negligible. The predominant differences among these agents lie in their metabolism and half-life. Caspofungin and micafungin are largely metabolized by the liver and eliminated as inactive metabolites in the feces and urine (111–114). Anidulafungin is not eliminated by hepatic metabolism, but undergoes slow nonenzymatic degradation in the blood to an inactive open-ring peptide (115). Less than 1 to 3% of an echinocandin dose is excreted unchanged in the urine (108, 112, 114, 115). In adults, the half-life of caspofungin is about 9 to 10 h (110), while that of micafungin is 13 h (112) and that of anidulafungin is 18 to 27 h (108, 115). The three echinocandins have a shorter half-life in children (116–118). The 24-hour area under the concentration-time curve (AUC)/MIC is a good indicator of the exposure-response relationship with a ratio that should exceed 10 to 20 (119).

Drug Interactions
The echinocandins do not interact with the human hepatic cytochrome P-450 system and their use has been associated with very few significant drug interactions.
Therapeutic Drug Monitoring
At this time, there is no established relationship between efficacy or toxicity of the echinocandins and serum concentrations (54). Routine monitoring of serum levels during treatment with these drugs is not required.

Toxicity and Adverse Effects
As a class, the echinocandins are well tolerated and their use is associated with very few significant adverse effects (112, 116, 117). The most common side effects are gastrointestinal in nature, but only occur in around 5% of patients. Occasional cases of infusion-related pain and phlebitis have been noted with anidulafungin and micafungin, but these are less common with caspofungin. Transient elevations of liver enzymes have been reported in a few patients.

Anidulafungin
Anidulafungin (Ecalta or Eraxis; Pfizer) was the first echinocandin to go into development and the most recent to be licensed for clinical use. It differs from caspofungin and micafungin in that it is insoluble in water. Anidulafungin is derived from a fermentation product of Aspergillus nidulans and is formulated for intravenous infusion.

Clinical Use
In the U.S., anidulafungin is currently approved for the treatment of esophageal candidiasis, candidemia, and two invasive forms of candidiasis (abdominal abscesses and peritonitis). In the European Union, anidulafungin is approved for the treatment of invasive candidiasis in nonneutropenic patients. Anidulafungin has not been evaluated in sufficient numbers of neutropenic patients to determine its effectiveness in that group.

Caspofungin
Caspofungin (Cancidas; Merck) is a water-soluble lipopeptide derived from a fermentation product of Glarea lozoyensis. It is formulated for intravenous infusion.

Clinical Use
In the U.S., caspofungin is currently approved for the treatment of esophageal candidiasis, candidemia, and certain invasive forms of candidiasis, including abdominal abscesses, peritonitis, and pleural-space infections. Caspofungin is also licensed for the salvage treatment of invasive aspergillosis in patients who have failed to respond to or are intolerant of other antifungal agents. Caspofungin is approved for the empiric treatment of presumed fungal infections in febrile neutropenic patients. It has similar indications in the European Union, with a license for the treatment of invasive candidiasis in adult and pediatric patients, salvage treatment of aspergillosis, and empiric treatment of febrile neutropenia in adult or pediatric patients.

Micafungin
Micafungin (Mycamine; Astellas Pharma, Fujisawa Healthcare) is a water-soluble antifungal agent derived from a fermentation product of Coleophoma empetri. It is formulated for intravenous administration.

Clinical Use
In the U.S., micafungin is currently approved in adults for the treatment of esophageal candidiasis, candidemia, and several invasive forms of candidiasis, including abdominal abscesses and peritonitis, and for prophylaxis of Candida infections in HSCT patients. In the European Union, the drug is approved for the treatment of esophageal candidiasis in adults and for invasive candidiasis in adults and children, including neonates. In addition, micafungin is licensed as prophylactic treatment to prevent Candida infections in HSCT recipients in the U.S. and European Union. In Japan, the license includes respiratory and gastrointestinal mycosis due to Aspergillus spp.

POLYENES
Around 100 polyene antibiotics have been described, but few have been developed for clinical use. Amphotericin B and its lipid formulations are used for the treatment of systemic fungal infections. Nystatin, natamycin, and mephamycin are topical polyene agents used in the treatment of oral, vaginal, and ocular fungal infections. A liposomal formulation of nystatin entered clinical trials, but its development has ceased. The polyenes are large molecules that consist of a closed macrolide lactone ring. One side of the ring is composed of a rigid lipophilic chain with a variable number of conjugated double bonds, and on the opposite side there are a similar number of hydroxyl groups. Thus, the molecule is amphiphilic and this feature of its structure is believed to be important in its mechanism of action.

Mechanism of Action
The polyenes bind to sterols, principally ergosterol, in the membranes of susceptible fungal cells, causing impairment of membrane barrier function, leakage of cell constituents, metabolic disruption, and cell death (120). In addition to its membrane-permeabilizing effects, amphotericin B can cause oxidative damage to fungal cells through a cascade of oxidative reactions linked to liperoxidation of the cell membrane.

Amphotericin B
Amphotericin B (Fungizone; Apothecon) is a fermentation product of Streptomyces nodosus available for intravenous infusion. The conventional micellar suspension formulation of this drug (amphotericin B deoxycholate) is often associated with serious toxic side effects, particularly renal damage. During the 1990s, three new lipid-associated formulations of amphotericin B were developed in an effort to alleviate the toxicity of the agent. These are liposomal amphotericin B (Ambisome; Astellas Pharma, Gilead Sciences), in which the drug is encapsulated in phospholipid-containing liposomes; amphotericin B lipid complex (ABLC) (Abelcet; Enzon Pharmaceuticals), in which the drug is complexed with phospholipids to produce ribbon-like structures; and amphotericin B colloidal dispersion (ABCD) (Amphocet; Three Rivers Pharmaceuticals), in which the drug is packaged into small lipid disks containing cholesterol sulfate. These formulations possess the same broad spectrum of activity as the micellar suspension, but are less nephrotoxic.

Spectrum of Activity
Amphotericin B is active against a broad spectrum of pathogenic fungi including most Aspergillus spp., Candida spp., C. neoformans, and the mucormaceous moulds (43, 56–58, 60, 64, 96). However, most isolates of A. terreus are resistant to amphotericin B (57, 58, 60, 121), as are isolates of Aspergillus lentulus, a new sibling species of A. fumigatus (122). Candida krusei also demonstrates reduced susceptibility to amphotericin B (123). Amphotericin B is effective against the dimorphic fungi (B. dermatitidis, Coccidioides spp., H. capsulatum, and P. brasiliensis) and many dematiaceous fungi (61, 63, 64). Strains of P. boydii, S. prolificans, Fusarium spp., and
Trichosporon spp. are often intrinsically resistant to amphotericin B (42, 64, 65, 81).

Acquired Resistance
This is rare, but amphotericin B-resistant strains of C. albi-
cans, C. glabrata, C. guilliermondii, C. tropicalis, Cryptococcus neoformans, and especially C. lusitaniae with alterations in the cell membrane, including reduced amounts of ergosterol, have been reported following prolonged treatment (124, 125).

Pharmacokinetics
Amphotericin B is poorly absorbed after oral administration and must be administered as a slow intravenous infusion. The drug is widely distributed to many tissues, with the highest concentrations being found in the liver, spleen, and kidneys. Levels in the CSF are less than 5% of the simultaneous blood concentration. Amphotericin B is mostly excreted as unchanged drug in the urine (21%) and feces (42%) (126). No metabolites have been identified. The drug is cleared very slowly, with the conventional deoxycholate formulation having a terminal half-life of around 127 h.

The pharmacokinetics of lipid-based formulations of ampho-
tericin B are quite diverse. Maximal serum concentra-
tions of the liposomal formulation are much higher than those of the deoxycholate formulation, while levels of ABCD and ABLC are lower due to more rapid distribution of the drug to tissue (127). Administration of lipid-associated formulations of amphotericin B results in higher drug concentrations in the liver and spleen than are achieved with the conventional formulation (128). Renal concentra-
tions of the drug are lower and the nephrotoxic side effects are greatly reduced.

Clinical Use
Although other agents have subsequently been introduced, amphotericin B remains the treatment of choice for many serious fungal infections, including blastomycosis, coccidioidomycosis, histoplasmosis, sporotrichosis, cryptococcosis, and mucormycosis (49–52, 75). However, with the advent of voriconazole and the echinocandins, amphotericin B is no longer regarded as the drug of first choice for many cases of aspergillosis or candidiasis (48, 76). The three lipid-based formulations of amphotericin B are currently licensed for treatment of invasive fungal infections in patients who are refractory to, or intolerant of, conventional amphotericin B. In addition, liposomal amphotericin B is licensed for the treatment of cryptococcal meningitis in persons with AIDS, as well as for the empirical treatment of presumed fungal infection in febrile neutropenic patients. Clinical experience with these preparations has demonstrated that they are safer and no less active than the conventional formulation and, for some infections, they are more effective, espe-
cially since the reduced toxicity allows them to be used at a higher dose.

Drug Interactions
Amphotericin B can augment the nephrotoxicity of many other agents, including aminoglycoside antibiotics and cyclosporine.

Therapeutic Drug Monitoring
Serum and tissue concentrations of amphotericin B show marked variation with formulation, especially among the lipid-based products, and there are few data relating either efficacy or toxicity to blood levels. Therefore, there is no need to monitor serum concentrations of amphotericin B during therapy (53). However, due to the risk of toxicity, kidney function should be monitored.

Toxicity and Adverse Effects
Amphotericin B deoxycholate causes infusion-related reac-
tions, including hypotension, fever, rigors, and chills, in approximately 70% of patients (129). The major adverse effect of the drug is nephrotoxicity. This is dose related and may occur in more than 80% of patients receiving treatment. The lipid-associated formulations all lower the risk of am-
photericin B-induced renal failure (130). However, infu-
sion-related side effects, such as hypoxia and chills, are more common in patients treated with ABCD. In contrast, infusion-related reactions are uncommon in patients receiv-
ing liposomal amphotericin B or ABLC (131).

OTHER MISCELLANEOUS AGENTS
Flucytosine
Flucytosine (5-fluorocytosine) (Ancobon; Valeant Pharma-
ceuticals) is a synthetic fluorinated analogue of cytosine and the only available antifungal agent acting as an antim-
tabolite. In the U.S., flucytosine is available as oral tablets; elsewhere it is also available as an infusion for parenteral administration.

Mechanism of Action
Flucytosine disrupts pyrimidine metabolism and thus the synthesis of DNA, RNA, and proteins within susceptible fungal cells. Flucytosine is transported into these cells by the enzyme cytosine permease and then converted by cytosine deaminase to 5-fluorouracil (5-FU). Two mechanisms then account for the antifungal activity. The first involves the conversion of 5-FU into 5-fluorouridine triphosphate, which is incorporated into fungal RNA in place of uridylic acid, with resulting inhibition of protein synthesis. The second mechanism involves the conversion of 5-FU to 5-fluoro-
deoxyuridine monophosphate, which blocks the enzyme thymidylate synthetase, causing inhibition of fungal DNA synthesis. Fungi lacking cytosine deaminase are intrinsically resistant to flucytosine.

Spectrum of Activity
Flucytosine has a narrow spectrum of activity. It includes Candida spp., C. neoformans, and some dematiaceous fungi causing chromoblastomycosis (56, 96). Primary resistance to flucytosine is very uncommon among Candida spp., occurring in around 2 to 3% of isolates (96, 132).

Acquired Resistance
Monotherapy with flucytosine often leads to the induction of resistance among Candida spp. and C. neoformans (133).

Pharmacokinetics
Flucytosine is rapidly and almost completely absorbed after oral administration. The drug is widely distributed, with levels in most body tissues and fluids usually exceeding 50% of the simultaneous blood concentration (134). Flucytosine is primarily eliminated by renal excretion of unchanged drug. The serum half-life is between 3 and 6 h, but may be greatly extended in renal failure, necessitating modification of the dosage regimen.
Clinical Use
Due to the risk of resistance, flucytosine is rarely administered as a single agent. It is most commonly used in combination with amphotericin B in the treatment of candidiasis and cryptococcosis (48, 50). Combination treatment with fluconazole has also been shown to be effective in AIDS-associated cryptococcal meningitis (50).

Drug Interactions
The antifungal activity of flucytosine is competitively inhibited by cytarabine (cytosine arabinoside), and the two drugs should not be administered together (134). Nephrotoxic drugs, such as amphotericin B, decrease the elimination of flucytosine, and serum concentrations of the latter should be monitored when these agents are administered together. Flucytosine is myelosuppressive (see below) and should be used with caution in patients receiving other drugs, such as zidovudine, that could enhance its immunosuppressive side effects.

Therapeutic Drug Monitoring
Regular monitoring of serum drug concentrations of flucytosine is advisable to reduce the risk of hepatoxicity and hematological toxicity; this is essential when there is renal impairment. To avoid toxicity, a peak concentration of 100 μg/ml of flucytosine should not be exceeded (54). In contrast to toxicity, there are few data relating efficacy to blood levels for flucytosine. A reasonable goal is to maintain a post-dose concentration of >25 μg/ml but <100 μg/ml (53, 54).

Toxicity and Adverse Effects
The most common, and least harmful, side effects of flucytosine are gastrointestinal, and include nausea, diarrhea, vomiting, and abdominal pain. The most severe adverse effects include bone marrow depression and hepatotoxicity (134). These complications are more likely to occur if excessively high blood concentrations are maintained.

Griseofulvin
Griseofulvin is an antifungal antibiotic derived from a number of Penicillium species, including P. griseofulvum. Introduced in 1958, oral griseofulvin transformed the treatment of dermatophytosis.

Mechanism of Action
Griseofulvin is a fungistatic drug that binds to microtubular proteins and inhibits fungal cell mitosis (135).

Spectrum of Activity
The spectrum of useful activity is restricted to dermatophytes causing skin, nail, and hair infections (Epidermophyton, Microsporum, and Trichophyton spp.) (2, 4). Resistance has rarely been reported.

Pharmacokinetics
Absorption of griseofulvin from the gastrointestinal tract differs between individuals, but is improved if the drug is given with a high-fat meal. Griseofulvin appears in the stratum corneum within a few hours of ingestion, as a result of secretion in perspiration. However, levels begin to fall soon after the drug is discontinued, and within 48 to 72 h it can no longer be detected. Griseofulvin is metabolized by the liver to 6-desmethyl griseofulvin, which is excreted in the urine.

Clinical Use
Newer oral agents, such as terbinaine or itraconazole, are often preferred for nail infections, but griseofulvin remains a useful second-line agent for moderate to severe dermatophytes of the skin and scalp hair, where topical treatment is considered inappropriate or has failed.

Drug Interactions
Absorption of griseofulvin is reduced in persons receiving concomitant treatment with barbiturates. Griseofulvin may decrease the effectiveness of oral anticoagulants, oral contraceptives, and cyclosporine.

Toxicity and Adverse Effects
In most cases, prolonged courses and high doses are well tolerated. Adverse effects occur in around 15% of patients and include headache, nausea, vomiting and abdominal discomfort, and rashes.

NOVEL ANTIFUNGAL AGENTS IN DEVELOPMENT
Two promising broad-spectrum triazole compounds, isavuconazole and albaconazole, are currently in clinical trials (136). Isavuconazole (Basilea Pharmaceutica, Astellas Pharma) is a water-soluble compound that can be administered orally or intravenously. The drug has predictable and dose-proportional pharmacokinetics and has completed phase III clinical trials for the treatment of invasive candidiasis and candidemia, treatment of invasive aspergillosis, and treatment of rare mould infections (137, 138).

Isavuconazole has shown good in vitro activity against both Candida and other yeast species, as well as Aspergillus sp. other than A. niger (139–141), and has been granted orphan drug status by the U.S. Food and Drug Administration for the treatment of invasive aspergillosis. Albaconazole (Stiefel) is an oral agent that has demonstrated high levels of bioavailability and antifungal activity. It was evaluated in a phase I trial for tinea pedis and has completed a phase II trial for the treatment of toenail onychomycosis (142).

CONCLUSION
The recent surge in development of new antifungal agents has greatly increased the number of drugs available to combat the growing number of serious fungal infections. There are now few life-threatening conditions for which there is no effective treatment, and there are many for which there are several therapeutic options. With judicious use of the available agents, antifungal drug resistance should continue to be a minor clinical problem. As more compounds have become licensed, the number of novel antifungal drugs entering preclinical development appears to have diminished. It remains to be seen which, if any, of these will reach the marketplace.

Mechanisms of Resistance to Antifungal Agents*

DAVID S. PERLIN

Globally, 300 million people of all ages suffer from serious fungal infections, resulting in over 1,350,000 deaths annually. Some fungal diseases are acute and severe (e.g., cryptococcal meningitis, invasive aspergillosis, and fungal eye infection), while others are recurrent (e.g., Candida vaginitis or oral candidiasis in AIDS). The most serious fungal infections occur as a consequence of other serious health problems such as asthma, AIDS, cancer, organ transplantation, and corticosteroid therapies (1). All require specialized testing for diagnosis and most require antifungal therapy.

More than 90% of all reported fungal-related deaths result from species that belong to one of three genera: Cryptococcus, Candida, and Aspergillus (1). Failure to treat effectively, because of either diagnostic delays or missed diagnosis, often leads to death, serious chronic illness, or blindness. This global recognition of the importance of fungal infections has led to a dramatic rise in the use of antifungal agents for treatment and prevention. Unfortunately, treatment options for invasive fungal infections are limited, as there are few chemical classes represented by existing antifungal drugs.

Classes of antifungal drugs include polyenes, azoles, allylamines, flucytosine, and echinocandins. The azoles (e.g., fluconazole, voriconazole, and posaconazole) and allylamines (e.g., terbinafine) target ergosterol biosynthesis. Like cholesterol in mammalian cells, ergosterol is the major sterol in the fungal plasma membrane. Polyenes, like amphotericin B, bind to ergosterol in the plasma membrane, where they form large pores that disrupt cell function. Flucytosine (5-fluorocytosine) inhibits pyrimidine metabolism and DNA synthesis. Finally, the echinocandins (caspofungin, anidulafungin, and micafungin) are cell wall-active agents that inhibit the biosynthesis of β-1,3-glucan, a major component of the fungal cell wall.

The expanding use of antifungal agents has led to rising drug resistance. The emergence of acquired drug resistance among prevalent fungal pathogens constrains or eliminates treatment options, with a devastating impact on patient management. A greater understanding of biological factors that contribute to mechanism-specific resistance and that promote strategies to overcome resistance is critical to the field of medical mycology. The detailed and complex biological nature of antifungal drug resistance mechanisms is the topic of this chapter.

DEFINING CLINICAL AND MICROBIOLOGICAL RESISTANCE

The development of antifungal resistance is complex and relies on multiple host and microbial factors. Any discussion of drug resistance must distinguish between multifaceted clinical resistance and microbial resistance to antifungal agents.

“Clinical resistance” refers to therapeutic failure, when a patient inadequately responds to an antifungal drug following administration of a standard dose. A variety of host, drug, and microbial factors contribute to therapeutic failure. A major factor is the immune status of the host. Antifungal drug action and the host immune system often must work synergistically to control and clear an infection. Patients with severe immune dysfunction are more refractory to treatment, as the antifungal drug must combat the infection without the positive benefit of the immune response. The immune system has a large dynamic range that can help eliminate or enhance the clinical manifestations of fungal diseases (1). The presence of indwelling catheters, artificial heart valves, and other surgical devices may also contribute to refractory infections, as the infecting fungus attaches to these objects, creating resilient biofilms that provide protection from drug therapy. The site of the infection also contributes to clinical resistance, since it may be inaccessible to drug therapy. Drug penetration is a major factor for many infections, as it is difficult to deliver drugs at an adequate concentration in certain infected tissues and organs. Appropriate therapy requires that the drug reach its microbial target at a suitable concentration to inhibit growth or kill the organism, and the pharmacokinetics (PK) of many antifungal drugs are known. Yet, we still do not have a good understanding of drug penetration at all sites of infection, with the result that some microorganisms are exposed to drug at inadequate levels. Finally, patient compliance with prescribed drug regimens is critical for effective treatment, as poor adherence reduces the effectiveness of the drug, contributing to development of persistent drug-tolerant cell populations. The selection of strains that fail to respond to drugs forms a significant component of drug failures during therapy. Overall, there remains a strong relationship between drug exposure and the emergence of resistance.

“Microbiological resistance” refers to decreased susceptibility of a fungal strain to an antifungal agent in standardized in vitro susceptibility testing relative to a susceptible standard
reference strain. (The details of antifungal susceptibility testing according to guidelines established by the Clinical and Laboratory Standards Institute [CLSI] and the European Committee on Antimicrobial Susceptibility Testing [EUCAST] are addressed in chapter 131.) Susceptibility testing provides a measure of the MIC. MIC resistance breakpoints refer to those drug concentrations that separate strains where there is a high likelihood of treatment success from those organisms where treatment is more likely to fail (2). Yet, interpreting the results of in vitro antifungal susceptibility testing can be problematic, as MIC values above the breakpoint do not always directly associate with response to antifungal therapy. This apparent discordance between in vivo and in vitro data is illustrated by the “90–60 rule,” which maintains that infections due to susceptible strains respond to appropriate therapy in ~90% of cases, whereas infections due to resistant strains respond in ~60% of cases (3). Microbiological resistance can be primary (intrinsic) or secondary (acquired). Primary resistance is found naturally among certain fungi without prior drug exposure. It may involve the same mechanism responsible for acquired resistance, or unknown mechanisms.

**Primary Resistance**

Antimicrobial agents are generally developed for efficacy against the most prominent pathogens causing disease. Universal broad-spectrum activity (e.g., panfungal), while desirable, is rarely achieved, and there will always be a subset of species or naturally occurring variants of mostly susceptible species that are inherently resistant. Presently, there are more than 200 species of *Candida*, and while fewer than 40 are known to cause human infections (4), there is great genetic diversity that can affect drug action. The extended application of antifungal agents against a wide spectrum of mycoses can result in the selection of naturally occurring species with inherent resistance (5). Nevertheless, the overall selection of resistant species, subspecies, or less susceptible variants from the environment or from patient reservoirs occurs uncommonly (6, 7). The common feature of intrinsic resistance is that the underlying resistance mechanism is inherent and not acquired during therapy.

**Polyenes**

The polyene drug amphotericin is fungicidal and resistance to it rarely occurs. When it does, it is almost always due to selection of strains with high intrinsic reduced susceptibility (MIC, >2 μg/ml) (8), which correlates with the amphotericin B epidemiological cutoff values (ECV) for most *Candida* species (9). The organisms *Scedosporium apiospermum*, * Fusarium* spp., *Trichosporon* spp., and *Sporothrix schenckii* are frequently resistant to amphotericin (10). Breakthrough infections have been reported for *Candida rugosa* (11), *Candida lusitaniae* (12), and *Candida tropicalis* (13). Among the *Aspergillus* spp., primary resistance to amphotericin B has been reported for strains of *A. terreus* (14, 15), *A. flavus* (16), and *A. ustus* (17).

**Azoles**

The azole antifungal agents are the most prominent example of drug selection for less susceptible species (10). Numerous global epidemiological studies have documented the impact of widespread triazole use on the distribution and shift of *Candida* species toward less susceptible strains like *C. glabrata* and *C. krusei*. In many regions where azole use (e.g., fluconazole) is prevalent, there has been a shift away from *Candida albicans* as the predominant cause of invasive infections toward less susceptible non-*C. albicans* species (18).

*C. glabrata* has inherent reduced susceptibility to fluconazole, and it is the species whose incidence has increased the most to account for a decrease in the prevalence of *C. albicans* (18, 19). Similarly, fluconazole use is linked to emergence of the highly resistant *C. krusei* (20) and *Candida guilliermondii* (21) as significant causes of candidemia. In many cases, inherent resistance in *Candida* species to fluconazole also carries with it resistance to more highly active triazoles like voriconazole. This is not true for *Aspergillus* and other moulds that are resistant to fluconazole but susceptible to more highly active triazoles. Yet, breakthrough infections against highly active triazole drugs have been reported for *A. ustus* (22) and *Aspergillus fumigatus*-like species such as *A. lentulus*, which show pleiotropic resistance to multiple antifungal drugs (23, 24).

Sometimes, a susceptible species develops a prevalent variant that is the source of resistant infections. In the bacterial world, the regional and global spread of drug-resistant strains from a common progenitor is commonly observed. Such transmission is not typically observed for fungal drug resistance. A notable exception occurred with the recent emergence of a multidrug-resistant variant of *A. fumigatus* in the Netherlands (25, 26). This resistant strain was encountered in patients who failed therapy for invasive aspergillosis despite having no prior azole exposure (27). This highly azole-resistant strain variant was selected in the environment as a consequence of the prevalent use of agricultural azoles. The resistance mechanism unique to these isolates is discussed later in the chapter; such resistant strains are spreading through Europe and into parts of Asia (28).

**Echinocandins**

Finally, the echinocandins are highly active against most *Candida* spp., but they have inherent reduced susceptibility against the *Candida parapsilosis* group (C. parapsilosis sensu stricto, *C. orthopsilosis*, and *C. metapsilosis*) and *C. guilliermondii* (29). Some breakthrough infections have been reported during therapy and have been attributed to the inherent reduced susceptibility of these strains (30). Resistance to echinocandin drugs has also been described for *A. lentulus* (24). In some filamentous fungi, such as *A. lentulus*, *A. ustus*, and *Fusarium* spp., there is coresistance that confers resistance to azoles and echinocandin drugs, and occasionally resistance to polyenes.

In summary, drug pressure is a powerful selection tool that results in infections of uncommon fungi with inherent reduced susceptibility to antifungal drugs. In a majority of cases, the nature of drug insensitivity is a reflection of underlying resistance mechanisms that emerge in susceptible strains in response to drug action.

**RESISTANCE TO AZOLES**

**Mechanism of Action of Azoles**

Azoles inhibit the biosynthesis of ergosterol, the principal sterol in fungal cell membranes, by interfering with the action of lanosterol 14α-demethylase, which is encoded by ERG11 (Cyp51A in *Aspergillus*). There are many licensedazole antifungal drugs (imidazoles, triazoles), yet the triazole drugs fluconazole, voriconazole, itraconazole, and posaconazole are the most commonly prescribed drugs for prophylaxis or treatment of systemic and mucosal fungal infections. Triazoles are chemically characterized by having a five-member ring moiety of two carbons and three nitrogen
The drugs differ in their target affinities, which influences their spectrum of activity. Fluconazole has the weakest interaction with its target and shows the narrowest spectrum of activity. It is active against many yeasts, but it has poor activity against moulds like A. fumigatus. The more highly active triazoles, like voriconazole and posaconazole, interact more strongly with the demethylase target and show broad-spectrum activity against yeasts and moulds, as well as activity on some fluconazole-resistant strains. Fluconazole and its chemical analogue voriconazole are structurally similar, while posaconazole and itraconazole are more closely related. It is this moderate chemical diversity around a core unit that promotes cross-reactivity, and at times differential susceptibility, which ultimately depends upon the nature of the resistance mechanism.

Epidemiology of Azole Resistance

The widespread use of fluconazole in the pre-antiretroviral therapy era as a safe and effective antifungal agent to treat HIV-infected patients with oropharyngeal or esophageal candidiasis led to the emergence of resistance among susceptible strains like C. albicans. A multitude of sentinel and population-based surveillance programs from more than 40 countries have contributed to our understanding of azole resistance (6, 31–38). Overall, the studies confirm that acquired resistance among susceptible species is low, while resistance is more significant in non-albicans Candida species. For example, the ARTEMIS DISK Global Antifungal Surveillance Study evaluated clinical isolates of Candida spp. from 142 sites in 41 countries over a 10-year period from 1997 to 2007. For all Candida spp. isolates, 90.2% were susceptible to fluconazole, while 95.0% were sensitive to voriconazole. Among 128,625 isolates of C. albicans, resistance was 1.4 and 1.2% for fluconazole and voriconazole, respectively. In 23,305 clinical isolates of C. glabrata, there was a higher population of resistant isolates: 15.7 and 10% for fluconazole and voriconazole, respectively. Importantly, there was a yearly trend upward for increased azole resistance among C. glabrata (39), and resistance to fluconazole varied by region (6, 34–37). Increases in resistance are notable with C. guilliermondii and C. krusei, and an overall increase in fluconazole resistance over time was seen with C. parapsilosis, C. guilliermondii, C. lusitaniae, and Candida pelliculosa (40). In contrast to the increase in azole resistance seen with C. glabrata, the trend has reversed for Cryptococcus neoformans in developed countries (29, 33, 41). In developing countries where AIDS is more prevalent, fluconazole resistance is low but more significant (42). The details of antifungal susceptibility testing according to guidelines established by the CLSI and EUCAST are addressed in chapter 131. Triazole-resistant strains of A. fumigatus were first reported in 1997 from patients in California treated with itraconazole (43). Azole-resistant A. fumigatus has now been reported in China, Canada, the United States, and several European countries. High rates in the United Kingdom (15 to 20%) (44, 45) and in the Netherlands (5 to 7%) have been observed (26, 46). Approximately 5% of Aspergillus isolates were found to be azole resistant in studies involving respiratory colonization of cystic fibrosis patients (47). The ARTEMIS global surveillance program reported a 5.8% resistance rate in 2008 and 2009 (48). Azole resistance among A. fumigatus is notably high due to both acquired resistance during therapy and acquisition of resistant environmental variants (28, 49, 50). Yet, the rates may underestimate the global prevalence of Aspergillus drug resistance. The true frequency of triazole resistance is unknown because A. fumigatus is cultured from less than 30% of infected patients. PCR can more efficiently identify the presence of Aspergillus in respiratory specimens that are otherwise culture negative, and the simultaneous detection of characteristic drug-resistance markers in these assays indicates that resistant strains are more prevalent than reported by culture (51).

MEchanisms of Azole Resistance

The underlying molecular mechanisms responsible for acquired azole resistance have been extensively studied over the past several decades, especially in the model organisms Saccharomyces cerevisiae and in laboratory and clinical strains of C. albicans. Early studies elucidating the biological machinery central to resistance have evolved into eloquent descriptions of cellular regulatory mechanisms and circuitry that help modulate azole resistance mechanisms following exposure of a susceptible strain to drug. Many excellent reviews have covered this topic (52–55). The general mechanisms and effectors of drug resistance are summarized in Table 1 and include:

1. reduced drug-target interaction;
2. increase in target copy number;
3. reduction of intracellular drug concentration mediated via drug efflux transporters and reduced uptake;
4. modification of other ergosterol biosynthesis pathway elements; and
5. biofilms and persister cells.

The biological responses revealing these resistance mechanisms involve adaptive cellular responses and modification of genetic regulatory elements. The relative contribution of individual mechanisms to development of resistance varies by genus and species. In some clinical strains, a single dominant mechanism may prevail, while in others, stepwise development of high-level resistance involves a combination of resistance mechanisms that may act additively or synergistically. The contribution of specific resistance mechanisms is strain dependent and generally falls into both multicomponent mechanisms and single dominant mechanisms represented by the major pathogens C. albicans, C. glabrata, and A. fumigatus.

Drug Target Modification

Genetic modification of the target Erg11p resulting in reduced affinity for drug is one of the most direct mechanisms of resistance. At least 60 amino acid substitutions in Erg11p from azole-resistant clinical isolates have been described (56–61). The impact of individual substitutions determines the relative degree of resistance and cross-reactivity within the class. For example, Y132H, G450E, G464S, R467K, and S405F reduce susceptibility to fluconazole and voriconazole, but not to the longer-chain drugs itraconazole or posaconazole. A limited number of mutations are predicted to strongly affect drug-target interactions, which would confer prominent cross-reactivity among the class. The overall contribution of many ERG11 mutations to fluconazole resistance is weak, as some have a modest impact on azole resistance phenotypes. Furthermore, in diploid C. albicans, nucleotide mutations may occur as homozygous (both alleles) or heterozygous (single allele) substitutions, which can alter the resistance phenotype. In C. neoformans, strains resistant to fluconazole may contain characteristic mutations in the ERG11

Nonsynonymous mutations in CYP51A (and ERG11) result in structural alterations to lanosterol 14-demethylase that reduce drug binding. Homology overlay modeling of Cyp51A and Erg11 using related high-resolution structural models has been used to describe the impact of specific amino acid substitutions on the interaction of triazole drugs with the target enzyme (73). Such models predict interactions based on different chemical structural properties of the various triazole drugs (e.g., voriconazole versus posaconazole) (73). Most mutations are clustered in three hotspot mutation regions (74). The most prominent resistance-conferring substitutions alter the apparent interaction of drug with the hormone cofactor. Yet, many Erg11 amino acid replacements from fluconazole-resistant C. albicans strains are peripheral and are predicted to exert a relatively weak action and resulting phenotype. In A. fumigatus Cyp51A, amino acids Gly54, Gly138, F219, M220, and Gly448 confer resistance (75). The acquisition of resistance-conferring mutations in Cyp51A requires drug pressure, as there appears to be a fitness cost that affects relative virulence (65).

**Environmentally Acquired Resistance Is a Major Factor**

In the Netherlands, most resistance (>90%) in A. fumigatus is due to a mutation in Cyp51A at the codon for Leu98 and a tandem repeat (TR) of 34 bp in the promoter region (25, 46, 66–68), which confers pan-azole resistance (Table 2). The TR/L98H resistant isolates arose as a consequence of azole use in the agricultural world (26). This singular mechanism (25) has been identified in many parts of Europe, India, and parts of Asia (69–71), but it has not been observed in patients who evolve resistance during therapy. Recently, a new TR46/Y121F/T289A mechanism has been observed that further suggests an environmental route of resistance selection (72).

**Structural Modeling of Resistance**

Nonsynonymous mutations in CYP51A (and ERG11) result in structural alterations to lanosterol 14-demethylase that reduce drug binding. Homology overlay modeling of Cyp51A and Erg11 using related high-resolution structural models has been used to describe the impact of specific amino acid substitutions on the interaction of triazole drugs with the target enzyme (73). Such models predict interactions based on different chemical structural properties of the various triazole drugs (e.g., voriconazole versus posaconazole) (73). Most mutations are clustered in three hotspot mutation regions (74). The most prominent resistance-conferring substitutions alter the apparent interaction of drug with the hormone cofactor. Yet, many Erg11 amino acid replacements from fluconazole-resistant C. albicans strains are peripheral and are predicted to exert a relatively weak action and resulting phenotype. In A. fumigatus Cyp51A, amino acids Gly54, Gly138, Pro216, and Gly448 confer resistance (75). Most mutations are clustered in three hotspot mutation regions (74). The most prominent resistance-conferring substitutions alter the apparent interaction of drug with the hormone cofactor. Yet, many Erg11 amino acid replacements from fluconazole-resistant C. albicans strains are peripheral and are predicted to exert a relatively weak action and resulting phenotype. In A. fumigatus Cyp51A, amino acids Gly54, Gly138, Pro216 and Phe219, Met220, and Gly448 confer triazole resistance are predicted to lie in close proximity to the opening of one of two ligand access channels, which would allow azole compounds to enter the enzyme active site (75–77) (Fig. 1). Modification of the channel openings is presumed to disturb the docking of azole molecules. The model helps predict why modification of Gly54 yields itraconazole and posaconazole resistance, yet retains voriconazole susceptibility. Leu98 is located on a loop that partly forms an arch-like structure highly conserved among the members of the Cyp51 family of proteins (68, 75).

**Increasing the Target Abundance**

Lanosterol 14C-demethylase is a key enzyme in the ergosterol biosynthesis pathway. In response to azole antifungals and/or sterol depletion, Candida strains may overexpress ERG11 (78) and other genes involved in ergosterol biosynthesis (79). Elevated abundance of target proteins decreases the effectiveness of azole drugs at a standard dosage. Increased ERG11 expression arises from cis-acting gain-of-function (GOF) mutations within the promoter region or from alterations in a trans-acting factor, Upc2p (80). The C. albicans Upc2p is a Zn$_2$Cys$_6$ cluster transcription factor homologous to S. cerevisiae paralogues UPC2 and ECM22 (81, 82). Upc2p is required for upregulation of ERG11 (83) and other sterol biosynthesis genes in response to sterol depletion (81, 82). Mutations in UPC2 result in increased expression of ERG11 and decreased fluconazole susceptibility (80, 82). The Upc2p activates transcription of target genes by binding to a conserved core sequence known as the sterol response element (81). An 11-bp sterol response element was identified in the promoters of ERG2 and ERG3, and Upc2 and Ecm22 directly bind to this element. Induced overexpression of ERG11 or UPC2 increases resistance to azoles, while mutants lacking UPC2 show no induction of ERG genes and they are hypersusceptible to these drugs (82). CaUPC2 activity can increase up to 100-fold with prolonged azole exposure. The CaUPC2 promoter contains a putative sterol response element (81), and transcriptional

![Homology structure model for Cyp51A from A. fumigatus showing amino acid positions of substitutions conferring azole resistance (from Snelders et al. [75]).](doi:10.1128/9781555817381.ch130.f1)
regulation of UPC2 expression occurs through Upc2p-dependent and independent mechanisms (84). UPC2 mutations may also potentiate resistance by influencing expression of other genes, including MDR1, which encodes a multiple drug resistance protein linked to resistance (80, 85). Stepwise enhancement of fluconazole resistance can involve constitutive high-level expression of ERG11 and overexpression of drug transporters (86, 87). Less is known about the regulation of Cyp51A in A. fumigatus, although upregulation has been described for itraconazole-resistant mutants (65, 88).

Reducing Cellular Drug Levels: Drug Efflux Transporters

Fungi encode numerous putative drug efflux transporters that have the potential to influence susceptibility to azole-class antifungal agents, which serve as transport substrates. These high-capacity efflux systems, present in all higher eukaryotes, reduce the effective cellular concentration of drugs below their target inhibitory threshold. Overexpression of multidrug efflux transporters is well recognized as an important mechanistic component conferring resistance to azole antifungal drugs (89, 90). There are two main classes of efflux pumps that contribute to azole resistance phenotypes in fungi. They include ATP-binding cassette (ABC) transporters (e.g., CaCdr1, CaCdr2), which use energy derived from ATP hydrolysis to transport drugs, and the major facilitator superfamily (MFS) transporters (e.g., CaMdr1), which utilize the plasma membrane electrochemical gradient to translocate substrates.

The ABC superfamily is one of the largest protein families known. These proteins transport a wide variety of substrates across extracellular and intracellular membranes, including metabolic products, lipids and sterols, and drugs. A common feature of all ABC transporters is that they consist of two distinct domains, the transmembrane domain and the nucleotide-binding domain composed typically of Walker A and Walker B motifs. The C. albicans genome contains at least 27 genes with ABC domains that include these topologies (91). In C. albicans, Cdr1 is an integral plasma membrane protein of 1,501 amino acids (92). Cdr1 was first identified as a protein capable of transporting a variety of unrelated cytotoxic drugs and was shown to be one of the major determinants of fluconazole resistance in clinical isolates of C. albicans (93). The closely related transporter Cdr2 exhibits 84% amino acid sequence identity with Cdr1. Cdr2 confers resistance to azole antifungal agents, other antifungals (e.g., terbinafine), and a variety of metabolic inhibitors. However, CDR2 overexpression is also observed in resistant mutants that revert spontaneously to wild-type levels of susceptibility (94), which suggests that its impact on clinical azole resistance is less pronounced than that of CDR1. In C. glabrata, azole resistance is almost exclusively due to enhanced drug efflux, which is a consequence of overexpression of the ABC transporter family. The genes encoding these transporters, CgCdr1 (95), CgCdr2 (PDH1) (96), and CgSnh2 (97), have been well described in laboratory and clinical isolates. In C. glabrata, petite mutants displaying a loss of mature mitochondria can become azole resistant through increased expression of CgCdr1 and, to a lesser extent, CgCdr2 (98). Similarly, in C. neoformans, an ABC transporter-encoding gene, CnAFR1, can confer resistance to fluconazole (99). In C. krusei, ABC1 is strongly upregulated in response to azole exposure, where it may play a role in intrinsic resistance (100).

MFS transporters account for nearly half of the solute transporters encoded within the genomes of microorganisms. The C. albicans genome contains at least 95 open reading frames that may encode an MFS transporter (101). MFS transporters are single-polypeptide secondary carriers capable only of transporting small solutes in response to electrochemical ion gradients. In C. albicans, Mdr1 (formerly BEN) (102) was originally identified because it was highly overexpressed in an azole-resistant clinical isolate (89). CaMdr1 confers intermediate-level resistance to fluconazole, in contrast to CaCdr1, which is associated with efflux of a wider range of substrates at higher capacity. In most C. albicans strains, MDR1 is not significantly expressed, but it is induced in the presence of certain chemicals like benomyl, H2O2, or azoles (103). Another MFS transporter, Flu1, confers resistance to fluconazole and is closely related to CaMdr1. However, FLU1 expression varies among azole-susceptible and azole-resistant C. albicans clinical isolates, and therefore it does not appear to be an important factor in clinical resistance (104).

In A. fumigatus, overexpression of ABC and MFS drug transporters has also been described, as they may confer resistance to highly active triazole antifungal agents (105). Multiple mechanisms can occur in resistant strains whereby both target-site mutations and upregulation of drug efflux transporters like AfuMdr3 and AfuMdr4 may occur (88, 106), as well as newly described Cdr1b (107). Overexpression of Cyp51A confers reduced susceptibility (108), as does Cyp51B (109). Finally, in a significant percentage of A. fumigatus isolates, the mechanism of triazole resistance is unclear and may be novel (44).

It is important to note that resistance to azoles in all fungi is highly dependent on the level of CDR or MDR overexpression (110). This raises the question of whether reporting overexpression of any one or all CDR or MDR genes is a sufficient indicator of resistance, and what threshold level of overexpression is required for resistance. Overall, high-level azole resistance most often correlates with overexpression of CDR1 and to a lesser extent CDR2. However, in some isolates, MDR1 is the only pump gene overexpressed (89). Finally, clinical isolates of azole-resistant C. albicans and other Candida species show overexpression of multiple efflux pump classes, including CaCdr1p, CaCdr2p, and CaMdr1p (87, 111). It has been demonstrated in serial isolates from patients exposed to azole antifungal agents that multifactorial resistance develops stepwise with drug exposure and involves CDR and/or MDR gene expression (86, 87, 112) and other mechanisms (e.g., ERG11 overexpression).

Regulation of Azole Resistance

The underlying mechanism regulating overexpression is an important component for development of azole resistance phenotypes. A major emphasis in recent years has been directed at understanding regulatory circuits controlling the expression of these genes. It is well established for C. albicans and other Candida spp. that activating GOF mutations in the zinc cluster transcription factors Tac1 and Mrr1 regulates the expression of CDR and MDR genes, respectively (114–118). Specific mutations in TAC1 mediate the overexpression of the genes encoding ABC transporters CDR1 and CDR2 (114, 119), while Mrr1 regulates the MFS transporter Mdr1 in azole-resistant isolates (118, 120, 121). Mutants lacking these transcription factors cannot upregulate their target genes in response to drugs, and mutations render the transcription factors constitutively active even under noninducing conditions. In C. glabrata, CgPdr1p is a Zn2+-Cys6 transcription factor involved in the regulation of the
ABC transporter genes CgCDR1, CgCDR2, and CgSNQ2 (122, 123). GOF mutations in CgPDR1 are responsible for intrinsic high expression of ABC transporters (122, 124), and a salient feature is their extraordinarily high diversity among CgPDR1 alleles from azole-resistant clinical isolates, with more than 65 nonsynonymous substitutions identified (122, 124). Finally, mRNA stability is an important factor as it contributes to message stability and sustained overexpression of CDR1 in azole-resistant C. albicans isolates (125).

**Loss of Heterozygosity and Other Chromosomal Abnormalities**

High-level azole resistance may occur when C. albicans upregulates and/or carries mutations in ERG11 and TAC1. An increase in copy number can occur for these genes as a consequence of loss of heterozygosity (LOH). TAC1 is located on chromosome 5 (Chr 5), along with ERG11. Chr 5 rearrangements lead to TAC1 homozygosity but also to LOH in other Chr 5 regions, including the mating type locus (MTL) and ERG11 loci. Finally, azole resistance can result from segmental aneuploidy on Chr 5, which increases copies of TAC1, MTL, and ERG11 via formation of isochromosome 5L [i(5L)] (119, 126). This genetic plasticity provides C. albicans with a dynamic response toazole drugs that is prevalent in resistant clinical isolates (127). In C. neoformans, heteroresistance to fluconazole is an adaptive mode of azole resistance (128). Heteroresistant cell populations respond differentially to drug and adapt in a stepwise manner to higher concentrations of the drug. Strains adapting to fluconazole levels above the MIC often contain disomy of Chr 1. The duplication of Chr 1 is associated with both the target encoding gene ERG11 and the major transporter Afr1 (63, 129, 130). In the absence of drug, the strains return to their basal level of susceptibility by losing the extra copy of Chr 1, followed by loss of the extra copies of the remaining disomic chromosomes.

**Azole Resistance and Virulence**

It is generally anticipated for most pathogens that acquisition of drug resistance may be associated with a loss of fitness or virulence. In C. albicans, GOF mutations in Mrr1, Tac1, and Upc2 that result in resistance appear to have a fitness cost, suggesting that regulation of drug pumps must be tightly controlled by the cell (131). In A. fumigatus, acquisition of azole resistance involving modification of Cyp51A can alter virulence (132). Furthermore, acquisition of azole resistance in the absence of known Cyp51A mutations can also lead to reduced virulence (65). Virulence defects suggest that resistant strains should be self-limiting in a fast reservoir of highly fit wild-type strains. Yet, this does not appear to be the case for L98H/TR or other environmentally driven strains, since they maintain cellular fitness and virulence which is manifested as widespread transmission of infecting strains. Similarly, C. glabrata GOF mutations in CgPDR1 modulate host interactions in ways that promote increased virulence in murine models of disseminated infection (122). Several host-based mechanisms appear to play a role in this phenomenon. For example, GOF CgPDR1 mutations decrease adherence and uptake by macrophages, which may allow evasion from the host’s innate cellular immune response (133). Similarly, enhanced virulence is observed for azole-resistant strains of C. glabrata with mitochondrial DNA deficiency (petite mutants), which upregulate the ABC transporter genes CDR1 (CgCDR1), CgCDR2, and CgSNQ2 (134).

**Other ERG Genes**

ERG3 encodes sterol Δ^5,8-desaturase, which contributes to sterol biosynthesis. Azole exposure results in the accumulation of 14α-methylated sterols and 14α-methylergosterol, 8,24(28)-dien-3,6-diol, and formation of the latter sterol metabolite is catalyzed by sterol Δ^5,8-desaturase. Inactivation of ERG3 suppresses toxicity, which facilitates azole resistance (135). Clinical isolates of C. albicans resistant to both azoles and amphotericin B have been shown to have sterol depletion and defects in ERG3 (136, 137). Yet, inactivation of ERG3 does not always result in azole resistance since, in C. glabrata, a null ERG3 mutant was not azole resistant (138).

**Biofilms**

Biofilms are one of the most prevalent forms of microbial growth in nature, and a characteristic property of biofilms is that they are often refractory to common antifungal agents. Candida species are among the most common etiologic agents of yeast-related biofilm infections (139), although C. albicans is the most prominent fungal biofilm producer (140). Other yeasts and filamentous fungi are important biofilm producers, including other Candida spp., Cryptococcus, Blastoschizomyces, Trichosporon, Pneumocystis, Saccharomyces, Aspergillus, and Coccidioides (140). The mature C. albicans biofilm displays an organized three-dimensional structure composed of a dense network of yeast and filamentous cells embedded in an exopolymeric matrix consisting of carbohydrates, proteins, and nucleic acids. The complex organization of the extracellular biofilm matrix is a major feature that distinguishes biofilms from planktonic cells (Fig. 2). C. albicans biofilms are intrinsically resistant to azoles like fluconazole. The mechanisms for this resistance against azoles and other drugs in Candida biofilms are multifactorial, involving both induction of drug efflux transporters and drug sequestration within the extensive matrix structure (139–143) (Fig. 2). In biofilms, drug efflux transporter genes CDR and MDR are upregulated during biofilm development (143, 144). Yet, a larger component of the multidrug resistance phenotype is imparted by drug sequestration within the extracellular matrix (145). The complex matrix provides infrastructure for biofilm accumulation, conferring protection from antimicrobial peptides and environmental antagonists (146, 147). A key constituent of the C. albicans matrix is β,1,3-glucan produced by glucan synthase, which is encoded by FKS genes in Candida. This glucan is modified and incorporated into both the cell wall and the extracellular matrix, and a variety of genes are responsible for the delivery and arrangement of β,1,3-glucan in the matrix (145, 148–150). Glucan synthesis by Fks1 is critical for biofilm-specific drug resistance in C. albicans, which helps to sequester drug, thus reducing the effective concentration encountered by the cell (148) (Fig. 2). Other cellular proteins, such as alcohol dehydrogenases Adh5, Csh1, and Id6 and glucoamylases CaGCA1 and CaGCA2, have roles in matrix production and resistance phenotypes (151). Heat shock protein 90 (Hsp90) is a conserved and essential chaperone that regulates cellular signaling by stabilizing numerous client proteins involved in signal transduction (152). It is important for biofilm health, as its depletion in C. albicans reduces biofilm growth and maturation and causes impaired dispersal and diminished resistance to azole antifungals (153). Impairment of Hsp90 function, genetically or pharmacologically, enables fluconazole to be effective in eradicating azole-insensitive biofilms in vivo (153). Collect-
tively, \textit{C. albicans} matrix production is highly regulated and is a key resistance factor. It is also a factor in a number of other \textit{Candida} spp., including \textit{C. glabrata}, \textit{C. parapsilosis}, \textit{C. tropicalis}, and \textit{C. dublinensis} (154).

**Persister Cells: Stress Adaptation**

Persister cells that are tolerant to drug are an important mechanism of resistance for infections requiring prolonged antifungal therapy, and biofilms provide an important source of such drug-tolerant cells (55). In \textit{C. albicans}, \textit{C. krusei}, and \textit{C. parapsilosis}, persistence was observed in a small subset of yeast cells in biofilms exposed to drug that displayed resistance to amphotericin B and were independent of upregulation of efflux pumps and cell membrane composition (140, 155, 156). Cellular stress-response mechanisms are critical for persistence. Hsp90, a cellular stress modulator, plays a critical role in promoting cell adaptation. Loss of Hsp90 function reduces tolerance of \textit{Candida} species to azoles (157). Inhibition of Hsp90 can also block the development ofazole resistance and mitigateazole resistance upon loss of function of Erg3 or host-induced factors (158). Overall, Hsp90 helps regulate the cellular circuitry that is involved in stress responses and promotes the emergence of resistance to azoles (157, 159, 160).

**MECHANISMS OF POLYENE RESISTANCE**

The polyenes nystatin and amphotericin B are among the oldest antimicrobial drug class. Amphotericin B deoxycholate was the first antifungal agent approved in the United States (1957) for human use to treat potentially life-threatening invasive fungal infections (161). Polyene drugs interact with the fungal-specific sterol ergosterol in the cellular membrane to create concentration-dependent high-conductance channels that allow ions and other cellular components to flow from the cell, causing cell death. For decades, amphotericin B was a mainstay therapy for invasive fungal infections including invasive aspergillosis, cryptococcosis, blastomycosis, candidemia, coccidioidomycosis, histoplasmosis, and mucormycosis. However, its avidity for sterols such as cholesterol in animal cell membranes contributes to renal toxicity, and it has been relegated to largely a second-line antifungal option. Lipid formulations of amphotericin B overcome the most serious limitations but still suffer from issues of cost and potential toxicity.

**Epidemiology of Resistance**

Refractive therapeutic response to polyenes generally involves inherently insensitive moulds such as \textit{A. terreus}, \textit{Pseudallescheria boydii}, \textit{Scedosporium} spp., \textit{Purpureocillium lilacinum}, and \textit{Fusarium} spp. (14, 23, 162). In recent years, the prevalence of polyene resistance in \textit{Aspergillus} species has increased, with only 11.5% of \textit{A. fumigatus} isolates inhibited at 1 \textmu\text{g}/ml (163, 164). Less common \textit{Aspergillus} species, such as \textit{A. ustus} and \textit{A. lentulus} (23, 24), are highly resistant to amphotericin B as well as other antifungal agents. For yeasts, acquired resistance to polyenes among \textit{Cryptococcus} and \textit{Candida} strains is rare, although reports of high MICs to amphotericin B and/or poor therapeutic outcome have been reported for \textit{C. albicans}, \textit{C. krusei}, \textit{C. rugosa}, \textit{C. lusitaniae}, and \textit{C. glabrata} (165, 166).

**Mechanisms of Polyene Resistance**

The mechanism of resistance to amphotericin B in yeasts and moulds typically involves a reduced content of ergosterol in the cell membrane. Acquired resistance to amphotericin B is rare, even among patients with long-term exposure who ultimately fail therapy (8). In this context, prior exposure to an azole, which lowers cellular sterol levels, can confer stable polyene resistance (167). Resistant mutants of \textit{A. fumigatus} can be selected in vitro in response to amphotericin B (168), and occasionally high-MIC isolates are identified from patient failures. However, acquired resistance to amphotericin B has been most extensively evaluated in yeasts. Mutant yeast strains with defects in sterol pathway genes ERG1, ERG2, ERG3, ERG4, ERG6, and ERG11 are largely depleted of ergosterol, which confers varying levels of resistance to polyene agents (137, 165, 169). In \textit{C. neoformans}, strains with defective C8-isomerase activity and diminished sterol content exhibit reduced susceptibility to polyenes (170). In \textit{C. albicans}, clinical and laboratory strains resistant to both azole antifungals and amphotericin B were found to be defective in ERG3 (136, 138). In \textit{A. fumigatus}, however, deletion of ERG3 did not alter amphotericin B susceptibility, even though total sterol content was reduced (171). Resistance to amphotericin B appears to be more complex in \textit{Aspergillus} spp. and most likely involves other mechanisms (172). Biofilm formation is an important factor that restricts drug entry, as highly hydrophobic drugs get trapped in the extensive glucan matrix. Other mechanisms may involve cell stress adaptation to drug exposure.
MECHANISMS OF ECHINOCANDIN RESISTANCE

ECHINOCANDIN ANTIFUNGAL DRUGS

The echinocandin drugs anidulafungin, caspofungin, and micafungin are lipopeptides that target and inhibit glucan synthase, which is responsible for the biosynthesis of β-1,3-glucan, a central building block of most fungal cell walls (173). Echinocandins are now the preferred antifungal for the treatment of invasive candidiasis (174). The fungal cell wall consists of three sugar polymers (glucan, chitin, and mannann) and is a layered matrix consisting of an outer layer of glycoproteins and an inner layer of carbohydrate polymers. The cell wall is a dynamic structure, as polymers are modified and rearranged during cell wall biosynthesis (175). Consistent with the observation that cell wall integrity is essential for cell survival, echinocandin drugs show in vitro fungicidal activity against susceptible Candida spp. (176). Yet they are only fungistatic against moulds, where they can lyse the tips of some growing hyphae but do not completely block cell growth (177, 178). Echinocandin drugs are generally impotent against invasive Zygomycetes, Cryptococcus spp., or Fusarium spp. Importantly, isolates resistant to echinocandins do not exhibit cross-resistance to other antifungal agents, which enables them to be effective against azole-resistant yeasts (179) and some Candida biofilms (180, 181). The expanding use of these agents has resulted in growing echinocandin resistance among Candida spp. (182, 183).

The echinocandin target β-1,3-glucan synthase is a multisubunit enzyme complex that catalyzes the transfer of sugar moieties from activated donor molecules to specific acceptor molecules, forming glycosidic bonds. The enzyme complex consists of at least two subunit components, Rho and Fks. The GTP-binding protein Rho helps regulate the overall activity of glucan synthase (184). The catalytic subunit Fks is encoded by three related genes, FKS1, FKS2, and FKS3. The FKS1 gene is essential in C. albicans (185) and other Candida spp., but in C. glabrata, FKS1 and FKS2 are functionally redundant (186).

FIGURE 3  Fks amino acid substitutions and polymorphisms in hot-spot regions conferring reduced susceptibility to echinocandin drugs among clinical isolates of Candida spp.

doi:10.1128/9781555817381.ch130.f3

Epidemiology of Echinocandin Resistance

Candida spp. isolates resistant to echinocandin drugs are increasingly encountered (187), although the frequency remains relatively low (<2 to 3%) with C. albicans and most other Candida spp. (188–190). The exception is C. glabrata, in which resistance is growing more severe. The widespread use of echinocandins and azoles has resulted in an epidemiologic shift with C. glabrata emerging as the most dominant fungal bloodstream pathogen in some health care centers (191). Drug resistance may occur after prolonged therapy (192) or it may be rapid, even within the initial days of therapy (193). The SENTRY Antimicrobial Surveillance Program from 2006–2010 reported echinocandin resistance of 8.0 to 9.3% among 1,669 bloodstream infections of C. glabrata (39). Furthermore, in a 10-year study involving 293 unique episodes of C. glabrata bloodstream infections, echinocandin resistance of C. glabrata rose from 2 or 3% during 2001–2006 to >13% in 2009–2010 (194).

Fks Mechanism of Resistance

Clinical resistance resulting in breakthrough infections involves modification of Fks subunits of glucan synthase, and clinical breakpoints reflect this underlying mechanism (195). Unlike azole antifungal agents, echinocandins are not substrates for multidrug transporters (196, 197). Echinocandin resistance is conferred by characteristic amino acid substitutions in Fks subunits (198), which induce elevated MIC values (0.5 to 2 log) and reduce the sensitivity of glucan synthase (IC50) to drug by 50- to 3,000-fold (199–201). The most prominent FKS1 mutations in C. albicans, resulting in amino acid substitutions at positions Ser641 or Arg1361 (205). For C. albicans, amino acid changes at Ser641 or Ser645 are the most abundant and cause the most pronounced resistance phenotype (183, 198, 200). In C. glabrata, comparable mutations conferring resistance occur in...
both FKS1 and FKS2. S663P, -F, and -Y (equivalent to C. albicans S645) in Fks2 are the most prominent amino acid substitutions (>50%) (199). Other high-frequency resistance substitutions include S629P in Fks1 and F659Y, Y in Fks2. Resistance-conferring mutations occur in FKS2 of C. glabrata clinical isolates at twice the frequency of FKS1 mutations (183, 198, 199).

The echinocandin resistance level conferred by hot-spot mutations in FKS1 or FKS2 may also depend on the relative expression of their genes, which can vary more than 20-fold (186, 199). FKS2 expression is calcineurin dependent and downregulated by FK506 (tacrolimus) (206). Resistance conferred by FKS2 but not FKS1 was reversed following treatment with the calcineurin inhibitor FK506 (186).

Recently, a third hot-spot region was identified that confers in vitro resistance. It is defined by W695 of S. cerevisiae Fks1 and equivalent residues F695 and W760 from Scedosporium species and Schizosaccharomyces pombe, respectively (207). Hot-spot 3 is well conserved among both yeasts and moulds (207). Finally, amino acid substitutions in Fks1 of C. albicans are more likely to confer reduced fitness (186, 199), as they often result in a decrease in the catalytic reaction rate maximum for glucan biosynthesis (199, 200), resulting in altered cell wall morphology (208). The consequence of reduced fitness is that echinocandin-resistant strains compete poorly with their wild-type counterparts (208), which may help explain why resistance is associated with acquired de novo resistance and not transmission.

Hot-Spot Polymorphisms and Inherent Reduced Susceptibility

Candida parapsilosis complex (C. parapsilosis sensu stricto, C. orthopsilosis, and C. metapsilosis) and C. guilliermondii display higher echinocandin antifungal MIC values (MIC 0.5 to 8 μg/ml) relative to other highly susceptible Candida species (209, 210), and resistance breakpoints reflect this inherent reduced susceptibility (211). The clinical significance of this intrinsic reduced susceptibility is unclear since patients with these infecting strains are often successfully treated with echinocandin drugs at standard dosages (212, 213), although clinical efficacy may vary with patient population (30, 214). The mechanism underlying reduced echinocandin susceptibility appears to be naturally occurring polymorphisms in FKS hot-spot regions, which confer moderate reduced sensitivity of glucan synthase to drug (215). In C. parapsilosis complex, the highly conserved proline at the distal edge of hot-spot 1 (Pro 660) is present as an alanine (Fig. 3). Overall, it appears that naturally occurring Fks1 polymorphisms in hot-spot 1, hot-spot 2, and hot-spot 3 of non-albicans Candida spp. and other fungi account for reduced susceptibility to echinocandin drugs.

Biofilms

As with azole resistance, the glucan matrix acts to sequester echinocandin drugs, preventing them from reaching the cell membrane. Disruption of this process by genetic or chemical modification of 1,3-glucan synthase decreases drug sequestration in the matrix, rendering biofilms susceptible to antifungal agents (150). This mechanism accounts for a large fraction of the drug resistance phenotype during biofilm growth (149), and it is a factor in the observation of persister cells that may be encountered in the presence of drug. A role has been proposed for SMI1 in biofilm matrix glucan production and development of the associated drug resistance phenotype. This pathway appears to act through transcription factor Rlm1 and glucan synthase Fks1p. Smi1 appears to function in conjunction with Rlm1 and Fks1 to produce drug-sequestering biofilm β-glucan (150).

Cellular Stress, Tolerance, and Resistance Emergence

Fungi possess adaptive mechanisms (e.g., Hsp90, cell wall integrity pathway, chitin biosynthesis) that help protect against cellular stresses such as those encountered following inhibition of glucan synthase by echinocandin drugs (216, 217). These stress adaptation responses may result in elevated in vitro MIC values to echinocandins, but they are not typically associated with clinical failures (218, 219). This is because glucan synthase remains sensitive to drug and treated cells are attenuated. Fungal cells acutely sense cell wall stress. Inhibition of glucan biosynthesis by the echinocandins induces stress-tolerance pathways including cell wall integrity, PKC, Ca2+/calcineurin/Crz1, and HOG (220, 221) (Fig. 4). Furthermore, modulation of sphingolipid biosynthesis can lead to a mixed phenotype in which strains are resistant to caspofungin and hypersensitive to micafungin (222). Cowen and colleagues have shown that Hsp90 helps orchestrate tolerance to echinocandin drugs through its principal client protein calcineurin and its downstream effector Crz1 (157, 159, 223). Pharmacological or genetic impairment of Hsp90 function reduces tolerance and resistance of laboratory and clinical isolates of C. albicans and C. glabrata to caspofungin (223, 224). Echinocandin action also results in compensatory increases in chitin synthesis, which are induced by cell wall stress/adaptation and play an increasing role in predisposing cells for high-level resistance. Cell wall mutants with higher basal chitin contents are less susceptible to caspofungin (220, 221, 225) and can confer stable albeit low-level resistance in vivo (226). Paradoxical growth at very high drug levels (227) is also linked to compensatory responses in chitin biosynthesis (228).

These adaptive responses are important in stabilizing cells in the presence of drug. Ultimately, they likely predispose cells for resistance even though they are not sufficient to induce therapeutic failure themselves. The consequence of drug tolerance is a physiological state that allows cells to break through drug action by forming stable FKS mutations.

MECHANISMS OF ALLYLAMINE RESISTANCE

Dermatophytosis is a common infection of the keratinized tissues (skin, hair, and nails) caused by dermatophytes. Among the three known genera of dermatophytes—Epidermophyton, Microsporum, and Trichophyton—Trichophyton species, especially T. mentagrophytes, T. tonsurans, and T. rubrum, are the most common pathogens, with T. rubrum being the most frequently isolated organism. Treatment often involves the fungicidal allylamine terbinafine, which is the most frequently prescribed oral antifungal agent in the U.S. and Canada for onychomycosis. Antifungal resistance in dermatophytes is rare, despite the high worldwide incidence of dermatophytosis and required long-term therapy for some infections. Nevertheless, resistance is associated with mutations in yeast ERG1, which encodes the squalene epoxidase target (229, 230). Mutations in the equivalent ErgA of Aspergillus spp. confer resistance in vitro (231), but this has not been observed in clinical isolates.

MECHANISMS OF FLUCYTOSINE RESISTANCE

Flucytosine (5-fluorocytosine or 5FC) is a prodrug that, when taken up by cells, is metabolized by organisms expressing cyto-
sine deaminase to a toxic form, 5-fluorouracil, which disrupts DNA and protein synthesis. 5FC is generally administered in combination with other antifungal agents (e.g., amphotericin or fluconazole) because of a high propensity for fungal cells to develop resistance, since it targets a nonessential salvage pathway. In yeasts, decreased activity of either cytosine deaminase or uracil phosphoribosyltransferase uracil (UPRTase) plays a major role. In C. albicans, nucleotide polymorphism in the FUR1 gene (uracil pyrophosphorylase) is responsible for resistance to 5FC and plays a major role in clinical resistance (232, 233). In C. lusitaniae, inactivation of FCY2 (cytosine permease), FCY1 (cytosine deaminase), and FUR1 genes yielded differential resistance to 5FC (234). In C. glabrata, high-level 5FC resistance is conferred by a wide array of mutations conferring null phenotypes for FCY1 or FUR1, while low-level resistance is conferred by mutations in one or more FCY2 permeases (235).

SUMMARY AND PERSPECTIVE

As the global burden of fungal infections rises, antifungal therapy will continue to be an important element of patient management. Yet, treatment choices remain restricted due to the limited classes of antifungal agents and the emergence of antifungal resistance. The mechanisms contributing to resistance are well characterized. They include reducing the drug-target interaction by either modifying the target (drug affinity changes or target abundance) or reducing the effective cellular content of drug (ABC or MFS drug pumps, biofilm glucan trap). C. albicans shows a full complement of resistance mechanisms, yet not all mechanisms are present in all fungal strains despite the genetic potential. For example, the expression of CDR pump genes is more important for azole resistance in C. glabrata than is the development of target site mutations. In contrast, echinocandin resistance in all Candida strains is dependent on development of target site mutations, while drug pumps play no role. Azole resistance in Aspergillus is mostly influenced by target site mutations, while in some strains drug pumps and unknown mechanisms may play a significant role.

Enormous progress has been made in understanding the importance of biofilms, as they convert normally susceptible planktonic cells into highly resistant cell communities and create persister cells that seed resistance. Similarly, a great deal has been learned about the genetic regulatory elements that influence overexpression of ERG11 and FKS, as well as prominent ABC and MFS transporters. In some strains, point mutations in transcription factors are sufficient to upregulate expression, while in others, large-scale changes in chromosomes alter the transcriptional profiles. Fungal cells are highly dynamic and adapt to environmental challenges, including antifungal agents. Compensatory mechanisms, such as enhanced chitin biosynthesis following inhibition of glucan synthase by echinocandin action, help ensure cell wall integrity. Furthermore, a wide range of cellular stress response pathways contribute to cell stability. Critical cellular factors such as Hsp90 stabilize enzymes during stress, which promotes cell survival. All of the components contribute to the development of persister cells that can transiently adapt to drug exposure with the potential to break through therapy by induction of more permanent resistance mechanisms.

A detailed understanding of the principal resistance mechanisms and the factors that contribute to their evolution is important for developing new diagnostic approaches to more easily identify drug resistance and create new strategies for therapeutic intervention that prevent and overcome resistance. Advances in molecular diagnostic tools now...
make it highly feasible to rapidly determine genus and species while simultaneously assessing mutations conferring drug resistance. Furthermore, by interfering with adaptive responses, it may be possible to develop combination drug regimens that both overcome and prevent resistance.

Susceptibility Test Methods:
Yeasts and Filamentous Fungi*

ELIZABETH M. JOHNSON AND MAIKEN CAVLING-ARENDRUP

ANTIFUNGAL SUSCEPTIBILITY TESTING

Rationale
The groups of antifungal agents licensed for the systemic treatment of invasive fungal infection include the polyene amphotericin B and its three lipid formulations; the azoles fluconazole, itraconazole, ketoconazole, posaconazole, and voriconazole; the echinocandins anidulafungin, caspofungin, and micafungin; the pyrimidine flucytosine; and the allylamine terbinafine (see chapter 129). With their increasing use has come the recognition of innate resistance to one or more agents in some isolates of yeast and mould (1–9) and the emergence of resistance during therapy (10–17). Moreover, a recent worrying development has been the emergence of strains of Aspergillus fumigatus with cross-resistance to therapeutic triazole drugs due to environmental exposure to agricultural azoles (18–23). As a result, clinical laboratories are now asked to assume a greater role in the selection and monitoring of antifungal chemotherapy. Thus, accurate and predictive antifungal susceptibility testing has become imperative and is now so widely accepted as a useful tool for informing decision making during the management of patients with invasive fungal infections that recommendations for testing are starting to appear in management guidelines (24, 25).

In order to be clinically useful, the requirements of in vitro susceptibility tests are that they should (i) provide a reproducible and reliable indication of the activities of antifungal agents, (ii) provide results that correlate with in vivo activity and therefore help to predict the likely outcome of therapy, (iii) provide a means with which to detect the development of resistance during therapy by applying clinical breakpoints, (iv) act as a surveillance tool for monitoring the development of resistance mechanisms among a normally susceptible wild-type population of organisms by adopting species-specific epidemiological cutoff values (ECV/ECOFF), and (v) have value as a screening tool to predict the therapeutic potential of newly discovered investigational agents. In order to provide this information, there has to be a careful analysis of the pharmacokinetic and pharmacodynamic interactions of the drug, as well as host- and-organism interactions.

The basic methodology of reference antifungal susceptibility testing has remained stable since the introduction in the early 1990s of the first standardized broth dilution method (National Committee for Clinical Laboratory Standards (NCCLS) M27-P) (26), which has since been modified to include a microdilution method conducted in a microtiter plate (CLSI M27-A3) (27). The accepted reference methods published by the Committee for Clinical and Laboratory Standards (CLSI) Subcommittee on Antifungal Susceptibility Testing and the Subcommittee on Antifungal Susceptibility Testing (AFST) of the European Society of Clinical Microbiology and Infectious Diseases (ESCMID) European Committee for Antimicrobial Susceptibility Testing (EUCAST) are now well established (27–32). The CLSI Subcommittee has developed reference methods for broth macro- and microdilution susceptibility testing of yeasts (CLSI M27-A3 document) and moulds (CLSI M38-A2 document), as well as disk diffusion methods for yeasts (CLSI M44-A2 document) and moulds (CLSI M31-A document) (27, 28, 31, 32), while EUCAST has developed broth microdilution methods for fermentative yeast (EDef 7.2 document) and for conidia-forming moulds (EDef 9.1 document) (29, 30). The main differences between the EUCAST and CLSI reference methods were the EUCAST recommendation of a higher glucose and inoculum concentration, and for yeast, a shorter incubation time and a spectrophotometer reading rather than 2 days of incubation and visual reading as recommended by CLSI. However, as experience with these methods has become more widespread and their impact better understood, there have been changes. Thus, recent evaluation of the CLSI M27 method (27) for yeast susceptibility testing suggests that, in agreement with the EUCAST reference method (30) for most yeast species, results with fluconazole, amphotericin B, and the echinocandins can be evaluated after 24 h of incubation, thus reducing the total time to result from 72 to 48 h (27, 33–35). Studies have also suggested that, in line with EUCAST methodology, posaconazole and voriconazole MICs for Candida spp. can also be read at 24 h (36).

The most significant recent development has been the introduction of species-specific breakpoints for the systemically active antifungal agents, together with revision of the CLSI breakpoints based on the 24-h reading that has brought them in line with those proposed by EUCAST.
and published in document CLSI M27-S4 (35, 37–40) and Table 1.

Basic Test Principles

Minimum Inhibitory Concentration

In its simplest form, susceptibility testing is a measure of the potency of an agent to inhibit the growth in vitro of an organism, and the MIC is the lowest concentration of the agent able to inhibit growth to a predetermined degree. Growth inhibition may be determined in a broth format, usually in microtiter plates, or on solid agar by either incorporation of the agent into the agar base or impregnation into a disk or strip applied to the surface of a previously inoculated plate. Solid agar incorporation is particularly useful in high-throughput testing required for surveillance screening of environmental isolates. Commercial plates with four wells containing three different antifungal agents—itraconazole (4 mg/liter), posaconazole (0.5 mg/liter), and voriconazole (1 mg/liter)—and a control well have been designed for this purpose (made to order by Balis Laboratorium VOF, Boven Leeuwen, the Netherlands) (41) (Fig. 1). However, in vitro susceptibility testing is heavily influenced by a number of technical variables, including inoculum size and preparation, medium formulation and pH, duration and temperature of incubation, and the criterion used for MIC endpoint determination, all of which have to be considered when developing and interpreting test methods (42–46). In addition, antifungal susceptibility testing is complicated by problems unique to fungi, such as slow growth rates (relative to bacteria) and the ability of certain fungi (dimorphic) to grow either as a unicellular yeast form that produces blastoconidia or as a hyphal or filamentous fungal form that may have the ability to produce conidia or sporangiospores. Finally, the basic properties of the antifungal agents themselves, such as solubility, chemical stability, modes of action, and the tendency to produce partial inhibition of growth over a wide range of concentrations above the MIC, must be taken into account.

Minimum Fungicidal/Lethal Concentration

Many of the patients contracting invasive fungal infections are immunocompromised and thus unable to mount a significant immune response. Therefore, it has been postulated that antifungal agents that demonstrate fungicidal activity at concentrations that can be achieved in vivo may provide better outcomes than those agents that are fungistatic and thus rely on some host phagocytic cell activity to remove the remaining viable pathogens. It has thus been reported that the clinical outcome is significantly better for patients with invasive candidiasis due to Candida albicans and treated with echinocandin (fungical) compared to those receiving fluconazole (fungistatic) despite the fact that C. albicans is susceptible to both (47, 48).

Standard testing parameters are not yet available for evaluation of the fungicidal activity of antifungal agents. The determination of minimum fungicidal concentrations (MFCs) requires the subculturing onto an agar medium of fixed volumes from each MIC tube or well that shows complete inhibition of growth. The criteria for MFC determination vary in different publications, and the MFC has been described as the lowest drug concentration resulting in either no growth or three to five
...MIC results spanning three 2-fold dilutions ranging from 2.0 to 8.0 mg/liter, almost directly mirroring those results produced when 35 different C. glabrata isolates were tested. It was postulated that variation within the wild-type population could be explained solely by test variation allowing for a doubling dilution on each occasion. Therefore, in a normal distribution the MIC₅₀ reflects the susceptibility of the entire wild-type population and is a useful predictor of species susceptibility.

Microbiological Resistance and Epidemiological Cutoff Values

In the absence of interpretable clinical outcome data to predict clinical breakpoints, the wild-type distributions can be used to define ECOFF/ECV. This provides an indication of the normal susceptibility patterns encountered with a given drug-organism combination and thus confirms whether a given isolate conforms to the predicted wild-type susceptibility profile or is displaying a less susceptible or non-wild-type phenotype. An MIC above the ECOFF/ECV cannot be explained by inherent test variation. Such outlier organisms can most often be found to harbor resistance mechanisms (5, 8). Clinical breakpoints should therefore not be set higher than ECOFF/ECV unless there is supporting clinical evidence to demonstrate that such isolates do respond to standard therapy (55). In some cases clinical breakpoints can reflect the need to achieve higher than normal blood concentrations for a given drug in order to achieve good outcomes. CLSI has used the term “susceptible dose dependent” (SDD) for such isolates. Such categorization has been used with itraconazole and fluconazole where there is clear clinical evidence that higher doses, and therefore higher blood concentrations, can influence outcome in isolates with MICs above the usual susceptible range (56). When this supporting clinical evidence is lacking, isolates with MIC results only just in excess of the normal wild-type MIC₅₀ may be described as having intermediate susceptibility, which really means that the data currently available do not allow the organism to be categorized as either fully susceptible or resistant. EUCAST has a slightly different terminology and has not adopted the SDD category. In line with the antibacterial classification of susceptibility (S), I and R are used. The "I" category is assigned for isolates/species that may respond to treatment under certain conditions (e.g., high drug concentration at the target site) in order to accommodate use of the antifungal compound in some clinical situations. Another important point to consider when setting breakpoints is that they should not divide wild-type distributions of important target species (54), species-specific breakpoints have been introduced to...
ANTIFUNGAL AGENTS AND SUSCEPTIBILITY TEST METHODS

Broth microdilution testing (Table 2) has become the most widely used reference technique for antifungal susceptibility testing; this approach is described in the M27-A3 document (27) and the EUCAST EDef 7.2 document (29) and is also outlined below. Although the antifungal broth microdilution test was the first method proposed by the CLSI Subcommittee, this test is cumbersome for use in the clinical laboratory. The microdilution test provides consistent MIC results, and interlaboratory agreement of the microdilution MICs can be higher than that of the microdilution MICs for some drugs (64).

Standard Medium

The test medium recommended for both established reference methods is the Roswell Park Memorial Institute (RPMI) 1640 broth medium with L-glutamine and a pH indicator and without sodium bicarbonate (04–525Y from BioWhittaker, Walkersville, MD), and American Bioanalogics, Inc., Niagara Falls, NY, and R–5504 from Sigma Chemical Co., St. Louis, MO). The medium should be buffered to a pH of 7.0 at 25°C with morpholinepropanesulfonic acid (MOPS; final molarity at pH 7.0, 0.165). This medium is suitable for testing most fungi (27, 28, 64, 65), but it may not be adequate to support the growth of some strains of Cryptococcus neoformans or to determine amphotericin B MICs (66). RPMI medium containing a higher concentration of 2% dextrose (67, 68) is the basal medium used in EUCAST testing as it allows faster growth of the yeast, thus facilitating the determination of MICs at 24 h (29). This modification to include glucose at a final concentration of 20 g/liter is also included in the CLSI M27-S4 as a suggestion to simplify endpoint determination (37).

Drug Stock Solutions

Antifungal powders can be obtained directly from the drug manufacturers or from reputable commercial sources. Clinical intravenous or oral preparations should not be used. Antifungal stock solutions should be prepared at concentrations at least 10 times the highest concentration to be tested (e.g., 1,280 μg/ml for fluconazole and fluconazole). Solutions of standard powders of hydrophilic substances are prepared in distilled water. For testing non-water-soluble agents, sufficient drug standard should be weighed to prepare a solution of 1,600 μg/ml. EUCAST and CLSI methodology specifies the use of dimethyl sulfoxide (DMSO) for all non-water-soluble agents. Following a study of MICs obtained with caspofungin and micafungin dissolved in water or DMSO that suggested that the latter solvent yielded lower MICs and tighter ranges for a panel of known echinocandin-resistant or -susceptible isolates, it is recommended that all the echinocandins should be dissolved in DMSO (69). The use of DMSO has also been confirmed to allow storage of prepared plates for up to 6 months without loss of echinocandin potency (70). The actual amount to be weighed must be adjusted according to the specific biological activity of each standard. Amphotericin B solutions must be protected from light, and drug stock solutions prepared with solvents should be allowed to stand for 30 min before use.

The sterile stock solutions may be stored in small volumes in sealed, sterile polypropylene or polyethylene vials, ideally at −70°C or below and certainly no higher than −20°C; caspofungin can be stored at −80°C for 3 to 6 months without significant loss of activity. Vials should be removed as needed and used on the same day. The use of quality

control (QC) strains such as those listed in Table 3 is mandatory in evaluating drug activity (27, 29).

**Preparation of Inocula**

Inocula should be prepared by the spectrophotometric method (71) as outlined in Table 2. The inoculum suspension is prepared by picking five colonies, each at least 1 mm in diameter, ideally from 24-h-old cultures of C. neoformans or 48-h-old cultures of C. albicans. These are then suspended in 5 ml of sterile 0.85% NaCl or sterile distilled water for the EUCAST method and vigorously shaken on a vortex mixer. The turbidity of the cell suspension measured at 530 nm is adjusted with the appropriate suspension medium to match the transmittance produced by a 0.5 McFarland barium sulfate standard. This procedure produces a cell suspension containing 1 × 10^5 to 5 × 10^5 CFU/ml. For the CLSI method, this is then diluted 1:1,000 with RPMI medium to provide the 2× test inoculum (1 × 10^3 to 5 × 10^3 CFU/ml). The 2× inoculum is diluted 1:1 when the wells are inoculated to achieve the desired final inoculum size (0.5 × 10^3 to 2.5 × 10^3 CFU/ml). For the EUCAST method, which utilizes a higher final inoculum, a working suspension is prepared from a 1:10 dilution of the standard suspension in sterile distilled water to produce 1 × 10^5 to 5 × 10^5 CFU/ml.

**Drug Dilutions and Performance of Microdilution Test for Yeasts**

For hydrophobic drugs dissolved in solvents other than water (e.g., the polyenes, intracanaolose, posaconazole, voriconazole, anidulafungin, capsofungin, and micafungin), intermediate test drug dilutions are prepared from stock solutions to be 100 times the strength of the final drug concentration, with 100% DMSO used as a diluent (e.g., 1,600 to 3 μg/ml for amphotericin B, echinocandins, and all azoles except fluconazole). Dilutions should be prepared according to ISO recommendations (72). This procedure prevents precipitation of agents with low solubility in aqueous media. Alternative dilution schemes may be used if they are shown to perform as well as the reference method (73). Despite careful procedures, intracanaolose and some other agents do not remain completely solubilized upon dilution into aqueous media, which makes the use of QC procedures vital to minimize inaccuracies (74). For water-soluble drugs, such as fluconazole and some formulations of fluconazole, dilutions are prepared from the stock to be 10 times the final test drug concentrations directly in RPMI medium according to the additive, 2-fold drug dilution schema (27) (e.g., 640 to 1.2 μg/ml for fluconazole and fluconystine). The 10× and 100× drug concentrations should be diluted 1:5 and 1:50, respectively, with RPMI to achieve the 2× drug concentrations needed for the microdilution test; after the inoculation step the drug concentrations are 16 to 0.03 μg/ml for amphotericin B and triazoles and 64 to 0.12 μg/ml for fluconazole and fluconystine. As the echinocandins are potent at lower concentrations and to encompass the EUCAST breakpoints, drug dilution series from 8 to 0.015 μg/ml or lower are recommended for these compounds.

The broth microdilution test is performed by using sterile, disposable, multwell microdilution plates (96 U-shaped wells or flat-bottom plates for EUCAST) (e.g., Dynatech Laboratories, Inc., Alexandria, VA). A multichannel pipette (or a large dispensing instrument for 96-well trays) is used to dispense the 2× drug concentrations in 100-μl volumes into the wells of columns 1 to 10 of the microdilution plates. Column 1 contains the highest drug concentration and column 10 contains the lowest drug concentration. Microdilution trays can be sealed in plastic bags and stored frozen at −70°C (or −80°C) for up to 6 months or at −20°C for not more than 1 month (27, 29, 70). Each well is inoculated on the day of the test with 100 μl of the corresponding 2× inoculum, which brings the drug dilutions and inoculum densities to the final test concentrations (final volume in each well, 200 μl). The growth control wells (column 11) contain 100 μl of sterile drug-free medium (for water-soluble agents) or 100 μl of sterile drug-free medium with 2% solvent (for non-water-soluble agents) and are inoculated with 100 μl of the corresponding 2× inoculum. The QC yeasts are tested in the same manner as the other isolates and are included each time an isolate is tested. Row 12 of the microdilution plate can be used for the sterility control (drug-free medium only).

**Incubation and Determination of Microdilution MICs for Yeasts**

The microdilution plates are incubated at 35°C in ambient air. For the EUCAST method, 24 h of incubation is recommended. For the CLSI method and in most instances when testing Candida spp., results with fluconazole, posaconazole, voriconazole, amphotericin B, and the echinocandins can also be evaluated after 24 h (27, 33–36). The breakpoints suggested for fluconazole, voriconazole, and the echinocandins are based on a 24-h reading (37).

The determination of MIC endpoints is a critical step in antifungal susceptibility testing, especially with the azoles (for yeasts) and echinocandins (for yeasts and moulds). For the CLSI methodology, the endpoint reading is undertaken by eye, whereas the flat-bottom plates used for EUCAST testing allow a nonsubjective spectrophotometric reading and cutoff defined by a fixed percentage of the optical density achieved in the corresponding control well. The recommended absorbance for reading the plates is 530 nm, although others can be used (e.g., 405 or 450 nm), and the value of the blank background should be deducted from the readings for the other wells. For the CLSI methodology, the growth in each well is compared with that in the growth control (drug-free) well with the aid of a reading mirror (e.g., Cooke Engineering Co., Alexandria, VA). The MIC for amphotericin B is defined as the lowest concentration at which complete absence of growth (optically clear) is observed, i.e., 100% inhibition or ≥90% inhibition if read with a spectrophotometer for the EUCAST method.

The partial inhibition or trailing that is observed with fungistatic compounds such as the azoles prevents adoption of a complete absence-of-growth endpoint. Moreover, the highest degree of reproducibility is obtained if the steepest part of the growth inhibition curve is taken as the endpoint. Therefore, the MIC of the azoles, echinocandins, and fluconazole is defined as the lowest concentration at which complete absence of growth (optically clear) is observed, i.e., 100% inhibition or ≥90% inhibition if read with a spectrophotometer for the EUCAST method.

Heavy trailing endpoints are seen with about 5% of isolates when reading fluconazole MICs at 48 h, but studies of the in vivo response of such isolates in animal models of infection and in patients with oropharyngeal candidiasis suggest that they respond in the same way to low-dose fluconazole therapy as fully susceptible strains (56, 75).

aData from EUCAST EDef 7.2 and 9.1, M27-S3, M38-A2, and M27-S4 (27–30, 100, 102), NA, not available. Data for further strains are available in these publications.

The QC range for caspofungin and C. krusei ATCC 6258 was established using data generated in 2010 from 15 reference laboratories. Since then, caspofungin susceptibility testing has been associated with significant variation; the reason for which has not yet been fully elucidated. The clinical breakpoints approved in the M27-S4 document are based on the use of high-potency caspofungin powder for which the 24-h MIC range (mode) for the C. krusei ATCC 6258 was 0.06–0.25 μg/ml (0.125 μg/μl). Misclassification of susceptible isolates may therefore occur despite acceptable performance of the QC strain according to the range above (100).

Macrodilution
Broth macrodilution tests are adequate for the testing of all antifungal agents and are suitable for small laboratories in which the volume of these tests is low. Only the steps and testing conditions that are relevant to the macrodilution test are discussed in detail here (Table 2). Each intermediate drug concentration solution is further diluted (1:10) in RPMI medium to obtain 10 times the final strength. This reduces the final solvent concentration to 1%. The 10^x drug dilutions are dispensed in 0.1-ml volumes into round-bottom, snap-cap, sterile polystyrene tubes (12 by 75 mm; e.g., Falcon 2054; Becton Dickinson Labware, Lincoln Park, NJ); these tubes can be stored at −75°C or lower for 3 to 6 months. On the day of the test, each tube is inoculated with a 0.9-ml volume of the inoculum suspension. This step brings the drug concentrations to the final test drug concentrations mentioned above and the corresponding solvent to 1% in each MIC tube. The stock inoculum suspensions are prepared and adjusted as described above for the microdilution test and are then diluted 1:2,000 with RPMI to provide a inoculum of 0.5 x 10^6 to 2.5 x 10^6 CFU/ml. The growth control tube(s) is inoculated with a 0.9-ml volume of the inoculum suspension(s) and a 0.1-ml volume(s) of drug-free medium with 1% of the corresponding solvent. The QC yeasts are tested in the same manner as the other isolates and are included each time an isolate is tested. In addition, 1 ml of unincoculated drug-free medium (for water-soluble agents) or drug-free medium with 1% of the corresponding solvent is included as a sterility control.

Incubation and Determination of Macrodilution MICs for Yeasts
The MIC tubes are incubated at 35°C without agitation for 24 to 48 h (Candida) or 70 to 74 h (C. neoformans) in ambient air; the turbidity or growth in each tube is visually graded. For amphotericin B, the MIC is read as the lowest concentration that prevents any discernible growth. For azoles and flucytosine, the MIC is defined as the lowest drug concentration that causes a prominent decrease in turbidity to about 50% relative to that of the growth control (Table 2) (27).

Quality Control for Yeast Testing
QC of MIC tests is essential to good laboratory practice. Candida parapsilosis ATCC 22019 and Candida krusei ATCC 6258 are frequently selected as the QC strains according to the CLSI and EUCAST guidelines for such selection. However, the EUCAST guidelines caution against use of these as QC strains when testing caspofungin as they are not sufficiently sensitive in detecting variation in caspofungin potency, so for this drug C. albicans ATCC 64548 or ATCC 64550 is preferred (29, 70). Table 3 summarizes the expected MIC ranges of 10 antifungal agents for these QC isolates (27, 37). Each new batch of medium and lot of macrodilution tubes and microdilution trays should be checked with one of the two QC strains to determine if the MICs are within these ranges. In addition, the overall performance of the test system should be monitored by testing either or both QC isolates each day on which a test is performed for each drug. Details regarding corrective measures when the MICs for the QC isolates are not within the expected ranges are found in the M27-A3 document (27) and the EUCAST 7.2 document (29). A selection of potentially useful reference strains has been deposited with the American Type Culture Collection (ATCC) (Table 3).

YEAST GENERA OTHER THAN CANDIDA
Although the CLSI and EUCAST methods only provide suggested breakpoints for the most common human pathogenic Candida spp. (see Table 1), with certain caveats these methods are broadly suitable for most fermentative yeast. However, there are certain issues with nonfermentative
yeast species such as Cryptococcus spp., Malassezia spp., Pichia spp., Yarrowia lipolytica, Geotrichum spp., Rhodotorula spp., Sporobolomyces spp., and Trichosporon spp. The CLSI method (27) and EUCAST method (29) do encompass the testing of Cryptococcus spp. As they are slower growing than Candida spp., a 72-h incubation period is advised (27), or with EUCAST methodology the plates can be read when the optical density exceeds 0.2. It is suggested that if this value is not reached then tests should be repeated with incubation of the trays at 30°C. Moreover, there is a suggestion in CLSI M27-S4 (37) for the use of yeast nitrogen base glucose (YNBG) broth, which may enhance the growth of C. neoformans, thus facilitating the determination of MICs (76–78). A recent study examined a number of different parameters for testing a range of nonfermentative yeast species. These included growth medium (RPMI versus YNBG); glucose at 0.2 or 2%; shaken or static; a different nitrogen source; incubation temperature (30 versus 35°C); and inoculum size (10^3, 10^4, or 10^5 CFU/ml). It concluded that the use of YNBG medium, shaking, and a lower incubation temperature enhanced the growth rate of Cryptococcus spp. and most of the other nonfermentative yeast species tested. This allowed reading after 24 h and more consistent endpoint determination; however, there were no significant differences in MIC obtained by the different methods (66).

Two large global studies utilized the CLSI M27-A3 method in RPMI medium read at 72 h to define ECVs for fluconazole, itraconazole, posaconazole, and voriconazole (79, 80). The results of these (80) reported susceptibility patterns for more than 3000 isolates of C. neoformans and more than 700 isolates of Cryptococcus gattii. A much smaller subset of isolates was tested in YNBG medium, and the medium MIC was higher for fluconazole as has been noted previously (81), which suggests some variability of susceptibility test results using different methodologies. Most Malassezia spp. will not grow in RPMI medium as they require a lipid-rich environment, and to date there is not a standard method validated through a consensus procedure. Malassezia pachydermatis will grow in RPMI medium but is slower growing than most fermentative yeast species, although microdilution testing as well as a number of other procedures have been reported in the literature. However, this has resulted in conflicting results in terms of both absolute MIC values and interpretive results, and there are no established breakpoints for this genus. Recent publications have utilized the CLSI M27-A3 methodology and applied the breakpoints developed for Candida spp. (82, 83). To date, susceptibility testing of Malassezia is still investigational and not recommended for clinical practice (84). Moreover, this method is not validated for the yeast form of dimorphic endemic pathogens.

**SPECIAL CONSIDERATIONS**

**Amphotericin B**

Amphotericin B MICs determined by the microdilution methods are clustered between 0.25 and 1.0 μg/ml for 94% of clinical yeast isolates and are >2 μg/ml for the other 6%. An Amphotericin B MIC of 2.0 μg/ml (or greater) suggests probable clinical resistance and is often used as a breakpoint for this drug. The difference in amphotericin B MICs for susceptible and potentially resistant isolates is therefore probably very small, so caution should be exercised in the interpretation of results. Although it has been suggested that antibiotic medium 3 provides reliable detection of resistant isolates, lot-to-lot variability has been documented (85). In addition, this medium did not improve the detection of potentially amphotericin B-resistant isolates recovered from patients with candidemia, who had failed amphotericin B therapy (microbiological failure) (86). Application of Etest methodology may more readily detect amphotericin B resistance in vitro (87). Further optimization is needed but is difficult due to the lack of isolates with confirmed resistance mechanisms.

**Caspofungin**

The validity of performing microdilution testing with caspofungin by either the CLSI or EUCAST methodology has recently been cast in doubt (88, 89). In a multicenter study of data from 17 laboratories analyzing up to 11,550 Candida isolates, wide discrepancies were found for most species in modal values, as well as truncated and bimodal distributions. Despite examination of many different testing parameters, including caspofungin powder source, storage time and temperature, solvent, and MIC determination, no single source of this variability could be established (89). In general, the efficacy of the three echinocandins against Candida isolates is uniform in the sense that resistance mutations confer resistance across all three compounds. Therefore both anidulafungin and micafungin have been evaluated as markers for caspofungin resistance (40, 90, 91). However, differential activity has been demonstrated for some C. glabrata strains where FKS mutations have conferred resistance to anidulafungin and caspofungin but not to micafungin in vitro and in animal models (8). Therefore, the recommendation at this time is to use anidulafungin as a marker of echinocandin susceptibility or resistance, and to retest C. glabrata isolates for susceptibility to micafungin if found anidulafungin resistant (89). EUCAST has only proposed interpretative breakpoints for anidulafungin and micafungin (55, 92).

**CLSI AND EUCAST BREAKPOINTS FOR CANDIDA SPECIES**

There is now a considerable body of data indicating that standardized antifungal susceptibility testing (27, 29) for Candida spp. and some triazoles, amphotericin B, as well as the echinocandins provides results that have predictive utility consistent with the 90-60 rule. Interpretive MIC breakpoints (Table 1) have been established for isolates tested by the CLSI M27-A3 method for fluconazole, voriconazole, anidulafungin, caspofungin, and micafungin following some correlation with clinical data predominantly from patients with oropharyngeal candidiasis, candidemia in nonneutropenic patients, and some more invasive infections but also taking into account epidemiological cutoff values (37, 93, 94). Breakpoints for yeast isolates tested by the EUCAST EDef 7.2 method are available for amphotericin B, fluconazole, posaconazole, voriconazole, anidulafungin, and micafungin (55, 92, 95–97). Considerable effort has been expended on rationalization of the discrepant CLSI and EUCAST breakpoints for yeast isolates, as there was concern that the results of two very similar methods should be interpreted with different breakpoint criteria (35, 36, 39, 98–100). This is especially true since the publication of CLSI M27-A3, which, like EUCAST EDef 7.2, allows the reading of results at 24 h, which has led to lower CLSI MICs for most drug-organism combinations (as illustrated also by the lower QC ranges for the 24-h reading) (27). Changes to the CLSI breakpoints have now been published in a supplement to the reference method, document M27-S4 (37), and these, together with the EUCAST breakpoints, are presented in Table 1. There are for the first time species-spe-
cific breakpoints, which makes accurate species identification a vital part of breakpoint interpretation. Harmonization has been achieved for almost all drug-organism combinations; where differences remain is mainly dependent on differences in the endpoints achieved by the two methods (e.g., for anidulafungin).

Flucytosine inhibits the majority (~90%) of Candida spp. at concentrations of ≤2 μg/ml, so this is the breakpoint for susceptibility for the majority of species; 4.0 μg/ml is considered SDD, and ≥8 μg/ml is considered resistant. The SDD designation for flucytosine encompasses isolates in which susceptibility is dependent on achievable peak levels in serum of 40 to 60 μg/ml at lower dosages. The pharmacodynamic parameter that predicts efficacy for flucytosine is ~100 (area under the concentration-time curve [AUC]/MIC ratio). Flucytosine MICs for C. glabrata and C. krusei are generally higher than for other species, at 4 to 16 and ≥264 μg/ml, respectively (101). The EUCAST recommendation is that these species are not good targets for flucytosine, but C. glabrata is not fully resistant, the C. glabrata wild-type population is classified as intermediate in order to accommodate use of these compounds in some clinical situations (29, 35). The CLSI also states that C. krusei is intrinsically resistant but suggests that isolates of C. glabrata with MICs of ≤32 mg/liter may respond to high-dose flucytosine (37).

Breakpoints for intracranial use are not addressed in M27-S4, but non-species-specific breakpoints for this agent were included in M27-S3 (102). Intracranial use is generally quite active in vitro, with MICs of 0.01 to 1.0 μg/ml or less for most yeast isolates, except for C. glabrata (0.06 to 8 μg/ml) and C. krusei (0.5 to 2 μg/ml). Overall, ≥99% of isolates of Candida spp. are inhibited by ≤1 μg/ml, so this was the suggested resistance breakpoint (103). Isolates with an MIC of ≤0.125 μg/ml were considered susceptible, while those with an MIC of 0.5 μg/ml were classified as SDD. For intracranial use, an MIC within the SDD range indicates the need for higher serum concentrations for an optimal response. The need for species-specific breakpoints has been recognized, and species-specific ECOFFs/ECVs have recently been published that may assist in detecting and monitoring any acquired resistance development (93).

For voriconazole, a consensus susceptible breakpoint of ≤0.12 μg/ml has been agreed upon by CLSI and EUCAST groups for most Candida spp. documented, but whereas the CLSI document specifies an SDD of 0.5 μg/ml and a resistant breakpoint of ≥1.0 μg/ml (Table 1), EUCAST classifies isolates with MICs of >0.12 μg/ml as resistant. Isolates for which the voriconazole MIC is ≥1.0 μg/ml (CLSI resistant endpoint) are mostly C. glabrata, for which there are no accepted breakpoints, but also include non-Candida genera such as Sporobolomyces salmonicolor and Rhodotorula rubra, as well as some C. albicans isolates (101). Pharmacokinetics and pharmacodynamic parameters indicate that 24-h free-drug AUC/MIC ratios of 24 and 75 to 100 are predictive of the 50% effective dose and a 2-log CFU reduction, respectively. Recommended doses would produce free-drug AUCs of ~20 μg h/ml (104). However, voriconazole has nonlinear and variable pharmacokinetics, and the coefficient of variation of the AUC has been estimated to be 74 to 100%. Monte Carlo simulations showed that a target free-drug AUC/MIC of 24 would inhibit ≥99% of isolates with an MIC of ≤0.5 μg/liter if treatment were given intravenously and ≥99% of isolates with MICs of ≥0.25 μg/liter if treatment were given orally (97).

The EUCAST group has also addressed breakpoints for posaconazole for Candida species and suggests a susceptible breakpoint of ≤0.06 μg/ml and resistant breakpoint of >0.12 μg/ml, again based on careful evaluation of known wild-type distributions and the pharmacokinetic parameters of the drug (96). A recent multilaboratory analysis of ECVs of eight Candida spp. to fluconazole, posaconazole, and voriconazole suggests that breakpoints should be higher if assessed by CLSI methodology (105).

Reevaluation of the clinical CLSI breakpoints for the echinocandins following the analysis of accumulated data suggested that the previous CLSI breakpoint threshold of ≤2.0 μg/ml as susceptible and ≥2.0 μg/ml as nonsusceptible were too high for most Candida species. This led to the misclassification as susceptible of a significant number of isolates from infections that were refractory to echinocandin therapy and had known FKS mutations, which are recognized as a marker for echinocandin resistance (99). Thus, with the exception of C. parapsilosis and C. guilliermondii, lower drug- and species-specific epidemiological cutoff values have been suggested for the echinocandins (see Table 1). The CLSI breakpoints differ between the three echinocandins and are lower for C. glabrata than for most other Candida species. Applying these new lower breakpoints to 15,269 isolates of Candida spp. from 100 centers worldwide collected over an 8-year period from 2001 to 2009, Pfaffer and colleagues detected a significant number of isolates with non-wild-type resistance patterns that would have been missed by applying the higher clinical breakpoints (40). At present, EUCAST has refrained from setting breakpoints for caspofungin due to significant variation associated with in vitro testing of this compound (89). The EUCAST breakpoints for anidulafungin and micafungin are lower than those proposed by the CLSI because the EUCAST method provides lower MICs than are obtained by CLSI. Hence, for both methods, the breakpoints basically mirror the ECOFFs/ECVs and the differences are method driven. Anidulafungin is considered a good marker for caspofungin susceptibility until the reproducibility issue has been solved and breakpoints can be established for this agent (93). Differential activity has, however, been demonstrated for micafungin and C. glabrata, as some weaker mutations elevate the anidulafungin and caspofungin MIC but not the micafungin MIC and are not associated with efficacy loss in an animal model (8). Hence anidulafungin is the preferred testing agent for caspofungin and anidulafungin susceptibility.

The breakpoints suggested for amphotericin B are ≤1.0 μg/ml (susceptible) and >1.0 μg/ml (resistant) (95). These have been applied historically and numerous publications support their application, although very little clinical experience exists for Candida isolates with MICs above 1 mg/liter.

**ALTERNATIVE APPROACHES FOR YEASTS**

Although the CLSI and EUCAST methods for in vitro susceptibility testing were essential for standardization and for improving interlaboratory reproducibility, they may not be the best methods for testing all organisms or all drugs or for routine use in clinical laboratories. Once reference methods become established, this allows the introduction of commercially available methods that produce comparative results. The methods that have been most frequently applied to antifungal susceptibility testing are listed in Table 4.

**Colorimetric Methods**

Colorimetric indicators or fluorescent dyes can facilitate determination of MIC endpoints. Commercial (Sensititre
YeastOne, ASTY, and Fungitest) and noncommercial (tetrazolium salt methods and substrate uptake indicators) procedures have been adapted for antifungal susceptibility testing (106–109). The Sensititre YeastOne Y021VD plate (TREK Diagnostic Systems, Inc., Cleveland, OH) follows the same microdilution format as the CLSI reference method; it has been approved by the U.S. Food and Drug Administration (FDA) and is CE-marked for the testing of nonfastidious yeast species with fluconazole, itraconazole, voriconazole, fluconazole, and caspofungin, with the facility to include a QC organism on the same plate. Other systemic antifungal agents included on the Sensititre YeastOne Y09 plate, such as amphotericin B, posaconazole, anidulafungin, and micafungin, are available for nondiagnostic use in the United States, but the same range of antifungals on Sensititre YeastOne Y10 has been CE marked for use in Europe. Reading of endpoints is enhanced by the inclusion of Alamar Blue as the oxidation-reduction colorimetric indicator. If wells remain blue, there is no growth; pink wells indicate growth, and purple wells indicate partial inhibition. Agreement to within 2 doubling dilutions with reference broth microdilution MICs has been excellent with posaconazole and voriconazole (95.4%) and with anidulafungin, caspofungin, and micafungin (100%), all read after 24-h incubation (107, 109). Recent evaluation against the CLSI microdilution method using the new clinical breakpoints and epidemiological cutoff values for the echinocandins with 404 isolates of Candida spp. showed excellent (100%) essential agreement and close agreement with categorical values. For C. albicans, categorical agreement ranged from 93.6% (caspofungin) to 99.6% (micafungin) with less than 1% very major or major errors (110). For C. glabrata and C. krusei and caspofungin, it was somewhat less optimal (87.9 and 69.1%, respectively). However, an important caveat is that virtually no isolates with acquired resistance (87.9 and 69.1%, respectively) were included in any of the evaluation studies of the Sensititre test (and most others), and therefore the performance as to detection of such isolates remains largely unknown.

**Vitek 2 Yeast Susceptibility Testing**

In an effort to automate yeast susceptibility testing, bioMérieux (Hazelwood, MO) developed the Vitek 2 yeast susceptibility test, a commercial test system based on spectrophotometric analysis and incorporating a card-based miniaturized version of the doubling-dilution reference method. This was shown to produce reproducible, rapid, and accurate results consistent with those produced by the CLSI broth microdilution method for amphotericin B, fluconazole, fluconazole, and voriconazole with several hundred isolates of Candida spp. (111, 112). One study investigated the potential of the Vitek 2 system to specifically detect resistance to fluconazole and voriconazole in 36 isolates of C. albicans and 86 isolates of C. glabrata with well-characterized resistance mechanisms (113). The Vitek 2 system exhibited excellent agreement with the reference broth microdilution method for detecting resistance, with overall categorical agreement of 97.5% for both fluconazole and voriconazole. In a study of 154 isolates, including some resistant to the azoles and amphotericin B, Cuenca-Estrella and colleagues (114) compared the Vitek 2 antifungal susceptibility testing system with the CLSI and EUCAST broth dilution reference methods and with the Sensititre YeastOne and Etest techniques. With essential agreement to within 2 doubling dilutions of >95% for Candida spp. and 92% for Cryptococcus neoformans, they concluded that the Vitek 2 was a reliable technique to determine antifungal susceptibility of yeast species and, moreover, was a more rapid and easier alternative to the reference procedures. The average time to reading was 15.5 h for Candida spp. and 34 h for Cryptococcus. Recently, caspofungin has been included in the panel. A drawback is that the MIC range that can be reported is ≤0.25 to ≥4 mg/liter and thus does not include the revised breakpoint for C. glabrata (S: ≤0.125 mg/liter), and hence susceptible and intermediate isolates cannot be discriminated. A recent study evaluated the performance of the Vitek 2 for caspofungin testing using a well-defined panel of wild-type and resistant mutants of the five most common Candida spp. If C. glabrata isolates with an MIC of ≤0.25 were considered susceptible, there were no misclassifications of susceptible wild-type isolates. However, 19.4% (6/31) of isolates harboring FKS hot-spot resistance mutations were misclassified as susceptible (115). The AST-YS05 card for use with the Vitek 2 system, which contains fluconazole, voriconazole, and caspofungin, is available in the United States and Europe.

**Flow Cytometry**

Flow cytometric methods also have been adapted for antifungal susceptibility testing by introducing DNA-binding vital dyes into the culture to detect fungal cell damage after
exposure to an antifungal agent. MICs determined by this approach have been comparable to those obtained by the M27-A3 methods (116, 117). Although these methods produce faster results (4 to 6 h), the need for a flow cytometer for MIC determination would preclude their use in small laboratories; moreover, they are not FDA approved or CE marked.

**Standardized Disk Diffusion Method for Yeasts**

Worldwide, the most commonly used technique for antibacterial susceptibility testing is the disk diffusion test, which yields a quantitative result (zones of inhibition) and a qualitative interpretive category (e.g., susceptible or resistant) based on correlation of zone sizes obtained with organisms with known MICs. Agar disk diffusion testing is a simple, flexible, and cost-effective alternative to broth dilution testing. The CLSI Subcommittee on Antifungal Susceptibility Testing has developed a disk diffusion method (Table 5) for testing *Candida* spp. with caspofungin, fluconazole, posaconazole, and voriconazole, although interpretive criteria are only available for caspofungin, fluconazole, and voriconazole, and as yet there are no commercially available FDA-approved disks (CLSI M44-A2 document) (118). One significant advantage of the M44-A2 disk diffusion method is that results can be obtained after 20 to 24 h of incubation. Extensive worldwide testing with fluconazole and voriconazole as part of a global survey suggests this method performs very well (119). It has also demonstrated good performance with caspofungin (120). The M44 disk test method has also shown to be a useful approach for determining the susceptibility of *C. neoformans* and other genera of yeast (119, 121). Zone interpretive criteria have been approved for fluconazole, voriconazole, caspofungin, and micafungin (99) (CLSI M44-S3) (122).

**Standard Medium**
The CLSI M44-A2 method uses Mueller-Hinton agar supplemented with 2% glucose to improve growth and 0.5 μg/ml methylene blue to produce sharper zone definition (118). The pH of the medium should be 7.2 to 7.4 at room temperature after gelling, and the surface of the agar should be moist but without moisture droplets. The medium can be prepared and poured with the two supplements, or the supplements can be added to commercially prepared Mueller-Hinton agar plates; the latter enables the use of routine agar plates from the bacteriology laboratory. Detailed instructions for the preparation of the agar plates are found in the M44-A2 document (118).

**Preparation of Inocula**
The M44-A2 method employs an inoculum suspension adjusted to the turbidity of a 0.5 McFarland standard by the spectrophotometer, as described above for broth dilution standard methods (Table 2) (27).

**Performance of Disk Diffusion Method for Yeasts**
The agar plates are inoculated within 15 min of adjusting the inoculum suspension, as follows (Table 5). Briefly, a sterile cotton swab is dipped into the undiluted inoculum suspension, rotated several times, and pressed firmly against the inside wall of the tube above the fluid level to remove excess fluid. The entire dried agar surface is evenly streaked in three different directions, swabbing the rim of the plate as the final step. The lid of the plate should be left ajar to allow the agar surface to dry for no more than 15 min. Fluconazole (25 μg), posaconazole (5 μg), voriconazole (1 μg), caspofungin (5 μg), and micafungin (10 μg) disks are dispensed onto the inoculated agar surface. Disks must be pressed down to ensure complete contact with the agar and distributed evenly so they are not closer than 24 mm from center to center. After the disks are placed, they cannot be moved because drug diffusion is almost instantaneous. Plates should be incubated in 15 min after disks have been placed (118).

**Incubation and Determination of Disk Diffusion**

**Zone Diameters for Yeasts**

After 20 to 24 h of incubation at 35°C, the resulting inhibition zones should be uniformly circular and a confluent lawn of growth should be present. The plates are read above a black, nonreflecting background illuminated with reflected light (118). The zone diameters surrounding the disks are measured to the nearest whole millimeter at the point at which there is prominent reduction in growth. Pinpoint microcolonies at the zone edge or large colonies within a zone are encountered frequently and should be ignored. If growth is insufficient, the plates should be read at 48 h (Table 5) (118). QC zone diameter limits have been defined for fluconazole, posaconazole, voriconazole, and caspofungin when testing *Candida* spp. (122).

**Agar-Based Alternative Approaches for Yeasts**

NeoSensitabs Tablets

A commercial agar diffusion test from Rosco Diagnostica (Rosco Laboratory, Taastrup, Denmark; distributor, Key Scientific Products, Stamford, TX) is available for antifungal susceptibility testing of yeasts. Tablets of established and some of the new antifungal agents (e.g., voriconazole, caspofungin, and posaconazole) are available. Preliminary comparisons with both reference broth dilution and disk diffusion methods have provided promising results and they are CE marked (123).

*Data from CLSI M44-A2 (31).*
Gradient Strip Testing

The Etest (bioMérieux; Marcy l’Étoile, France, and Durham, NC) was the first antifungal gradient strip test to be produced, but others are now commercially available. Such tests are based on the diffusion of a stable concentration gradient of an antimicrobial agent from a plastic strip onto an agar medium. There are commercially available gradient strips for amphotericin B, fluconazole, fluconazole, voriconazole, caspofungin, and micafungin. For clinical use, the FDA has approved fluconazole, voriconazole, caspofungin, and fluconazole Etest strips; all are CE marked. Agreement of Etest and reference MICs has been species and medium dependent. The medium that provides the best performance for Etest MICs is solidified RPMI medium supplemented with 2% glucose, and reading requires expertise and close adherence to the manufacturer’s instructions. If a clear zone is seen, the MIC may easily be read where the zone of inhibition intersects the strip, and false susceptibility has not been reported. Problems can arise when inexperienced readers incorrectly interpret faint background growth of small colonies within the zone as resistance. This is most often seen with fluconazole, and if an isolate is unexpectedly found to be fluconazole resistant by Etest, it should be retested by a reference method. In this regard, it is crucial to ensure that a pure culture is used; for example, with a mixture of C. albicans and C. glabrata, the susceptibility of the more susceptible C. albicans would be read, and the smaller C. glabrata colonies in the C. albicans inhibition zone could be mistaken as trailing that should be ignored. The Etest may be useful in testing yeasts suspected of being potentially resistant to amphotericin B (87, 124). Amphotericin B MICs of ≥0.38 μg/ml determined by Etest for Candida spp. have been associated with therapeutic failure in patients treated with amphotericin B for candidemia (125). However, there are conflicting reports suggesting that even when isolates are tested by this methodology, susceptibility data for Candida spp. do not appear to correlate with treatment failure or success. This suggests that factors other than MIC may have a greater impact on the outcome of invasive candidiasis (126). This method has also been evaluated and found to correlate well with CLSI methodology for testing the susceptibilities of Candida spp. to triazoles and echinocandins (127–129). It is clear that the breakpoints developed for the clinical tests cannot necessarily be applied to results obtained with the commercial methods. A recent study suggests that if the modified CLSI breakpoints for caspofungin are applied to Etest results for some isolates of C. glabrata and C. krusei, a significant number will be misclassified as intermediate (130). This finding has been confirmed for C. glabrata when evaluating the clinical response for patients with infections involving isolates with MICs just above the CLSI breakpoint (131).

Direct Susceptibility Testing

Although most published susceptibility data have been derived following subculture of organisms, there have been attempts to perform tests directly on blood samples from patients with fungemia, thus still further reducing the incubation time required to complete the test (132, 133). In a recent study of 195 prospectively collected and 133 laboratory-simulated specimens of a wide range of clinically relevant yeast species, Guinea and colleagues were able to show high rates of agreement between direct Etest results obtained within 24 h and the reference CLSI M27-A3 method obtained in 48 to 72 h for fluconazole, voriconazole, isavuconazole, and caspofungin (133).

Proteomics and Antifungal Susceptibility Testing

Early work suggests that proteomic methodology can be used to detect the presence of resistance to several classes of antifungal drugs (134, 135). The protein composition of yeast cells varies in relation to the inhibition of cell growth in varying drug concentrations, and analysis of such changes could be exploited to herald a new generation of antifungal susceptibility testing. Marinach and colleagues (134) studied the effect of different fluconazole concentrations on the spectral profiles produced by one reference and 16 other strains of C. albicans with different susceptibilities to fluconazole and different resistance mechanisms. They analyzed deviations from the control spectra that were quantifiable in order to produce minimal profile change concentration endpoints representing the lowest drug concentration at which mass spectrum profile changes can be detected. There was a high degree of correlation (100% ± 2 doubling dilutions, 94% ± 1 doubling dilution) between minimal profile change concentration results and MIC results obtained with the standard CLSI methodology, and only one isolate would have been in a different susceptibility category (minor error). This methodology has also been applied to an analysis of caspofungin susceptibility testing of 34 yeast and 10 mould isolates with and without known resistance-associated FKS mutations (135). As in earlier tests, minimal profile change concentration results were compared with MIC (or minimum effective concentration [MEC] for the moulds) results obtained by the appropriate CLSI methodology. There was 100% essential agreement (± 2 dilutions) for both yeast and mould isolates and 94.1% categorical agreement.

Matrix-assisted laser desorption ionization–time-of-flight mass spectrometry-based methods appear to be a reliable and reproducible tool for antifungal susceptibility testing with results analyzed after 15 h incubation as compared to 24 h for CLSI and EUCAST methods; moreover, objective analyses are produced for both yeast and mould isolates. Although currently as labor-intensive and time-consuming as a full susceptibility testing method, such a process has the potential to be adapted to breakpoint testing to provide an early surveillance test for antifungal drug resistance in a given isolate or as a screening tool for emerging resistance within a population.

Molecular Methods

There are multiple mechanisms that lead to reduced susceptibility or overt resistance toazole antifungal drugs in Candida species; these include changes in cell wall composition leading to reduced uptake, increased efflux, upregulation of target gene production, and mutation in the target enzymes (see chapter 130). One or more of these may be present in a cell, and stepwise acquisition appears to be common (136, 137). Thus, any method for molecular determination of resistance must be a multiplex system and must also be capable of determining not just presence but upregulation of housekeeping genes. For this reason, such methods are currently the province of research laboratories. Resistance to echinocandins usually centers on mutations of two hot-spot regions of the FKS1 gene, although other mutations have been induced in the laboratory setting (55). There is a new class to receive the utility of a Luminex-based multiplex assay that can be used for high-throughput screening and proved to be 100% concordant with DNA sequencing results on 102 isolates of C. glabrata with mutations in the FKS1 and FKS2 hot-spot
domains (139). However, molecular techniques will be unable to detect previously uncharacterized mechanisms of resistance so should always be confirmed by phenotypic testing.

STANDARDIZED BROTH DILUTION METHODS FOR MOULDS

Antifungal susceptibility testing of moulds is becoming increasingly important due to the range of emerging opportunistic pathogens and the reporting of both innate and emergent resistance among the most common mould pathogens (1). Both CLSI (M38-A2) (28) and EUCAST (EDef 9.1) (30) have developed broth microdilution methods for filamentous fungi that are similar to those for yeast and are summarized in Table 6.

**Microdilution**

**Standard Medium and Drug Stock Solutions**

The test medium employed by the CLSI method is the same MOPS-buffered standard RPMI recommended for yeast testing and for the EUCAST method supplemented with 2% glucose. Drug stock solutions are prepared as described above for yeast testing (27, 29) and in the CLSI M38-A3 and EUCAST EDef 9.1 documents (28, 30).

**Preparation of Inocula**

Since nongerminated conidia are easier to prepare and standardize, this is the method of inoculum preparation described and is broadly similar in both documents. For the CLSI method, the inoculum for each isolate is prepared by first growing the mould on potato dextrose agar slants (oatmeal agar for *T. rubrum*) for 7 days at 35°C or until good sporulation is obtained, which may be 48 h for some genera. Each slant is then flooded with 1 ml of sterile 0.85% saline (addition of 0.01 ml of Tween 20 will help for *Aspergillus* spp.), and the surface of the colony is gently probed with the tip of the pipette. The resulting mixture is withdrawn, and the heavy particles are allowed to settle for 3 to 5 min. The upper homogeneous suspension, containing the mixture of nongerminated conidia or sporangiopores and hyphal fragments, is aliquoted and mixed for 3 to 5 min. The turbidity is measured with a spectrophotometer at 530 nm, and the optical density adjusted by addition of sterile saline to 0.09 to 0.13 for *Aspergillus* spp., *Paecilomyces* spp., *Exophiala dermatitidis*, and *S. schenckii*; to 0.15 to 0.17 for *Fusarium* spp., *Scedosporium apiospermum*, *Scolecosporium gallowayi* (formerly *Ochroconis gallowayi*), *Cladosporium bantiana*, and mucormaceous moulds; and to 0.25 to 0.3 for * Bipolaris* spp. and * Alternaria* spp. Stock inoculum suspensions are then diluted 1:50 in medium to obtain 2× the final inoculum of 0.4 × 10^5 to 5 × 10^5 CFU/ml. Certain genera (e.g., *Scedosporium*, *Bipolaris*, and * Alternaria*) may require a lower (50%) dilution factor (28).

The main difference with the EUCAST method is that the inoculum is higher and is prepared by counting in a hemocytometer as opposed to spectrophotometric determination. Conidia are harvested in 5 ml of sterile water + 0.1% Tween 20 by rubbing 2- to 5-day growth at 35°C on potato dextrose agar slants with a sterile cotton swab and then transferring the suspension to a sterile tube and homogenizing on a vortex mixer for 15 s. The resulting suspension is diluted as appropriate for hemocytometer counting. Suspensions containing clumps should be vortexed for a further 15 s and if hyphae are present should be filtered through an 11-μm pore size filter. The inoculum is adjusted with sterile distilled water to give a 2 × 10^6 to 5 × 10^6 CFU/ml suspension, which is diluted 1:10 with sterile distilled water to obtain a final working inoculum of 2 × 10^5 to 5 × 10^5 CFU/ml, which must be used within 30 min.

**Drug Dilutions and Performance of Microdilution Test for Moulds**

Drug dilutions are prepared and dispensed in sterile, disposable, multiwell microdilution trays, as described above for yeast testing. On the day of the test, each well is inoculated with 100-μl volumes of the diluted conidial or sporangiopore suspensions.

**Incubation and Determination of Broth Microdilution MICs for Moulds**

All microdilution trays are incubated at 35°C without agitation, and MICs are determined visually after 21 to 74 h. Most mucoraceous moulds should be read at 24 h and most other opportunistic fungi at 48 h; occasionally, 72 to 74 h may be required to allow sufficient growth in the control wells. Testing of the dimorphic fungi may require 5 to 7 days of incubation. The MIC endpoint criterion for moulds is the lowest drug concentration that shows complete growth inhibition when testing amphotericin B, itraconazole, voriconazole, and posaconazole. Endpoint determination with the echinocandin agents is difficult to assess and requires microscopic evaluation (see below) of the MEC, which for most moulds is read at 21 to 26 h and at 46 to 72 h for *Scedosporium* spp.

**Echinocandins: MEC**

When testing the echinocandins, most *Aspergillus* isolates show trailing growth, and conventional MIC determination could categorize these trailing isolates as resistant to caspofungin. A more careful examination of the microdilution wells reveals the presence of compact, round microcolonies that correspond to significant morphologic alterations. The hyphae grow abnormally as short, highly branched filaments with swollen germ tubes. Kurz and colleagues (140) defined the concentration of drug producing these morphologic changes as the MEC to distinguish it from conventional MICs. A multicenter study demonstrated that caspofungin MECs were reliable endpoints in 14 of 17 laboratories (141), and in another study in eight of these laboratories, evaluating anidulafungin MECs against a variety of mould species provided reliable endpoints (142). More recently, an international study involving five laboratories was able to determine wild-type distributions and epidemiological cutoff points for caspofungin against *Aspergillus* spp. (143). However, it is notable that broth microdilution testing failed to identify an animal-model-confirmed resistant isolate from a patient failing therapy as non-wild type even though this isolate failed to produce an inhibition ellipse with a caspofungin Etest strip (6). Consequently, because conflicting results have been reported from some laboratories, caution and further refinement of this testing approach are needed (141).

**Macrodilution**

There is good agreement between results obtained by both micro- and macrodilution methods for moulds (144). This test format may be more suitable for testing those organisms that require longer incubation periods due to problems with evaporation from the microtiter plates on prolonged incubation. Macrodilution testing conditions are described in the

CLSI M38-A2 document (28). Briefly, inoculum stock suspensions and drug dilutions are prepared as for the microdilution test. The 100-fold drug dilutions should be diluted 1:10 with RPMI to achieve 10 times the strength needed for the macrodilution test. The stock inoculum suspensions are diluted 1:100 with medium to obtain 0.4 ×10⁴ to 5 × 10⁴ CFU/ml. The 10× drug concentrations are dispensed into 12- by 75-mm sterile tubes in 0.1-ml volumes. Each tube is inoculated on the day of the test with 0.9 ml of the corresponding suspension. Tubes are incubated at 35°C without agitation and observed for the presence or absence of visible growth. The MICs are determined as described above for the microdilution method for moulds.

Quality Control for Mould Testing
Either one of the QC yeast organisms or the QC Paecilomyces variotii ATCC MYA-3630 isolate may be tested in the same manner as the other mould isolates or as described above for yeasts and should be included each time an isolate is evaluated with any antifungal agent. In addition, other moulds have been selected as reference isolates by CLSI and EUCAST (Table 3) (28, 30).

Expected Results and Interpretation of Breakpoints for Moulds
EUCAST has published clinical breakpoints for selected Aspergillus species with some drugs (Table 7), but few corre-

³Breakpoints are presented as S ≤ X, R > Y (except for the revised fluconazole breakpoint for C. glabrata). The “I” category (if present) is readily interpreted as the values between the S and the R breakpoints.
⁴IE (insufficient evidence)–MICs are higher than for A. fumigatus. There is insufficient evidence that this species is a good target for treatment.
⁵Provided sufficient drug levels can be achieved.
⁶Note the MICs exhibited by this species are similar to those exhibited by A. fumigatus but clinical data are insufficient to establish a breakpoint.
lations of in vitro results with in vitro response have been reported for mould infections. Clinical failures in the treatment of aspergillosis and hyalohyphomycosis have been correlated with itraconazole MICs of $>8 \mu g/ml$ and amphotericin B MICs of $>2 \mu g/ml$ (145–147). There are also failures and breakthrough infections with moulds reported in patients on caspofungin therapy (6, 148). Moreover, there are experiences with treating infections with other groups of fungi, such as Scedosporium, where the finding of greater in vivo susceptibility to voriconazole than to amphotericin B translates into better clinical outcomes in patients treated with this drug (149).

Amphotericin B MICs determined by either reference method are $\leq 1.0 \mu g/ml$ for most mould species, including most mucoraceous moulds (150, 151). High amphotericin B MICs ($\geq 2.0 \mu g/ml$) have been reported for Purpureocillium lilacinum, most Scedosporium and Pseudallescheria spp., and some isolates ofAlternaria spp., Aspergillus spp. (especially A. terreus and A. flavus), Fusarium spp., Talaromyces (formerly Penicillium) marneffei, Phialophora spp., and S. schenckii (53, 151, 152), and infections with these species are often refractory to treatment (153).

The EUCAST breakpoints for amphotericin B with $A. fumigatus$ and $A. niger$ are $\leq 1.0 \mu g/ml$ (susceptible) and $>2.0 \mu g/ml$ (resistant) (Table 7). A. terreus has not been assigned breakpoints as it is not considered a good target for amphotericin B and for A. flavus and A. nidulans, insufficient clinical data are available for breakpoint selection.

MICs of itraconazole are also usually $\leq 1.0 \mu g/ml$ for most other moulds; the exceptions are its high MICs for$A. fumigatus$ ustus/calidoustus (some isolates), Fusarium solani, F. oxysporum, P. lilacinum, S. schenckii, S. prolificans, Trichoderma longibrachiatum, and many mucoraceous moulds (152, 154). EUCAST has established itraconazole breakpoints for A. flavus, A. fumigatus, A. nidulans, and A. terreus ($S: \leq 1 \mu g/liter; R: >2 \mu g/liter$) (Table 7).

Azole resistance in $A. fumigatus$ isolates has been associated with target gene mutations (Cyp51A gene, efflux pumps and upregulation of the target gene) (see chapter 130). Such alterations may confer resistance to itraconazole only, to itraconazole and posaconazole, or may induce pan-azole resistance. Typically, the itraconazole MICs are elevated to a much greater extent than those of posaconazole and voriconazole, so itraconazole may serve as an initial azole-screening compound in Aspergillus.

Voriconazole and posaconazole display an extended spectrum of antimould activity and, particularly for posaconazole, good in vitro activity against the mucoraceous moulds has been reported (150, 151, 155, 156). Publications have agreed on epidemiological breakpoints for$A. fumigatus$ tested by the CLSI and EUCAST methods (157–159). The consensus epidemiological cutoff results were $\leq 1.0 \mu g/ml$ for itraconazole, ravucconazole, and voriconazole, and $\leq 0.25 \mu g/ml$ for posaconazole. The EUCAST breakpoints reflect these accepted ECVs: voriconazole breakpoints are $\leq 1.0 \mu g/ml$ (susceptible) and $>2.0 \mu g/ml$ (resistant) for A. fumigatus, A. flavus, A. nidulans, and A. terreus, while posaconazole breakpoint are $\leq 0.125 \mu g/ml$ (susceptible) and $>0.25 \mu g/ml$ (resistant) for A. fumigatus and A. terreus (Table 7).

The breakpoint for posaconazole is conservative and one step below the ECOFF/ECV due to the variable bioavailability of the current oral solution and the pharmacokinetic/pharmacodynamic data suggesting the wild-type MIC is only just covered. It is likely that the breakpoint may be elevated if future formulations of posaconazole provide better exposure in the clinical setting.

Published have cited resistance to itraconazole and some cross-resistance to voriconazole in $A. fumigatus$ from certain chronic clinical conditions necessitating long-term use of these agents (10, 160). More recently, there have been reports from the Netherlands and other countries of primary azole resistance in 6 to 12.8% of recent clinical $A. fumigatus$ isolates (13, 18–20). This has been linked to the significant environmental use of azoles for plant protection, and a correlation of frequency of such-resistant isolates in the environment (most of which harbor a unique TR$_{fL98H}$/L98H alteration) with the proportional global use of antifungal pesticides has been established (21). Resistance frequencies therefore vary. A recent publication of more than 700 clinical isolates of Aspergillus spp. showed that only 2.2% had itraconazole MICs of $\geq 4 \mu g/ml$ (resistant), although a further 9.6% had an MIC of $\geq 2.0 \mu g/ml$ (intermediate) (161). Cross-resistance to posaconazole was encountered in 53.5% of 43 isolates with elevated itraconazole MICs, whereas only 7% of the isolates appeared cross-resistant to voriconazole, which corresponds to the degree of similarity in the molecular structures of the drugs (161).

MICs/MECs of the echinocandins are usually $<1.0 \mu g/ml$ for most$A. fumigatus$ spp. (144, 162). However, a study that tested 81 isolates of Aspergillus flavus by EUCAST methodology found them to be uniformly resistant to caspofungin, anidulafungin, and micafungin, with MIC$_{50}$ results at $>16.0 \mu g/ml$ (162). In contrast, a study employing CLSI methodology reported that 95% of 432 isolates of A. flavus yielded a caspofungin MIC of $\leq 0.25 \mu g/ml$ (144). Higher MICs/MECs are often reported for other mould species for which the echinocandins usually demonstrate low to moderate activity (33, 162). However, MICs of $<1.0 \mu g/ml$ have been reported for some isolates of dimorphic fungi, Acremonium spp., Phialophora spp., and S. apiospermum (162, 163).

For the echinocandins, Aspergillus spp. have been characterized as susceptible or nonsusceptible based on their wild-type distributions and epidemiological cutoff values, and based on large numbers of isolates in a multicenter collaboration, species-specific caspofungin ECVs were proposed, ranging from 0.25 to 1.0 $\mu g/ml$ (144). However, unacceptable variation in the MIC range for caspofungin against Aspergillus is found if various publications are compared over laboratories and time, as has been reported for caspofungin testing of Candida. Until this variability has been reduced to an acceptable level, it will not be meaningful to adopt ECOFFs/ECVs or attempt to establish breakpoints (164–168). As there are clinical data to suggest that $A. fumigatus$ isolates may acquire echinocandin resistance and that infections due to such isolates may fail therapy, it is of utmost importance to optimize and validate echinocandin testing of Aspergillus (6).

### Broth Microdilution Method for Dermatophytes

Susceptibility testing of dermatophytes has lagged behind that of other moulds, but the M38-A2 broth microdilution method has been successfully adapted, with minor modifications, to the testing of dermatophytes (169). These modifications include the use of oatmeal agar for inulin preparation when testing Trichophyton rubrum in order to induce conidium formation, and 4 to 5 days of incubation at 35°C for MIC determination (80% growth inhibition endpoints).

Two isolates ofTrichophyton spp. have been validated as reference strains (Table 3).
Blue color change (optical density) produced when tetrazolium salts (yellow) are cleaved to their formazan derivative (purple), using a microtiter plate spectrophotometer, has also been evaluated for moulds (173, 174). Again, further evaluations, including interlaboratory studies, are needed with more isolates and species, and, particularly important, such studies should whenever possible include wild-type as well as resistant isolates for as many species as possible.

Agar-Based Alternative Approaches for Filamentous Fungi

As for yeasts, agar-based methods have been applied to susceptibility testing of moulds, including agar dilution, disk diffusion, and Etest methods and semisolid agar (175).

Agar Dilution Methods

Agar dilution methods involve the preparation of 10× double dilutions of the agent, which are incorporated into molten agar. Drug-containing plates are inoculated with suspensions of the organism being tested. In one study, results with an itraconazole-resistant isolate tested by agar incorporation and broth microdilution correlated well with a mouse model of infection (145). Since standard methods are not available, the size of the inoculum varies among the different studies. Such methods are particularly useful for the high throughput required for environmental surveillance and for initial and early screening for azole resistance of clinical cultures, as testing can be done directly from the primary plate before a pure culture is available.

Plates with four wells containing different concentrations of three antifungal agents in RPMI-1640 with 2% glucose agar (itraconazole 4 mg/liter, posaconazole 0.5 mg/liter, and voriconazole 1 mg/liter) and a control well have been developed for this purpose (Balis Laboratorium VOE, Boven Leeuwen, Netherlands) (41). Surveillance plates are inoculated with 50 μl of a test suspension and examined after 24, 48, and 72 h of incubation at 37°C. The use of such screening plates may reduce the number of isolates that need further evaluations, including interlaboratory studies, are needed with more isolates and species, and, particularly important, such studies should whenever possible include wild-type as well as resistant isolates for as many species as possible.

Disk Diffusion Method

Disk diffusion methodology has been evaluated for amphotericin B, anidulafungin, caspofungin, micafungin, itraconazole, posaconazole, and voriconazole against a wide range of opportunistic pathogenic moulds (176–180). The CLSI Subcommittee has published an approved method for testing caspofungin, amphotericin B, and the triazoles against nondermatophyte filamentous fungi (M51-A1) (32). It is similar to that for yeasts (M44-A2) (31) but employs Mueller-Hinton agar not supplemented with methylene blue or increased dextrose, as in a collaborative multicenter study these conditions were found to be unsuitable for many moulds (177). The inoculum concentration is prepared as for CLSI M38-A3, and plates are inoculated in the same way as for yeast disk diffusion methodology. After incubation at 35°C for 16 to 24 h for mucoraceous moulds, 24 h for Aspergillus spp., and 48 h for other moulds, there should be a confluent lawn of growth surrounding a circular inhibition zone, which is measured to the nearest whole millimeter (177). Good levels of overall categorical agreement were found as compared to CLSI M38 results when testing large numbers of isolates from many mould species. However, there were reservations about using amphotericin B disks except with mucoraceous moulds, and the itraconazole disks should not currently be used to test mucoraceous moulds but are suitable for other genera (177). Three strains have been selected as QC isolates (A. fumigatus ATCC 3626, P. variotii ATCC MYA-3630, and C. krusei ATCC 6258) for which zone diameter ranges have been established for amphotericin B, itraconazole, posaconazole, and voriconazole (181).

Neo-Sensitabs Diffusion Method for Moulds

This commercial agar diffusion test (Rosco, Denmark) is available in Europe for antifungal susceptibility testing of yeast, although early studies proved disappointing for some drug-organism combinations when testing moulds (178). A more recent study compared susceptibility results obtained with Neo-Sensitabs with those obtained by Etest, although there was no comparison with a reference method. A group of 100 isolates including Aspergillus spp., Fusarium spp., Scedosporium spp., mucoraceous and other moulds were tested with amphotericin B, caspofungin, itraconazole, posaconazole, and voriconazole. When the recently published epidemiological cutoff points for moulds were applied (144, 159), high levels of categorical agreement were reported between these two tests with all drugs except amphotericin B (182). However, few resistant strains, and none with molecular evidence of resistance mutations, were included.

Etest and Other Gradient Strips

Numerous studies have assessed the utility of Etest for testing mould pathogens (179, 182–186). Since the trailing effect is not a major problem for azole testing against most moulds, Etest inhibition ellipses are usually sharp and MICs are easily interpreted. In contrast with the echinocandins, there may be quite heavy background growth within the inhibition zone, but much heavier growth within the inhibition ellipse may indicate resistance (6). Overall, comparisons of Etest and M38-A methods have demonstrated better agreement when testing the triazoles (>90%) than amphotericin B (>80%). Amphotericin B Etest MICs for A. fumigatus, S. apiospermum, and S. prolificans are usually higher than reference values, especially after 48 h of incubation (184). In a case study, an isolate of A. fumigatus was found to be multiresistant to azoles with corresponding genetic mutation and also appeared resistant to caspofungin by Etest, with an MIC of >32 mg/liter, although this resistance had not been detected by broth microdilution testing (6). On molecular testing, the isolate was shown to have upregulation in the expression of the FKS gene and displayed reduced susceptibility to caspofungin in an animal model of infection. The reliability of the Etest method and the clinical relevance of its MICs for moulds should be addressed.

Although Etest strips for amphotericin B, anidulafungin, ketoconazole, posaconazole, voriconazole, and caspofungin are commercially available, the U.S. FDA has not to date approved any antifungal strip for clinical use in susceptibility testing of moulds.

Molecular Tests

The application of molecular methods to the detection of resistance in isolates of filamentous fungi has proved to be easier in mould isolates than in yeast as resistance mechanisms appear to be fewer. A multiplex PCR assay to detect the three most frequent A. fumigatus cyp51A gene mutations leading to triazole resistance and cross-resistance has been developed (187). Such a test could be beneficial particularly in the azole-naive setting, as it included the most common environmental resistance mechanism also seen in isolates of...
from invasive infections (TR₄₃/L98H). However, in the setting of chronic aspergillosis, a huge variety of CYP51A mutations have been associated with mono-, multi-, or pan-azole resistance, and up to 40% of the resistant isolates are found to have other underlying mechanisms apart from target gene mutations, thereby rendering the negative predictive value of absence of mutations unacceptably low (21, 188). Furthermore, two new alterations have been described recently in azole-resistant isolates found in either azole-naive patients or in the environment, suggesting rapid molecular detection of azole resistance in A. fumigatus in the routine setting may be a complex and difficult task (189–191). The molecular mechanisms behind echinocandin resistance in Aspergillus are less well understood. FKS1 gene mutations have been induced in laboratory strains and shown to confer resistance, but have so far not been detected in clinical isolates. Moreover, additional mechanisms not involving the FKS target gene have been found in isolates exposed to cell wall digestion and subsequently cultured in the presence of caspofungin (192). Gene expression profiling by Northern blotting and real-time PCR has revealed overexpression of the FKS1 gene leading to reduced susceptibility in an isolate of A. fumigatus from a patient who had failed caspofungin therapy (6).

Fungicidal Activity
A CLSI study has demonstrated that laboratories can reliably perform MFC testing (50) and time-kill curves. In contrast to what is observed with yeasts, the azoles appear to have a certain degree of fungicidal activity, as mentioned above, for a variety of common and rare opportunistic mould pathogens. MFCs of 0.2 to 4 μg/ml have been reported with the triazoles for various mould species (50). However, standardization of this procedure is needed to reliably assess the potential value of the MFC endpoint in patient management. These standardization efforts should include the correlation of in vitro results with the clearing of target organs of the infecting organism in animal models and the further clinical relevance of MFC data. Recent studies incorporating an indicator of metabolic activity, 2,3-bis-(2-methoxy-4-nitro-5-sulfophenyl)-2H-tetrazolium-3-carboxanilide in microdilution broth-based formats have examined fungicidal activity of amphotericin B and voriconazole and have shown to direct initial therapy (see chapter 129), but given the increasing problem of resistance to azole antifungals in A. fumigatus in some countries, the use of drug-containing screening agars is to be encouraged for primary isolates to provide an early indication of resistance while isolates are being purified for reference testing. The strong move towards consensus in the standardized methodology employed and the principles by which breakpoints are selected in the United States and Europe has meant that internationally agreed ECV breakpoints can be applied for some drug-fungus combinations. This has helped to improve surveillance of resistance patterns worldwide and will help in the further development of clinically relevant breakpoints.

SUMMARY AND CONCLUSIONS
A great deal of progress has been achieved in the field of antifungal susceptibility testing with both yeast and filamentous fungi since testing began in earnest in the early 1980s. Standardized broth macrodilution and microdilution methods are available for testing moulds and yeasts, as are standardized disk diffusion methods for systemically active antifungal drugs. Progress is also being made in establishing the relationship between test results and patient responses to therapy in varied clinical settings and with many of the currently available antifungal agents. Breakpoints are available for common yeast species with most systemically active drugs, and there are some breakpoints for A. fumigatus. Moreover, some commercial methods have been approved for the antifungal susceptibility testing of Candida spp., but care should be taken in selecting appropriate breakpoints based on the ECV for these methods, which may vary from those produced by the standardized reference tests. Often, identifying the yeast or mould pathogen to the species level is sufficient to direct initial therapy (see chapter 129), but given the increasing problem of resistance to azole antifungals in A. fumigatus, the use of drug-containing screening agars is to be encouraged for primary isolates to provide an early indication of resistance while isolates are being purified for reference testing. The strong move towards consensus in the standardized methodology employed and the principles by which breakpoints are selected in the United States and Europe has meant that internationally agreed ECV breakpoints can be applied for some drug-fungus combinations. This has helped to improve surveillance of resistance patterns worldwide and will help in the further development of clinically relevant breakpoints.

This page intentionally left blank.
The term parasite is traditionally applied to several disparate groups of eukaryotic organisms ranging from single-celled protozoa to birds and even mammals; however, it is mostly used with reference to protozoa and helminth worms (including nematodes, cestodes, trematodes, and acanthocephalans). Medical parasitology is concerned with the 200 or so species of helminth worms and about 80 species of protozoans that infect humans. Many of them are rare and accidental parasites, but more than 100 species are commonly found in humans. Some of them are responsible for a disproportionate number of important diseases, particularly in the warmest parts of the world, and they invariably receive the most attention. This chapter is concerned with the broad overall classification of the parasitic protozoa and helminth worms commonly encountered in humans. More detailed information can be found in chapters 136 to 147 of this volume.

Taxonomy is the study of the classification of living organisms, and classification is the science of establishing and defining systematic groups of organisms in a hierarchical manner that reflects evolutionary past and present relationships between the groups. The classification of higher organisms has in the past been largely determined using morphological criteria, structural similarities, and the fossil record; however, there is now increasing reliance on molecular techniques to establish evidence of relatedness. The basic unit in classification is the species, a grouping in which, among higher organisms, all members are morphologically similar and able to interbreed successfully. The universally used system for the classification of eukaryotic organisms is the Linnaean system, in which species are given two names, the generic name and the specific name; thus, humans are Homo sapiens. All organisms are placed in specific taxonomic groups, or taxa. Species are grouped into families and families into orders, orders into classes, classes into phyla, and phyla into one of six kingdoms (see chapter 113 and below), each taxonomic group, or taxon, subsuming the characteristics of the taxon above it. Taxa are frequently subdivided (e.g., suborders and subfamilies, infraspecies, superfamilies), resulting in a plethora of layers often impenetrable even to experts in taxonomy. This chapter errs on the side of simplicity rather than complexity.

Morphological characteristics have long been the gold standards of systems of classification and remain so for the identification of parasites. In recent years, however, other methods have been increasingly relied on for estimating evolutionary distances, the basis of rational hierarchical classifications. Some of the methods used include molecular analyses, particularly DNA and RNA sequences, distance matrices as measures of genetic distances, maximum likelihoods of the probability of particular relationships, maximum parsimony based on estimates of the smallest number of evolutionary events necessary to account for observable data, and Bayesian probability theory based on an assumption of prior probabilities. There is at present no consensus as to which methods are likely to produce scientifically sound and acceptable classifications of parasites, so all current systems must be regarded as interim working schemes.

The Linnaean system of classification of eukaryotes is logical and scientifically sound; however, it does not necessarily meet the needs of those interested not in the finer points of taxonomy but in having a system that is comprehensible and usable (in the words of John Corliss, a “user-friendly” system) (1). This subject is discussed in some detail in a parasitological (and equally mycological) context by Tibayrenc (2), who identifies some 24 concepts of species and goes on to say that “biological researchers need more pragmatic approaches that can be understood by nonspecialists. Decision makers need precise answers for cost-effective and efficient control measures against transmissible diseases.” This is what underlies the adoption of the systems of classification described in this chapter, which are intended to serve as frameworks within which researchers and others, particularly those concerned with the diseases caused by parasites and not the parasites themselves, can communicate with one another.

CLASSIFICATION OF THE PROTOZOA

The single-celled protozoa are, and always have been, difficult to classify and have always constituted an enigmatic group. From the mid-1970s until fairly recently, the consensus among scientists was that there were five kingdoms of living organisms, Prokaryota (bacteria), Animalia (animals), Plantae (plants), Fungi (fungi), and Protista (an unnatural assemblage of single-celled eukaryotic organisms with affinities to animals [Protozoa], plants [Protophyta],
The affinities of these single-celled organisms have long been the subjects of controversy and frequent reappraisal on a somewhat arbitrary basis. Three things have made it possible to put the classification of the protozoa on a sound scientific basis: a new understanding of symbiogenesis, advances in molecular and biochemical techniques, and the use of phylogenetic trees. Symbiogenesis is the phenomenon whereby eukaryotic cells have acquired prokaryotic cell organelles such as mitochondria, chloroplasts, and flagella, resulting in permanent associations between the organelles and the host cell (4). Studies of these associations have provided new insights into the evolution of various protozoan groups. Our understanding of symbiogenesis (coupled with the use of molecular and biochemical techniques and the construction of multigene trees) has now made it possible to arrange single-celled organisms into groups based on evolutionary distances and has enabled taxonomists to organize all living organisms within realistic and evolutionarily sound overall schemes—but not necessarily in a hierarchical way. The most important aspect of this classification is that its major elements are compatible with more traditional classifications. Essentially, there are now six kingdoms: the five classical groups, Bacteria, Animalia, Fungi, Plantae, and Chromista (sister to the Plantae, sometimes referred to as the Stramenopila), plus Protozoa (5–7). With the gradual removal of a number of former protozoa to the Chromista (now a massive kingdom with 10 phyla) and also to the plant and fungal kingdoms, the diversity in the former Protozoa has become much reduced to what was formerly known as the Protozoa, and thus the use of the word Protista becomes redundant.

The classification used in this chapter, based on that developed by Cavalier-Smith (5–9), places the Protozoa as the basal eukaryotic kingdom and reestablishes the validity of the kingdom Protozoa; it thus brings the protozoa and helminths under the same rules, whereby all species are named according to the guidelines set out in the International Code of Zoological Nomenclature (http://www.iczn.org). From a practical point of view, this confers stability in the naming of species and ensures priority for the names originally given while permitting corrections or amendments when necessary. It must be remembered, however, that the International Code is not a panacea for all taxonomic problems. This revised classification resulted in the redistribution of some taxa, including some parasites of humans. In this chapter, some of the generic and specific names are different from those in the 10th edition of this Manual, but all such changes can be justified on grounds of new discoveries and interpretations.

There are estimated to be more than 200,000 named species of single-celled eukaryotic organisms (10), of which only about 10,000 (some 5%) are parasitic; thus, any system of classification must primarily satisfy zoologists and protozoologists working with free-living protozoa. Traditionally, the phylum Protozoa embraced four great groups of single-celled organisms recognized on the basis of their mode of locomotion: Rhizopoda or Sarcodina (amoebae, moving by pseudopodia), Mastigophora (flagellates, moving by flagella), Ciliophora or Ciliata (ciliates, moving by cilia), and Sporozoa (sporozoans, spore-forming protozoans without any obvious means of locomotion). Rapid developments in our understanding of the protozoa during the 1960s and 1970s necessitated a new classification. In 1980, the Society of Protozoologists published a classification (11) that recognized seven phyla: Sarcomastigophora (amoebae and flagellates), Apicomplexa (essentially equivalent to the Sporozoa), Ciliophora (ciliates), Microspora (now classified with the phylum Fungi), Myxozoa (now classified in the phylum Animalia), Ascetospora, and Labyrinthomorpha (groups of little interest to protozoologists). However, by the beginning of the 1990s, a number of protozoologists (12, 13) had reverted to what was essentially the traditional four “groups”: the flagellated protozoa, the amoeboid protozoa, the ciliated protozoa, and the sporozoans (including the microsporidians). This approach had the merit of simplicity and maintained clear links with the traditional classification, but it was merely a classification of convenience and did not stand up to rigorous analysis at either the evolutionary or molecular level. Further attempts to resolve this problem resulted in an “interim user-friendly” classification (1) that served its purpose well until more rational and natural classifications emerged.

Over the past decade or so, developments in molecular biology have given us a clearer understanding of phylogenetic relationships involving particular groups of single-celled eukaryotic organisms, but unfortunately this has once again resulted in a plethora of classifications. In 2005, a quarter of a century after the publication of the Society of Protozoologists’ classification, another attempt was made by the then International Society of Protozoologists to produce an “updated and comprehensive classification” of the single-celled eukaryotes or protists (14), which has since been superseded (15). The authors of these classifications abandoned the traditional higher taxa in favor of a series of groups and ranks but succeeded merely in producing a classification so complex that it is unlikely to be of use to any scientists except specialist protozoologists working with free-living organisms. It now seems unlikely that protozoologists, particularly those working with free-living organisms, will ever come up with a scheme of classification acceptable to everyone. These apparent vacillations have confused parasitologists, most of whom are concerned with fewer than 0.05% of all named species that affect humans, who simply require a stable framework within which to classify parasites—particularly those of medical and veterinary importance.

The classification in Table 1, based on that by Cavalier-Smith (5–9), embraces traditional and novel elements, meets the requirements of parasitologists, and bridges the gap between those working with free-living protozoa and those working with parasitic protozoa. There are two major and important differences between the traditional (1980) classification (11) and the one outlined below. There are two important changes from the schemes of classification found in most medical and veterinary textbooks. First, the microsporidians, some of which infect humans, mainly immunocompromised individuals, have traditionally been classified with the Protozoa sensu stricto but are now classified with the Fungi (16). Second, the taxonomic position of Blastocystis has always been enigmatic, and this genus has been shuffled between the Fungi and Protozoa but is now placed in the kingdom Chromista (8, 17).

With the removal of these groups, the Protozoa becomes a kingdom containing 11 to 13 phyla, depending on which particular classification is used, of which six contain parasites that infect humans. The phylum Amoebozoa, containing the amoebae, is equivalent to the old Rhizopoda (Sarcodina); the flagellates belonging to the former Mastigophora are now distributed among three phyla, Metamonada, Percolozoa, and Euglenozoa. Two phyla remain unchanged, the Ciliophora, containing the ciliates, and the Apicomplexa (Sporozoa). The status of the phylum Apicomplexa requires some explanation. Sporozoa is the traditional name applied to a large group of sexually repro-
Apicomplexa has gradually crept into the literature and is now largely synonymous with Sporozoa, and the two names are now used interchangeably. Nevertheless, the compactness, the taxon Apicomplexa has also acquired a number of nonparasitic flagellated species belonging to the order Dientamoebida.

*Also known as Giardia intestinalis or Giardia lamblia. Molecular and epidemiological evidence suggests that there is more than one assemblage of Giardia spp. that infect humans and, possibly, more than one species.

Molecular phylogenetic studies suggest that humans harbor a small number of Babesia spp. that cannot be identified as B. microti, B. divergens, B. gibsoni, or B. duncani.

Producing, spore-forming protozoans with recognizably similar morphology at the electron microscope level and comparable life cycles. In the 1970s, a new parasite genus, Perkinsus, containing parasites of marine molluscs, which was quite different from any of the other sporozoans, was allocated to this group. The phylum Sporozoa was downgraded to a class and the name of the phylum was changed to Apicomplexa in order to incorporate two classes, Sporozoa and Perkinsina (11). Not all parasitologists liked this change, but the word Apicomplexa has gradually crept into the literature and is now widely used. It is now clear that Perkinsia spp. do not belong with the sporozoans and should be classified close to, or with, the dinoflagellates (18). Since its original description, the taxon Apicomplexa has also acquired a number of nonparasitic flagellated species belonging to the order Colpodellida; therefore, Apicomplexa now includes both the traditional sporozoans and a number of nonparasitic species. Unfortunately, Apicomplexa has now become largely synonymous with Sporozoa, and the two names are often used interchangeably. Nevertheless, the compact group of species of most interest to parasitologists, the sporozoans sensu stricto, are members of the class Coccidea in the
subphylum Sporozoa, a taxon included in Table 1. Therefore, when considering these important parasitic protozoa, reference should be made to the subphylum Sporozoa and sporozoans rather than to the phylum Apicomplexa and apicomplexans. More information about the parasitic protozoa that affect humans can be found in chapters 136 to 142 in this volume.

CLASSIFICATION OF THE HELMINTH WORMS

Although usually considered together by parasitologists, helminth worms actually constitute three entirely separate phyla, Nematoda, Platyhelminthes, and Acanthocephala. The nematodes and acanthocephalans have affinities close to the arthropods, whereas the affinities of the platyhelminths lie with the annelids and molluscs. For these reasons, these three groups are considered separately.

CLASSIFICATION OF THE NEMATODES

Estimates of the numbers of named nematodes range from 15,000 to 20,000, and some experts believe that there may be more than a million. Nematodes occupy every conceivable habitat, but fewer than 10% of named species are parasites of vertebrates and, of these, very few are parasitic in humans. The classification of nematodes faces the problems encountered when classifying the protozoa; the interests of most scientists concerned with free-living forms contrast with the interests of the minority interested in parasites—particularly those of medical or veterinary importance. It is unlikely, therefore, that there will ever be a system of classification satisfactory to both kinds of interest and, as for the protozoa, the views of the majority will always tend to dominate.

Nematodes are typically bilaterally symmetrical, round, and tubular in shape, with an outer cuticle, a hydrostatic body cavity, the pseudocoelum (a gut that runs from mouth to anus), and a well-developed reproductive system with separate sexes. Respiratory and circulatory systems are absent. The typical life cycle consists of an egg, four larval stages, and male and female adults. The classification of the nematodes has been traditionally based on the morphological characteristics of the adult male and, to a lesser extent female, worms—particularly the nature of the cuticle; the shape of the mouth and lips, the length of the esophagus, cephalic papillae, vulval appendages; and the nature of the male bursa. All these features are easily observable and can be measured, but, as indicators of evolutionary relationships, they are not really satisfactory. Since 1974, there have been at least 10 different major attempts to devise systems of classification that more closely reflect evolutionary relationships, and recent classifications have tended to place more weight on evidence obtained using molecular techniques than on morphology. Early classifications divided the nematodes into two classes, the Phasmida and Aphasmida, based on the presence or absence of paired granular secretory organs, the caudal phasmids. These major groups were subsequently changed to Adenophorea and Secernentea, the latter group containing most of the nematodes of medical importance (19). The most widely used classification of the nematodes is that developed over a number of years by the Centre for Agricultural Bioscience International, formerly the Commonwealth Agricultural Bureau Institute, and brought together in the Keys to the Nematode Parasites of Vertebrates (20). The editors of these volumes agree that this classification is somewhat dated but, regardless of whatever new classifications emerge, the keys are, and will remain, the most useful source of information for those involved in the day-to-day tasks of identifying nematodes of human, veterinary, and agricultural importance. This is the classification used in this chapter and shown in Table 2.

A radically different classification of the nematodes developed by De Ley and Blaxter is gaining some acceptance among those working with free-living (the majority of) nematodes (21). This classification, based largely on the use of morphological data and small subunit rDNA sequences, embeds the Secernentea within the Adenophorea, thus undermining the traditional two-class classification. This has necessitated many other changes, so this classification is very different from the traditional one. This classification is still in the process of being developed, so the version adopted in this chapter is essentially the traditional one with some minor modifications. As such, it is compatible with the classifications used in most parasitological textbooks. More information about the nematodes that affect humans can be found in chapters 143, 144, and 147 in this volume.

CLASSIFICATION OF THE PLATYHELMINTHES: TREMATODES

The phylum Platyhelminthes is usually divided into three classes, the flatworms or flukes, Monogenea and Digenea, and the tapeworms, Cestodaria. There are no monogenean parasites that affect humans, and the tapeworms are considered in the next section, so this section is restricted to the Digenea. There are about 18,000 species of digenews belonging to over 140 families, by far the largest group of metazoan parasites. All are dorsally flattened and leaflike, with a well-developed alimentary system with a blind gut and an oral sucker surrounding the mouth and also a ventral sucker, both of which are used for attachment to the host. The classification of digenetic trematodes is reasonably straightforward, because all species are parasites; thus, it is not necessary to take into account the requirements of scientists concerned with free-living organisms. The classification of the digeneans has, therefore, remained fairly stable, as can be seen from an examination of Yamaguti’s monumental Synopsis of Digenetic Trematodes of Vertebrates (22) and the Centre for Agricultural Bioscience International’s three-volume Keys to the Trematoda (23–25). There is also a very good classification by Olson and colleagues (26) based partly on DNA sequences. These authors believed that it was necessary to reassign some species between the Echinostomida, a polyphyletic group, and the Plagiorchiida, both of which contained nonnatural groupings. These changes have had little impact on the classification of parasites of medical interest but have been incorporated into Table 3 by bringing closely related groups nearer together, but otherwise the classification remains very much a traditional one. More information about the trematodes that affect humans can be found in chapters 146 and 147 of this volume.

CLASSIFICATION OF THE PLATYHELMINTHES: CESTODES

The classification of the cestodes, or tapeworms, presents very few problems, largely because they have distinctive morphological characteristics. There are more than 1,000 species characterized by the possession of a distinct anterior

REFERENCES

ACANTHOCEPHALAN WORMS

The Acanthocephala, or thorny-headed worms, contains about 1,100 species, all intestinal parasites mainly of fish. Two species are occasional parasites of humans, Macracanthorhynchus hirudinaceus and Moniliformis moniliformis. Neither is an important pathogen. An outline classification of the acanthocephalan worms that affect humans is shown in Table 5.

The aim of this chapter is to present an outline classification of the parasites that affect humans in order to provide a framework within which particular genera or species can be placed. There are several lists of parasites available in the literature, the most authoritative and comprehensive, but now somewhat dated, is Ashford and Crewe (28); there is also an excellent list of foodborne intestinal parasites by Fried and colleagues (29). There is also a lot of information on various websites, but much of this must be treated with caution. The most useful accounts of the more important parasites, particularly those that occur in the tropics and subtropics, are the 22nd edition of Manson’s Tropical Diseases (30) and the 10th edition of Topley and Wilson’s Microbiology and Microbial Infections (12).

scolex and a body that consists of “segments” called proglottids. There are 14 orders in the class Cestoda, of which two contain species that infect humans: the Pseudophyllidea, which attach by means of grooves on the sides of the scolex, and the Cyclophyllidea, which attach by means of four cup-like suckers assisted in some cases by hooks. The classification adopted here (Table 4) is based on the one given by Khali (27) and widely used in textbooks. More information about the cestodes that affect humans can be found in chapter 145 of this volume.

Routine diagnostic parasitology generally includes laboratory procedures designed to detect organisms within clinical specimens by using morphological criteria rather than culture, biochemical tools, and/or physical growth characteristics (Table 1). Parasite identification is frequently based on brightfield microscopic analysis of concentrated and/or stained preparations. Small organisms often require high magnification such as with oil immersion (×1,000). Electron microscopy for species characterization of organisms has been replaced in recent years mainly by molecular methods (PCR and sequence analyses of selected genes). Furthermore, new commercial test kits designed especially for detection of fecal antigens (e.g., coproantigens of *Giardia* spp., *Cryptosporidium* spp., and *Entamoeba histolytica* [Table 2] or circulating *Plasmodium* antigens in blood) have expanded the methodological repertoire. In addition to methods for direct parasite detection (morphology, antigens, and DNA), methods for indirect detection of parasite infections demonstrating specific antibodies directed to a variety of native or recombinant parasite antigens have been developed and made commercially available (Table 3). Diagnostic techniques are available to detect a large range of protozoan and helminth species in different clinical specimens. An important precondition for reliable diagnostic results is the proper collection, processing, and examination of clinical specimens. Based on the biology of the parasites and the procedural features of the tests, multiple specimens must often be submitted and examined before the suspected organism(s) is found and its identity is confirmed or a suspected infection can be excluded.

**SPECIMEN COLLECTION AND TRANSPORT**

Various collection methods are available for specimens suspected of containing parasites or parasitic elements (Tables 4, 5, 6, and 7) (1–7). When collection methods are selected, the decision should be based on a thorough understanding of the value and limitations of each. The final laboratory results are based on parasite recovery and identification and depend on the initial handling of the specimen. Unless the appropriate specimens are properly collected and processed, these infections may not be detected. Therefore, specimen rejection criteria have become much more important for all diagnostic microbiology procedures. Diagnostic laboratory results based on improperly collected specimens may require inappropriate expenditures of time and supplies and mislead the physician. As a part of any continuous quality improvement program for the laboratory, the generation of test results must begin with stringent criteria for specimen acceptance or rejection. In addition, diagnostic laboratories should provide clear information on preanalytical requirements to the physician. All fresh specimens should be handled carefully, since each specimen represents a potential source of infectious material. Safety precautions should include proper labeling of fixatives; specific areas designated for specimen handling (biological safety cabinets may be necessary under certain circumstances, such as parasite cultures); proper containers for centrifugation; acceptable discard policies; appropriate policies of no eating, drinking, or smoking in work areas; and, if applicable, correct techniques for organism culture and/or animal inoculation. Precautions must be followed when applicable, particularly when blood and other body fluids are being handled (8, 9).

**Collection of Fresh Stool**

Collection of stool for parasite detection should always be performed before barium is used for radiological examination. Stool specimens containing the opaque, chalky sulfate suspension of barium are unacceptable for examination, and intestinal protozoa may be undetectable for 5 to 10 days after barium is given to the patient. Certain substances and medications also interfere with the detection of intestinal protozoa, including mineral oil, bismuth, antibiotics (metronidazole and tetracyclines), antimalarial agents, and nonabsorbable anti diarrheal preparations. After administration of any of these compounds, parasites may not be recovered for a week to several weeks. Therefore, specimen collection should be delayed for 5 to 10 days or at least 2 weeks after barium or antibiotics, respectively, are administered (1, 2, 10, 11). Some laboratories add the following comment to their negative reports: "Certain antibiotics such as metronidazole or tetracycline may interfere with the recovery of intestinal parasites, particularly the protozoa."

Fecal specimens should be collected in clean, wide-mouthed containers; often, a waxed cardboard or plastic container with a tight-fitting lid is selected for this purpose. The specimens should not be contaminated with water or urine because water may contain free-living organisms that can be mistaken for human parasites, and urine may destroy...
motile organisms. Stool specimen containers should be placed in plastic bags when transported to the laboratory for testing. If postal delivery services are used, any diagnostic specimens must be packed according to national or international rules (e.g., labeling with UN code 3373; three-container approach). Specimens should be identified with the patient’s name and identification number, physician’s name, and the date and time the specimen was collected. The specimen must also be accompanied by a request form indicating which laboratory procedures should be performed. The presumptive diagnosis or relevant travel history information is helpful and should accompany the test request. The presumptive diagnosis or relevant travel history information is helpful and should accompany the test request.

In some situations, it may be necessary to contact the physician for additional patient history.

In the past, it has been recommended that a normal examination for stool parasites before therapy include three specimens. Three specimens, collected as outlined above, have also been recommended for posttherapy examinations. However, a patient who has received treatment for a protozoan infection should be checked 3 to 4 weeks after therapy, and those treated for Taenia infections should be checked 5 to 6 weeks after therapy. In many cases, the posttherapy specimens are not collected, often as a cost containment measure; if the patient becomes symptomatic again, additional specimens can be submitted (3, 4).

Although some recommend collection of only one or two specimens, there are differences of opinion regarding this approach. It has also been suggested that three specimens be pooled and examined as a single specimen; again, this approach is somewhat controversial. However, physicians should be aware that the probability of detecting clinically relevant parasites in a single stool specimen may be as low as 50 to 60% but is >95% if three samples are examined (4).

If a series of three specimens is collected, they should be submitted on separate days. If possible, the specimens should be submitted every other day; otherwise, the series of three specimens should be submitted within no more than 10 days. If a series of six specimens is requested, the specimens should also be collected on separate days or within no more than 14 days. Many organisms, particularly the intestinal protozoa, do not appear in the stool in consistent numbers on a daily basis, and the series of three specimens is considered the minimum for an adequate examination. Multiple specimens from the same patient should not be submitted on the same day. One possible exception would be a patient who has severe, watery diarrhea, in whom any organisms present might be missed because of a tremendous dilution factor related to fluid loss. These specimens should be accepted only after consultation with the physician. It is also not recommended that the three specimens be submitted one each for 3 consecutive days; however, use of this collection time frame would not be cause enough to reject the specimens.

To evaluate patients who are at risk for giardiasis, the negative predictive value of some of the immunoassays on a single stool specimen is not sufficiently high to exclude the possibility of a Giardia infection. In cases in which the

*a* This is not a complete listing of all available products but reflects readily available information.

*b* Bordier Affinity Products (http://www.bordier.ch); Hemagen (http://www.hemagen.com); InBios (http://www.inbios.com); Launch Diagnostics Limited (http://launchdiagnostics.com); NovaTec (http://www.novatec-id.com); Operon (http://operonac); Oxford Biosystems and Cadama (http://oxfordbiosystems.com); Scimedx Corp. (http://scimedx.com).

**Abbreviations:** EIA: enzyme immunoassay; IC: rapid immunochromatography (some are dipstick, cartridge, or other rapid test formats).

Clinical suspicion for *Giardia* infection is moderate or high and the first assay yields a negative result, testing of a second specimen is recommended (12). Fresh specimens are mandatory for the recovery of motile trophozoites (amebae, flagellates, or ciliates). The protozoan trophozoite stage is normally found in cases of diarrhea; the intestinal tract contents move through the system too rapidly for cyst formation to occur. Once the stool specimen is passed from the body, trophozoites do not encyst but may disintegrate if not examined or preserved within a short time after passage. However, most helminth eggs and larvae, coccidian oocysts, and microsporidial spores survive for extended periods. Liquid specimens should be examined within 30 min of passage, not 30 min from the time they reach the laboratory. If this general time recommendation of 30 min is not possible, the specimen should be placed in one of the available fixatives (2). Soft (semiformed) specimens may have a mixture of protozoan trophozoites and cysts and should be examined within 1 h of passage; again, if this time frame is not possible, preservatives should be used. Immediate examination of formed specimens is not as critical; in fact, if the specimen is examined any time within 24 h after passage, the protozoan cysts should still be intact.
### TABLE 4 Specimen preparation and procedures, recommended stain(s) and relevant parasites, and additional information

<th>Procedures and specimens</th>
<th>Recommended methods and relevant parasites</th>
<th>Additional information</th>
</tr>
</thead>
<tbody>
<tr>
<td>Blood</td>
<td>Microscopy: thin and thick blood films. Fresh blood (preferred) or EDTA-blood (fill EDTA tube completely with blood and then mix)</td>
<td>Giemsa stain (all blood parasites); hematoyxlin-based stain (sheathed microfilariae)</td>
<td>Most drawings and descriptions of blood parasites are based on Giemsa-stained blood films. Although Wright’s stain (or Wright-Giemsa combination stain) works, stippling in malaria may not be visible, and the organisms’ colors may not match the descriptions. However, with other stains (those listed previously, in addition to some of the “quick” blood stains), the organisms should be detectable on the blood films.</td>
</tr>
<tr>
<td></td>
<td>Concentration methods: EDTA-blood</td>
<td>Buffy coat, fresh blood films for detection of moving microfilariae or trypansomes</td>
<td>The use of blood collected with anticoagulant (rather than fresh) has direct relevance to the morphology of malaria organisms seen in peripheral blood films. If the blood smears are prepared after more than 1 h, stippling may not be visible, even if the correct pH buffers are used. Also, if blood is kept at room temperature (with the stopper removed), the male microgametocyte may exflagellate and fertilize the female macrogametocyte, and development continues within the tube of blood (as it would in the mosquito host). The ookinete may actually resemble Plasmodium falciparum gametocytes.</td>
</tr>
<tr>
<td></td>
<td>Antigen detection: EDTA-blood for malaria, serum or plasma for circulating antigens (hemolized blood can interact in some tests)</td>
<td>QBC, a screening method for blood parasites (hematocrit tube contains acridine orange), has been used for malaria, Babesia, trypansomes, and microfilariae. It is usually impossible to identify malaria organisms to the species level; requires high levels of training. Commercial immunoassay test kits for malaria and some microfilariae. Sensitivity is not higher than for thick films for Plasmodium spp., much more sensitive for Leishmania spp. (peripheral blood is used from immunodeficient patients only).</td>
<td>PCR: so far, no commercial tests are available; high laboratory standards are needed (may work with frozen, coagulated, or hemolyzed blood samples).</td>
</tr>
<tr>
<td></td>
<td>Specific antibody detection: serum or plasma, anticoagulated or coagulated blood (hemolized blood can cause problems in some tests)</td>
<td>Sequencing of PCR product is often used for species or genotype identification.</td>
<td>Many laboratories use in-house tests; only a few fully defined antigens are available; sensitivities and specificities of the tests should be documented by the laboratory.</td>
</tr>
<tr>
<td></td>
<td>Bone marrow</td>
<td>Most commonly used are EIA (many test kits commercially available), EITB (commercially available for some parasites), and IFA.</td>
<td>Leishmania spp. amastigotes are recovered in cells of the reticuloendothelial system; if films are not prepared directly after sample collection, infected cells may disintegrate. Sensitivity of microscopy is low; use only in combination with other methods.</td>
</tr>
<tr>
<td></td>
<td>Biopsy samples or aspirates</td>
<td>Giemsa stain (all blood parasites)</td>
<td>(Continued on next page)</td>
</tr>
<tr>
<td></td>
<td>Microscopy: thin and thick blood films with aspirate collected in EDTA</td>
<td>Culture for Leishmania spp. (or Trypanosoma cruz)</td>
<td></td>
</tr>
<tr>
<td></td>
<td>Culture: sterile material in EDTA or culture medium</td>
<td>PCR for blood parasites, including Leishmania and Toxoplasma spp. and other rare parasites</td>
<td></td>
</tr>
<tr>
<td></td>
<td>PCR: aspirate in EDTA</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Central nervous system</td>
<td>Microscopy: spinal fluid and CSF (wet examination, stained smears), brain biopsy (touch or squash preparations, stained)</td>
<td>Stains: Giemsa (trypansomes, Toxoplasma spp.); Giemsa, trichrome, or calcofluor (amebae [Naegleria spp.-PAM, Acanthamoeba spp. or Balamuthia spp.-GAE]); Giemsa, acid-fast, PAS, modified trichrome, silver methenamine (microsporidia) (tissue Gram stains also recommended for microsporidia in routine histologic preparations); H&amp;E, routine histology (larval cestodes, Taenia solium [cysticerci], Echinococcus spp.)</td>
<td>If CSF is received (with no suspect organism suggested), Giemsa is the best choice; however, modified trichrome or calcofluor is also recommended as a second stain (amebic cysts, microsporidia). If brain biopsy material is received (particularly from an immunocompromised patient), PCR is recommended for diagnosis and identification to the species or genotype level.</td>
</tr>
</tbody>
</table>

<tr>
<th>Body site</th>
<th>Procedures and specimens</th>
<th>Recommended methods and relevant parasites</th>
<th>Additional information</th>
</tr>
</thead>
<tbody>
<tr>
<td>Culture</td>
<td>Culture: sterile aspirate or biopsy material (in physiological saline)</td>
<td>Free-living amebae (exception: Balamuthia spp. do not grow in the routine agar/bacterial overlay method). Toxoplasma spp. can be cultured in tissue culture media.</td>
<td>A small amount of the sample should always be stored frozen for PCR analyses in case the results of the other methods are inconclusive.</td>
</tr>
<tr>
<td>PCR: aspirate or biopsy material, native, frozen, or fixed in ethanol</td>
<td>Protozoa and helminths; species and genotype characterization</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Cutaneous ulcers</td>
<td>Microscopy: aspirate, biopsy material (smears, touch or squash preparations, histologic sections)</td>
<td>Giemsa (Leishmania spp.); H&amp;E, routine histology (Acanthamoeba spp., Entamoeba histolytica)</td>
<td>Most likely causative parasites would be Leishmania spp., which stain with Giemsa. PAS could be used to differentiate Histoplasma capsulatum from Leishmania spp. in tissue. Sensitivity of microscopy may be low. In immunocompromised patients, skin ulcers have been documented with amebae as causative agents. Cultures of material from cutaneous ulcers may be contaminated with bacteria; PCR would be the method of choice.</td>
</tr>
<tr>
<td>Culture (less common)</td>
<td>Cultures: aspirate, biopsy material, native, frozen, or fixed in ethanol</td>
<td>Leishmania spp., free-living amebae (often bacterial contaminations)</td>
<td></td>
</tr>
<tr>
<td>PCR: aspirate, biopsy material, native, frozen, or fixed in ethanol</td>
<td>Leishmania spp. (species identification), free-living amebae</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Eye</td>
<td>Microscopy: biopsy material (smears, touch or squash preparations), scrapings, contact lens, sediment of lens solution</td>
<td>Calcofluor (Acanthamoeba spp. cyst only); Giemsa (amebic trophozoites, cysts); modified trichrome (preferred) or silver methenamine stain, PAS, acid-fast (microsporidial spores); H&amp;E, routine histology (cysticerci, Loa loa, Toxoplasma spp.)</td>
<td>Some free-living amebae (most commonly Acanthamoeba) have been implicated as a cause of keratitis. Although calcofluor stains the cyst walls, it does not stain the trophozoites. Therefore, in suspected cases of amebic keratitis, both stains should be used. H&amp;E (routine histology) can be used to detect and confirm cysticercosis. The adult worm of Loa loa, when removed from the eye, can be stained with a hematoxylin-based stain (DelafIELD’s) or can be stained and examined by routine histology. Microsporidial confirmation to the species or genotype level is done by PCR and sequence analyses; however, the spores can be found by routine light microscopy with modified trichrome and/or calcofluor stain. Sensitivity of microscopic methods may be low. Stool fixation with formalin or formalin-containing fixatives preserves trophozoite morphology, allows prolonged storage (room temperature) and long transportation, and prevents hatching of Schistosoma spp. eggs but makes Strongylus larvae concentration impossible and impedes further PCR analyses. Taeniid eggs cannot be identified to the species level. Microsporidia: confirmation to the species or genotype level requires PCR; however, modified trichrome and/or calcofluor stain can be used to confirm the presence of spores.</td>
</tr>
<tr>
<td>Culture (above) supplemented with antibiotics if possible to avoid bacterial growth</td>
<td>Cultures: free-living amebae and Toxoplasma spp.</td>
<td></td>
<td></td>
</tr>
<tr>
<td>PCR: native material in physiological NaCl or PBS, ethanol, or frozen</td>
<td>Free-living amebae, Toxoplasma, microsporidial species and genotype identification</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Intestinal tract</td>
<td>Stool and other intestinal material</td>
<td>Concentration methods: formalin-ethyl acetate sedimentation of formalin- or SAF-fixed stool samples (most protozoa); flotation or combined sedimentation</td>
<td>Stool fixation with formalin or formalin-containing fixatives preserves trophozoite morphology, allows prolonged storage (room temperature) and long transportation, and prevents hatching of Schistosoma spp. eggs but makes Strongylus larvae concentration impossible and impedes further PCR analyses. Taeniid eggs cannot be identified to the species level. Microsporidia: confirmation to the species or genotype level requires PCR; however, modified trichrome and/or calcofluor stain can be used to confirm the presence of spores.</td>
</tr>
<tr>
<td>Microscopy: stool, sigmoidoscopy material, duodenal contents (all fresh or preserved (see Table 4), direct wet smear, concentration methods</td>
<td>(Continued on next page)</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Anal impression smear</td>
<td>Direct wet smear (direct examination of unpreserved fresh material is also used); (motile protozoan trophozoites; helminth eggs and protozoan cysts may also be detected)</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Adult worms or tapeworm segments (proglottids)</td>
<td>Stains: trichrome or iron hematoxylin (intestinal protozoa); modified trichrome (microsporidia); modified acid-fast (Cryptosporidium spp., Cyclospora spp., Cystoisospora spp.)</td>
<td></td>
<td></td>
</tr>
</tbody>

<table>
<thead>
<tr>
<th>Body site</th>
<th>Procedures&lt;sup&gt;a&lt;/sup&gt; and specimens</th>
<th>Recommended methods and relevant parasites&lt;sup&gt;a&lt;/sup&gt;</th>
<th>Additional information</th>
</tr>
</thead>
<tbody>
<tr>
<td>Muscle</td>
<td>Biopsy material Microscopy: unfixed, touch and squash preparations or fixed for histology and EM PCR: unfixed or native, frozen or ethanol fixed</td>
<td>Larvae of Trichinella spp. can be identified unstained (species identification with single larvae by PCR). H&amp;E, routine histology (Trichinella spp., cysticerci); silver methenamine stain, PAS, acid-fast, tissue Gram stains, EM (rare microsporidia). Microsporidial identification to the species level requires subsequent sequencing.</td>
<td>If Trypanosoma cruzi organisms are present in the striated muscle, they could be identified in routine histology preparations. Modified trichrome and/or calcofluor stain can be used to confirm the presence of microsporidial spores. Larvae of Trichinella spp. may be detected in heavy infections only. Biopsies are not recommended as standard procedures.</td>
</tr>
<tr>
<td>Skin</td>
<td>Aspirates, skin snips, scrapings, biopsy samples Microscopy: wet examination, stained smear (or fixed for EM) PCR: unfixed native, frozen or fixed in ethanol</td>
<td>Wet preparations (microfilariae), Giemsa-stained smears or H&amp;E, routine histology (Onchocerca volvulus, Dipetalonema streptocerca, Dirofilaria repens, other larvae causing cutaneous larva migrans [zoonotic Strongyloides spp., hookworms], Leishmania spp., Acanthamoeba spp., Entamoeba histolytica, microsporidia, and arthropods [Sarcoptes scabiei and other mites])</td>
<td>Any of the parasites can be identified by routine histology procedures, but the sensitivities of these methods may be low.</td>
</tr>
<tr>
<td>Amniotic fluid</td>
<td>PCR (and/or culture): native material Animal inoculation (Toxoplasma)</td>
<td>PCR based on the detection of highly repetitive gene sequences is the method of choice.</td>
<td>Only applicable to confirm suspected prenatal Toxoplasma spp. infections.</td>
</tr>
<tr>
<td>Urogenital system</td>
<td>Vaginal discharge, saline swab, transport swab (no charcoal), air-dried smear for FA, urethral discharge, prostatic secretions, urine (single unpreserved, 24-h unpreserved, or early-morning specimen). Microscopy: wet smears, smears of urine sediment, stained smears Cultivation: vaginal or urethral discharge or swab preparations Molecular: native material, frozen or fixed in ethanol</td>
<td>Giemsa, immunoassay reagents (Trichomonas vaginalis); Delafiel's hematoxylin (microfilariae); modified trichrome (microsporidia); H&amp;E, routine histology, PAS, acid-fast, tissue Gram stains (microsporidia). Direct examination of urine sediment for Schistosoma haematobium eggs or microfilariae Identification and propagation of T. vaginalis (commercial plastic envelope culture systems available); moving trophozoites can be detected microscopically (or in Giemsa-stained smears)</td>
<td>Although T. vaginalis is probably the most common parasite identified, there are others to consider, the most recently implicated organisms being in the microsporidial group. Microfilariae could also be recovered and stained. Fixation of urine with formalin prevents hatching of Schistosoma eggs. Material must be put into culture medium immediately after collection; do not cool or freeze.</td>
</tr>
</tbody>
</table>

<sup>a</sup>CSF, cerebrospinal fluid; EIA, enzyme immunoassay; EITB, enzyme-linked immunoelectrotransfer blot (Western blot); EM, electron microscopy; FA, fluorescent antibody; GAE, granulomatous amebic encephalitis; GI, gastrointestinal, H&E, hematoxylin and eosin; IFA, indirect immunofluorescence assay; PAM, primary amebic encephalitis; PAS, periodic acid-Schiff stain; PBS, phosphate-buffered saline; QBC, quantitative buffy coat.

<sup>b</sup>Many parasites or parasite stages may be detected in standard histologic sections of tissue material. However, species identification is difficult, and additional examinations may be required. Usually, these techniques are not considered first-line methods. Additional methods like EM are carried out only by specialized laboratories and are not available for standard diagnostic purposes. EM examination for species identification has largely been replaced by PCR.

<sup>c</sup>Material/specimens suitable for PCR: native (unfixed), in saline, PBS (ethanol), or frozen; avoid formalin.

**Preservation of Stool**

If there are delays from the time of specimen passage until examination in the laboratory, the use of stool fixative should be considered. To preserve protozoan morphology and prevent the continued development of some helminth eggs and larvae, the stool specimens can be placed in fixative either immediately after passage (by the patient, using a collection kit) or once the specimen is received by the laboratory. Several fixatives are available; however, regardless of the fixative selected, adequate mixing of the specimen and preservative is mandatory. Specimens preserved in stool fixatives should be stored at room temperature. It is also important to use the correct ratio of stool and fixative to ensure proper fixation. If commercial vials are used, they...

<thead>
<tr>
<th>Options</th>
<th>Pros</th>
<th>Cons</th>
</tr>
</thead>
<tbody>
<tr>
<td>Although physicians can order stools for parasitology when deemed appropriate, many laboratories include in their protocols the rejection of stools from inpatients who have been in-house for &gt;3 days. Examination of a single stool (O&amp;P examination)</td>
<td>Patients may become symptomatic with diarrhea after they have been inpatients for a few days; symptoms are usually not attributed to parasitic infections but are generally due to other causes.</td>
<td>There is always a chance that the problem is related to a nosocomial parasitic infection (rare), but Cryptosporidium spp., Giardia spp., and microsporidia may be possible considerations.</td>
</tr>
<tr>
<td>Examination of a second stool specimen only after the first one is negative and the patient is still symptomatic</td>
<td>If parasites are diagnosed in the first sample or if the patient becomes asymptomatic after collection of the first stool, subsequent specimens may not be necessary. However, with some intestinal parasitic infections, patients may alternate with constipation and diarrhea.</td>
<td>Diagnosis from examination of a single stool specimen depends on the parasite load in the specimen. Of organisms present, 40 to 60% are found with only a single stool exam; two O&amp;P examinations are acceptable, but three specimens are more sensitive; any patient remaining symptomatic would require additional testing. In a series of three stool specimens, frequently not all three specimens are positive and/or may be positive for different organisms (may be a cost-effective approach).</td>
</tr>
<tr>
<td>Examination of a single stool and a Giardia immunoassay</td>
<td>With additional examinations, yield of protozoa increases (Entamoeba histolytica, 22.7%; Giardia spp., 11.3%; and Dientamoeba fragilis, 31.1%).</td>
<td>Assumes the second (or third) stool specimen is collected within the recommended 10-day time frame for a series of stools; protozoa are shed periodically. May be inconvenient for the patient, and the correct diagnosis might be delayed.</td>
</tr>
<tr>
<td>Pooling of three specimens for examination; one concentration and one permanent stain are performed.</td>
<td>Three specimens are collected over 7–10 days, which may save time and expense.</td>
<td>Procedure not recommended. Decreases strongly the sensitivity of the procedure; organisms present in low numbers may be missed due to the dilution factor.</td>
</tr>
<tr>
<td>Permanent stained smears are performed, one from each of the three specimens; subsequently, three specimens are pooled for a single concentration on the pooled specimen.</td>
<td>Three specimens are collected over 7–10 days; would maximize recovery of protozoa in areas of the United States where these organisms are most common.</td>
<td>Might miss light helminth infection (eggs and larvae) due to the pooling procedure.</td>
</tr>
<tr>
<td>Three stool specimens are collected, but samples of stool from all three are put into a single vial (patient is given a single vial only).</td>
<td>Pooling of the specimens would require only a single vial.</td>
<td>Absolutely not recommended. Lack of sensitivity; proper mixing of specimen and fixative complicates patient collection and depends on patient compliance.</td>
</tr>
<tr>
<td>Immunoassays are performed only for selected patients* (children &lt;5 yr old, children from day care centers, patients with immunodeficiencies, and patients from diarrheal outbreaks) for intestinal protozoa.</td>
<td>Would be more cost-effective than performing immunoassay procedures on all specimens</td>
<td>The competence and the information needed to group patients are often not available in the laboratory. Ordering guidelines for clients are highly recommended (see Table 7).</td>
</tr>
</tbody>
</table>

*It is difficult to recognize an early outbreak situation in which screening of all specimens for Giardia spp., Cryptosporidium spp., or both may be relevant. If it appears that an outbreak is in the early stages, performing the immunoassays on request can be changed to screening all stools.

are marked with a “fill-to” line for the addition of stool to the container.

When selecting an appropriate fixative, keep in mind that a permanent stained smear is mandatory for a complete examination for parasites (1, 2, 9, 10, 13; chapter 134). Make sure that the fixative you are using is compatible with the kit or the method you have selected. It is also important to remember that disposal regulations for compounds containing mercury are becoming stricter; each laboratory must check applicable regulations to help determine fixative options.

Formalin

Formalin is an all-purpose fixative appropriate for helminth eggs and larvae and for protozoan cysts. Two concentrations are commonly used: 5%, which is recommended for preservation of protozoan cysts, and 10%, which is recommended for helminth eggs and larvae. Although 5% is often recommended for all-purpose use, most commercial manufacturers...
provide 10%, which is more likely to kill all helminth eggs. To help maintain organism morphology, the formalin can be buffered with sodium phosphate buffers (i.e., neutral formalin). Selection of specific formalin formulations is at the user’s discretion. Aqueous formalin permits the examination of the specimen as a wet mount only, a technique much less accurate than a stained smear for the identification of intestinal protozoa.

Protozoan cysts (not trophozoites), coccidian oocysts, helminth eggs, and larvae are well preserved for long periods in 10% aqueous formalin. Formalin heated to 60°C can be used for specimens containing helminth eggs, since in cold formalin, some thick-shelled eggs may continue to develop, become infective, and remain viable for long periods. Several grams of fecal material should be thoroughly mixed in 5% or 10% formalin (ratio, 1:10).

Formaldehyde vapor concentrations must be monitored and maintained at concentrations below the 8-hour time-weighted average. In the United States, these limits are 0.75 ppm and the 15-minute short-term exposure limit (i.e., 2.0 ppm) (1). However, these limits may vary from country to country. Generally, the amount of formaldehyde used in microbiology is quite small; laboratory monitoring values are usually well below the required maximum concentrations. Initial monitoring must be repeated any time there is a change in production, equipment, process, personnel, or control measures that may result in new or additional exposure to formaldehyde. Stool fixatives that contain formaldehyde indicate that fact on the label. A number of single-vial fixative collection systems are now available; although they may not contain formaldehyde, the actual formulas are proprietary.

**Sodium Acetate-Acetic Acid-Formalin (SAF)**

Both the concentration and the permanent stained smear can be performed with specimens in SAF. It is a liquid fixative, much like the 10% formalin described previously. The sediment is used to prepare the permanent smear, and it is frequently recommended that the stool material be placed on an albumin-coated slide to improve adherence to the glass (14, 15).

</table>

<sup>a</sup>Modified from reference 2.
<sup>b</sup>Depending on the particular immunoassay kit used, various single or multiple organisms may be included. Selection of a particular kit depends on many variables such as clinical relevance, cost, ease of performance, training, personnel availability, number of test orders, training of physician clients, sensitivity, specificity, equipment, and time to result. Very few laboratories handle this type of testing in exactly the same way. Many options are clinically relevant and acceptable for patient care.

<sup>c</sup>Two stool specimens should be tested using an immunoassay in order to rule out an infection with Giardia spp.; fecal immunoassays may also be negative in cases with a low parasite load.
### TABLE 7  Fecal fixatives: pros and cons

<table>
<thead>
<tr>
<th>Stool preservative</th>
<th>Pros</th>
<th>Cons</th>
</tr>
</thead>
<tbody>
<tr>
<td>Formalin</td>
<td>Good overall fixative for stool concentration. Easy to prepare; long shelf life. Concentrated sediment can be used with different stains but not with all immunoassays (see Table 5). Does not preserve trophozoites well. Does not adequately preserve organism morphology for a good permanent stained smear; not optimal for all immunoassays; not appropriate for molecular diagnosis (PCR).</td>
<td></td>
</tr>
<tr>
<td>SAF</td>
<td>Can be used for concentration and permanent stained smears. Contains no mercury compounds. Easy to prepare; long shelf life. Concentrated sediment can be used with most of the new immunoassay methods and special stains. Poor adhesive properties; albumin-coated slides recommended. Protozoan morphology is better if iron hematoxylin stain is used for permanent stained smears (trichome is not quite as good). May be a bit more difficult to use; however, this is really not a limiting factor. Not appropriate for molecular diagnosis (PCR).</td>
<td></td>
</tr>
<tr>
<td>Schaudinn’s fixative (mercury base)</td>
<td>Fixation of slides prepared from fresh fecal specimens or samples from the intestinal mucosal surfaces. Provides excellent fixation of protozoan trophozoites and cysts. Not generally recommended for concentration procedures. Contains mercuric chloride; creates disposal problems. Poor adhesive qualities with liquid or mucoid specimens.</td>
<td></td>
</tr>
<tr>
<td>PVA (mercury base)</td>
<td>Can prepare permanent stained smears and perform concentration techniques (less common). Provides excellent fixation of protozoan trophozoites and cysts. Specimens can be shipped to the laboratory for subsequent examination; organism morphology excellent after processing. Suitable for PCR analysis. This formulation is considered the gold standard against which all other fixatives are evaluated (organism morphology after permanent staining). Trichuris trichiura eggs and Giardia spp. cysts are not concentrated as easily as from formalin-based fixative. Strongyloides stercoralis larval morphology is poor (better from formalin-based preservation). Cystoisospora belli oocysts may not be visible from PVA-fixed material (better from formalin-based preservation). Contains mercury compounds and may pose a disposal problem (chemical waste). May turn white and gelatinous when it begins to dehydrate or when refrigerated. Difficult to prepare in the laboratory. Specimens containing PVA cannot be used with the immunoassay methods.</td>
<td></td>
</tr>
<tr>
<td>Modified PVA (copper or zinc base)</td>
<td>Can prepare permanent stained smears and perform concentration techniques (less common). Many workers prefer the zinc substitutes over those prepared with copper sulfate. Does not contain mercury compounds. Overall protozoan morphology of trophozoites and cysts is poor when they are fixed in modified PVA, compared with organisms fixed in mercuric chloride-based fixatives. Zinc-based fixatives appear to be some of the better alternatives. Staining characteristics of protozoa are not consistent; some are good, and some are poor. Organism identification may be difficult, particularly with small protozoan cysts (Endolimax nana).</td>
<td></td>
</tr>
<tr>
<td>Single-vial systems (with or without PVA)</td>
<td>Can prepare permanent stained smears and perform concentration techniques. Can perform immunassays. May not contain formalin or mercury compounds. Unless organism numbers are rare, acceptable organism recovery and identification are possible; additional training may be required to recognize the organisms because the overall morphology is not comparable to that seen with mercury-based fixatives. Concentration, permanent stains, some immunassays, and some molecular testing can be performed. Overall protozoan morphology of trophozoites and cysts is not as good as that of organisms fixed with mercuric chloride-based fixative; similar to modified PVA options. Staining characteristics of protozoa are not consistent; some are good, and some are poor. Identification of Endolimax nana cysts may be difficult. Not all immunassays can be performed from stool specimens in these fixatives. However, in spite of the cons, single-vial systems are becoming more widely used for concentrations, permanent stained smears, and fecal immunassays.</td>
<td></td>
</tr>
</tbody>
</table>

SAF is considered to be a "softer" fixative than mercuric chloride. The organism morphology is not quite as sharp after staining as that of organisms originally fixed in solutions containing mercuric chloride. The pairing of SAF-fixed material with iron hematoxylin staining provides better organism morphology than does staining of SAF-fixed material with trichrome (personal observation). Although SAF has a long shelf life and is easy to prepare, the smear preparation technique may be a bit more difficult for less experienced personnel who are not familiar with fecal specimen techniques. Laboratories that have considered using only a single preservative have selected this option. Helminth eggs and larvae, protozoan trophozoites and cysts, coccidial oocysts, and microsporidian spores can be recovered using this method.

**Schaudinn’s Fluid**

Schaudinn’s fluid containing mercuric chloride can be used with fresh stool specimens or samples from the intestinal
mucosal surface. Many laboratories that receive specimens from in-house patients (with no delay in delivery times) often select this approach. Permanent stained smears are then prepared from fixed material. A concentration technique using Schaudinn’s fluid-preserved material is also available but is not widely used (1, 10, 11).

Polyvinyl Alcohol (PVA)

PVA is a plastic resin that is normally incorporated into Schaudinn’s fixative. The PVA powder serves as an adhesive for the stool material (i.e., when the stool-PVA mixture is spread onto the glass slide, it adheres because of the PVA component). Fixation is still accomplished by Schaudinn’s fluid itself. Perhaps the greatest advantage in the use of PVA is that a permanent stained smear can be prepared. Like SAF, PVA fixative solution is recommended as a means of preserving cysts and trophozoites for later examination and permits specimens to be shipped (by regular mail service) from any location in the world to a laboratory for subsequent examination. PVA is particularly useful for liquid specimens and should be used in the ratio of 3 parts PVA to 1 part fecal specimen (16).

Modified Polyvinyl Alcohol

Although fixatives that do not contain mercury compounds have been developed, some of the substitute compounds have not provided the quality of fixation necessary for good protozoan morphology on the permanent stained smear. Copper sulfate has been tried but does not provide results equal to those seen with mercuric chloride (17). Zinc sulfate has proven to be an acceptable mercury substitute and is used with trichrome stain. Substitutes containing zinc have become widely available; each manufacturer has a proprietary formula for the fixative (18, 19).

Single-Vial Collection Systems

Several manufacturers now have available single-vial stool collection systems, similar to SAF or modified PVA methods. From the single vial, both the concentration and permanent stained smear can be prepared. It is also possible to perform immunoassays from some of these vials. Ask the manufacturer about all diagnostic capabilities (concentrate, permanent stained smear, immunoassay procedures, and molecular analyses) and for specific information indicating that there are no formula components that would interfere with any of the methods. Like the zinc substitutes, these formulas are proprietary (19). New formulations continue to be developed, and some of them appear to adhere to the slide without the use of albumin or PVA. These formulations can be used to perform concentrations and some of the immunoassays and to prepare permanent stained smears. One commercially available single-vial fixative of stool specimens is mercury-, formalin- and PVA-free, preserves morphology, and alleviates many disposal and monitoring problems encountered by laboratories.

Collection of Blood

Depending on the life cycle, a number of parasites may be recovered in a blood specimen, either whole blood, buffy coat preparations, or various types of concentrations (2, 10, 11). These parasites include Plasmodium spp., Babesia spp., Trypanosoma spp., Leishmania spp., Toxoplasma spp., and microfilariae. Although some organisms may be motile in fresh, whole blood, species identification is normally accomplished from the examination of permanent stained blood thin and/or thick films. Blood films can be prepared from fresh, whole blood collected with no anticoagulants, anticoagulated blood, or sediment from the various concentration procedures.

Unless it is certain that well-prepared slides will be available, it is necessary to request a tube of fresh blood (EDTA anticoagulant is preferred) and prepare the smears. The tube should be filled with blood to provide the proper blood/anticoagulant ratio. For detection of stippling, the smears should be prepared within 1 h after the specimen is drawn. After that time, stippling may not be visible on stained films; however, the overall organism morphology will still be excellent. Most laboratories routinely use commercially available blood collection tubes; preparation of EDTA collection tubes in-house is neither necessary nor cost-effective.

The time the specimen was drawn should be clearly indicated on the tube of blood and also on the result report. The physician will then be able to correlate the results with any fever pattern (most likely seen in a semi-immune patient with past exposure to malaria with antibodies) or other symptoms that the patient may have. In immunologically naive patients or travelers with no previous exposure to malaria, there may be no periodicity at all; symptoms will mimic many other infections or medical problems. There should also be comments on the test result report sent back to the physician stating that one negative specimen does not rule out the possibility of a parasitic infection (1, 20).

Collection of Specimens from Other Body Sites

Although clinical specimens for examination can be obtained from many other body sites, these specimens and appropriate diagnostic methods are not as commonly performed as those used for the routine stool specimen or for blood specimens (21, 22). Most specimens from other body sites (Table 1) are submitted as fresh specimens for further testing.

DIRECT DETECTION BY ROUTINE METHODS

Intestinal Tract Specimens

The most common specimen submitted to the diagnostic laboratory is the stool specimen, and the most commonly performed procedure in parasitology is the ova and parasite (O&P) examination, which is composed of three separate protocols: the direct wet mount, the concentration, and the permanent stained smear. The direct wet mount requires fresh stool, is designed to allow the detection of motile protozoan trophozoites, and is examined microscopically at low and high dry magnifications (×100, entire 22- by 22-mm coverslip [larvae, larger helminth eggs]; ×400, one-third to one-half of a 22- by 22-mm coverslip [protozoan cysts and/or trophozoites, smaller helminth eggs]). If the specimens are received in the laboratory in stool collection fixatives, the direct wet preparation may be eliminated from the routine O&P examination.

The second part of the O&P examination is the concentration, which is designed to facilitate the recovery of protozoan cysts, coccidian oocysts, microsporidial spores, and helminth eggs and larvae. Both flotation (zinc sulfate, zinc chloride, and others) and sedimentation methods are available, the most common procedure being the formalin-ethyl acetate sedimentation method (formerly called the formalin-ether method). The concentrated specimen is examined as a wet preparation, with or without iodine (personal preference), using low and high dry magnifications (×100 and ×400) as indicated for the direct wet smear examination.
It is important to remember that large, heavy helminth eggs (unfertilized *Ascaris* eggs) or eggs that are operculed (trematode and some cestode eggs) do not float optimally when flotation fluids with densities of <1.35 are used; both the surface film and sediment must be examined by this method. It is also important to note that the flotation media with high densities may change the morphological characteristics of some parasites.

The third part of the O&SP examination is the permanent stained smear, which is designed to facilitate the identification of intestinal protozoa. Several staining methods are available, the two most common being the Wheatley modification of the Gomori's tissue trichrome and the iron hematoxylin stains. This part of the O&SP examination is critical for the confirmation of suspicious objects seen in the wet examination and identification of protozoa that might not have been seen in the wet preparation. The permanent stained smears are examined using oil immersion objectives (×600 for screening and ×1,000 for final review of ≥300 oil immersion fields).

Other specimens from the intestinal tract such as duodenal aspirates or drainage, mucus from the Entero-Test capsule technique, and sigmoidoscopy material can also be examined as wet preparations and as permanent stained smears after processing with either trichrome or iron hematoxylin staining. Adult and pediatric Entero-Test capsules are currently available from Nutri-Link Ltd., Newton Abbot, United Kingdom (www.nutri-linkltd.co.uk). Although all laboratories examine these types of specimens, they are included to give some idea of the possibilities for diagnostic testing.

**Amniotic Fluid**

Methods for the diagnosis of congenital *Toxoplasma* infection are summarized in chapter 138. Amniotic fluid collected under sterile conditions allows both mouse or tissue culture isolation and molecular diagnostic testing. Prenatal diagnosis by more sensitive antigen detection or molecular methods (Table 3) (24).

Examination of urinary sediment may be indicated in certain filarial infections. Administration of the drug diethylcarbamazine (Hetrazan) has been reported to enhance the recovery of microfilariae from urine. The triple-concentration technique is recommended for the recovery of microfilariae (1). The membrane filtration technique can also be used with urine for the recovery of microfilariae (1). *Schistosoma haematobium* eggs can be concentrated by centrifugation of urine specimens; a membrane filter technique for the egg recovery has also been useful (1). Fresh samples or fixed samples in formalin should be used to prevent hatching of eggs.

Microsporidial spores of *Encephalitozoon intestinalis* can also be recovered from urine sediment. This organism primarily infects the intestinal tract but can also disseminate to the kidneys in immunocompromised individuals.

**Sputum**

Although not one of the more common specimens, expectorated sputum may be submitted for examination for parasites. Organisms in sputum that may be detected and may cause pneumonia, pneumonitis, or Löeffler's syndrome include the migrating larval stages of *Ascaris lumbricoides*, *Strongyloides stercoralis*, and hookworm; the eggs of *Paragonimus* spp.; *Echinococcus granulosus* hooklets; and *Entamoeba histolytica*, *Entamoeba gingivalis*, *Trichomonas tenax*, *Cryptosporidium* spp., and possibly, the microsporidia. In a *Paragonimus* infection, the sputum may be viscous and tinged with brownish flecks, which are clusters of eggs (“iron filings”), and may be streaked with blood. Sputum is usually examined as a wet mount (saline or iodine), using low and high dry power (×100 and ×400). The specimen is not concentrated before preparation of the wet mount. If the sputum is thick, an equal amount of 3% sodium hydroxide (NaOH) (or undiluted chlorine bleach) can be added; the specimen is thoroughly mixed and then centrifuged at 500 × g for 5 min. NaOH should not be used if one is looking for *Entamoeba* spp. or *T. tenax*. After centrifugation, the supernatant fluid is discarded, and the sediment can be examined as a wet mount with saline or iodine. If examination has to be delayed for any reason, the sputum should be fixed in 5 or 10% formalin to preserve helminth eggs or larvae or in PVA fixative to be stained later for protozoa.

**Aspirates**

The examination of aspirated material for the diagnosis of parasitic infections may be extremely valuable, particularly when routine testing methods have failed to demonstrate the organisms. These specimens should be transported to the laboratory immediately after collection. Aspirates include liquid specimens collected from a variety of sites where organisms might be found. The aspirates most commonly processed in the parasitology laboratory include fine-needle and duodenal aspirates. Fluid specimens collected by bronchoscopy include bronchoalveolar lavage fluid and bronchial washings (25).

Fine-needle aspirates may be submitted for slide preparation, culture, and/or molecular analyses. Aspirates of cysts and abscesses for amebae may require concentration by centrifugation, digestion, microscopic examination for motile organisms in direct preparations, and cultures and microscopic evaluation of stained preparations. Antigen detection and PCR are other possibilities, depending on individual laboratory testing options.
Bone marrow aspirates for Leishmania spp. amastigotes, Trypanosoma cruzi amastigotes, or Plasmodium spp. require Giemsa staining or the use of other stains for blood and tissues. Examination of these specimens may confirm an infection that has been missed by examination of routine blood films. In certain situations, culture, immunosassays for antigen detection, or PCR also provide more sensitive results (26).

**Biopsy Specimens**

Biopsy specimens are recommended for the microscopic detection of tissue parasites (Table 5). The following procedures may be used for this purpose in addition to standard histologic preparations: impression smears and teased and squash preparations of biopsy tissue from skin, muscle, cornea, intestine, liver, lung, and brain. Tissue to be examined by permanent sections or electron microscopy should be fixed as specified by the laboratories that will process the tissue. In certain cases, a biopsy may be the only means of confirming a suspected parasitic infection. Specimens that are going to be examined as fresh material rather than as tissue sections should be kept moist in saline and submitted to the laboratory immediately.

Detection of parasites in tissue depends in part on specimen collection and on having sufficient material to perform the recommended diagnostic procedures. Biopsy specimens are usually quite small and may not be representative of the diseased tissue. Multiple tissue samples often improve diagnostic results. To optimize the yield from any tissue specimen, all areas should be examined by as many procedures as possible. Tissues are obtained by invasive procedures, many of which are very expensive and lengthy; consequently, these specimens deserve the most comprehensive procedures possible.

Tissue submitted in a sterile container in sterile saline or on a sterile sponge dampened with saline may be used for cultures or molecular analyses of protozoa after mounts for direct examination or impression smears for staining have been prepared. Bacteriologic transport media should be avoided. If cultures for parasites are to be made, sterile slides should be used for smear and mount preparation.

**Blood**

Depending on the life cycle, a number of parasites may be recovered in a blood specimen, either whole blood, buffy coat preparations, or various types of concentrations (1, 25). Although some organisms may be motile in fresh whole blood, species identification is normally accomplished from the examination of permanent stained blood films, both thick and thin films. Blood films can be prepared from fresh whole blood collected with no anticoagulants, anticoagulated blood, or sediment from the various concentration procedures. The recommended stain of choice is Giemsa staining. However, the parasites can also be seen on blood films stained with Wright’s stain. Delafaille’s hematoxylin stain is often used to stain the microfilarial sheath; in some cases, Giemsa stain does not provide sufficient stain quality to allow differentiation of the microfilariae.

**Thin Blood Films**

In any examination of thin blood films for parasitic organisms, the initial screen should be carried out with the low-power objective (×100) of a microscope. Microfilariae may be missed if the entire thin film is not examined. Microfilariae are rarely present in large numbers, and frequently only a few organisms are present in each thin film preparation. Microfilariae are commonly found at the edges of the thin film or at the feathered end of the film because they are carried to these sites during spreading of the blood. The feathered end of the film, where the erythrocytes (RBCs) are drawn out into one single, distinctive layer of cells, should be examined for the presence of malaria parasites and trypanosomes. In these areas, the morphology and size of the infected RBCs are most clearly seen.

Depending on the training and experience of the microscopist, examination of the thin film usually takes 15 to 20 min (≥300 oil immersion fields) for the thin film at a magnification of ×1,000. Although some people use a 50× or 60× oil immersion objective to screen stained blood films, there is some concern that small parasites such as Plasmodium spp., Babesia spp., or Leishmania spp. may be missed at this lower total magnification (×500 or ×600) compared with the ×1,000 total magnification obtained using the more traditional 100× oil immersion objective. Because people tend to scan blood films at different rates, it is important to examine a minimum number of fields. If something suspicious has been seen in the thick film, the number of fields examined on the thin film is often considerably greater than 300. The request for blood film examination should always be considered a STAT procedure, with all reports (negative as well as positive) being relayed by telephone to the physician as soon as possible. If positive, notification of appropriate governmental public health agencies (local, state, and federal) should be done within a reasonable time frame in accordance with guidelines and laws.

Both malaria and Babesia infections have been missed with automated differential instruments, and therapy was delayed. Although these instruments are not designed to detect intracellular blood parasites, the inability of the automated systems to discriminate between uninfected RBCs and those infected with parasites may pose serious diagnostic problems (27).

**Thick Blood Films**

In the preparation of a thick blood film, the highest concentration of blood cells is in the center of the film. The examination should be performed at low magnification to detect microfilariae more readily. Examination of a thick film usually requires 5 to 10 min (approximately 100 oil immersion fields). The search for malarial organisms and trypanosomes is best done under oil immersion (×1,000). Intact RBCs are frequently seen at the very periphery of the thick film; such cells, if infected, may prove useful in malaria diagnosis, since they may demonstrate the characteristic morphology necessary to identify the organisms to the species level.

**Blood Stains**

For accurate identification of blood parasites, a laboratory should develop proficiency in the use of at least one good staining method. It is better to select one method that will provide reproducible results than to use several on a hit-or-miss basis. Blood films should be stained as soon as possible, since prolonged storage may result in stain retention. Delay in staining positive malarial smears may result in failure to demonstrate typical staining characteristics for individual species.

The most common stains are of two types. Wright’s stain has the fixative in combination with the staining solution, so that both fixation and staining occur at the same time; therefore, the thick film must be laked before staining. In Giemsa stain, the fixative and stain are separate; therefore, the thin film must be fixed with absolute methanol before staining.
Buffy Coat Films

Trypanosomes, occasionally Histoplasma capsulatum (a fungus that manifests as small oval yeast cells resembling those of Leishmania amastigote stages), and, in immunocompromised patients, potentially Leishmania spp. (L. infantum, L. chagasi, and L. donovani) are detected within the large mononuclear cells in the buffy coat (a layer of leukocytes resulting from centrifugation of whole anticoagulated blood). The amastigote form of Leishmania spp. possesses a kinetoplast, a nucleus that stains dark red-purple, and the cytoplasm stains light blue. H. capsulatum appears as a large dot of nuclear material (dark red-purple) surrounded by a clear halo area. Trypanosomes in the peripheral blood also concentrate with the buffy coat cells (1).

Screening Methods

Microhematocrit centrifugation with use of the QBC malaria test, a glass capillary tube, and closely fitting plastic insert (QBC malaria blood tubes; Becton Dickinson, Tropical Disease Diagnostics, Sparks, MD) has been used for the detection of blood parasites. Tubes precoated with acridine orange provide a stain that induces fluorescence in the parasites. At the end of centrifugation of 50 to 60 μl of capillary or venous blood (5 min in a QBC centrifuge, 14,387 × g), parasites or RBCs containing parasites are concentrated into a 1- to 2-mm region near the top of the RBC column and are held close to the wall of the tube by the plastic float, making them readily visible by fluorescence microscopy. This method automatically prepares a concentrated smear, which represents the distance between the float and the walls of the tube. Once the tube is placed into the plastic holder (Para-viewer) and immersion oil is applied to the top of the hematocrit tube (no coverslip is necessary), the tube is examined with a 40× to 60× oil immersion objective (which must have a working distance of 0.3 mm or greater) (1). Cost of the equipment and technical expertise may limit use of this test methodology.

Antigen and DNA Detection for Blood Parasites

Several antigen detection tests are available. Many among them are designed for rapid and individual diagnoses. Most of the kits are not available in the United States but have proven to be very useful in other countries. Rapid tests are available to diagnose specifically Plasmodium falciparum or, on a genus level, Plasmodium spp. infections. These tests are simple to perform and can be applied during the more time-consuming microscopic identification of the thin and thick blood smears. However, one has to be aware that false-positive and false-negative reactions do occur (28–31). The general recommendation is to use these tests only in addition to the microscopic examination of thick and thin blood smears. Various PCR-based methods have been described in the scientific literature. Although the methods are more sensitive than standard microscopic examinations of blood films, they are not routinely used for malaria diagnosis.

Knott Concentration

The Knott concentration procedure is used primarily to detect the presence of microfilariae in the blood, especially when a light infection is suspected. Aqueous formalin is added to anticoagulated blood and centrifuged at 300 × g to concentrate microfilaria. The sediment is examined microscopically (×100 and ×400). A thick prep can be made with the remainder of the sediment. Microfilariae will be nonmotile in the wet smear; however, they will exhibit diagnostic morphologic characteristics when stained. The disadvantage of the procedure is that the microfilariae are killed by the formalin and are therefore not seen as motile organisms.

Membrane Filtration Technique

The membrane filtration technique using Nuclepore filters (25-mm Nuclepore filter [3-μm porosity]) has proved highly efficient in demonstrating filarial infections when microfilaremias are of low density. It has also been successfully used in field surveys (1).

Culture Methods

Very few clinical laboratories offer specific culture techniques for parasites. The methods for in vitro culture are often complex, while quality control is difficult and not really feasible for the routine diagnostic laboratory. In certain institutions, some techniques may be available, particularly where consultative services are provided and for research purposes.

Few parasites can be routinely cultured, and the only procedures that are in general use are for Entamoeba histolytica, Naegleria fowleri, Acanthamoeba spp., Trychomonas vaginalis, Toxoplasma gondii, Trypanosoma cruzi, Encephalitozoon spp., and the leishmanias. These procedures are usually available only after consultation with the laboratory and on special request. Commercial tests are available only for T. vaginalis (InPouch TV; BioMed Diagnostics, San Jose, CA).

Animal Inoculation and Xenodiagnosis

Most routine clinical laboratories do not have the animal care facilities necessary to provide animal inoculation capabilities for the diagnosis of parasitic infections. Host specificity for many animal parasite species is well known and limits the types of animals available for these procedures. In certain suspect infections, animal inoculation may be requested and can be very helpful in making the diagnosis, although animal inoculation certainly does not take the place of other, more routine procedures. Mouse inoculation with amniotic fluid has been used in the past for diagnosis of congenital toxoplasmosis; this method, however, has mostly been replaced by PCR. Intraperitoneal inoculation of Echinococcus multilocularis metacestode material from surgical resection or from biopsy samples from mice or gerbils is still the most reliable procedure available for viability testing after long-term chemotherapy.

Xenodiagnosis is a technique that uses the arthropod host as an indicator of infection. Uninfected reduviid bugs are allowed to feed on the blood of a patient who is suspected of having Chagas’ disease (T. cruzi infection). After 30 to 60 days, feces from the bugs are examined over a 3-month time frame for the presence of developmental stages of the parasite, which are found in the hindgut of the vector. This type of procedure is used primarily in South America for fieldwork, and the appropriate bugs are raised in various laboratories specifically for this purpose.

Antigen Detection

The detection of parasite-specific antigen is indicative of current infection. Immunoassays are generally simple to perform. Some formats allow the processing of large numbers of tests at one time, thereby reducing overall costs; others are specially designed for rapid individual diagnoses. A major disadvantage of antigen detection is that in most cases the method can detect only a single pathogen at one time.
Therefore, additional parasitological examinations must be performed to detect other parasitic pathogens. The current commercially available immunoassays for the detection of intestinal protozoa have excellent sensitivity and specificity compared with routine microscopy (32–35). Specific ordering approaches using both immunoassays and routine O&P examinations are listed in Table 6. Rapid tests for the diagnosis of malaria should be used only in parallel to the examination of thick and thin blood smears.

**Parasite DNA Detection**

Molecular testing is becoming more readily available for most diagnostic laboratories. Assays for *Trichomonas vaginalis*, *Entamoeba histolytica*, *Giardia* spp., and Cryptosporidium spp. are commercially available and FDA-approved. Intestinal gastrointestinal panels are available that can test simultaneously for multiple gastrointestinal pathogens, including bacterial, viral, and parasitic pathogens. As with antigen detection, only select pathogens can be detected, and other pathogens may be missed.

Nucleic acid-based diagnostic tests (particularly PCR, with its inherent potential for highly efficient and specific amplification of DNA) have been developed for almost all species of parasites. However, only a few are routinely used in diagnostic settings. The main reason for this minor role of diagnostic PCR in parasitology is the fact that many parasite stages can be adequately diagnosed using established, more traditional techniques (microscopy, detection of antigens and antibodies, or in vitro cultivation) that are generally less expensive and technically less demanding than PCR. Therefore, diagnosis by PCR is of great value in cases in which these techniques are insufficient, that is, in cases in which (i) the immune response is not informative (e.g., acute infections, short-term follow-up after therapy, congenital infections); (ii) high sensitivity is needed because of low parasite levels (e.g., cutaneous leishmaniasis); or (iii) morphologically indistinguishable organisms need to be identified (e.g., *Entamoeba histolytica*/*Entamoeba dispar* and eggs of taeniid tapeworms).

Diagnostic PCR may become more widespread when simple, fully standardized (commercial) test kits are available and costs are reduced through the implementation of pre- and post-PCR automated techniques. Furthermore, the possibilities to not only detect and identify but also quantify organisms and determine their genotypes by analyzing the diagnostic PCR product extend the diagnostic power of PCR. Indeed, PCR coupled with genetic characterization is already widely used in parasitology to address questions such as parasite host range and host specificity, ways of transmission, and molecular epidemiology. Such genotyping applications should increase in the future with increasing knowledge of the relationship between genetic variation in parasites and features such as virulence or drug resistance.

An important limitation of PCR-based diagnosis is the fact that sensitivity dramatically decreases with material stored for more than 1 day in formalin due to the fragmentation (fragment length of a few hundred base pairs) of the DNA. However, by selecting primers that produce PCR products as short as possible, which is recommended for real-time PCR, sensitivity might be reasonably high. Therefore, it seems to be the best choice to avoid formalin fixation if PCR analyses have to be considered. Such tests, however, are not yet widely available in parasitology.

**REFERENCES**

The evaluation of clinical specimens for ova and parasites in the clinical laboratory can involve the use of direct macroscopic examination of the specimen and microscopic examination of fresh and preserved specimens, as well as culture for some parasitic organisms. These examinations necessitate the use of a variety of stains, reagents, and media, the most common of which are discussed in this chapter.

Because many parasitic organisms cannot be cultured, microscopic examination is the mainstay of diagnostic parasitology. Examination after proficient staining of fresh and unconcentrated specimens, as well as preserved and/or concentrated specimens with permanent stained preparations, most often provides a rapid and accurate diagnosis. A variety of reagents and stains are available for these purposes, and each laboratory must decide which ones to use to best serve its patient population. In addition, because most specimens are submitted in fixatives and preservatives, the reader should note the specific interference of polyvinyl alcohol (PVA) and mercury reagents with immunoassays that are commonly used for parasitic diagnosis. As immunnostains and nucleic acid amplification assays become more commonly used for the detection of parasites, reagents needed to perform these tests must be considered.

Caution should be taken when using reagents in the parasitology laboratory. Many routinely used compounds can be dangerous if not handled appropriately. For example, formalin and formaldehyde solutions can cause severe skin irritation and, if swallowed, can cause violent vomiting and diarrhea; mercury compounds are local irritants and systemic poisons that can be absorbed through the skin; phenol is a skin irritant, and exposure to large amounts can affect the central nervous system; and xylene can cause serious skin irritation, with extended exposure causing gastrointestinal, neurologic, and tissue damage (1). It is also important to remember that reagents that contain formalin and/or mercury require special disposal. Proper disposal should be made using state and federal regulatory guidelines.

REAGENTS
All of the following reagents are preservatives and/or fixatives. Table 1 lists several types of preservatives along with their content, specific permanent stained smears that can be performed, and immunostains for which they can be used, as well as additional comments concerning the fixative. Today, most clinical laboratories purchase premixed, packaged vials of preservatives and fixatives/adhesives that can be either inoculated with fecal sample sent to the laboratory or sent home with the patient for home collection. A list of commercially available transport vials can be found in Table 2.

**Formalin Preparations**

- **Formalin**
  Formalin has been used in parasitology as an all-purpose preservative for concentration procedures. However, formalin should not be used to prepare smears for permanent stains, because the reagent does not adequately preserve organism morphology (2). It is easy to prepare and has a long shelf life. It is most routinely used as a preservative for stool and duodenal aspirate specimens. Formalin works well to preserve the morphologies of helminth ova and larvae and those of protozoan cysts, oocysts, and spores, although it does not preserve protozoan trophozoites well. Although both 5% and 10% solutions of formalin are currently used (5% for the best preservation of protozoan stages and 10% for ova and larvae), the 10% formulation is most widely used in clinical parasitology today. A formalin vial is often paired with a vial containing a fixative such as PVA or Schaudinn’s to ensure that a permanent stained smear can be prepared and read. Formalin (10%) is prepared as indicated below:

  Formaldehyde (37% to 40% HCHO solution) .... 100 ml
  Saline (0.85% NaCl) OR distilled water ............. 900 ml

- **Buffered formalin**
  Formalin buffered with sodium and potassium phosphates can be used to help maintain the morphology of parasites for long-term storage and is used for concentration procedures. To make buffered formalin, mix the following dry ingredients and store in a tightly closed container. Add 0.8 g of this mixture to 1 liter of 10% (or 5%) formalin.

  Sodium phosphate, dibasic (Na₂HPO₄) ............. 6.1 g
  Potassium phosphate, monobasic (KH₂PO₄) ....... 0.15 g

- **Merthiolate-iodine-formalin (MIF)**
  Protozoa and helminth ova and larvae can be distinguished on direct wet mount after stool and duodenal aspirate speci-

*PVA (plastic powder used as "glue" to attach stool onto the glass slide/no fixation properties per se) and Schaudinn's fixative (mercuroic chloride base) are still considered to be the gold standard against which all other fixatives are evaluated for organism morphology after permanent staining. Additional fixatives prepared with nonmercuric chloride-based compounds are being developed and tested.

This modification uses a copper sulfate base rather than mercuroic chloride.

This modification uses a zinc base rather than mercuroic chloride and apparently works well with both trichrome and iron hematoxylin stains.

These modifications use a combination of ingredients (including zinc) but are prepared from proprietary formulas. The aim is to provide a fixative that can be used for the fecal concentration and permanent stained smear. Acceptability for use with immunoassays for *Giardia duodenalis* and *Cryptosporidium* species varies, so verify with the manufacturer's package insert for proper use. Testing for *Entamoeba histolytica* and/or the *E. histolytica*/*E. dispar* group still requires fresh or frozen specimens.

Remember that two stock solutions listed below be combined into a fresh working solution immediately before use. In addition, after mixing specimens with MIF, the mixture must be left undisturbed for 24 h before preparation of smears from the bottom two layers of the three layers that will form. Parasitological examination of specimens placed in MIF can be performed for several weeks after preservation, making it very useful for field surveys. MIF is also readily available commercially.

PVA-Containing Preservatives and Fixatives

PVA acts as an adhesive for stool material, allowing the stool to adhere to glass slides. Several modifications are commercially available. The accompanying compound with the PVA, specifically, mercuric chloride, zinc sulfate, or cupric sulfate, acts as the preservative and allows fixation of protozoan cysts and trophozoites for use with trichrome or iron hematoxylin stains for permanent smears. All PVA-containing preservatives interfere with immunoassays. PVA is not an appropriate reagent to use for stool specimen concentration and should be paired with a reagent vial (formalin, MIF, SAF) that can be used for that purpose.

Hg-PVA

The Hg-PVA fixative uses mercuric chloride as the preservative. Protozoan morphology is best preserved with PVA-incorporating mercury compounds. However, due to the toxic nature of mercury compounds and the difficulty in preparation, most laboratories no longer prepare Hg-PVA.

Zn-PVA

The Zn-PVA fixative uses zinc sulfate in place of mercury as a preservative and fixative for protozoa. Specimens treated with Zn-PVA may also be stained with trichrome or iron hematoxylin stains for permanent smears.

Cu-PVA

The Cu-PVA fixative uses cupric sulfate in place of mercury as a preservative and fixative for protozoa. Specimens treated with Cu-PVA may also be stained with trichrome or iron hematoxylin stains for permanent smears.

Schaudinn's fixative/solution

Schaudinn’s solution is a fixative made of mercuric chloride, distilled water, and 95% ethyl alcohol that gives excellent morphological preservation of protozoan organisms. It is used primarily in the preparation of permanent stained smears for parasitological examination from fresh, nonpreserved specimens. Specimens fixed in Schaudinn’s solution can be used with either trichrome or iron hematoxylin stains. As with Hg-PVA, due to the toxic nature of mercurophile compounds and the difficulty in preparation of this fixative, Schaudinn’s solution is not routinely made in the clinical microbiology laboratory. In addition, Schaudinn’s fixative is becoming increasingly more difficult to purchase commercially. Many laboratories are opting to use a mercury-free or low-level mercury single-vial that can be used to prepare both a concentration and permanent stained smears. See “Nonmercury or low-level mercury, nonformalin fixatives: single-vial systems” below.

Sodium acetate-acetic acid-formalin (SAF)

SAF is very similar to formalin in that it is a liquid fixative and contains no mercury. However, unlike formalin, SAF can be used for both concentration techniques and permanent stained smears. The sediment from the concentration procedure is used for both the wet preparation and the permanent stain. Albumin-coated slides allow better adhesion of the concentrated material to the slide and are recommended for use with SAF. SAF is an acceptable substitute for PVA or Schaudinn’s solution for permanent smears stained with either trichrome or iron hematoxylin. SAF is available commercially and has a long shelf life, but it can also readily be made in the laboratory by mixing the reagents listed below:

Nonmercury or low-level mercury, nonformalin fixatives: single-vial systems

Several nonmercury, nonformalin proprietary fixatives are commercially available for both concentration of stool specimens and the preparation of permanently stained smears (Medical Chemical Corporation, Torrance, CA; Meridian Bioscience, Cincinnati, OH). There is also a low-level mercury, nonformalin proprietary fixative available that can be used as above (Alpha-Tec, Vancouver, WA). The beauty of these systems is that only one vial is needed to prepare both a concentration and a permanent stained smear and that the vials can be discarded along with other biohazardous waste in the laboratory. Acceptability for use in fecal immunoassays varies (check with manufacturers for specific uses). Special stains are also available for use with some of these fixatives.

STAINS

Table 3 lists the stains that are most commonly used to detect and aid in the identification of parasitic organisms. The description and procedures for stains used in parasitology are given below.

ogy are listed below. A list of commercially available parasitology stains can be found in Table 4.

**Iodine (Lugol’s or D’Antoni’s)**

A solution of iodine can be used when preparing direct or concentrated wet mounts for parasitological examination. These nonspecific dyes allow the differentiation of parasitic cysts from leukocytes, the former of which retain the iodine and appear light brown. Iodine can easily overstain eggs; thus, a wet prep without iodine should be used to detect eggs. Iodine stains can be purchased commercially for use in routine parasitology. These solutions should be stored in dark containers in a dark environment. D’Antoni’s iodine preparation has the advantage of use without further dilution, whereas Lugol’s iodine must first be diluted into a working solution (1:5 dilution in distilled water) before use. Working solutions of both iodine preparations fade with time and should be discarded and replaced when their dark tea color lightens.

**Basic procedure**

Place 1 drop of iodine on a slide; add to this a small amount of fecal specimen and mix until homogeneous. The iodine stains fecal material immediately, and the timing of this step is not important. Place a coverslip on top of the suspension and view under ×100 magnification. Examine any suspicious material under ×400 magnification.

**Acid-Fast Stains (Modified)**

*Cryptosporidium, Cyclospora cayetanensis,* and *Cystoisospora belli,* and *Cyclospora cayetanensis* are coccidian parasites that can cause diarrheal disease in humans. These organisms are more easily detected when a modified acid-fast stain is used. The modification to the acid-fast stains is the use of decolorizing agents that are less harsh than those used for staining mycobacteria. The carbol fuchsin and counterstain (methylene blue) reagents used for mycobacteria can be used for staining coccidian parasites; however, the decoloring agents are not interchangeable. In the modified acid-fast staining procedures, a 1% solution of sulfuric acid (1 ml of sulfuric acid in 99 ml of water) is used, as opposed to the 3% solution used in the acid-fast bacillus Kinyoun staining procedure, and a 5% sulfuric acid solution (5 ml of concentrated sulfuric acid in 95 ml of distilled water) is used, as opposed to the 3% HCl solution in 95% ethanol that is used in the acid-fast bacillus Ziehl-Neelsen staining procedure.

**Modified Kinyoun stain (cold method)**

**Basic procedure (modified Kinyoun stain)**

Specimen (1 or 2 drops) is applied to a slide, allowed to air dry, and fixed with absolute methanol for 1 min. Carbol fuchsin is applied to the slide for 5 min, and then the slide is rinsed with 50% ethanol, followed by a water rinse. Sulfuric acid (1%) decolorizer is added for 2 min, and the slide is rinsed again with water. Methylene blue is added for 1 min, and then the slide is rinsed again with water. The slide is then air dried and examined at ×100 to ×1,000 magnification.

**Modified Ziehl-Neelsen stain (hot method)**

Specimen (1 or 2 drops) is applied to a slide and allowed to air dry, then dry on a heating block (70°C) for 5 min. Place slide on rack and flood with carbol fuchsin. With an alcohol lamp or Bunsen burner, gently heat the slide until steam appears. Allow to stain for 5 min and then rinse. Decolorize with 3% sulfuric acid for 30 seconds and rinse. Counterstain with methylene blue for 1 minute and rinse. The slide is then air dried and examined at ×100 to ×1,000 magnification.

**Blood Film Stains**

**Giemsa and Wright’s stains**

Examination of blood films for parasites includes the use of two common stains, the Giemsa stain and Wright’s stain, both derivatives of the original Romanowsky stain. These stains are very similar, differing primarily in that no fixative is included in the Giemsa stain and the blood film must be fixed with absolute methanol before staining. Erythrocytic stippling, seen in some malaria infections, can be seen using only the Giemsa stain (5). Although stock solutions of these stains can be prepared in the laboratory, the procedure is very cumbersome and involves grinding of powdered stain with methanol and/or glycerol with a mortar and pestle, days to weeks of storage with shaking, and removal of supernatant or filtering before use. In addition, it is recommended that the Giemsa stain be prepared fresh each day of use by diluting the stain stock solution with phosphate-buffered water, pH 7 to 7.2 (6). Alternatively, Giemsa, Wright’s, and Wright-Giemsa stains are readily available from commercial suppliers in liquid form and may need only dilution in a buffer solution. Blood films may be stained manually, but many laboratories rely on automated hematologic instruments for staining of thin (not thick) blood films, with acceptable results. These stains allow the detection of blood parasites, including the agent of malaria, microfilariae, and Leishmania, Babesia, and Trypanosoma species. Although for many years, Giemsa stain has been the stain of choice, the parasites can also be seen on blood films stained with Wright’s stain, a Wright-Giemsa combination stain, or one of the more rapid stains such as Diff-Quik (American Scientific Products, McGaw Park, IL), Wright’s Dip Stat Stain (Medical Chemical Corp.), or Field’s stain. It is more appropriate to use a stain with which you are
familiar rather than Giemsa, which is somewhat more complicated to use. Polymorphonuclear leukocytes can serve as the quality control organism for any of the blood stains. Any parasites present will stain like the polymorphonuclear leukocytes, regardless of the stain used.

### Hematoxylin Stains

#### Delafield’s hematoxylin stain

Delafield’s hematoxylin stain is used for thin and concentrated blood films for the detection of microfilariae and may show greater detail of the nuclei and sheaths than that shown with Giemsa and Wright’s stains. Although the stain is not procedurally difficult to prepare, it does involve an aging process of 1 week followed by 1 month before it can be used. Delafield’s hematoxylin stain is not readily available commercially and is used only in special circumstances. Preparation of the stain involves dissolving 180 g of aluminum ammonium sulfate in 1 liter of distilled water, heating until dissolved, and cooling (ammonium alum). Hematoxylin crystals (4 g) are dissolved in 25 ml of 95% ethyl alcohol, and the solution is then added to 400 ml of the ammonium alum. The solution is then covered with a cotton plug and exposed to sunlight and air for 1 week, after which it is filtered. To this solution, 100 ml each of glycerol and 95% ethyl alcohol is added. This solution is placed in sunlight for at least 1 month (8).

**Basic procedure**

Allow the specimen on a slide to air dry. Lake blood films with distilled water for 15 min and fix in absolute methanol for 5 min, followed by air drying. Stain for 10 to 15 min and rinse in water. Air dry, add a coverslip with mounting fluid, and examine the slide under \( \times 1,000 \) magnification.

#### Iron hematoxylin stain

Iron hematoxylin stains are used for the detection, identification, and enumeration of intestinal protozoan parasites. There are many derivations of the iron hematoxylin stain, all of which can be used with fresh fecal specimens, fixed specimens containing PVA, or specimens preserved in Schaudinn’s solution or SAF to make permanent stained slides. Hematoxylin-stained tissue, is used for the detection, identification, and enumeration of intestinal protozoan parasites (9). This stain uses chromotrope 2R and light green SF stains to visually distinguish internal elements of protozoan parasitic cysts and trophozoites. Trichrome staining is usually performed on fixed fecal specimens containing PVA or Schaudinn’s solution-preserved specimens. MIF- or SAF-preserved specimens may also be stained with the trichrome stain, as well as specimens preserved with single-vial systems. In addition, some proprietary stains are also available that may work better with these and other fixatives to make permanent stained preparations. Trichrome stain can be easily prepared in the laboratory or purchased from a commercial supplier.

**Basic procedure**

Place a prepared slide in 70% ethanol for 5 min. Place the slide in 70% ethanol with iodine for 5 min if mercury-based fixatives are being used and then again in 70% ethanol for 5 min more (these last two steps are not necessary for non-mercury-based fixatives). Wash the slide in running tap water for 10 min, followed by placement in iron hematoxylin working solution for 5 min. After this staining step, wash again in running tap water for 10 min and then place the slide in the following reagents for 5 min each: 70% ethanol, 95% ethanol, 100% ethanol (twice), and xylene (or a substitute) (twice). Add Permount, and add a coverslip. Examine under \( \times 1,000 \) magnification.

#### Trichrome stain (Wheatley trichrome stain)

The Wheatley trichrome stain, a modification of the Gomori tissue stain, is used for the detection, identification, and enumeration of intestinal protozoan parasites (9). This stain uses chromotrope 2R and light green SF stains to visually distinguish internal elements of protozoan parasitic cysts and trophozoites. Trichrome staining is usually performed on fixed fecal specimens containing PVA or Schaudinn’s solution-preserved specimens. MIF- or SAF-preserved specimens may also be stained with the trichrome stain, as well as specimens preserved with single-vial systems. In addition, some proprietary stains are also available that may work better with these and other fixatives to make permanent stained preparations. Trichrome stain can be easily prepared in the laboratory or purchased from a commercial supplier.

**Basic procedure**

Place a prepared slide in 70% ethanol for 5 min. Place the slide in 70% ethanol with iodine for 1 minute (fresh specimens) or for as long as 10 min (PVA-fixed air-dried specimens). Then place again in 70% ethanol for 5 min (twice). Place in trichrome stain for 10 min, followed by a 1- to 3-s rinse in 90% ethanol with acetic acid. Dip the slide several times in 100% ethanol, and then place it in 100% ethanol for 3 min (twice), followed by xylene for 5 to 10 min (twice). Add Permount, and add a coverslip. Dry overnight or for 1 h at 37°C. Examine under \( \times 1,000 \) magnification. If 95% alcohol is substituted for 100% ethanol and xylene substitutes are used, it is important to increase the dehydration times for both the alcohol and xylene substitute by at least 5 to 10 min.

#### Acid-fast trichrome stain

The acid-fast trichrome staining technique allows the detection of acid-fast coccidia (Cryptosporidium spp., C. belli, and C. cayetanensis) (10). Smears prepared from fresh or preserved fecal material can be used in this staining procedure.

**Basic procedure**

Place a prepared, air-dried slide in absolute methanol for 5 to 10 min and then again allow it to air dry. Place in carbol fuchsin solution for 10 min before rinsing in tap water. Decolorize with 0.5% acid-alcohol and rinse in tap water. Place in trichrome stain for 30 min at 37°C. Rinse in acid-alcohol for 10 s and then dip the slide several times in 95% alcohol for

Other Stains

■ Modified Field’s stain

Modified Field’s stain facilitates the identification of Acanthamoeba species. This stain was evaluated and shown to give very good contrast compared with other stains such as Wright’s, Giemsa, Ziehl-Neelsen, and trichrome stains. For information on preparation and use of modified Field’s stain, refer to the article by Pirehama and colleagues (11).

■ Modified safranin stain

Modified safranin stain allows the detection of Cyclospora oocysts in formalin-fixed specimens and fecal concentrates. The stain most commonly used in the past for these organisms was the modified acid-fast stain; however, tremendous variations in staining properties can be seen with this stain. The modified safranin stain reportedly uniformly stains oocysts of Cyclospora. It has also been shown to be fast, reliable, and easy to perform (12).

Basic procedure

Place a prepared, thin smear of stool on a 60°C slide warmer until dried. Cover smear with a 1% safranin solution and heat in a microwave oven at full power (650 W) for 30 to 60 seconds. Rinse the smear with tap water for 30 s, counterstain with 1% aqueous methylene blue for 1 min, rinse with tap water, and air dry. Examine at ×1,000 magnification.

■ Calcofluor white stain

Calcofluor white, one of a number of optical brighteners, binds to cellulose and chitin and fluoresces best when exposed to long-wavelength UV light. These properties allow its use in detecting fungi, including Pneumocystis jiroveci and free-living amebae like Naegleria, Acanthamoeba, and Balamuthia species, as well as the larvae of Dirofilaria species (its cuticle contains chitin). Calcofluor white is available through several commercial suppliers and is also easily made in the laboratory by following the manufacturer’s recommendations.

Basic procedure

Place the specimen on a slide and allow it to air dry. Fix the slide in methanol for 1 to 2 min, rinse with distilled water, and allow it to air dry. Add 1 or 2 drops of 10% KOH, place the slide in methanol for 1 to 2 min, rinse with distilled water, and allow it to air dry. Fix the specimen on a slide and allow it to air dry. Place the specimen on a slide and allow it to air dry. Fix the specimen on a slide and allow it to air dry. Examine at ×1,000 magnification.

REFERENCES

This chapter discusses various approaches and diagnostic methods currently used for the diagnosis of parasitic infections. Assuming that clinical specimens have been properly collected and processed according to specific specimen rejection and acceptance criteria, the examination of prepared wet mounts, concentrated specimens, permanent stained smears, thick and thin blood films, and various culture materials can provide critical information leading to organism identification and confirmation of the suspected cause of clinical disease (1–6). With the exception of a few fecal immunoassay kits, the majority of this diagnostic work depends on the knowledge and microscopy skills of the microbiologist. The field of diagnostic parasitology has taken on greater importance during the past few years for a number of reasons. Expanded world travel has increased the potential levels of exposure to a number of infectious agents, as well as expanding epidemiologic boundaries and organism changes in pathogenicity. It is important to be aware of those organisms commonly found within certain areas of the world and the makeup of the patient population being serviced at your institution, particularly if immunocompromised patients are frequently seen as a part of your routine patient population. It is also important for the physician and microbiologist to recognize and understand the efficacy of any diagnostic method for parasite recovery and identification. Specific information on specimen collection and processing can be found in chapter 133. In order to become proficient in diagnostic medical parasitology, there is no substitute for performing extensive benchwork and the required microscopy associated with this type of testing.

**STOOL SPECIMENS**

For review, see the list of options for the collection of fecal specimens in chapter 133, Table 3, and Table 6. Algorithms for the processing of stool specimens are presented in Fig. 1, 2, and 3. The procedures that normally comprise the ova and parasite (O&P) examination are provided below and include the direct wet mount in saline, the concentration, and the permanent stained smear (1–4, 6–14).

**Direct Wet Mount in Saline**

The purpose of a direct wet mount is to confirm the possibility of infection with certain protozoa and helminths, to assess the worm burden of the patient, and to look for organism motility (Table 1) (1, 10, 13). Any fresh stool specimens that have not been refrigerated and that have been delivered to the laboratory within specified time frames are acceptable for testing; however, it is much more important to examine liquid or soft stools, rather than formed stools. Liquid and soft stools are much more likely to contain motile protozoan trophozoites than cysts, which do not demonstrate motility. Low-power examination (magnification, ×100) of the entire coverslip preparation (22 mm by 22 mm) and high dry power examination (magnification, ×400) of at least one third to one half of the coverslip area are recommended before the preparation is considered negative. Often, results from the direct smear examination should be considered presumptive; however, some organisms (Giardia duodenalis [G. lambia, G. intestinalis] cysts and trophozoites, Entamoeba coli cysts, Iodameba bütschlii cysts, helmhing eggs and larvae, and Cystoisospora bellii oocysts) can be definitively identified. Reports of results obtained by this method should be considered preliminary, with the final report available after the results of the concentration wet mount and permanent stained smear are available.

If iodine is added to the preparation for increased contrast, the organisms will be killed and motility will be lost. Specimens that arrive in the laboratory in stool preservatives do not require a direct smear examination; proceed to the concentration and permanent stained smear. Examination of the wet mount using iodine is not required, but is the decision of each user performing this type of microscopy.

**Concentration Wet Mount**

The purpose of the concentration method is to separate parasites from fecal debris and to concentrate any parasites present through either sedimentation or flotation (1, 6, 10, 13). The concentration is specifically designed to allow recovery of protozoan cysts, coccidian oocysts, microsporidian spores (now classified with the fungi), and helminth eggs and larvae (Table 2). Any stool specimen that is fresh or preserved is acceptable for testing. Wet mounts prepared from concentrated stool are examined in the same manner as that used for the direct wet mount method. The addition of too much iodine may obscure helmhing eggs (the eggs may resemble debris); the use of iodine is an individual decision. Often, results from the concentration examination should be considered presumptive; however, some organisms...
FIGURE 1  Processing liquid stool for O&P examination. Either PVA or Schaudinn’s fixative can be used for the preparation of the permanent stained smear. Organism motility is seen when saline is used; iodine kills the organisms, so motility will no longer be visible. The use of ethyl acetate may remove the entire specimen and pull it into the layer of debris that will be discarded (liquid specimen normally contains mucus); centrifuge at 500 × g for 10 min (normal centrifugation time), but do not use ethyl acetate in the procedure. In general, laboratories have switched to nonmercury substitutes; the original Schaudinn’s fixative contains mercuric chloride. However, in some instances the term “Schaudinn’s fixative” is still used to describe not the original fixative but a formulation that is prepared with a copper or zinc base or other proprietary compounds. When fixatives are selected, it is important to know the contents in order to comply with disposal regulations. Reprinted from reference 9. doi:10.1128/9781555817381.ch135.f1

(G. intestinalis [G. lamblia, G. duodenalis] cysts, E. coli cysts, I. bütschlii cysts, helminth eggs and larvae, and I. belli oocysts) can be definitively identified. As with the direct wet mount, results obtained by the concentration wet mount should be considered preliminary, with the definitive report available after the results of the permanent stained smear are available.

FIGURE 2  Processing preserved stool for O&P examination (two-vial collection kit). The formalin can be buffered or non-buffered, depending on the laboratory protocol in use. Fixative prepared with mercuric chloride provides the best organism preservation. Alternatives are available, including zinc-based PVA, copper sulfate-based PVA, SAF, and the one of the single vial fixatives that requires no adhesive (PVA or albumin). Reprinted from reference 9. doi:10.1128/9781555817381.ch135.f2

The formalin-ethyl acetate sedimentation concentration procedure is the most commonly used procedure, and the recommended centrifugation speed and time are 500 × g and 10 min, respectively. In this procedure, the use of ether has been replaced with ethyl acetate. However, it is important to remember that ethyl acetate should not be used for liquid specimens or those containing a great deal of mucus. The ethyl acetate may pull the liquid/mucus specimen contents into the debris layer, which will be discarded. Although the recovery of parasites from a liquid specimen or one containing a lot of mucus may not be successful, this simple centrifugation approach is still recommended. The standard zinc sulfate flotation procedure does not detect operculated or heavy eggs; when using this method, both the surface film and sediment should be examined before a negative result is reported.

Permanent Stained Smears

Trichrome, Iron-Hematoxylin, or Iron-Hematoxylin/Carbol Fuchsin

The permanent stained smear provides contrasting colors for both the background debris and the parasites present (Table 3, Table 4, and Table 5) (1, 6, 10, 13). Permanent stained stool smears are designed to allow examination and recognition of detailed organism morphology under oil immersion magnification (magnification, ×1,000). This method is primarily designed to allow the recovery and identification of the more common intestinal protozoan trophozoites and cysts, excluding the coccidia (unless the iron-hematoxylin/carbol fuchsin method is used) and microsporidia. Oil immersion examination of a minimum of 300× oil immersion fields is recommended; additional fields may be required if suspect organisms have been seen in the wet mounts. The use of a specific time for slide examination
Diagnostic characteristics of organisms in wet mounts

The examination of permanent stained smears by using different guidelines. Some laboratories use a 60× oil immersion objective for screening purposes; however, it is important to examine a sufficient number of fields at a total magnification of ×1,000 before reporting the specimen as negative (no parasites seen).

Modified Acid-Fast Staining

The modified acid-fast staining method is used to provide contrasting colors for the background debris and the parasites present and to allow examination and recognition of the acid-fast characteristic of the organisms under high dry magnification (magnification, ×400). Organisms that can be identified with this stain are the coccidia Cryptosporidium spp., Cyclospora cayetanensis, and Cryptosporidium. Other modified acid-fast stains are recommended for the detection of microsporidian spores.

Modified Trichrome

Modified acid-fast staining methods are excellent for staining coccidian oocysts. Limitations of the procedure are generally related to specimen handling, including proper collection, centrifugation speed and time, and the percentage acid used for the destain step.

Immuoassay Methods

Immunoassay reagents are available commercially for several of the protozoan parasites, including G. intestinalis (G. Lamblia), G. duodenalis, Cryptosporidium spp., the Entamoeba

These methods (enzyme immunoassay [EIA], fluorescent-antibody assay [FA], and immunochromatographic assay [cartridge]) are designed to detect the antigens of select organisms; a negative result does not rule out the possibility that these organisms/antigens are present in low numbers or that other intestinal parasites are etiologic agents causing disease, including *Dientamoeba fragilis*, the microsporidia, and helminth parasites (1, 17–19). Immunoassay reagents are currently under development and trial for *D. fragilis* and *Blastocystis* spp. Fecal immunassays for the microsporidia are available; however, none are currently FDA-approved for use within the United States.

### Molecular Methods

In January 2013, the FDA approved the first test that can simultaneously detect 11 common viral, bacterial, and parasitic (Cryptosporidium, Giardia) causes of infectious gastroenteritis from a single patient sample (xTAG Gastrointestinal Pathogen Panel, Luminex, Inc., Austin, TX).

---

The helminths listed in Table 2 are those commonly found in human fecal samples. This table does not include every possible helminth that could be found as a human parasite; however, the most likely helminth infections are included.

---

Note: The following parasites have been identified in human feces: *Entamoeba histolytica*—*Entamoeba dispar* group, and *Entamoeba histolytica* (Table 6). These methods (enzyme immunoassay [EIA], fluorescent-antibody assay [FA], and immunochromatographic assay [cartridge]) are designed to detect the antigens of select organisms; a negative result does not rule out the possibility that these organisms/antigens are present in low numbers or that other intestinal parasites are etiologic agents causing disease, including *Dientamoeba fragilis*, the microsporidia, and helminth parasites (1, 17–19). Immunoassay reagents are currently under development and trial for *D. fragilis* and *Blastocystis* spp. Fecal immunassays for the microsporidia are available; however, none are currently FDA-approved for use within the United States.

**Molecular Methods**

In January 2013, the FDA approved the first test that can simultaneously detect 11 common viral, bacterial, and parasitic (Cryptosporidium, Giardia) causes of infectious gastroenteritis from a single patient sample (xTAG Gastrointestinal Pathogen Panel, Luminex, Inc., Austin, TX).
There are also several molecular tests that are in clinical trials for the detection of select gastrointestinal parasites. These tests are molecular gastrointestinal panels and target the most commonly occurring bacterial, viral, and parasitic stool pathogens. Although there are laboratory-developed tests for most parasites, these are not commercially available or available only in specialized testing centers. When such tests are used, there should be attention given to the use of internal amplification controls to detect inhibition, since common specimens, such as blood and stool, contain PCR inhibitors. Thorough validation is required before these are implemented for clinical testing.

**ADDITIONAL TECHNIQUES FOR STOOL EXAMINATION**

Although the routine O&P examination consisting of the direct wet mount, the concentration, and the permanent stained smear is an excellent procedure recommended for the detection of most intestinal parasites, several other diagnostic techniques are available for the recovery and identification of specific parasitic organisms (1, 6, 10). Most laboratories do not routinely offer all of these techniques, but many can be performed relatively simply and inexpensively. Occasionally, it is necessary to examine stool specimens for the presence of scolices and proglottids of cestodes and adult nematodes and trematodes to confirm the diagnosis and/or for species identification (Table 7). A method for the recovery of these stages is also described in this chapter.

**Culture of Larval-Stage Nematodes**

Nematode infections giving rise to larval stages that hatch in soil or in tissues may be diagnosed by using fecal culture methods to concentrate the larvae (1, 6, 10, 15). *Strongyloides stercoralis* larvae are the most common larvae found in stool specimens. Depending on the fecal transit time through the intestine and the patient’s condition, rhabditiform and filariform larvae may be present. Caution must be exercised when handling larval cultures because infective filariform larvae may be present. Culture of feces for larvae is useful for (i) revealing their presence when they are too scanty to be detected by concentration methods; (ii) distinguishing whether the infection is due to

<sup>a</sup>Entamoeba histolytica refers to the Entamoeba histolytica/Entamoeba dispar group/complex. *E. histolytica* (pathogenic) can be determined by finding red blood cells in the cytoplasm of the trophozoites. Otherwise, on the basis of morphological grounds *E. histolytica* (pathogen) and *E. dispar* (nonpathogen) cannot be differentiated. A report should read: Entamoeba histolytica/E. dispar group (or complex).

<sup>b</sup>It is very difficult to differentiate Entamoeba polecki trophozoites from those of the *E. histolytica/E. dispar* group, *E. col*, or *E. moshkovskii*.

<sup>c</sup>Although some I. bütschlii cysts are larger than 10 μm, the majority of cysts measure 9 to 10 μm and the typical glycogen vacuole ensures the proper identification.

*Although these two methods have been used in the past, currently the World Health Organization recommendation is the Kato-Katz thick fecal smear method with the McMaster egg count method being an excellent alternative for monitoring large scale eradication programs. In the majority of diagnostic laboratories, none of these procedures are routinely performed; generally their use is limited to relevant geographic areas and/or studies (24).*

be refrigerated, since some parasites are susceptible to cold and may fail to develop after refrigeration. Also, caution must be exercised in handling the filter paper strip itself, since infective *Strongyloides* larvae may migrate upward as well as downward on the paper strip.

**Filter Paper/Slant Culture Technique (Petri Dish)**

An alternative technique for culturing *Strongyloides* larvae is a filter paper/slant culture on a microscope slide placed in a glass or plastic petri dish (1). As with the techniques described above, sufficient moisture is provided by continuous soaking of filter paper in water. Fresh stool material is placed on filter paper, which is cut to fit the dimensions of a standard (1 by 3 in.) microscope slide. The filter paper is then placed on a slanted glass slide in a glass or plastic petri dish containing water. This technique allows direct examination of the culture system with a dissecting microscope to look for nematode larvae and free-living stages of *S. stercoralis* in the fecal mass or the surrounding water without having to sample the preparation.

**Egg Studies and Scolex Search**

**Estimation of Worm Burdens**

The only human parasites for which it is reasonably possible to correlate egg production with adult worm burdens are *Ascaris lumbricoides*, *Trichuris trichiura*, and the hookworms (*Necator americanus* and *Ancylostoma duodenale*). The specific instances in which information on approximate worm burdens is useful are when one is determining the intensity of infection, deciding on possible chemotherapy, and evaluating the efficacies of the drugs administered. With current therapy, the need for the monitoring of therapy through egg counts is no longer as relevant. Remember that egg counts are estimates; you will obtain count variations regardless of how carefully you follow the procedure. If two or more fecal specimens are being compared, it is best to have the same individual perform the technique with both samples and to do multiple counts. A number of methods have been described (1, 4, 7, 10, 13, 20).

**Hatching of Schistosome Eggs**

When schistosome eggs are recovered from either urine or stool, they should be carefully examined to determine viability. The presence of living miracidia within the eggs indicates an active infection that may require therapy. The viability of the miracidia can be determined in two ways: (i) the cilia of the flame cells (primitive excretory cells) may be seen on a wet smear by using high dry power and are usually actively moving, and (ii) the miracidia may be released from the eggs by the use of a hatching procedure (1). The eggs usually hatch within several hours when placed in 10 vol of dechlorinated or spring water (hatching may begin soon after contact with the water). The eggs that are recovered in the urine (24-h specimen collected with no preservatives) are easily obtained from the sediment and can be examined under the microscope to determine viability. A sidearm flask has been recommended, but an Erlenmeyer flask is an acceptable substitute.

Because adult worms occasionally reside in veins other than their normal site, both urine and stool specimens must be collected. Specimens should be collected without preservatives and should not be refrigerated prior to processing. Hatching does not occur until the saline is removed and non-chlorinated water is added. If a stool concentration is performed, use saline throughout the procedure to prevent premature hatching. Make sure that the light is not too close to the side arm or top layer of water in the Erlenmeyer flask. Excess heat kills the miracidia. The lamp light mimics the sun shining on a water source, and the hatched larvae tend to swim toward the light. The absence of live miracidia does not rule out the presence of schistosome eggs. Nonviable eggs or eggs that failed to hatch are not detected by this method. Microscopic examination of direct or concentrated specimens should be used to demonstrate the presence or absence of eggs. Egg viability can be determined by placing some stool or urine sediment (the same material used for the hatching flask) on a microscope slide. Low-power magnification (×100) can be used to locate the eggs. Individual eggs can be examined with high dry magnification (×400); moving cilia on the flame cells (primitive excretory system) confirm egg viability.
Search for Tapeworm Scoleces

Since therapy for the elimination of tapeworms is usually very effective, a search for the tapeworm scolex is rarely requested and is no longer clinically relevant. However, stools specimens may have to be examined for the presence of scoleces and gravid proglottids of cestodes for proper species identification. This procedure requires mixing a small amount of feces with water and straining the mixture through a series of wire screens (graduated from coarse to fine mesh) to look for scoleces and proglottids. Remember to use standard precautions and to wear gloves when performing this procedure. The appearance of scoleces after therapy is an indication of successful treatment. If the scolex has not been passed, it may still be attached to the mucosa; the parasite is capable of producing more segments from the neck region of the scolex, and the infection continues.

Sigmoidoscopy Material

Material obtained from sigmoidoscopy can be helpful in the diagnosis of amebiasis that has not been detected by routine fecal examinations, and the procedure is recommended for this purpose. However, usually a series of at least three routine stool examinations for parasites should be performed for each patient before a sigmoidoscopy examination is done (1).

Material from the mucosal surface should be aspirated or scraped and must not be obtained with cotton-tipped swabs. At least six representative areas of the mucosa should be sampled and examined (six samples, six slides). Usually, the amount of material is limited and should be processed immediately to ensure the best examination possible (Table 8). Three methods of examination can be performed. All three are acceptable; however, depending on the availability of trained personnel, the availability of proper fixation fluids, or the amount of specimen obtained, one or two procedures are recommended. If the amount of material limits the examination to one procedure, the use of one of the fecal fixatives is highly recommended for the subsequent preparation of permanent stains.

Although the fecal immunoassays are rarely performed on sigmoidoscopy specimens, they can be used on fecal specimens for the detection of the Entamoeba histolytica/E. dispar group or confirmation of the pathogen Entamoeba histolytica. However, this testing requires fresh or frozen stool; preserved stool is not acceptable.

Physicians performing sigmoidoscopy procedures may not realize the importance of selecting the proper fixative for material to be examined for parasites when using the concentration and permanent stained smear methods. It is recommended that a parasitology specimen tray (containing Schaudinn’s fixative, a liquid fixative containing PVA, 5 or 10% formalin, or one of the single vial fixatives) be provided or that a trained technologist be available at the time of sigmoidoscopy to prepare the slides.

Direct Saline Mount

If there is no lag time after collection and a microscope is available in the immediate vicinity, some of the material should be examined as a direct saline mount for the presence of motile trophozoites (1). A drop of material is mixed with a drop of 0.85% sodium chloride and is examined under low light intensity for the characteristic movement of amebae. It may take time for the organisms to become acclimated to this type of preparation; thus, motility may not be obvious for several minutes. There will be epithelial cells, macrophages, and possibly polymorphonuclear leukocytes (PMNs) and erythrocytes, which will require a careful examination to reveal amebae.

Since specific identification of protozoan organisms can be difficult when only the direct saline mount is used, this technique should be used only when there is sufficient material left to prepare permanent stained smears.

Permanent Stained Smear

Most of the material obtained at sigmoidoscopy can be smeared (gently) onto a slide and immediately immersed in SAF or one of the single vial fixatives (1). These slides can then be stained with trichrome or iron hematoxylin stain and examined for specific cell morphology, either protozoa or otherwise. The procedure and staining times are identical to those for routine fecal smears.

If the material is bloody, contains a lot of mucus, or is a "wet" specimen, a few (no more than 2 or 3) drops of fixative containing PVA can be mixed with 1 or 2 drops
of material directly on the slide, which is allowed to air dry (a 37°C incubator can be used) for at least 2 h before staining. If time permits, the smears should be allowed to dry overnight; they can be routinely stained with trichrome stain and examined as a permanent mount.

Material from sigmoidoscopy can be placed in small amounts of SAF or one of the single vial fixatives. After fixation for 30 min, the specimen can be centrifuged at 500 × g for 10 min, and smears from the small amount of sediment can be prepared for permanent staining. The most relevant organism for consideration when sigmoidoscopy is performed is *E. histolytica*, the morphology of which is normally seen from the permanent stained smear. However, if fresh stool or aspirated material is obtained, then both the permanent stained smear and an antigen detection reagent kit for the detection of the *Entamoeba histolytica*/*E. dispar* group or confirmation of the pathogen *Entamoeba histolytica* can be used. If enough material is present for only a single procedure, then the permanent stained smear is recommended, particularly if the iron hematoxylin stain (incorporating the carbol fuchsin step) is used (1). This method would enhance the detection of the coccidia, which are modified acid-fast positive.

**Duodenal Contents**

**Duodenal Drainage**

In infections with *G. intestinalis* (G. lamblia, G. duodenalis) or *S. stercoralis*, routine stool examinations may not reveal the organisms. Duodenal drainage material can be submitted for examination (Table 8).

A fresh, unpreserved specimen should be submitted to the laboratory; the amount may vary from <0.5 ml to several milliliters of fluid. The specimen may be centrifuged (at 500 × g for 10 min) and should be examined immediately as a wet mount for motile organisms (iodine may be added later to facilitate identification of any organisms present). If the specimen cannot be completely examined within 2 h after it is taken, any remaining material should be preserved in one of the fecal fixatives for permanent staining.

If the duodenal fluid contains mucus, this is where the organisms tend to be found. Therefore, centrifugation of the

*a Immunoassay tests for the *Entamoeba histolytica*/*E. dispar* group or *Entamoeba histolytica* require fresh or frozen stool; preserved stool specimens are not acceptable for testing. Immunoassays for *Cryptosporidium spp.* and *Giardia lamblia* (name designation on commercial kits) are approved for use on stool; immunoassay use for other intestinal tract specimens (sigmoidoscopy) may or may not be appropriate, depending on specimen source, consistency, volume, and appropriate validation documentation.

*b Some genus-specific immunoassay reagents for the microsporidia are available commercially but are not FDA approved.

*c Although cysts may be present in stool, sigmoidoscopy specimens are often obtained from patients with severe diarrhea or dysentery. In these cases, the cyst forms are usually absent; trophozoites would be the most likely stage seen, particularly in the case of *Entamoeba histolytica.*

*d Duodenal specimens are often submitted as aspirates; in such cases the volume may be sufficient to perform concentrations. However, if small amounts of duodenal mucus and/or biopsy material are obtained, squash preparations preserved with Schaudinn’s fixative are preferred. This approach may require the use of slides precoated with albumin to facilitate adhesion. Mucus obtained from the Entero-Test capsule string may be treated as a fresh specimen; the string can also be immediately placed in preservative after retrieval, and the mucus can be processed as a permanent stained smear from a number of fixative options (with and without PVA).
specimen is important, and the sedimented mucus should be examined. *Giardia* trophozoites may be caught in mucus strands, and the movement of the flagella on the trophozoites may be the only subtle motility seen for these flagellates. *Strongyloides* larvae are usually very motile. Immunoassay methods for *Cryptosporidium* spp. and *G. intestinalis* (G. *lamblia*, G. *duodenalis*) can also be used with fresh or formalinized material; however, duodenal fluid is not included in many of the package inserts as an acceptable specimen.

If the amount of duodenal material submitted is very small, rather than using any of the specimen for a wet smear examination, permanent stains can be prepared. This approach provides a more permanent record, and the potential problems with unstained organisms, very minimal motility, and a lower-power examination can be avoided by using oil immersion examination of the stained specimen at ×1,000 magnification.

Duodenal Capsule Technique (Entero-Test)

A method of sampling duodenal contents that eliminates the need for intestinal intubation has been devised and consists of the use of a length of nylon yarn coiled inside a gelatin capsule (1, 6, 7, 10). The yarn protrudes through one end of the capsule, and this end of the line is taped to the side of the patient’s face. The capsule is then swallowed, the gelatin dissolves in the stomach, and the weighted string is carried by peristalsis into the duodenum. The weight is released and passes out in the stool when the line is retrieved after a period of 4 h. Bile-stained mucus clinging to the yarn is then scraped off with gloved fingers and is collected in a small petri dish. Usually 4 or 5 drops of material are obtained. Adult and pediatric capsules are currently available from Nutri-Link Ltd, United Kingdom (http://www.nutri-linkltd.co.uk/).

The specimen should be examined immediately as a wet mount for motile organisms. Organism motility is similar to that described above for duodenal drainage. If the specimen cannot be completely examined within an hour after the yarn has been removed, the material should be preserved in SAF or one of the single vial fixatives or fixative containing PVA. Mucus smears should be prepared.

The pH of the terminal end of the yarn should be checked to ensure adequate passage into the duodenum (a very low pH means that it never left the stomach). Also, since the bile duct drains into the intestine at this point, the terminal end of the yarn should be a yellow-green color.

**UROGENITAL SPECIMENS**

Several parasites may be recovered and identified from urogenital specimens. Although the most common pathogens are probably *Trichomonas vaginalis* and *Schistosoma haematobium*, other organisms, such as the microsporidia, are becoming much more important (*Table 9*). Also, the membrane filtration for the recovery of microfilariae can be performed from urine.

**Direct Wet Mount**

The identification of *T. vaginalis* is usually based on the examination of a wet preparation of vaginal and urethral discharges and prostatic secretions or urine sediment and may require the testing of multiple specimens to confirm the diagnosis. These specimens are diluted with a drop of saline and are examined under low power and reduced illumination for the presence of actively motile organisms. As the jerky motility begins to diminish, it may be possible to observe the undulating membrane, particularly under high dry power (magnification, ×400).

While the membrane filtration technique can be used for the recovery of microfilariae, examination of urinary sediment may be indicated in certain filarial infections. The occurrence of microfilariae in urine has been reported with increasing frequency in *Onchocerca volvulus* infections in Africa.

Urine is collected in a bottle, this volume is recorded, and thimerosal (1 ml/100 ml of urine) is added. The specimen is placed in a funnel fitted with tubing and a clamp; this preparation is allowed to settle overnight. On the following day, 10 to 20 ml of urine is withdrawn and centrifuged. The supernatant is discarded, and the sediment is resuspended in 0.85% NaCl. This preparation is again centrifuged, and 0.5 to 1.0 ml of the sediment is examined under the microscope for the presence of nonmotile microfilariae. The membrane filtration technique can also be used with urine for the recovery of *Schistosoma haematobium* eggs (1). This approach uses a 25-μm Nuclepore filter (5-μm porosity) (1, 6, 10).

*Staining procedures and fluorescent antibody tests for organism detection performed on centrifuged sediment (500 × g for 10 min).*

*Immunooassays are available commercially but are not yet FDA approved for use within the U.S.*
using optical brightening agents such as calcofluor white (1). Multiple methods are recommended for confirmation of the diagnosis. It is recommended that any patient suspected of microsporidiosis submit both stool and urine for examination.

Culture
Specimens from women for culture (for T. vaginalis) may consist of vaginal exudate collected from the posterior fornix on cotton-tipped applicator sticks or genital secretions collected on polyester sponges. Specimens from men can include semen, urethral samples collected with a polyester sponge, or urine. Urine samples collected from the patient should be the specimen first voided in the morning. It is critical that clinical specimens be inoculated into culture medium as soon as possible after collection (1, 12, 20). Although collection swabs can be used, there are often problems with specimens drying prior to culture; immediate processing is mandatory for maximum organism recovery. Another approach would be to use the plastic envelope methods (Trichomonas Culture System [Empyrean Diagnostics, Mountain View, CA] or InPouch TV [BioMed Diagnostics, San Jose, CA]), which are simplified techniques for transport and culture (4). The following control strain should be available when using these cultures for clinical specimens: T. vaginalis ATCC 30001. Many media for the isolation of T. vaginalis are available, and some of these can be purchased commercially and have relatively long shelf lives, particularly the plastic envelope methods. If no trophozoites are seen after 4 days of incubation, then discard the tubes and report the culture as negative. Results for patient specimens should not be reported as positive unless control cultures are positive. Since culture may take as long as 3 to 4 days and the clinical specimens may contain nonviable organisms, it is recommended that microscopic examination of wet smears be performed as well (possible dead organisms may be present, although they will be difficult to see).

Antigen Detection (Trichomonas vaginalis)
The culture method is considered to be very sensitive for the diagnosis of trichomoniasis; however, due to the time and effort involved, some laboratories have decided to use some of the new immunoassay detection kits (1). The Osmo Trichomonas Rapid Test (Genzyme Diagnostics, Cambridge, MA) is an immunochromatographic method for antigen detection using the dipstick format. Results are available within 10 min, and according to the manufacturer, there is a 95% agreement with the reference standard (culture and wet mount). The Affirm VPIII DNA probe technology (Becton, Dickinson and Co, Franklin Lakes, NJ) offers a dependable, rapid means for the early identification of three organisms causative of Trichomonas vaginalis. Also, the APTIMA Trichomonas vaginalis Assay (GenProbe, San Diego, CA) is available.

SPECIMENS FROM OTHER BODY SITES
When routine testing methods have failed to demonstrate the organisms, the examination of aspirated material for the diagnosis of parasitic infections may be extremely valuable (Table 10). Specimens should be transported to the laboratory immediately after collection. Aspirates include liquid specimens collected from a variety of sites as well as fine-needle aspirates and duodenal aspirates. Fine-needle aspirates are often collected by the cytopathology staff who process the specimens, or they may be collected and sent to the laboratory directly for slide preparation and/or culture. Fluid specimens collected by bronchoscopy include bronchoalveolar lavage and bronchial washing fluids.

Procedural details for processing sputum samples and scrapings for the recovery of E. histolytica and techniques for preparation of duodenal aspirate material have been presented earlier in this chapter.

Biopsy specimens are recommended for use in the diagnosis of parasitic infections in tissues (Table 10). In addition to standard histologic preparations, the following can be used: impression smears and teased and squashed preparations of biopsy tissue from skin, muscle, cornea, intestine, liver, lung, and brain. Tissue to be examined as permanent sections or by electron microscopy should be fixed as specified by the laboratories that will process the tissue, and in certain cases, testing of a biopsy specimen may be the only means of confirming a suspected parasitic problem. Specimens that are going to be examined as fresh material rather than as tissue sections should be kept moist in saline and submitted to the laboratory immediately.

Detection of parasites in tissue depends on specimen collection and the retrieval of sufficient material for examination. Tissue samples often improve diagnostic results. To optimize the yield from any tissue specimen, examine all areas and use as many procedures as possible. Tissues are obtained from invasive procedures, many of which are very expensive and lengthy; consequently, these specimens deserve the most comprehensive procedures possible.

Tissue submitted in a sterile container on a sterile sponge dampened with saline may be used for cultures of protozoa after mounts for direct examination or impression smears for staining have been prepared. If cultures for parasites will be made, use sterile slides for smear and mount preparation or inoculate cultures prior to smear preparation.

Bone Marrow
Bone marrow aspirates to be evaluated for Leishmania amastigotes, Trypanosoma cruzi amastigotes (African trypanosomiasis organisms are not relevant), Plasmodium spp., or Toxoplasma gondii (bone marrow is a less common site for this organism) require Giemsa staining. However, if stained with a hematoxylin/Giemsa combination or other blood stains, the organisms will be visible as well. If specimens are to be processed for culture, it is important to maintain sterility of the specimen prior to inoculation of media for parasitology cultures. After inoculation of appropriate media, the remaining specimen can be processed for smear preparation and staining.

Brain
Generally, when cerebrospinal fluid or brain aspirates or biopsy specimens are received, the most likely parasites would include the free-living amebae Acanthameba spp., Balamuthia mandrillaris, Naegleria fowleri, or Sappinia spp. The use of non-nutrient agar (with bacterial overlayers) cultures is recommended for Acanthameba spp. and N. fowleri; quality control cultures with known positive organisms are recommended as a basis for acceptable interpretation of patient culture results. Sappinia spp. will also grow using the non-nutrient agar with bacterial overlay culture system. If free-living ameba cultures are ordered for central nervous system specimens, the agar plates should be incubated at 37°C (room air, no CO₂) (1, 6, 10). Unfortunately, cultures for B. mandrillaris are difficult to perform; consultation with the Centers for Disease Control and

\(^a\)This table does not include every possible parasite that could be found in a particular body site. Parasite stages include trophozoites, cysts, oocysts, spores, adults, larvae, eggs, hooklets, amastigotes, and trypomastigotes. Although PCR methods have been used in the research setting for most of the organisms listed in the table, reagents are generally not commercially available.

\(^b\)Routine histology can be used for the detection and identification of many parasites. In some cases, it may be the only means of diagnosis.

\(^c\)Although eye specimens are much preferred, free-living amebae have been cultured from patient contact lenses and lens solutions; we would not reject these specimens. An exception would be unopened commercial lens care solutions; these solutions would be rejected.

\(^d\)The examination of abscess aspirates for the presence of Entamoeba histolytica trophozoites is an uncommon procedure and not always reliable in diagnosing extraintestinal amebiasis; serologic tests would be preferred.

Prevention (CDC) is recommended if this infection is suspected. The remaining specimen can then be processed for smear preparation and staining. Although T. gondii would also be seen in stained smears, one could also use immunospecific reagents, cell line culture, or PCR. Spinal fluid should not be diluted before examination. Impression smears from tissues should be prepared and stained with a blood stain. The material is pressed between two slides, with the smear resulting when the slides are pulled apart (one across the other). The smears are allowed to air dry and are then processed like a thin blood film (fixed in absolute methanol and stained with one of the blood stains).

Patients with primary amebic meningoencephalitis are rare, but the examination of spinal fluid may reveal the amebae, usually Naegleria fowleri. Unspun sedimented spinal fluid should be placed on a slide, under a coverslip, and observed for motile amebae; smears can also be stained with trichrome, Wright’s, or one of the blood stains. Spinal fluid, exudate, or tissue fragments can be examined by light microscopy or phase-contrast microscopy. Care must be taken not to confuse leukocytes with actual organisms and vice
versa. The spinal fluid may be clear or appear cloudy or purulent (with or without erythrocytes), with a cell count of from a few hundred to more than 20,000 leukocytes (primarily neutrophils) per ml. Failure to find bacteria in this type of spinal fluid should alert one to the possibility of primary amebic meningoencephalitis; however, false-positive bacterial Gram stains have been reported due to the excess debris. Isolation of these organisms from tissues can be done by using special media. When spinal fluid is placed in a counting chamber, organisms that settle to the excess debris. Isolation of these organisms from tissues can be done by using special media. When spinal fluid is placed in a counting chamber, organisms that settle to the bottom of the chamber tend to round up and look very much like leukocytes. For this reason, it is better to examine the spinal fluid on a slide directly under a coverslip, not in a counting chamber.

Possible infection with microsporidia (the most likely organism would be Encephalitozoon spp.; less common would be Trachipleistophora antropophthera) should also be considered. Specific methods would include modified trichrome, acid-fast, and blood stains; a nonspecific optical brightening agent (calcofluor white); routine histology (methenamine silver, periodic acid-Schiff [PAS], and tissue Gram stains); and electron microscopy. Electron microscopy or immunospecific reagents would be required to identify the microsporidia to the genus and species levels.

Helminth parasite stages such as Taenia solium cysticerci and hydatid cysts of Echinococcus spp. would generally be identified through examination of routine histologic slides; however, confirmation of hydatid disease could also be made from the hooklets seen in the hydatid cyst fluid contents.

Eyes
Eye specimens could include those from the cornea, conjunctiva, contact lens, or contact lens solutions. Although eye specimens are preferred, Acanthameba spp. have been cultured from patient contact lenses and lens solution. These specimens would be acceptable; however, due to risk management issues, the laboratory should not accept unopened commercial lens care solutions. These solutions could be referred to laboratories or agencies, such as the U.S. Food and Drug Administration (FDA), that handle testing and approval of commercial products. Also, the presence of Acanthameba in a lens solution does not automatically equate to Acanthameba keratitis; it is only suggestive at best. A corneal scraping is recommended. After appropriate microscopy, smear, and tissue Gram stains; and electron microscopy. Electron microscopy or immunospecific reagents would be required to identify the microsporidia to the genus and species levels. Specific methods would include modified trichrome, acid-fast, and blood stains; a nonspecific optical brightening agent (calcofluor white); routine histology (methenamine silver, PAS, and tissue Gram stains); and electron microscopy. Electron microscopy or immunospecific reagents would be required to identify the microsporidia to the genus and species levels.

Kidneys and Bladder
The kidneys serve as the primary site for the adult worm Diocysthyema renale. These worms generally live in the pelvis of the right kidney or in body cavities. Although these infections have been isolated from dogs in many areas of the world, they tend to be uncommon in humans. Infections can be confirmed at autopsy, by the migration of worms from the urethra, by discharge of worms from the skin over an abscessed kidney, or by recovery of eggs in the urine. Possible infection with microsporidia (the most likely organism would be Encephalitozoon spp.; less common would be Enterocytozoon bieneu) should also be considered. Specific methods would include modified trichrome, acid-fast, and blood stains; a nonspecific optical brightening agent (calcofluor white); routine histology (methenamine silver, PAS, and tissue Gram stains); and electron microscopy. Electron microscopy or immunospecific reagents would be required to identify the microsporidia to the genus and species levels.

Mucosa from the bladder wall may reveal eggs of Schistosoma haematobium (tissue squash preparation) when they are not being recovered in the urine. The eggs in the bladder wall should be checked for viability by either a hatching technique or microscopic observation of the functioning flame cells within the miracidium larva; the hatching test would be most appropriate for a urine specimen (1).

Liver and Spleen
Although the liver and spleen can serve as sites for a number of organisms as the secondary site, specific organisms that need to be considered for these organs as primary sites include Leishmania donovani, Toxoplasma gondii, Echinococcus spp., Toxocara canis, Toxocara cat, Capillaria hepatica, Clonorchis sp., Opisthorchis sp., Cryptosporidium spp., Entamoeba histolytica, Encephalitozoon spp., and Enterocytozoon intestinalis (liver). Typical methods for diagnosis would include wet mounts, routine histology, blood stains, culture, modified acid-fast stains, immunospecific reagents, and trichrome stains (routine and modified).
Examination of aspirates from lungs or liver abscesses may reveal trophozoites of *E. histolytica*; however, demonstration of the organisms may be difficult (1). Liver aspirate material should be taken from the margin of the abscess rather than the necrotic center. The organisms are often trapped in the viscous pus or debris and do not exhibit typical motility. A minimum of two separate portions of exudate should be removed (more than two are recommended). The first portion of the aspirate, usually yellowish white, rarely contains organisms. The last portion of the aspirated abscess material is reddish and is more likely to contain amebae. The best material to be examined is that obtained from the actual wall of the abscess. The Amebiasis Research Unit, Durban, South Africa, has recommended the use of proteolytic enzymes to free the organisms from the aspirate material.

After the addition of the enzyme streptodornase to the thick pus (10 U/ml of pus), the mixture is incubated at 37°C for 30 min and shaken repeatedly. After centrifugation (500 × g for 5 min), the sediment may be examined microscopically as wet mounts or may be used to inoculate culture media. Some of the aspirate can be mixed directly with PVA on a slide and examined as a permanent stained smear (1). In a suspected case of extraintestinal amebiasis, many laboratories prefer to use a serologic diagnostic approach.

Aspiration of cyst material for the diagnosis of hydatid disease is a dangerous procedure and is usually performed only when open surgical techniques are used for cyst removal. Aspirated fluid usually contains hydatid sand (intact and degenerating scolices, hooklets, and calcareous corpuscles). Some of the older cysts contain material that resembles curded cottage cheese, and the hooklets may be very difficult to see. Some of this material can be diluted with saline or 10% KOH or concentrated HCL; usually, scolices or daughter cysts will have disintegrated. However, the diagnosis can be made from seeing the hooklets under high dry power (magnification, ×400) or using special stains. The absence of scolices or hooklets does not rule out the possibility of hydatid disease, since some cysts are sterile and contain no scolices and/or daughter cysts. Histologic examination of the cyst wall should be able to confirm the diagnosis.

**Lungs**

**Expectorated Sputum and Induced Sputum**

Although it is not one of the more common specimens, expectorated sputum may be submitted for examination for parasites (Table 10). Organisms in sputum that may be detected and that may cause pneumonia, pneumonitis, or Loeffler’s syndrome include the migrating larval stages of *Ascaris lumbricoides*, *S. stercoralis*, and hookworm; the eggs of *Paragonimus* spp.; *Echinococcus granulosus* hooklets; the protozoa *E. histolytica* and *Cryptosporidium* spp.; and possibly the microsporidia (1). In a *Paragonimus* infection, the sputum may be viscous and tinged with brownish flecks (“iron filings”), which are clusters of eggs, and may be streaked with blood. Although *Entamoeba gingivalis* and *Trichomonas tenax* may be found in sputum, they are generally indicators of poor oral hygiene and/or periodontal disease, not pulmonary disease.

A sputum specimen should be collected properly so that the laboratory receives a “deep sputum” sample from the lower respiratory tract for examination rather than a specimen that is primarily saliva from the mouth. If the sputum is not induced, then the patient should receive specific instructions regarding collection.

Care should be taken not to confuse *E. gingivalis*, which may be found in the mouth and saliva, with *E. histolytica*, which could result in an incorrect suspicion of pulmonary abscess. *E. gingivalis* usually contains ingested PMNs, while *E. histolytica* may contain ingested erythrocytes but not PMNs. *T. tenax* would also be found in saliva from the mouth and thus would be an incidental finding and normally not an indication of pulmonary problems.

**Direct Wet Mount**

Sputum is usually examined as a wet mount (saline or iodine), using low and high dry power (magnifications, ×100 and ×400, respectively). The specimen is not concentrated before preparation of the wet mount. If the sputum is thick, an equal amount of 3% sodium hydroxide (or undiluted chlorine bleach) can be added; the specimen is thoroughly mixed and then centrifuged. However, NaOH destroys any protozoan trophozoites that might be present. After centrifugation, the supernatant fluid is discarded, and the sediment can be examined as a wet mount with saline or iodine. If examination must be delayed for any reason, the sputum should be fixed in 5 or 10% formalin to preserve helminth eggs or larvae or in one of the fecal fixatives to be stained later for protozoa. Another option is the use of a dithiothreitol-based product such as Sputasol (Oxoid Code #SR0233A, Remel, Lenexa, KS). Sputasol is formulated to break down mucus and liberate organisms without killing them.

**Permanent Stained Smears**

If *Cryptosporidium* spp. are suspected (which is rare), then acid-fast or immunosassay techniques normally used for stool specimens can be used (1). Trichrome or iron hematoxylin stains of material may aid in differentiating *E. histolytica* from *E. gingivalis*, and Giemsa stain may better define larvae and juvenile worms.

**Bronchoscopy Aspirates**

Fluid specimens collected by bronchoscopy may be lavage or washing fluids, with bronchoalveolar lavage fluids preferred. Specimens are usually concentrated by centrifugation prior to microscopic examination of stained preparations. Organisms that may be detected in such specimens are *Paragonimus* spp., *S. stercoralis*, *T. gondii*, *Cryptosporidium* spp., and the microsporidia.

If *T. gondii* is suspected, one of the blood stains, immunospecific reagents, and/or culture (tissue culture) can be used to confirm the diagnosis. A number of cell lines have been used (human foreskin fibroblast is one example), and most routine cell lines work well for the growth and isolation of this organism.

**Lymph Nodes and Lymphatics**

Material from lymph nodes and lymphatics may confirm parasitic infections (noxoplasmosis, Chagas’ disease, trypanosomiasis, microsporidiosis, or filariasis) and should be processed as follows. Fluid material can be examined under low power (magnification, ×100) and high dry power (magnification, ×400) as a wet mount (diluted with saline) for the presence of motile organisms.

Material obtained from lymph nodes should be processed for tissue sectioning and as impression smears that should be processed as thin blood films and stained with one of the blood stains. Appropriate culture media can also be inoculated, again making sure that the specimen has been collected under sterile conditions.

If microsporidia are suspected, modified trichrome stains can be used; calcofluor white and immunosassay methods (currently under development) are also excellent options (1). If *T. gondii* is suspected, Giemsa stain, immunospecific
reagents, and/or culture (tissue culture) can be used to con-
firm the diagnosis.
Specific filarial infections generally are caused by Wuchereria bancrofti, Brugia malayi, and Brugia spp. In most cases, the microfilariae can be recovered and identified through examination of thick blood films, specific concentration sediment, and/or membrane filtration methods (1).

Muscle
Muscle is considered the primary site for the following organ-
isms: Sarcozystis spp., microsporidia (Pleistophora spp., Trachipleistophora hominis, or Nosema spp.), Gnathostoma spp., Trichinella spp. larvae, and cestode larval forms (coenu-
rus [Taenia spp.], cysticercosis [T. solium], and sparganum). As a secondary site, T. cruzi amastigotes can also be found in muscle; Baylisascaris procyonis and Ancylostoma spp. are also possibilities, as are hydatid cysts (Echinococcus spp.). In most cases, biopsy specimens processed by routine histologic methods provide the most appropriate specimens for exami-
nation and confirmation of the causative agent.

The presumptive diagnosis of trichinosis is often based on patient history; ingestion of raw or rare pork, walrus meat, reindeer meat, or horse meat; diarrhea followed by edema and muscle pain; and the presence of eosinophilia. Gener-
ally, the suspected food is not available for examination. The diagnosis may be confirmed by finding larval Trichinella spp. in a muscle biopsy specimen. The encapsulated larvae can be seen in fresh muscle if small pieces are pressed be-
tween two slides and examined under the microscope (1). Larvae are usually most abundant in the diaphragm, masseter muscle, or tongue and may be recovered from these muscles at necropsy. Routine histologic sections can also be pre-
pared.

Human infection with any of the larval cestodes may present diagnostic problems, and frequently, the larvae are re-
ferred for identification after surgical removal (1). In addi-
tion to E. granulosus (hydatid disease) and the larval stage of Taenia solium (cysticercosis), other larval cestodes occa-
sionally cause human disease. The larval stage of tapeworms of the genus Multiceps, a parasite of dogs and wild canids, is called a coenurus and may cause human coenurosis. The coenurus resembles a cisticercus but is larger and has multiple scolecis developing from the germinal membrane surrounding the fluid-filled bladder. These larvae occur in extraintestinal locations, including the eye, central nervous system, and muscle.

Human sparganosis is caused by the larval stages of tape-
worms of the genus Spirometra, which are parasites of various canine and feline hosts; these tapeworms are closely related to the genus Diphyllobothrium. Sparganum larvae are elongated, ribbon-like larvae without a bladder and with a slightly ex-
panded anterior end lacking suckers. These larvae are usually found in superficial tissues or nodules, although they may cause ocular sparganosis, a more serious disease.

Finding prominent calcareous corpuscles in the tape-
worm tissue frequently supports the diagnosis of larval cestodes; specific identification usually depends on referral to specialists.

Nasopharynx and Sinus Cavities
Organisms that might be found in these body sites include the microsporidia, Acanthameba spp., and Naegleria. Specimens submitted for examination could include scrapings, aspirates, and/or biopsy specimens. A number of the special stains would include modified trichrome, acid-fast, and tissue Gram stains. Giemsa, calcofluor white, and regular trichrome stains would also be appropriate. If Naegleria or Acanthameba spp. are suspected, culture is highly recommended. In certain cases of mucocutaneous leishmaniasis, Leishmania spp. could also be found from these body sites; one of the blood stains would be recommended for confirmation in both aspirates and bi-
opsy specimens; cultures would also be an option (1).

Rectal Tissue
Often when a patient has an old, chronic infection or a light infection with Schistosoma mansoni or Schistosoma japonicum, the eggs may not be found in the stool and an examination of the rectal mucosa may reveal the presence of eggs. The fresh tissue should be compressed between two microscope slides and examined under the low power of the microscope (low-intensity light) (1). Critical examination of these eggs should be made to determine whether living miracidia are still found within the egg. Treatment may depend on the viability of the eggs; for this reason, the condition of the eggs should be reported to the physician.

Skin
The use of skin snips is the method of choice for the diagno-
sis of human filarial infections with O. volvulus and Manso-
ella streptocerca (1, 7). Microfilariae of both species emerge chiefly in the skin, although O. volvulus microfilariae may rarely be found in the blood and occasionally in the urine. Skin snip specimens should be thick enough to include the outer part of the dermal papillae. With a surgical blade, a small slice may be cut from a skin fold held between the thumb and forefinger, or a slice may be taken from a small “cone” of skin pulled up with a needle. Significant bleeding should not occur, and there should be just a slight oozing of fluid. Corneal-scleral punches (either Holth or Walser type) have been found to be successful in taking skin snips of uniform size and depth and an average weight of 0.8 mg (range, 0.4 mg to 1.2 mg); this procedure is easy to perform and is painless. In African onchocerciasis, it is preferable to take skin snips from the buttock region (above the iliac crest); in Central American onchocerciasis, the preferred skin snip sites are from the shoulders (over the scapula).

Skin snips are placed immediately in a drop of normal saline or distilled water and are covered so that they will not dry; teasing of the specimen with dissecting needles is not necessary but may facilitate release of the microfilariae. Microfilariae tend to emerge more rapidly in saline; how-
ever, in either solution, the microfilariae usually emerge within 30 min to 1 h and can be examined with low-
intensity light and the 10× objective of the microscope. To see definitive morphological details of the microfilariae, allow the snip preparation to dry, fix it in absolute methyl alcohol, and stain it with Giemsa or one of the other blood stains.

Skin biopsy specimens used for the diagnosis of cutaneous amebiasis (Entamoeba histolytica or Acanthameba spp.) and cutaneous leishmaniasis should be processed for tissue sec-
tioning and subsequently stained by the hematoxylin and eosin technique (21).

Although cutaneous disease is an unusual presentation for schistosomiasis, it does occur with skin lesions as the only manifestation. Based on routine histologic examination of皮肤 biopsies, eggs can be found in the cells usually emerge from within the lesion. When evaluating patients with unus-
ual skin lesions, a complete history may reveal travel to an area where schistosomiasis is endemic.

Material containing intracellular Leishmania organisms can be aspirated from below the ulcer bed through the unininvolved skin, not from the surface of the ulcer. The surface of the ulcer must be thoroughly cleaned before speci-
mens are taken; any contamination of the material with bacteria or fungi may prevent recovery of the organism from culture. Aspirated material is placed on a slide and stained with Giemsa or one of the blood stains.

Some prefer to perform a punch biopsy through the active margin of the lesion (after cleaning the lesion); good results have also been seen with the use of dermal scrapings from the bottoms of the ulcers. When microscopic examinations of dermal scrapings of both the ulcer bottom and active margins are combined, the sensitivity of diagnosis may increase to 94% (21). Aspirate culture has been shown to be the most sensitive method for the diagnosis of patients with chronic ulcers. However, any successful culture depends on the prevention of contamination with bacteria and/or fungi; sampling of the ulcers must be done correctly in order to prevent false-negative culture results.

**BLOOD**

Depending on the life cycle, a number of parasites may be recovered in a blood specimen, either whole blood or buffy coat preparations, or following concentration by various types of procedures. These parasites include *Plasmodium*, *Babesia*, and *Trypanosoma* species, *Leishmania donovani*, and microfilariae. Although some organisms may be motile in fresh, whole blood, species identification is usually accomplished from the examination of permanent stained thick and thin blood films. Blood films can be prepared from fresh whole blood collected with no anticoagulants, anticoagulated blood (EDTA is recommended; heparin is acceptable, but organism morphology is not as good; other anticoagulants are not recommended), or sediment from the various concentration procedures. Although for many years Giemsa stain has been the stain of choice, the parasites can also be seen on blood films stained with Wright’s stain, a Wright/Giemsa combination stain, or one of the more rapid stains such as Diff-Quik (American Scientific Products, McGaw Park, IL), Wright’s Dip Stat stain (Medical Chemical Corp., Torrance, CA), or Field’s stain. It is more appropriate for personnel to use a stain with which they are familiar rather than having to use Giemsa stain, which is somewhat more complicated to use. PMNs serve as the quality control cell for any of the blood stains. Any parasites present stain like the PMN nuclear and cytoplasmic material, regardless of the stain used. Delafield’s hematoxylin stain is often used to stain the microfilarial sheath; in some cases, Giemsa stain is not provide sufficient stain quality to allow differentiation of the microfilariae (Table 11).

When handling blood, as well as other clinical specimens, standard precautions should be observed (1, 4, 5, 22).

**Preparation of Thick and Thin Blood Films**

Microfilariae and trypanosomes can be detected in fresh blood by their characteristic shape and motility; however, specific identification of the organisms requires a permanent stain. Two types of blood films are recommended. Thick films allow a larger amount of blood to be examined, which increases the possibility of detecting light infections (1, 5, 12). However, only experienced workers can usually make species identification with a thick film, particularly in the case of malaria, and the morphological characteristics of blood parasites are best seen in thin films.

The accurate examination of thick and thin blood films and identification of parasites depend on the use of absolutely clean, grease-free slides for preparation of all blood films. Old (unscratched) slides should be cleaned first in detergent and then with 70% ethyl alcohol; new slides should additionally be cleaned with alcohol (use gauze, not cotton) and allowed to dry before use.

Thick and thin blood films should be handled on a STAT basis (ordering, collection, processing, examination, reporting). Blood films should be prepared when the patient is admitted or seen in the emergency room or clinic; typical fever patterns are frequently absent, and the parasite may not be suspected of having malaria. If malaria remains a possible diagnosis, after the first set of negative smears, samples should be taken at intervals of 6 to 8 h for at least 3 successive days. Often, after a day or two, other etiologic agents may be suspected and no additional blood specimens will be received. Another option is to collect blood immediately on admission; if the initial blood films are negative, collect daily specimens for 2 additional days (ideally between paroxysms if present; however, there is often no periodicity seen). Using either collection option, quality patient care depends on the fact that both the physician and laboratory staff know that one negative set of blood films does not eliminate *Plasmodium* spp. as possible etiologic agents.

After a finger stick, the blood should flow freely; blood that has to be “milked” from the finger is diluted with tissue fluids, which decrease the number of parasites per field. An alternative approach to the fingerstick is collection of fresh blood containing anticoagulant (preferably EDTA) for the preparation of blood films. Ideally, the smears should be prepared within 1 h after the specimen is drawn. After that time, stipping may not be visible on stained films and other morphologic changes will occur the longer the blood stands; however, the overall organism morphology may still be acceptable within 1 to 2 h.

The time that the specimen was drawn should be clearly indicated on the tube of blood and on the result report. The physician will then be able to correlate the results with any symptoms that the patient may have. There should also be some indication on the slip that is sent back to the physician that one negative specimen does not rule out the possibility of a parasitic infection.

**Thick Blood Films**

To prepare the thick film, place 2 or 3 small drops of capillary blood directly from the fingerstick (no anticoagulant) on an alcohol-cleaned slide. With the corner of another slide and using a circular motion, mix the drops and spread them over an area 2 cm in diameter. Continue stirring for 30 s to prevent the formation of fibrin strands that may obscure the parasites after staining. If blood containing an anticoagulant is used, 1 or 2 drops may be spread over an area about 2 cm in diameter; it is not necessary to continue stirring for 30 s, since there will be no formation of fibrin strands. If too much blood is used or any grease remains on the slide, the blood may flake off during staining. Allow the film to air dry (room temperature) in a dust-free area. Never apply heat to a thick film, since heat fixes the blood, causing the erythrocytes to remain intact during staining; the result is stain retention and an inability to identify the parasites. However, the thick films can be placed in a 37°C incubator for 10 to 15 min to dry; this seems to work quite well. Remember: do not make the films too thick; one should be able to see newsprint through the wet film prior to drying. After the thick films are thoroughly dry, they can be laked to remove the hemoglobin. To lake the films, place them in buffer solution before staining for 10 min or directly into a dilute, buffered aqueous Giemsa stain. If thick films are to be stained at a later time, they should be laked before storage (1). Although not as commonly used, other methods for the preparation of combination thick/thin blood films are available (1, 6).
Thin Blood Films

The thin blood film is routinely used for specific parasite identification, although the number of organisms per field is much reduced compared with the number in the thick film. The thin film is prepared exactly as one used for a differential count, and a well-prepared film is thick at one end and thin at the other (one layer of evenly distributed erythrocytes with no cell overlap). The thin, feathered end should be at least 2 cm long, and the film should occupy the central area of the slide, with free margins on both sides. Holes in the film indicate the presence of grease on the slide. After the film has air-dried (do not apply heat), it may be stained. The necessity for fixation before staining depends on the stain selected.

Staining Blood Films

For accurate identification of blood parasites, a laboratory should develop proficiency in the use of at least one good staining method (1, 8, 6, 10). Since prolonged storage may result in stain retention, blood films should be stained on the same day or within a few days of collection. If thick blood films are not prepared or received, it is possible to stain one of the thin blood films as a thick film and examine the thick portion of the thin film. During staining, the red blood cells are laked, thus leaving the white blood cells, platelets, and any parasites present.

Wright's stain has the fixative in combination with the staining solution, so that both fixation and staining occur at the same time; therefore, the thick film must be laked before staining. In aqueous Giemsa stain, the fixative and stain are separate; thus, the thin film must be fixed with absolute methanol before staining.

When slides are removed from either type of staining solution, they should be dried in a vertical position. After being air-dried, they may be examined under oil immersion by placing the oil directly on the uncovered blood film. If slides are going to be stored for a considerable length of time for teaching or legal purposes, they should be protected with a coverglass by being mounted in a medium such as Permount. Blood films that have been stained with any of the Romanowsky stains and that have been mounted with Permount or other resinous mounting media are susceptible to fading of the basophilic elements and generalized loss of stain intensity. An antioxidant, such as 1% (by vol) 2,6-di-butyl-4-methylphenol (butylated hydroxytoluene; Sigma-Aldrich), can be added to the mounting medium. Without the addition of this antioxidant, mounted stained blood films eventually become pink; stained films protected with this compound generally remain unchanged in color for many years.

Giemsa Stain

Each new lot number of Giemsa stain should be tested for optimal staining times before being used on patient

*Molecular techniques are still experimental and are not always available; it is always important to verify FDA approval within the United States (contact the manufacturer). For those working outside of the United States, there are many other commercially available immunoassays for malaria detection; however, numerous publications are available for those specifically listed in the table.

QBC-Blood Parasite Detection Method (Becton Dickinson Tropical Disease Diagnostics, Sparks, MD). This test is not licensed for diagnostic use in the United States. This test is a dipstick format.

ParaSight F-Rapid Test for P. falciparum malaria (Becton Dickinson Tropical Disease Diagnostics, Sparks, MD). This test is a dipstick format.

Binax Now Malaria (all four Plasmodium species) (Alere, Inc., Waltham, MA), Binax Now ICT Filariaisis (Wuchereria bancrofti) (Binax, Inc., Portland, ME). These tests are in a dipstick format, and positive controls are available for both tests.

PATH IC Falciparum malaria IC test (PATH, Seattle, WA). This test is in a dipstick format.

Filariaisis Ag-CELISA (Wuchereria bancrofti), Malaria Ag-CELISA (P. falciparum), Rapimail Dipstick (P. falciparum), Rapimail Cassette (P. falciparum) (Cellsabs, Sydney, New South Wales, Australia).

OptiMAL (differentiates between P. falciparum and P. vivax) (Flow, Inc., Portland, OR). This test is in a dipstick format.

TropBio (James Cook University, Townsville, Queensland, Australia).
specimens. If the blood cells appear to be adequately stained, the timing and stain dilution should be appropriate to demonstrate the presence of malaria and other parasites. The use of prepared liquid stain or stain prepared from the powder depends on personal preference; there is apparently little difference between the two preparations. The commercial liquid stain or the stock solution prepared from powder should be diluted approximately the same amount to prepare the working stain solution (1, 5).

Stock Giemsa liquid stain is diluted 1:10 with buffer for both thick and thin blood films, with dilutions ranging from 1:10 up to 1:50. Staining times usually match the dilution factor (e.g., 1:20 for 20 min or 1:50 for 50 min). Some people prefer to use the longer method with more dilute stain for both thick and thin films. The phosphate buffer used to dilute the stock stain should be neutral or slightly alkaline (pH 7.0 to 7.2). Phosphate buffer solution may be used to obtain the right pH. In some laboratories, the pH of tap water may be satisfactory and may be used for the entire staining procedure and the final rinse. Some workers recommend the use of pH 6.8 to emphasize Schüffner’s dots.

Giemsa stain colors the blood components as follows: erythrocytes, pale red; nuclei of leukocytes, purple with pale purple cytoplasm; eosinophilic granules, bright purple-red; and neutrophilic granules, deep pink-purple. In malaria parasites, the cytoplasm stains blue and the nuclear material stains red to purple-red. Schüffner’s dots and other inclusions in the erythrocytes stain red. The nuclear and cytoplasmic staining characteristics of the other blood parasites such as Babesia spp., trypanosomes, and leishmaniae are like those of the malaria parasites. While the sheath of microfilariae may not always stain with Giemsa, the nuclei within the microfilaria itself stain blue to purple.

Wright’s Stain
Wright’s stain is available in liquid form and a powder form, which must be dissolved in anhydrous, acetone-free methyl alcohol before use. Since Wright’s stain contains alcohol, the thin blood films do not require fixation before staining. Thick films stained with Wright’s stain are usually inferior to those stained with Giemsa solution. Great care should also be taken to avoid excess stain precipitate on the slide during the final rinse. Before staining, thick films must be laked in distilled water (to rupture and remove erythrocytes) and air-dried. The staining procedure is the same as that for thin films, but the staining time is usually somewhat longer and must be determined for each batch of stain. Wright’s stain colors blood components as follows: erythrocytes, light tan, reddish, or buff; nuclei of leukocytes, bright blue with contrasting light cytoplasm; eosinophilic granules, bright red; and neutrophilic granules, pink or light purple.

In malaria parasites, the cytoplasm stains pale blue and the nuclear material stains red. Schüffner’s dots and other inclusions in the erythrocytes usually do not stain or stain very pale with Wright’s stain. Nuclear and cytoplasmic staining characteristics of the other blood parasites such as Babesia spp., trypanosomes, and leishmaniae are like those seen in the malaria parasites. While the sheath of microfilariae may not always stain with Wright’s stain, the nuclei within the microfilaria itself stain pale to dark blue.

Other Stains for Blood
Although Giemsa and Wright’s stains are excellent options, the parasites can also be seen on blood films stained with a Wright/Giemsa combination stain or one of the more rapid stains such as Diff-Quik (American Scientific Products), Wright’s Dip Stat stain (Medical Chemical Corp.), or Field’s stain. PMNs serve as the quality control organism for any of the blood stains. Any parasites present stain like the PMNs, regardless of the stain used. Remember, when using any of the blood stains, that color variations are common.

Proper Examination of Thin and Thick Blood Films
In cases where malaria parasites have not been indicated as the suspect organism, the initial screen of the thin blood film should be carried out with the low-power objective of a microscope because microfilariae may be missed if the entire thin film is not examined. Microfilariae are rarely present in large numbers, and frequently, only a few organisms occur in each thin film preparation. Microfilariae are commonly found at the edges of the thin film or at the feathered end of the film because they are carried to these sites during the process of spreading the blood. This approach to thin film examination is particularly important in cases where a suspect organism has not been indicated. The feathered end of the film where the erythrocytes are drawn out into one single, distinctive layer of cells should be examined for the presence of malaria parasites and trypansomes. In these areas, the morphology and size of the infected erythrocytes are most clearly seen.

In the case of a suspected malaria diagnosis, the request for blood film examination should always be considered a STAT procedure, with all reports (negative as well as positive) being reported by telephone to the physician as soon as possible (1, 5). Examination of the thin blood film should include viewing of 200× to 300× oil immersion fields at a magnification of ×1,000. Although some people use a 50× or 60× oil immersion objective to screen stained blood films, there is some concern that small parasites such as Plasmodium spp., Babesia spp., or Leishmania donovani may be missed at this smaller total magnification (×500 or ×600), although they are usually detected at the total magnification of ×1,000 obtained with the more traditional 100× oil immersion objective. Because people tend to scan blood films at different rates, it is important to examine a minimum number of fields, regardless of the time that it takes to perform this procedure. If something suspicious has been seen in the thick film, often the number of fields examined on the thin film may be considerably greater than 200 to 300.

Diagnostic problems with the use of automated differential instruments have been reported (1). Both malaria and Babesia infections can be missed with these instruments, and therapy is therefore delayed. Because these instruments are not designed to detect intracellular blood parasites, any reliance on the automated systems for discrimination between uninfected erythrocytes and those infected with parasites may pose serious diagnostic problems.

In the preparation of a thick blood film, the greatest concentration of blood cells is in the center of the film. A search for parasitic organisms on the entire thick film should be carried out initially at low magnification (10× objective) to detect microfilariae more readily. Examination of a thick film usually requires 3 to 5 min (approximately 100 oil immersion fields). The search for malarial organisms and trypanosomes is best done under oil immersion (total magnification, ×1,000). Close examination of the very periphery of the thick film may reveal intact erythrocytes; such cells, if infected, may prove useful in malaria diagnosis, since the characteristic morphology necessary to identify the organisms to the species level is more easily seen.

Immunochromatographic Tests for Malaria
Immunochromatography relies on the migration of liquid across the surface of a nitrocellulose membrane. Using monoclonal antibodies prepared against a malaria antigen target
that has been incorporated onto the strip of nitrocellulose, these tests are based on the capture of parasite antigen from peripheral blood. Currently, the malaria antigens used for these rapid diagnostic tests are histidine-rich protein 2 (HRP-2), parasite lactate dehydrogenase (pLDH), and Plasmodium aldolase (Table 11). These dipsticks offer the possibility of more rapid, nonmicroscopic methods for malaria diagnosis. The tests are easy to perform and interpret; however, there are a number of questions that remain concerning the relevant uses for this type of testing, especially considering the fact that the Binax Now Malaria Test is now FDA approved (Alere, Inc, Waltham, MA). A positive-control specimen is also available.

Sensitivity remains a problem, particularly for nonimmune populations. Parasite densities of >100 parasites/μl (0.002% parasitemia) should be detected and are reasonable targets to expect from dipsticks for Plasmodium falciparum diagnosis. However, this level of sensitivity is at the lower end of the capability of most devices using capture methods for HRP-2 or pLDH. This level of sensitivity is probably as good as obtainable using contemporary laboratory staff in nonspecialized laboratories with limited exposure to malaria cases would expect to provide using microscopy diagnosis. One of the potential benefits would be for inexperienced evening staff for whom the dipstick identification of a life-threatening parasitemia could prevent a missed infection. However, a negative test could not be accepted and would require confirmation by microscopic examination of both thick and thin blood films for the detected parasite species below the present threshold of detection by these rapid tests. Also, there are false positives for patients with certain rheumatologic disorders; this is noted in the package insert and has been confirmed by users in this patient population. The U.S. military has conducted FDA-approved trials because of possible use of the devices in the field.

Concentration Procedures

Buffy Coat Films

*L. donovani*, trypanosomes, and *Histoplasma capsulatum* (a fungus with intracellular elements resembling those of *L. donovani*) may occasionally be detected in the peripheral blood. The parasite or fungus is found in the large mononuclear cells that are found in the buffy coat (a layer of leukocytes resulting from centrifugation of whole citrated blood). The nuclear material stains dark red-purple, and the cytoplasm is light blue (*L. donovani*). *H. capsulatum* appears as a dot of nuclear material (dark red-purple) surrounded by a clear halo area. Trypanosomes in the peripheral blood also concentrate with the buffy coat cells.

Use alcohol-cleaned slides for preparation of the blood films. A microhematocrit tube can also be used; the tube is carefully scored and snapped at the buffy coat interface, and the leukocytes are prepared as a thin film. The tube can also be examined prior to removal of the buffy coat under low and high dry powers of the microscope. If trypanosomes are present, the motility may be observed in the buffy coat. Microfilaria motility would also be visible.

QBC Microhematocrit Centrifugation Method

Microhematocrit centrifugation with use of the QBC malaria tube, a glass capillary tube and closely fitting plastic insert (QBC malaria blood tubes; Becton Dickinson Tropical Disease Diagnostics, Sparks, MD), has been used for the detection of blood parasites (1). At the end of centrifugation of 50 to 60 μl of capillary or venous blood (5 min in a QBC centrifuge, 14,387 × g), parasites or erythrocytes containing parasites are concentrated into a small, 1- to 2-mm region near the top of the erythrocyte column and are held close to the wall of the tube by the plastic float, thereby making them readily visible by microscopy. Tubes precoated with acridine orange provide a stain that induces fluorescence in the parasites. This method automatically prepares a concentrated smear that represents the distance between the float and the walls of the tube. Once the tube is placed into the plastic holder (Paraviewer) and immersion oil is applied onto the top of the hemocrit tube (no coverslip is necessary), the tube is examined with a 40× to 60× oil immersion objective (it must have a working distance of 0.3 mm or greater).

Although a malaria infection could be detected by this method (which is much more sensitive than the thick or the thin blood smear), appropriate thick and thin blood films need to be examined to accurately identify the species of the organism causing the infection.

Knott Concentration

The Knott concentration procedure is used primarily to detect the presence of microfilariae in the blood, especially when a light infection is suspected (1, 12). The disadvantage of the procedure is that the microfilariae are killed by the formalin and are therefore not seen as motile organisms. An alternative blood concentration is the citrate-saponin method, where microfilaria can be seen as actively motile organisms—until killed for staining with dilute acetic acid—and where they remain straightened out, which aids in detecting identification landmarks (23).

Membrane Filtration Technique

The membrane filtration technique is highly efficient in demonstrating filarial infections when microfilaremias are of low density. This method is unsatisfactory for the isolation of *Mansonella perstans* microfilariae because of their small size. A 3-μm-pore-size filter could be used for recovery of this organism. Other filters with similar pore sizes are not as satisfactory as the Nuclepore filter (1).

Delafield’s Hematoxylin

Some of the material that is obtained from the concentration procedures can be allowed to dry as thick and thin films and then stained with Delafield’s hematoxylin, which demonstrates greater nuclear detail as well as the microfilarial sheath, if present. In addition, fresh thick films of blood containing microfilariae can be stained by this hematoxylin technique (1).

Triple-Centrifugation Method for Trypanosomes

The triple-centrifugation procedure may be valuable in demonstrating the presence of trypanosomes in the peripheral blood when the parasitemia is light (1). After repeated centrifugation of the supernatant, the sediment is examined as a wet preparation or is stained as a thin blood film.

SUMMARY

This chapter covers various approaches and diagnostic methods currently in use for the diagnosis of parasitic infections. If clinical specimens have been properly collected and processed according to specific specimen rejection and acceptance criteria, the examination of prepared wet mounts, concentrated specimens, permanent stained smears, blood films, and various culture materials provides detailed information leading to parasite identification and confirmation of the suspected etiologic agent (1, 2, 4, 9, 12, 13, 20). Although other
tests, such as immunoassay diagnostic kits, continue to become available commercially, the majority of medical parasitology diagnostic work depends on the knowledge and microscopy skills of the microbiologist.

REFERENCES

Parasites

Plasmodium and Babesia*

BOBBI S. PRITT

Plasmodium and Babesia are intraerythrocytic protozoan parasites that cause malaria and babesiosis, respectively. Both organisms are transmitted through the bite of an infected arthropod and cause significant human morbidity and mortality worldwide. Although they differ in their epidemiology and life cycle, there is overlap between both clinical and diagnostic features of these two parasites, and for these reasons, they are discussed together in this chapter.

TAXONOMY

Plasmodium and Babesia are genera in the Haemosporida (aka Haemosporidia, Haemospororina, or Haemospororida) and Piroplasmida orders, respectively. They both belong to the phylum Apicomplexa, a large complex group of eukaryotic single-celled parasites characterized by a specialized apical complex of rhoptries, polar rings, micronemes, subpellicular microtubules, conoid, and an apicoplast (1). The apicoplast is a plastid organelle thought to have been acquired by an ancient secondary endosymbiosis of a red alga and its chloroplast. While the apicoplast resembles a chloroplast, it is not involved in photosynthesis and instead is thought to be involved in the synthesis of heme, lipids, and isoprenoids (1).

PLASMODIUM

Description of the Agent

Members of the Plasmodium genus infect a wide range of birds, mammals, reptiles, and amphibians worldwide using blood-feeding dipteran vectors (2). Despite there being at least 200 named Plasmodium species, only five regularly infect humans: P. falciparum, P. vivax, P. malariae, P. ovale, and P. knowlesi (3). These species designations were originally based on morphologic characteristics, with P. ovale being one of the last to be described due to its morphologic similarities to P. vivax (4). Recently, multilocus genetic analysis identified the presence of polymorphisms in P. ovale, leading to the description of classic and variant strains (5). It is now widely accepted that P. ovale actually comprises two distinct, closely related species that coexist in the same geographic regions without interbreeding (6). In order to avoid confusion with a new species designation, the names Plasmodium ovale curtisi and P. ovale wallikeri have been proposed for the classic and variant strains, respectively (5, 6).

P. knowlesi has only recently been recognized as a significant cause of zoonotic malaria in parts of Southeast Asia (7). This species predominantly infects macaque monkeys (genus Macaca) but has been reported as the cause of malaria in 27.7% of cases in Malaysian Borneo hospitals in one study (8), and it has been identified in patients from northwestern Singapore (9), southern Thailand (10), central Vietnam (11), and the Philippines (12). Individual cases have also been reported from western travelers to Southeast Asia, including individuals from Finland, Sweden, Austria, Spain, Great Britain, and the United States (7).

Epidemiology and Transmission

Malaria is arguably one of the most important infectious diseases in the world, with 3.4 billion people at risk of disease (3). According to the World Health Organization (WHO), recent worldwide malaria control efforts have produced a 29% reduction in malaria mortality globally between 2000 and 2012; however, there were still an estimated 207 million cases and 627,000 deaths in 2012 (3). Approximately 90% of deaths occur in sub-Saharan Africa, where a close link between malaria mortality and poverty is observed. Seventy-seven percent of deaths occur in children younger than 5 years of age.

Malaria is found primarily in the tropics and subtropics today (Table 1). However, it was once widespread throughout many temperate regions, including Europe and North America (13). The Plasmodium parasite is transmitted primarily through the bite of an infected Anopheles mosquito (Fig. 1) and competent mosquito vectors are found throughout the world. A list of countries with endemic malaria is available through the Centers for Disease Control and Prevention (CDC) Yellow Book (14). Today, cases of malaria in the United States and Europe are almost exclusively imported from individuals traveling from countries with ongoing malaria transmission, although occasional autochthonous cases have been reported (15–18). In the United States, the majority of imported malaria is detected in individuals who travel to endemic countries to visit friends and relatives (VFRs) (19). These individuals often do not

*This chapter contains information presented by William O. Rogers in chapter 133 of the 10th edition of this Manual.

doi:10.1128/9781555817381.ch136

2338
consider themselves at risk for malaria and may not seek travel advice from their physician or take malaria prophylaxis. In 2011, 1,925 cases of malaria were reported in the United States by the CDC (19), with 70% of cases being reported in VFRs. Less common means of malaria transmission are via blood transfusion and across the placenta to the developing fetus. In 2011, the CDC detected one transfusion-related case of malaria in the United States (19), with 70% of cases being reported in VFRs.

Less common means of malaria transmission are via blood transfusion and across the placenta to the developing fetus. In 2011, the CDC detected one transfusion-related case of malaria in the United States (19), with 70% of cases being reported in VFRs.

**Clinical Significance**

Patients are asymptomatic for the initial 7- to 30-day incubation period during which parasites replicate in the liver (21). It is only with subsequent infection and destruction of host erythrocytes that parasite antigens such as glucose phosphate isomerase are released into the blood and stimulate cytokine production and resultant fever. The classic malarial fever paroxysm begins with rigors and chills, followed by an abrupt onset of fever which lasts for 1 to 2 hours. The paroxysm resolves with profuse sweating and a return to normal temperature. With time, infected cells may begin to rupture in synchrony, producing the classic (but infrequently observed) “tertian” or “quartan” fever cycles (Table 1). Fever is commonly preceded or accompanied by severe headache, malaise, and myalgia (21).

Infection can range from mild or asymptomatic disease, usually in individuals with pre-existing immunity, to severe, life-threatening disease. Severe malaria is defined by WHO criteria (22) and includes features such as unarousable coma, generalized convulsions, respiratory distress, hypoglycemia, circulatory collapse, renal failure, and hyperparasitemia (greater than 100,000 parasites/μl of blood). Young children,

\(^b\)Information is lacking due to the limited number of reported human cases.
FIGURE 1 The Plasmodium parasite is transmitted to humans when an infected female Anopheles mosquito takes a blood meal and inoculates sporozoites into the bloodstream (1). Sporozoites infect hepatocytes (2) and undergo asexual reproduction to form schizonts (3) in a process called exoerythrocytic schizogony (A). After 5 to 15 days, liver schizonts rupture to release hundreds of thousands of merozoites into the blood (4) which then infect erythrocytes (5). *P. vivax* and *P. ovale* have a dormant hypnozoite stage, which may remain in the liver and cause relapsing disease weeks to months later, while other human Plasmodium species do not have this stage. In erythrocytes, merozoites undergo asexual reproduction to form trophozoites and then schizonts in a process called erythrocytic schizogony (B). Schizonts rupture to release merozoites, which then infect other erythrocytes (6). This process is repeated every 1 to 3 days, resulting in the production of thousands to millions of infected erythrocytes in several days. Some merozoite-infected erythrocytes do not undergo asexual reproduction but instead develop into male microgametocytes and female macrogametocytes (7). When ingested by a female Anopheles mosquito during a blood meal (8), microgametocytes exflagellate to release microgametes, which penetrate macrogametes and form zygotes (9) via sexual reproduction in the sporogonic cycle (C). Zygotes become motile and elongated to form ookinetes (10) which invade the mosquito’s midgut wall and develop into oocysts (11). Over a period of 8 to 15 days, oocysts grow, rupture, and release thousands of sporozoites (12), which travel to the mosquito’s salivary glands to be inoculated into a new human host during the mosquito’s next blood meal (1). Life cycle courtesy of the CDC DPDx (http://www.cdc.gov/dpdx/). doi:10.1128/9781555817381.ch136.f1

nonimmune individuals, and pregnant women and their fetuses are at greatest risk of severe disease (3).

*P. falciparum* infection has the highest morbidity and mortality of the four human Plasmodium species, being responsible for nearly all cases of severe malaria and malaria deaths worldwide (21). The high morbidity and mortality of *P. falciparum* infection is attributed in part to the parasite’s ability to infect and destroy all stages of erythrocytes, leading to high levels of parasitemia and resultant severe anemia, splenomegaly, and jaundice. In contrast, the other Plasmodium species preferentially infect older erythrocytes (*P. malariae*) or young erythrocytes (*P. vivax* and *P. ovale*) and cause a lesser degree of total erythrocyte destruction (21).

*P. falciparum* virulence is also attributed to a phenomenon called cytoadherence, accomplished through insertion of parasite-derived adhesion molecules from the *P. falciparum* erythrocyte membrane protein 1 (PFEMP1) family onto the surface of infected erythrocytes during later stages of parasite development. The PFEMP1 molecules allow for clumping of uninfected erythrocytes around infected erythrocytes (rosetting) and receptor-mediated cytoadherence of infected erythrocytes to endothelial cells (sequestration).
(23). Accumulation of infected erythrocytes within the microvasculature is associated with metabolic acidosis, hypoxia, and release of detrimental inflammatory cytokines, particularly in the lung, kidney, and brain. During pregnancy, a special form of cytoadhesion occurs between infected erythrocytes and syncytiotrophoblasts in the placenta (23). Symptoms resulting from the high P. falciparum parasitemia and sequestration in the microvasculature include acute renal failure, respiratory distress, abortion, intratrunein growth retardation, mental status changes, coma, and death. Other Plasmodium species do not sequester and generally cause less severe disease (21).

Additional species-associated manifestations include splenic rupture (P. vivax), nephrotic syndrome (P. malariae in children), hypoglycemia (P. falciparum in children), extensive erythrocyte destruction with hemoglobinuria and kidney failure (“blackwater fever,” P. falciparum), recrudescence disease (P. malariae), and relapses due to reactivation of hypnozoites in the liver (P. ovale and P. vivax) (21). Fatal cases have also been reported in infections with P. knowlesi. Given that Plasmodium infection can cause a diverse spectrum of symptoms, including gastrointestinal and respiratory manifestations, it is essential that malaria be considered in the differential diagnosis for anyone with fever and recent exposure to malaria-endemic areas.

Collection, Transport, and Storage of Specimens

Since P. falciparum infection can cause rapidly progressive, fatal disease, blood collection and testing for malaria should always be performed on a STAT basis (24, 25). Preparation of thick and thin blood films is considered the gold standard for diagnosis of malaria. If a laboratory does not have the expertise to perform examination of thin and thick blood films, then consideration should be given to use of rapid antigen tests for preliminary screening (see "Diagnosis" below) or rapid transport to a neighboring laboratory that can receive and test the blood shortly after it is drawn. Testing options for malaria should be available 7 days a week on a 24-hour basis (25).

Blood is ideally collected via finger prick with immediate (bedside) preparation of thick and thin smears. However, it is more common in nonendemic settings to collect blood by venipuncture for rapid transport to the laboratory (25). EDTA is the preferred anticoagulant, as the use of other anticoagulants such as heparin may cause significant parasite distortion (25). Prolonged storage in EDTA may also cause parasite distortion, parasite maturation into sexual life cycle stages, and loss of diagnostic features such as stippling; therefore, blood films should be prepared within 1 hour of collection (25, 26). A single set of blood films may be insufficient to detect Plasmodium parasites. The Clinical and Laboratory Standards Institute (CLSI) recommends preparation of two thin and two thick blood films on initial evaluation of the patient, with preparation of repeat films every 6 to 8 hours if necessary for up to 3 days before excluding malaria from the clinical differential diagnosis (25).

Additional EDTA whole blood may be refrigerated for supplemental testing such as PCR if necessary. Unfortunately, parasite morphology rapidly degrades in stored blood and is not usually adequate for later identification or for species identification by morphologic methods. Chapters 133 and 135 of this Manual and the CLSI guidelines for diagnosis of blood-borne parasites (25) provide detailed directions for collecting and preparing blood films. Requests for blood films should be accompanied by important patient information such as clinical signs and symptoms, travel history, and receipt of malaria chemoprophylaxis or therapeutic antimalarial agents, which might suppress parasitemia or alter parasite morphology.

Direct Examination

Microscopy

Giemsa-Stained Blood Films

Microscopic examination of Giemsa-stained thick and thin blood films is the traditional method for malaria diagnosis. Accurate interpretation of this time-honored method relies on the availability of trained and experienced microscopists, high quality reagents, and well-maintained light microscopes. The thick film contains 1 to 2 drops of blood that have been lysed (killed) on the slide by placement into a hypotonic solution (25). This releases intracellular parasites and allows for examination of 20 to 30 layers of blood. The thick blood film is approximately 10 to 20 times more sensitive than the thin film, with a reported detection threshold of 10 to 50 parasites/μl of blood, or approximately 0.0002 to 0.001% parasitemia, assuming a total erythrocyte count of 5 × 10^12/μl of blood (27). Given this high sensitivity, the thick film is ideal for screening and parasite detection. Under field conditions, the estimated sensitivity may be somewhat lower (100 to 500 parasites/μl of blood) (27, 28).

Given the greater sensitivity of the thick film compared to the thin film, efforts should be made to quickly prepare and examine the thick film so that it can be used as the primary screening method. A common mistake is to use too much blood on the slide, thus requiring longer times for the film to dry. A well-made thick film should be approximately 1.5 to 2.0 cm in diameter and of a thickness through which newprint can barely be read (25). Drying of the thick film can be enhanced by placing the slides in a laminar flow hood or under the gentle breeze from a fan. Exposure to heat is not recommended since it may cause fixation of the blood and interfere with the laking process (25). Gently scratching grooves into the carrier slide with the edge of another glass slide while spreading the blood to the appropriate diameter will facilitate adhesion to the slide and obviate the need for extended drying times without negatively affecting the microscopic morphology (29); films may be safely stained as soon as the film is visibly dry.

Thin films are made in the same manner as hematologic blood films. A single drop of blood is spread on the slide in such a manner as to produce a feathered edge. The films are then fixed in methanol prior to staining.

Staining of thick and thin films is best performed with Giemsa at a pH of 7.0 to 7.2 to highlight potential stippling and other features of the parasites (25) (see chapter 134 for further information on malaria stains). Wright-Giemsa and the rapid Field stain may also be used. After staining, a well-prepared thick film should have a relatively clean background of lysed erythrocytes, leukocyte nuclei, and platelets, while thin films will demonstrate pale blue-gray to light pink erythrocytes and a well-formed feathered edge. Parasites will have pale to deep blue cytoplasm and pink-red chromatin (25).

Both thick and thin slides should first be screened at low power using the 10× objective for identification of microfilariae, followed by examination under oil immersion with the 100× objective (25). Examination of 200 to 300 microscopic fields on thick and thin films using the 100× objective should be performed before reporting a specimen as negative (25). Considerable practice is required to accurately differentiate parasites from platelets, stain debris, and
FIGURE 2  *Plasmodium* morphology on thick blood films encompasses the entire spectrum of forms including trophozoites, schizonts, and gametocytes. Shown are *P. falciparum* early trophozoites in a moderate (1) and heavy (2) infection; *P. vivax* early trophozoites (3); *P. malariae* (4) and *P. vivax* (5) schizonts; and *P. falciparum* (6), *P. malariae* (7), and *P. vivax* (8) gametocytes. Neutrophils are shown for size comparison in panels 4 and 7. (Giemsa, ×1,000.) doi:10.1128/9781555817381.ch136.f2

leukocyte granules on the thick film (Fig. 2), but the additional training effort is rewarded by the increased sensitivity that this method provides. The species of the infecting organism can be determined using the thick film, but this is best accomplished using the thin film. Thin films provide ideal erythrocyte and parasite morphology for species determination since they are fixed in methanol prior to staining, thus maintaining the structure of the erythrocytes and intraerythrocytic parasites (25). The area of the thin film that provides optimal parasite morphology is where the erythrocytes have minimal overlap and maintain their central pallor (Fig. 3), parasites outside of this region may be considerably distorted. Species determination is made using a number of morphologic features including the size and shape of the infected erythrocyte, presence of intracytoplasmic inclusions (e.g., stippling), stages of the parasite present in peripheral blood, and specific characteristics of each parasite stages (Table 2 and Fig. 4 through 8). Atlases

FIGURE 3  The ideal location for microscopic examination of a thin film is the region of the feathered edge where the erythrocytes have minimal overlap and maintain their central pallor (middle). In this location, the erythrocyte infected with *P. ovale* is clearly enlarged and ovoid. When examining similar cells in regions of the film that are too thin (left) or thick (right), the morphology is distorted and may be misleading. doi:10.1128/9781555817381.ch136.f3
and other resources are widely available for differentiating the various Plasmodium species (24, 30–33).

The size of the infected erythrocytes is a particularly important feature for determining the infecting Plasmodium species, since enlarged infected erythrocytes are characteristic of P. ovale and P. vivax infection, particularly in the later parasite stages, while small to normal-sized infected erythrocytes are characteristic of P. malariae and P. falciparum infection. Thus, the size of the infected cell can quickly allow the microscopist to halve the number of species in the differential diagnosis. The presence of Schüffner’s stippling supports the diagnosis of P. ovale and P. vivax infection. Care must be taken, however, not to confuse the finer Schüffner’s dots with the larger, coarser Maurer’s clefts that may occur in P. falciparum infections. Stippling and Maurer’s clefts are most commonly seen when smears are made shortly after blood collection and the pH of the Giemsa stain is 7.0 to 7.2. The life cycle stages present are also very useful for identification of species. Infection with P. falciparum usually consists solely of early trophozoites (“rings”) and, less commonly, gametocytes; intermediate stages (mature trophozoites and schizonts) are only rarely seen since they are sequestered in the microvascular beds. When intermediate stages of P. falciparum are present, they may indicate severe, overwhelming infection. In contrast to P. falciparum, a spectrum of forms including late-stage trophozoites and schizonts are commonly seen with other species. When examining peripheral blood films, it is important to remember that mixed malaria infections are not uncommon.

bIdentification of P. malariae in patients with recent travel to Southeast Asia should raise the possibility of P. knowlesi infection, given the morphologic similarities of these two parasites. In this situation, severe clinical disease and a high parasite burden are consistent with P. knowlesi infection.
and that *P. falciparum* may be found in conjunction with less virulent species in the same patient. It is also important to remember that other microorganisms may be seen on peripheral blood films such as *Babesia* intraerythrocytic parasites (see *Babesia* section below) and extracellular microfilariae (chapter 144), trypanosomes (chapter 137), and *Borrelia* spirochetes (chapter 59). Intraleukocytic Ehrlichia/Amplyzma morulae may also be seen on the peripheral blood film, although this is not the preferred method for detection of these bacteria (chapter 65).

When *Plasmodium* species are identified, it is important to quantify the degree of parasitemia to help guide initial ther-
apy, predict patient prognosis, and monitor response to treatment. This may be done using either the thin or thick film, and formulas for this purpose are widely available (24, 25, 31, 32, 34). When using the thick film for quantitation, it is common practice to express the number of parasites in relation to a standard number of leukocytes per microliter of blood (8,000/μl), although it is preferable to substitute the patient’s actual leukocyte count when known. Results are reported as the number of parasites per microliter of blood. When using the thin film, results are reported as the percentage of infected erythrocytes in the fields examined (number of infected cells counted/total number of erythrocytes counted × 100). When calculating the degree of parasitemia with either the thick or thin film, it is important to not include parasite sexual stages.

FIGURE 6  *P. vivax*, successive developmental stages in Giemsa-stained thin blood films: early stage trophozoite/ring (1), maturing ring (2), mature amoeboid trophozoites (3, 4), mature schizonts (5, 6), macrogametocyte (7), microgametocyte (8). Note the Schüffner’s dots (2, 4, 6, 8) and frequent molding of infected cells to neighboring erythrocytes. The infected erythrocytes are slightly larger than noninfected cells. doi:10.1128/9781555817381.ch136.f6

FIGURE 7  *P. ovale*, successive developmental stages in Giemsa-stained thin blood films: early stage trophozoite/ring (1, 2), developing trophozoite (3), mature trophozoite with “comet cell” morphology (4); early stage schizont (5), mature schizont (6), macrogametocyte (7), microgametocyte (8). Note the Schüffner’s dots (3, 4, 8) and oval/elongated shape of the infected cells (4, 6, 8). The infected erythrocytes are slightly larger than noninfected cells. doi:10.1128/9781555817381.ch136.f7

(Images reproduced from figures in reference 33 with permission.) doi:10.1128/9781555817381.ch136.f8

Other Microscopy Methods

Other microscopic methods are less commonly used for the identification of malaria parasites in whole blood, including stains for nucleic acid and hemoglobin (Table 3). Of these, the most commonly used is acridine orange (AO), a DNA-binding fluorescent dye that is excited at 490 nm, producing a yellow or apple-green fluorescence (28). Use of this method requires a fluorescence microscope or light microscope with appropriate adaptor. Identification of infected cells is relatively straightforward since mature erythrocytes lack DNA and do not produce a fluorescent signal, while parasites contain DNA and fluoresce brightly. However, leukocyte nuclei and Howell-Jolly bodies within erythrocytes will also fluoresce, occasionally making identification of low parasite levels challenging. A number of studies found AO staining to have a similar sensitivity and specificity to traditional Giemsa-stained thick films, with the ability to reliably detect <100 parasites/μl or 0.002% parasitemia (28). This method may also allow for more rapid screening than with traditional Giemsa-stained films (27, 28, 35). Another technique that uses

(gametocytes) in the total count since they are not infectious to humans and are not killed by most antimalarial drugs. With the thin film, it is also important to count consecutive fields, even if they do not include parasites, and not to count extracellular parasites. Multiply infected erythrocytes are only counted as a single infected cell. Regardless of the method used for calculating the degree of parasitemia, it is important to use the same method for initial and post-treatment specimens (28). Given the possibility of inter-observer variability, it may be prudent to limit the number of individuals performing the assessment on sequential specimens from the same patient.

*AO, acridine orange; BCP, benzothiocarboxypurine; FFPE, formalin-fixed, paraffin-embedded; HRP-2, histidine-rich protein 2; LDH, lactate dehydrogenase; QBC, quantitative buffy coat; WBC, white blood cell.*

AO staining is the quantitative buffy coat or QBC (QBC Diagnostics, Becton Dickinson, Port Matilda, PA). In this method, whole blood is stained with AO and spun in a micro-hematocrit tube. The buffy coat layer in the microcentrifuge tube is then directly examined using a fluorescence microscope with a specialized long-focal-length objective (28).

Rarely, malaria pigment (hemozoin) is detected via dark-field microscopy or in histologic tissue sections. In tissue sections, the pigment is concentrated within infected sequestered erythrocytes and macrophages in the capillaries of infected organs such as the lung, kidney, liver, brain, and placenta (Fig. 9).

**Antigen Detection**

Within the past decade, there has been a marked expansion of commercially available immunochromatographic tests for rapid detection of *Plasmodium* antigens (28, 36, 37). These tests, commonly referred to as rapid diagnostic tests (RDTs), are rapid and relatively easy to use, and many...
are stable in field conditions (36). They now form an integral part of the WHO’s strategy for combating malaria worldwide (36).

The antigens detected by the commercially available RDTs are parasite lactate dehydrogenase (pLDH), histidine-rich protein 2 (HRP-2), and Plasmodium aldolase (31). Some tests specifically detect *P. falciparum* and/or *P. vivax*, while others offer only pan-Plasmodium results. There are no specific tests for *P. ovale*, *P. malariae*, or *P. knowlesi* (37). At this time, the only FDA-approved RDT is the BinaxNow Malaria Test (Alere, Inc., Waltham, MA), which targets *P. falciparum* HRP-2 antigen and a pan-malarial antigen.

In general, malaria RDTs perform almost as well as microscopy for detection of *P. falciparum* at moderate or high parasite levels, but suffer from lower sensitivity for detection of non-*P. falciparum* infections and low levels of parasitemia for all species (28, 37). While parasite levels of 100 parasites/μl (0.002% parasitemia) are commonly seen in the clinical setting, many RDTs cannot reliably detect parasites at this level, even when the infecting species is *P. falciparum* (28, 37). The WHO, the Foundation for Innovative New Diagnostics (FIND), and the Special Programme for Research and Training in Tropical Diseases (TDR) launched a massive study in 2006, comparing commercially RDTs for their ability to detect *P. falciparum* and *P. vivax* at high (2,000 to 5,000 parasites/μl) and low (200 parasites/μl) concentrations (36). The publication of their most recent results, containing data on over 120 RDTs, demonstrates that RDT performance varies widely by kit, manufacturer, and even lot number (36). In these studies, the FDA-approved BinaxNow Malaria Test had 100% sensitivity for detection of *P. falciparum* at high levels but sensitivities of 91.1, 85, and 10% for detection of *P. falciparum* at low levels, *P. vivax* (high levels), and *P. vivax* (low levels), respectively (36). As with many immunochromatographic assays, false positives may be observed in the presence of autoantibodies such as rheumatoid factor. Antibodies can be detected for days after successful treatment; therefore, RDTs should not be used to monitor outcomes of treatment (37).

Given the limitations of RDTs, it is widely recommended that all results be confirmed with standard thick and thin blood films (28, 31). In nonendemic settings such as the United States and Europe, laboratories that may benefit from RDT use include those that lack the expertise to interpret traditional blood films or desire a more rapid diagnostic method for general or point-of-care testing (38–40). Rapid diagnostic tests may be particularly beneficial in STAT laboratories and during the evening shift, where expertise for sensitive detection of blood parasites using thick films is lacking; in these settings, the ability to immediately detect cases with high *P. falciparum* parasitemia may be life-saving.

**Nucleic Acid Detection**

Most nucleic acid detection methods use PCR for nucleic acid amplification and detection of *Plasmodium* parasite DNA, with the 18S small subunit rRNA gene being the most common target. Numerous assays have been described, including conventional (12, 41, 42) and real-time PCR (43–47) formats for *Plasmodium* detection, species differentiation (including *Plasmodium ovale* curtisi and *P. ovale* wallikeri), and identification of parasite resistance markers to antimalarial drugs (see “Antimicrobial Susceptibilities” below). Most PCR assays are laboratory developed, although some commercial tests exist; unfortunately, none of these has been approved or cleared by the FDA.

Although there is tremendous variability between published assays, PCR-based tests are generally recognized as having improved sensitivity over the traditional thick film, with detection limits below 10 parasites/μl of blood. A quantitated *P. falciparum* standard is available through the WHO (48) which can be used to determine the analytical sensitivity of new and existing molecular assays.

Tests for detection of *Plasmodium* nucleic acid are primarily limited to specialized reference or public health laboratories and are not generally suited for rapid diagnosis in the clinical setting. However, they may be useful for detection of low parasitemia, confirmation of suspected infection, differentiation of *Plasmodium* from Babesia parasites, *Plasmodium* species determination, and sensitive detection of mixed infections (31).

Despite the potential advantages of PCR assays, implementation in endemic resource-limited settings poses many challenges due to the associated expense and need for highly specialized equipment and facilities. Fortunately, isothermal amplification techniques, such as nucleic acid sequence-based amplification (NASBA) and loop-mediated isothermal amplification (LAMP), offer simpler and less expensive tests for detection of *Plasmodium* DNA and RNA, respectively (49, 50). One recently described innovative electricity-free system utilizes a calcium oxide-based heat-generating reaction within an improvised insulated container for malaria LAMP testing (51). Other methods of *Plasmodium* nucleic acid amplification that may be suitable for resource-limited settings include nucleic acid lateral flow immunoassay (NAL-IFA) (52) and PCR-based enzyme-linked immunosorbent assay (PCR-ELISA) (53). Further studies are needed to determine the performance characteristics of these alternative assay designs in a variety of clinical settings.

When positive results are obtained with malaria nucleic acid tests, thick or thin blood films should be examined so that the percent parasitemia can be determined. Quantitative PCR may one day replace the subjective manual parasite counts that suffer from lack of inter-observer reproducibility. Unfortunately, quantitative PCR results do not correlate well with the conventionally obtained percent parasitemia. This is because conventional counts do not include gametocytes and extracellular forms, and multiply infected cells are only counted once; in contrast, PCR will detect nucleic acid from each parasite in the specimen.
Serologic Tests
Serologic testing plays little role in diagnosis of acute malaria given that antibodies are frequently absent at the time of patient presentation. Also, a positive test indicates previous exposure but does not differentiate between acute and past infection. For these reasons, serology has its greatest utility in epidemiologic studies, blood donor screening (54), and occasionally for evaluating relapsing, recrudescence, or untreated malaria in nonimmune patients. Indirect fluorescent antibody (IFA) tests using antigens prepared from the four human Plasmodium species have been previously described (55, 56) and are available at specialized testing facilities. These tests are time-consuming and subjective but are highly sensitive and specific.

Other Diagnostic Laboratory Methods
Other nonconventional techniques for laboratory diagnosis include laser-desorption mass spectrometry (57) for detection of hemozoin in whole blood, and recently, detection of hemozoin-generated vapor nanobubbles across intact skin (58). These techniques hold promise for rapid and affordable malaria testing in the future.

Antimicrobial Susceptibilities
Parasite resistance to antimalarial medications is a serious problem worldwide (59). Chloroquine was a mainstay of treatment and prophylaxis for many years, but due to widespread P. falciparum resistance, it has been supplanted with other drugs such as atovaquone-proguanil (Malarone), doxycycline, and sulfadoxine-pyrimethamine (59–61). Chloroquine-susceptible P. falciparum is now only found in Mexico, the Caribbean, and parts of the Middle East and Central America (59). P. falciparum resistance to mefloquine and sulfadoxine-pyrimethamine, as well as P. vivax tolerance to chloroquine and primaquine, has also been detected in some endemic regions (59, 62). Only rare instances of quinine resistance have been reported, allowing this drug to remain a therapy for severe malaria (63, 64). Artemisinin compounds (e.g., artesunate, arteether) have been recognized as superior drugs for both malaria treatment and are now recommended by the WHO as first-line therapy, in combination with other antimalarial agents, for both uncomplicated and complicated disease (65). Unfortunately, decreased in vitro susceptibility to artesunate has been detected in P. falciparum strains along the Thai-Cambodian border, a historic site for emerging resistance to antimalarial agents (66). Containment interventions are urgently needed to prevent global spread of these partially resistant P. falciparum artesinin-resistant strains.

Detection of antimalarial resistance may be performed using in vitro susceptibility testing (67), although this method is not available clinically. A more practical approach is through molecular detection of single-nucleotide polymorphisms that have been associated with antimalarial resistance, such as dhps/dhpt (sulfadoxine-pyrimethamine), Pfcr (chloroquine), pfmdr (chloroquine, mefloquine, and quinine), and pfATP6e6/pfmdr (artesinin) (62), using PCR (47) and DNA microarray formats (64, 68).

Evaluation, Interpretation, and Reporting of Results
Detection of malaria parasites by any diagnostic method is considered a critical result and must be reported to the clinical team immediately. The final report for blood smear evaluation should include the Plasmodium species and calculated degree of parasitemia. It is important to convey when a mixed infection or late stage forms of P. falciparum are suspected, since these findings may have treatment implications. Similarly, parasite load above 100,000 parasites/μl (approximately 2% parasitemia) in nonimmune individuals is indicative of severe disease requiring urgent therapy (69), while parasite levels above 10% suggest a role for exchange transfusion (70). It may be useful to relay to the clinical team that a single set of negative blood films does not exclude the diagnosis of malaria and that serial smears should be performed if clinically indicated (25).

Asexual forms of the parasites may be seen in repeat blood films for 2 to 3 days following appropriate treatment. If the level of parasitemia does not fall by 75% in the first 48 hours of treatment or parasites are still present after day 3, then parasite resistance or lack of patient compliance with treatment should be considered. Gametocytes may circulate for 2 weeks or more, since they are not killed by most antimalarial drugs, and therefore should be excluded from the parasite count or reported separately.

If expertise for Plasmodium species determination or differentiation between Plasmodium and Babesia parasites is not available in the primary laboratory, it is important to inform the clinician that Plasmodium or Babesia parasites are identified and that blood and/or films are being sent to a reference or public health laboratory for further analysis. It is important to mention in the preliminary report that the potentially deadly P. falciparum cannot be excluded.

BABESIA

Description of the Agent
Members of the genus Babesia infect a wide range of wild and domestic animals worldwide using primarily ixodid tick vectors (71, 72). Despite there being more than 100 named Babesia species, only a few are known to regularly infect humans (72). Babesia microti is responsible for the vast majority of human cases in the U.S. Infection with B. duncani and B. duncani-like organisms have also been reported in Washington, Oregon, and California (73–75), and rare cases of B. divergens-like organisms have been detected in Kentucky, Missouri, and Washington state (72, 76). In Europe, B. divergens causes the majority of cases, with fewer cases attributable to B. venatorum and B. microti (77–80). Elsewhere a number of different Babesia species have been detected in humans, including B. microti-like organisms in Taiwan (81) and Japan (82), a new Babesia sp., the KO-1 strain, in South Korea (83), and uncharacterized species in Mexico, Brazil, Columbia, Egypt, Mozambique, South Africa, China, and India (72). Rare unverified human cases have also been attributed to B. canis and B. bovis (84).

Traditionally Babesia species were classified into small and large forms based on size, with B. microti and B. divergens being considered small form species (trophozoites <2.5 μm) (77). More recently, genetic analysis of the 18S rRNA gene has been used to clarify Babesia phylogeny and divide the piroplasms into four to five clades (77, 85). This analysis shows that B. microti and B. divergens are not closely related and they are now assigned to different clades (85).

Epidemiology and Transmission
In contrast to malaria, babesiosis is a disease of the temperate regions, including parts of North America and Europe. In the United States, classic hot spots for babesiosis due to B. microti include the northeastern coast (e.g., Martha’s Vineyard, Nantucket, and Long Island), upper Midwest states, and areas of the Atlantic and South-Central states, while a small number of cases due to other Babesia species...
have been described in Missouri, Kentucky, Washington, Oregon, and California (72). National U.S. surveillance was begun in 18 states where babesiosis is endemic and New York City on 1 January 2011 (86), with 1,124 probable and confirmed cases reported in the first year. The majority of cases were reported by just seven states; in order of increasing numbers of cases, these were Minnesota, Rhode Island, Connecticut, Wisconsin, New Jersey, Massachusetts, and New York. The majority of patients were ≥60 years of age (range 1 to 98 years) and most did not recall a tick bite (86). Given that most infections with Babesia are asymptomatic, the actual number of infections is probably much greater than reported.

Significantly fewer cases of babesiosis have been reported in Europe. To date, 30 or more cases of babesiosis due to *B. divergens* have been reported, primarily from patients in France, Great Britain, and Ireland, while only sporadic cases of babesiosis due to *B. venatorum* and *B. microti* infection have been documented (72, 77). *B. divergens* is primarily a bovine babesiosis that has a significant economic impact on the livestock industry (87).

Most cases of babesiosis are acquired through the bite of an infected ixodid tick (Fig. 10). In nature, disease is maintained between invertebrate and vertebrate hosts. Humans readily become infected but are considered dead-end hosts. *Ixodes scapularis* (the blacklegged or deer tick) and *Ixodes ricinus* (the castor bean tick or sheep tick) are the most common vectors in the U.S. and Europe, respectively. The primary vertebrate host in the life cycle of *B. microti* in the U.S. is the white-footed mouse, *Peromyscus leucopus*, and other rodents and shrews may serve as the host for *B. microti* cases in Europe. The primary hosts for *B. divergens* and *B. venatorum* in Europe are cattle and deer, respectively. Following a tick bite, Babesia sporozoites enter the blood and directly infect circulating erythrocytes to form trophozoites resembling malarial parasites. There is no liver stage as seen in malaria and thus no latent exoerythrocytic forms. Trophozoites divide asexually via budding, rather than schizogony as in malaria, to form similar-appearing merozoites and gametocytes (84). Lysis of infected erythrocytes releases merozoites into the blood, where they infect new erythrocytes. As with malaria, sexual reproduction with fertilization of the gametes occurs in the gut of the arthropod host. Fertilized gametes migrate across the intestinal wall and travel to the salivary glands to develop into sporoblasts.

**FIGURE 10** Babesia microti life cycle. The normal zoonotic life cycle involves a rodent (primarily *Peromyscus leucopus*, the white-footed mouse) and an *Ixodes* tick. The rodent becomes infected when an infected tick introduces *B. microti* sporozoites when taking a blood meal (1). Sporozoites enter the rodent erythrocytes and most undergo asexual reproduction (2), while some differentiate into female and male gametes (3). Ticks become infected when ingesting Babesia gametes in the blood of an infected rodent (4). Within the tick (A), the gametes undergo sexual reproduction to produce ookinetes (5). As with rodents, humans become infected through the bite of an infected *Ixodes* tick (6). Sporozoites enter human erythrocytes (B) and undergo asexual replication (7). Less commonly, humans are infected via blood transfusion (8). doi:10.1128/9781555817381.ch136.f10
The final step in maturation occurs when the tick takes a blood meal; sporozoites develop from the sporoblasts and are injected into the host during the final hours of feeding. The seasonality of babesiosis corresponds with the activity of the tick vectors, with most cases occurring in the spring, summer, and fall (86).

Less commonly, human babesiosis is acquired through receipt of infected blood products (88) or by vertical transmission across the placenta (89). Blood transfusion is recognized as an increasingly important source of infection (86, 88, 90), with 10 cases identified in the United States in 2011 (86). The largest review of transfusion-related babesiosis in the United States identified 159 cases during 1979–2009, with 156 cases due to B. microti and 3 due to B. duncani (90). Significantly fewer cases of transfusion-transmitted babesiosis have been reported in Europe (88). As expected, most implicated blood donations were collected during times of the year that ticks are active; however, a number of cases occurred from blood donated in the winter. In the latter cases, the original infections were presumably acquired by donors during the tick-biting season and remained dormant in the blood for months without causing symptoms. Most transfusion-transmitted cases have been associated with the receipt of whole blood, but cases associated with whole blood-derived platelets have also been reported (88, 90). The number of transfusion-related cases appears to be on the rise in the United States, and there is a need for a purpose and prevention is performed using only a donor questionnaire and indefinite donation deferral of patients with a history of babesiosis (88).

Clinical Significance
Symptoms of babesiosis due to B. microti and B. duncani/B. duncani-like parasites can range from asymptomatic or mild to life-threatening. When present, symptoms may include fever and a nonspecific influenza-like illness. Severe disease may behave like malaria, with high fever, chills, night sweats, myalgia, hemolytic anemia, hematuria, hepatosplenomegaly, and jaundice. Life-threatening complications include disseminated intravascular coagulation, acute renal or respiratory failure, congestive heart failure, and coma. Asplenia, immunosuppression, and advanced age are risk factors for severe disease (77).

Most patients with B. microti infection have a functioning spleen and symptoms tend to be mild. In contrast, patients infected with B. divergens in Europe are generally asplenic or immunocompromised and present with severe disease. Most infections with B. divergens-like agents in the United States have similar characteristics. At this point, only a small number of infections with B. venatorum have been reported, but preliminary evidence suggests that disease is relatively mild (77).

Collection, Transport, and Storage of Specimens
Collection and transport of whole blood specimens for babesiosis testing are performed in the same manner as for malaria. It is important to remember that Ixodes scapularis, the main vector of Babesia microti, is also a vector for other tick-borne pathogens, such as Anaplasma phagocytophilum and Borrelia burgdorferi, the agents of anaplasmosis and Lyme disease, respectively. Consideration should be given to concurrent testing for these agents.

Requests for blood films should be accompanied by important patient information such as clinical signs and symptoms, travel history, immune status, and presence or absence of a functioning spleen.

Direct Examination
Microscopy
As with malaria, the traditional method for diagnosis of babesiosis is microscopic examination of Giemsa-stained thick and thin blood films. Further details regarding the preparation and use of blood films are provided in the previous section on malaria. Babesia spp. parasites may present a diagnostic challenge on blood films due to the many morphologic similarities they share with Plasmodium species (specifically P. falciparum) on thick and thin films (Fig. 11 and 12). However, a number of diagnostic features can be used to differentiate between Babesia and Plasmodium in most instances (Table 4). In general, Babesia parasites demonstrate greater pleomorphism in size and shape than P. falciparum parasites, with ovoid, elliptical, pear, ratchet, and spindle shapes commonly seen. Extracellular forms are also common. Rarely, classic tetrads (“Maltese crosses”) are seen. It is important to note that only ring-type forms are seen in babesiosis. The presence of stippling, hemoglobin pigment, schizonts, or plasmodial-type gametocytes excludes the diagnosis of babesiosis. It is not possible to differentiate the various human Babesia species by morphology; this requires molecular methods.

When the morphology is insufficient for differentiation of Babesia and Plasmodium parasites, it is helpful to obtain a complete travel history, examine multiple blood samples for parasites, or perform an alternative detection method (e.g., PCR).

Determining the degree of parasitemia may be useful for patient management. Parasitemia levels usually vary between 1 and 10% but may reach up to 80% (72, 77). Monitoring the parasite load in conjunction with treatment may be especially important in immunocompromised and asplenic patients who are at risk for prolonged or relapsing disease (91).

Nucleic Acid Detection
Nucleic acid amplification assays such as PCR may be useful in instances of low parasitemia and when parasite morphol...
FIGURE 12 Babesia morphology on thin blood film. Note the presence of small intraerythrocytic ring forms resembling early trophozoites of *P. falciparum*, as well as thicker and markedly pleomorphic ring forms. Characteristic extracellular forms (arrow) and a tetrad form (arrow head) are also seen.

detected only by DNA testing. This is rarely performed in the clinical laboratory but may be available following consultation at the CDC or at other specialized centers.

**Serologic Tests**

Serologic testing plays little role in the diagnosis of acute babesiosis, but may be useful for epidemiologic studies and in cases of chronic disease. Antibodies to *B. microti* typically appear 2 weeks after the onset of illness and may be detectable for several years after infection (71, 72). The indirect fluorescence immunoassay (IFA) (97, 98) is the recommended method for detection of serum antibodies against *B. microti* and has a relatively high sensitivity (88 to 96%) and specificity (90 to 100%) (71, 97). Premade slides for *B. microti* IFA testing are commercially available in the United States and Europe. Interpretation of IFA results are subjective and the cutoff titer for defining a positive result varies by laboratory; titers of 1:128 to 1:256 may be associated with a higher specificity (71). Low antibody titers or negative results may be seen when serum is obtained early in disease or when patients are immunosuppressed or asplenic, while false positives may occur in patients with connective tissue disorders (e.g., rheumatoid arthritis). *B. microti* IFA serology does not demonstrate significant cross-reactivity with antibodies to *B. duncani*, *B. divergens*, or *B. venatorum* (97), so specific assays must be used for these organisms (99, 100).

**Isolation Procedures**

In rare instances, it may be necessary to inoculate the blood from a patient with suspected babesiosis into a laboratory animal such as a golden hamster (*B. microti*) (94, 96) or gerbil (*B. divergens*) (78, 87) to confirm the presence of a low-level infection or determine the viability of an organism.

**Evaluation, Interpretation, and Reporting of Results**

Detection of *Babesia* parasites by any diagnostic method should be considered a clinically significant result and should be promptly reported to the clinical team. The final blood film report should ideally include the calculated degree of parasitemia. When the blood film examination is negative, the report may include a statement that a single set of negative blood films does not exclude the diagnosis of babesiosis and that serial smears should be performed if clinically indicated.

If expertise for differentiation of *Babesia* and *Plasmodium* parasites is not available in the primary laboratory, it is important to inform the clinician that *Plasmodium* or *Babesia* parasites are identified and blood and/or films are being sent to a reference or public health laboratory for further analysis.
REFERENCES

Leishmania spp. and Trypanosoma spp. are protozoa belonging to the family Trypanosomatidae. Leishmaniasis is principally a zoonosis, and the organisms are obligate intracellular parasites transmitted to humans by bites from infected female sand flies. For Leishmania in the Old World, there is only one subgenus, Leishmania; however, in the New World, the genus has been split into subgenera (Leishmania and Viannia) according to the development of the organism in the digestive tract (peritryptorian or supratryptorian) of the sand fly (1). Depending on the geographic area, many different species can infect humans, producing a variety of diseases (cutaneous, diffuse cutaneous, mucocutaneous, and visceral diseases) (Table 1). The spectrum of clinical presentation is dependent on the host’s cell-mediated immune response (2).

Trypanosoma spp. are hemoflagellate protozoa that live in the blood and tissue of the human host. American trypanosomiasis (Chagas’ disease) is produced by Trypanosoma cruzi, which belongs to the subgenus Schizotrypanum and is confined to the American continent. Trypanosoma rangeli belongs to the subgenus Schizotrypanum, produces an asymptomatic infection, and is also present only on the American continent. African trypanosomiasis (sleeping sickness) is caused by Trypanosoma brucei gambiense and T. brucei rhodesiense species belonging to the subgenus Trypanozoon and is confined to the central belt of Africa. African trypanosomes and T. rangeli are transmitted directly into the bite wound by salivary secretions from the insect vector, whereas T. cruzi is transmitted through contamination of the bite wound with the feces from the reduviid bug (Table 2). The first documented case of human trypanosomiasis caused by Trypanosoma evansi was detected in India (3).

**LEISHMANIA SPP.**

Recent estimates suggest that there are approximately 350 million people at risk of acquiring leishmaniasis, with 112 million currently infected. More than 400,000 new cases are reported annually (4). New species of Leishmania, particularly in the New World, are being detected frequently. The taxonomy of leishmaniasis is controversial and in a state of dynamic flux. Species differentiation is currently based on molecular techniques rather than geographical distribution and clinical presentation (5–7).

**Life Cycle and Morphology**

The parasite has two distinct phases in its life cycle, amastigote and promastigote (Fig. 1). The amastigote stage (Leishman-Donovan body) is found in reticuloendothelial cells of the mammalian host. The amastigote form is small, is round or oval, measures 3 to 5 μm, and contains a large nucleus and small kinetoplast (Fig. 1 and 2). This stage undergoes multiplication within the reticuloendothelial cells of the host.

Upon ingestion during a blood meal by the insect vector (sand fly), the amastigote transforms into the promastigote stage (Fig. 3). Promastigotes multiply in the gut of the insect, transform to metacyclic promastigotes, and migrate to the hypostome of the sand fly, where they are released when the next blood meal is taken. The complete life cycle in the sand fly is 4 to 18 days. Upon inoculation into the bite site, the promastigote changes to the amastigote form after being engulfed by tissue macrophages. This form change helps to defeat the host’s immune response. Changes in the parasite’s surface molecules play an important role in macrophage attachment and evading the host’s immune response, including manipulating the macrophage’s signaling pathways (2, 8, 9).

The life cycles of Leishmania organisms are similar for cutaneous, mucocutaneous, and visceral leishmaniasis, except that infected reticuloendothelial cells can be found throughout the body in visceral leishmaniasis.

**Epidemiology and Transmission**

All adult female sand flies transmitting leishmaniasis belong to the genus Phlebotomus in the Old World and Lutzomyia in the New World. There are >30 species of sand flies that can transmit leishmaniasis. The disease is considered primarily a zoonosis, with natural reservoirs, including rodents, opossums, anteaters, sloths, and dogs. In certain areas of the world where the disease is endemic, the infection may also be transmitted by a human-vector-human cycle. The infection may also be transmitted by direct contact with an infected lesion or mechanistically through bites by stable or dog flies (Stomoxys calcitrans). If the blood meal of the fly is interrupted and it restarts its meal on another host, it can regurgitate part of the last meal with salivary juices into the bite site, thereby infecting that host. Greater than 90% of cutaneous leishmaniasis cases occur in Afghanistan, Algeria, Brazil, Iran, Iraq, Peru, Saudi Arabia, and Syria. There has been an increase in the number of cases among military personnel deployed in Afghanistan, Iraq, and Kuwait (27). Autochthonous human infections have been described in Texas and Oklahoma (10–12). Most of the diagnosed cases of mucocutaneous leishmaniasis are from Bolivia, Brazil, and Peru.
Visceral leishmaniasis may exist as an endemic, epidemic, and sporadic disease. The disease is a zoonosis except in India and Brazil, where kala-azar is an anthropoposis (13). Natural reservoirs are wild Canidae and various rodents for *Leishmania donovani*; dogs, other Canidae, and rats for *Leishmania infantum*; and Canidae and cats for *L. infantum* (*Leishmania chagasi*) in the Americas. Individuals with post-kala-azar dermal leishmaniasis may be very important reservoirs for maintaining the infection during interendemic periods. More than 90% of the cases of visceral leishmaniasis are found in Bangladesh, Brazil, India, Nepal, and Sudan.

**Clinical Significance**

Depending on the species involved, infection with *Leishmania* spp. can result in cutaneous, diffuse cutaneous, mucocutaneous, or visceral disease (Table 1) (14). A large number of disease variations have been described, which makes classical disease categories confusing (5). In areas of endemicity, Leishmania coinfection with human immunodeficiency virus (HIV)-positive patients is common. If coinfected patients remain severely immunocompromised, approximately one-quarter will die within the first month of being diagnosed with leishmaniasis. The leishmanial infection will manifest itself like an opportunistic infection, and parasites will be detected in atypical sites (15). The use of highly active antiretroviral therapy has significantly improved the prognosis of patients infected with HIV and visceral leishmaniasis (16).

The first sign of cutaneous disease is the appearance of a firm, painless papule at or near the insect bite site. The incubation period may be as short as 2 weeks (*Leishmania major*) or as long as several months to 3 years (*Leishmania tropica* and *Leishmania aethiopica*). Papules may be intensely pruritic and will grow to 2 cm or more in diameter. Lesions may progress from a simple papule or erythematous macule to a nodule and ulcerate within days to weeks. In simple cutaneous leishmaniasis, the infection remains localized at the insect bite site, where a definite self-limiting granulomatous response develops. Lesions have been mistaken for basal cell carcinoma, tropical pyodermatitis, sporotrichosis, or cutaneous mycobacterial infections.

Mucocutaneous leishmaniasis is produced most often by the *Leishmania braziliensis* complex. The primary lesions are similar to those found in other infections of cutaneous leishmaniasis. Untreated primary lesions may develop into the mucocutaneous form in up to 80% of cases. Metastatic spread to the nasal or oral mucosa may occur in the presence of the active primary lesion or many years later after the primary lesion has healed. Mucosal lesions do not heal spontaneously, and secondary bacterial infections are frequent and may be fatal. A small number of mucocutaneous leishmaniasis cases have been reported with *L. donovani* and *L. aethiopica*. Differential diagnoses have included lymphoma, midline granuloma, Wegener’s granulomatosis, paracoccidioidomycosis, histoplasmosis, cutaneous mycobacterial infection, syphilis, and leprosy.

Clinical features of the visceral disease vary from asymptomatic, self-resolving infections to frank visceral leishmaniasis. The incubation period may be as short as 10 days and as long as 2 years; usually it is within 2 to 4 months. Common symptoms include fever, anorexia, malaise, weight loss, and, frequently, diarrhea. Visceral leishmaniasis is an important
opportunistic infection in individuals infected with HIV. Concomitant HIV infection dramatically increases the risk of developing active visceral leishmaniasis in asymptomatic individuals and accelerates the progression to AIDS. Individuals coinfected with HIV may not elicit common symptoms seen in immunocompetent individuals, whereas the leukopenia will be unusually severe (15). Common clinical signs include nontender hepatomegaly and splenomegaly, lymphadenopathy, and occasionally acute abdominal pain; darkening of facial, hand, foot, and abdominal skin (kala-azar) is often seen in light-skinned persons in India. Anemia, cachexia, and marked enlargement of liver and spleen are noted as the disease progresses. Death may ensue after a few weeks or after 2 to 3 years in chronic cases. The majority of infected individuals are asymptomatic or have very few or minor symptoms, which resolve without therapy. There has been a significant increase in leishmaniasis in organ transplant recipients since 1990. Most of the reported cases in organ transplant recipients have been visceral leishmaniasis, with a much smaller number of mucocutaneous leishmaniasis cases and, rarely, cutaneous leishmaniasis cases (17, 18). Differential diagnoses in the acute stage include amebic liver abscess, Chagas’ disease, malaria, typhoid, typhus, and schistosomiasis. Subacute or chronic disease has been confused with malnutrition, bacteremia, brucellosis, histoplasmosis, leukemia, lymphoma, malaria, mononucleosis, and schistosomiasis.

Postdermal leishmaniasis or post-kala-azar dermal leishmaniasis (PKDL) is a condition seen in India and the Sudan in some patients unsuccessfully treated for visceral leishmaniasis. PKDL usually occurs 6 months or later after completion of therapy. This syndrome is rarely seen in Latin America but has been reported to occur in patients coinfected with HIV. The macular or hypopigmented dermal lesions are associated with few parasites, whereas erythematous and nodular lesions are associated with abundant parasites. This condition must be differentiated from leprosy, syphilis, and yaws.

**Diagnosis**

In areas where the disease is endemic, the diagnosis may be made on clinical grounds. Prolonged fever, progressive weight loss, anemia, leukopenia, hypergammaglobulinemia, and pronounced hepatomegaly and splenomegaly are highly suggestive of visceral leishmaniasis. The development of one or more chronic skin lesions with a history of exposure in an area of endemicity is suggestive of cutaneous leishmaniasis. In many areas of the world where the disease is endemic, laboratory testing (microscopy, culture, PCR, antigen tests, and serology) is almost impossible to obtain. Definitive diagnosis depends on detecting either the amastigotes in clinical specimens or the promastigotes in culture. Whenever leishmaniasis is suspected, multiple specimens should be taken and all of the diagnostic techniques should be employed if possible. When infected cells are in low numbers in specimens, one method may be successful in detecting the infection, while others may be negative.

**Collection of Specimens**

All cutaneous lesions should be thoroughly cleaned with 70% alcohol, and extraneous debris (the eschar and exudates) should be removed. After debridement, with precautions being taken to prevent bleeding, the base of the ulcer can be scraped with a scalpel blade to obtain an exudate for slide preparation, culture, or PCR. Specimens can be collected from the margin of the lesion by aspiration, scraping, or punch biopsy or by making a slit with a scalpel blade. Material scraped from the wall of the slit should be smeared onto a number of slides. PCR-based methods for the diagnosis of leishmaniasis have used a variety of specimens, including urine. PCR has been shown to be more sensitive than direct microscopy, histology, and culture, but availability is limited mainly to large hospitals or clinics. The PCR-based methods have not been standardized, and multicentered studies to validate these tests have not been done (19–22).
Laboratorians may want to contact their state public health laboratory or the Centers for Disease Control and Prevention (CDC) for diagnostic information and help in specimen selection and available tests. The CDC has the website address [http://www.cdc.gov/](http://www.cdc.gov/) and posts diagnostic guidelines, including “Practical Guide for Laboratory Diagnosis of Leishmaniasis” (http://www.cdc.gov/parasites/leishmaniasis/resources/pdf/cdc_diagnosis_guide_leishmaniasis.pdf).

The core of tissue from a punch biopsy specimen can be used to make imprints or touch preparations on a slide. A tissue core should also be submitted for histological examination. Recognition of amastigotes in tissues is more difficult than in smears or imprints because the organisms tend to be crowded within the cells, to appear small, and to be detected in bone marrow specimens, and buffy coat preparations of venous blood. Amastigotes with reticuloendothelial cells have been detected in bronchoalveolar lavage fluid, pleural effusions, and biopsy specimens collected from the gastrointestinal tract and oropharynxes of HIV-positive patients. *Anthroponosis, transmission involving a human-animal-human cycle; anthroponosis, transmission involving a human-human cycle.
indviduals with post-kala-azar dermal leishmaniasis have large numbers of parasites in the skin, particularly those with erythematous and nodular lesions (23).

**Direct Examination**

Microscopic Detection

Amastigote stages are found within macrophages or close to disrupted cells (Fig. 2). This stage can be recognized by its shape, size, staining characteristics, and, especially, the presence of an intracytoplasmic kinetoplast. The cytoplasm will stain light blue, and the nucleus and kinetoplast will stain red or purple with Giemsa stain. Amastigotes can be differentiated from intracellular fungal organisms because they will not stain positive with periodic acid-Schiff, mucicarmine, or silver stain. Intracellular fungal organisms do not have a kinetoplast that can be seen in amastigote stages.

PCR Detection

Molecular techniques (none are U.S. Food and Drug Administration [FDA] approved) for the detection of leishmanial DNA or RNA have been used for diagnosis, prognosis, and species identification. These methods are considered more sensitive than slide examination or culture, particularly for the detection of mucocutaneous leishmaniasis, for which organisms are difficult to culture (4, 24–39). Generally, organisms in mucocutaneous lesions are scant and difficult to detect microscopically. Because infections caused by species of the *Leishmania* subgenus Viannia are considered more aggressive and are more likely to result in treatment failure, molecular techniques to identify the organism to the species and strain levels can be very important for therapy (40–42). Multilocus enzyme electrophoresis (MLEE) and multilocus sequence typing (MLST) have been used to identify *Leishmania* species and strains, but this depends on having culturable isolates, and in some cases, these methods were not discriminatory enough. To improve on isolate identification, various rRNA and DNA targets, such as the minioxon or spliced leader, rRNA internal transcribed spacer (ITS), 7SL RNA gene, heat shock protein 70 gene, and cytochrome b gene, have been used (43–47). Multiple targets are necessary due to gene polymorphism within the target sequences.

Culture

If material is to be cultured, it must be collected aseptically. Tissues should be minced prior to culture. Culture media successfully employed to recover organisms include Novy, MacNeal, and Nicolle’s medium (NNN) and Schneider’s *Drosophila* medium supplemented with 30% fetal bovine serum (48). Cultures, incubated at 25°C, should be examined twice weekly for the first 2 weeks and once a week thereafter for up to 4 weeks before the culture is declared negative. Promastigote stages can be detected microscopically in wet mounts and then stained with Giemsa stain to observe their morphology.

Animal Inoculation and Culture

Animals such as the golden hamster can be inoculated with patient material. Animals are inoculated intranasally for cutaneous and mucocutaneous leishmaniasis and intraperitoneally for visceral leishmaniasis. It may take 2 to 3 months before an animal becomes positive. A combination of tissue smears, culture, and animal inoculation may be needed to optimize the laboratory diagnosis of the infection. PCR testing, if available, can be used as a supplemental diagnostic procedure (34, 49).

**Skin Testing**

The leishmanin (Montenegro) test (not available in Canada or the United States), a delayed-type hypersensitivity reaction, is useful for epidemiological surveys of a population to identify groups at risk of infection. This test may be available from clinics and institutions in areas of endemicity. The heavier the parasite burden and the longer the length of time of infection, the more likely one will have a positive skin test. Although skin test antigens are commercially available outside the United States, there is a lack of product standardization and stability. Positive reactions are usually seen in cutaneous and mucocutaneous leishmaniasis; however, patients with active visceral and diffuse cutaneous leishmaniasis exhibit negative reactions. Post-kala-azar patients may also exhibit a negative reaction. This test is of no value for the diagnosis of visceral leishmaniasis.

**Serologic Tests**

Serologic tests (none are FDA approved) are available for research or epidemiologic purposes; however, they are not very useful for the diagnosis of mucocutaneous and visceral leishmaniasis. In kala-azar, there is a large increase in gamma globulins, both immunoglobulin G (IgG) and IgM. This is the basis for the aldehyde or formol-gel test, which has been used as a screening test in areas of endemicity (50). The addition of 1 drop of formalin to 1 ml of serum promotes the precipitation of immunoglobulins. A number of serologies, including indirect fluorescent-antibody assay (IFA), enzyme-linked immunoassay (ELISA), and immunoblot tests have been developed for diagnostic purposes; however, they are not widely available except in areas of endemicity (51–53). An ELISA, dipstick test, and rapid immunochromatographic strip using *L. infantum*/*L. chagasi* recombinant k39 antigen has good sensitivity and specificity in diagnosing visceral leishmaniasis in immunocompetent people (54–57). Visceral leishmaniasis patients coinfected with HIV may have no detectable antileishmania antibodies (14, 58, 59). Serologic testing is available at some referral laboratories and the CDC. The detection of urinary antigens has been used for the diagnosis of visceral leishmaniasis (60).

**Treatment and Prevention**

Lesions in simple cutaneous leishmaniasis generally heal spontaneously. Treatment options have included cryotherapy, heat, photodynamic therapy, surgical excision of lesions, and chemotherapy (61). Chemotherapeutics include azoles (fluconazole, ketoconazole, posaconazole), amphotericin B, miltefosine, paromomycin, pentavalent antimonials, and pentamidine. Treatment is advocated to reduce scarring in cosmetic areas and to prevent dissemination and/or relapse of the infection. Although the optimal treatment for cutaneous leishmaniasis is unknown, standard therapy consists of injections of antimonial compounds. Intraleisonal antimonial therapy may be given to patients with a limited number of cutaneous lesions (≤3) whereas intramuscular or intravenous therapy should be given for more-disseminated infections. Topical therapy should not be advocated for mucocutaneous infections. Response to therapy varies depending on the species of *Leishmania* and the type of disease (62, 63); therefore, it is important to identify the species of *Leishmania* causing the infection (39, 64, 65). The risk of relapse is quite high within the first 6 to 12 months posttherapy (66, 67). Patients clinically cured of *L. (V.) braziliensis* infection, which is noted for its chronicity, latency, and metastasis, with mucosal membrane involvement, have been found to be PCR positive up to 11 years posttherapy (68).
Visceral leishmaniasis can be fatal if not treated, and individuals coinfected with HIV must be treated aggressively. In addition, the individual may have to be treated for life to prevent relapse of visceral leishmaniasis. Drugs most commonly used to treat visceral leishmaniasis include amphotericin B, miltefosine, paromomycin, and pentamidine. Liposomal amphotericin B has the highest therapeutic efficacy, whereas resistance to antimonial drugs is common in India and Nepal. Miltefosine is an effective oral agent, although failure rates as high as 30% have been reported.

To ensure that treatment has been effective, follow-up smears and cultures should be done 1 to 2 weeks posttherapy. PCR testing has been used to monitor the progress of therapy (68, 69).

In areas where leishmaniasis is endemic, vaccination is still a major goal for eliminating leishmaniasis. Inoculating the serum exudate from naturally acquired lesions of cutaneous leishmaniasis into an inconspicuous area of the body of a nonimmune person has been effective; however, vaccines against other forms of leishmaniasis have not worked. Vaccination with exudates from individuals with mucocutaneous leishmaniasis should never be tried due to the extensive pathology associated with this infection. Other possible prevention methods include spraying dwellings with insecticides, applying insect repellents to the skin, and using fine-mesh bed netting. Reservoir control has been unsuccessful in most areas, although in areas where canines may be a reservoir host, pyrethroid-impregnated collars are being used in most areas, although in areas where canines may be a reservoir host, pyrethroid-impregnated collars are being used to prevent infections. Individuals with lesions should be warned to protect the lesion from insect bites, and patients should be educated about the possibility of autoinoculation or infection.

AMERICAN Trypanosomiasis

Trypanosoma cruzi

American trypanosomiasis is a zoonosis caused by Trypanosoma cruzi. There are 100 million persons at risk of infection in 18 Latin American countries, and 16 to 18 million persons are actually infected (15). Patients can present with either acute or chronic disease. Chagas’ disease was considered a disease of rural areas; however, it is now ubiquitous due to social-pattern changes as a result of disease acquisition through blood transfusion and organ transplantation (20, 70). A large number of patients with positive serology can remain asymptomatic (71).

Life Cycle and Morphology

Trypomastigotes (Fig. 4 and 5) are ingested by the reduviid bug (triatomids, kissing bugs, or conenose bugs) as it obtains blood and infects the host cells. The amastigote form extends along the outer edge of an undulating membrane from the posterior end. A flagellum arises from the basal body and extends along the outer edge of an undulating membrane until it reaches the anterior end of the body, where it projects as a free flagellum. When the trypomastigotes are stained with Giemsa stain, the cytoplasm stains blue and the nucleus, kinetoplast, and flagellum stain red or violet. The amastigote (2 to 6 μm in diameter) is indistinguishable from those found in leishmanial infections. It contains a large nucleus and a rod-shaped kinetoplast that stains red or violet with Giemsa stain, and the cytoplasm stains blue (Fig. 2 and 7).

Epidemiology and Transmission

Chagas’ disease is a zoonosis occurring throughout the American continent, including Central and South America, California, Louisiana, and Texas (72). It involves reduviid bugs living in close association with reservoirs (dogs, cats, armadillos, opossums, raccoons, and rodents). Human infections occur mainly in rural areas in which poor sanitary and socioeconomic conditions and poor housing provide excellent breeding places for reduviid bugs. Chagas’ disease is found in 18 countries in Central and South America. There have been 6 autochthonous cases identified in the United States (72). The disease distribution has been broken into 2 ecological zones: the southern cone, where the reduviid vector lives inside the human home, and the northern cone, Central America, and Mexico zone, where the reduviid lives in a more rural situation. Strains of T. cruzi have large differences in infectivity of potential vectors, antigenicity, histotropism, pathogenicity, and response to therapy (73–76). Based on molecular epidemiology, T. cruzi has been broken into 6 genotypes or lineages (77, 78). Most human infections in the southern cone are due to T. cruzi II, whereas in the northern cone, T. cruzi I predominates (79, 80). Transmission by blood or blood product transfusion is a serious concern in areas of endemicity, and serologic screening of blood donors can be used, whereas in areas where the disease is not endemic, questionnaires may be used to refer prospective donors from areas of endemicity (81, 82).

Clinical Significance

In addition to contracting T. cruzi infections through the insect’s bite wound or exposed mucous membranes, one can be infected by blood transfusion, placental transfer, organ transplant, and accidental ingestion of parasitized reduviid bugs or their feces in food or drink (81–85). Most congenital infections are asymptomatic. A localized inflammatory reaction may ensue at the infection site with the development of a chagoma (erythematous subcutaneous nodule) or Roña’s sign (edema of the eyelids and conjunctivitis). The incubation period following exposure is usually 1 to 2 weeks. Most patients have nonspecific symptoms or no symptoms at all. Acute systemic signs occur around the second to third week of infection and are characterized by high fevers, hepatosplenomegaly, myalgia, erythematous rash, acute myocarditis, lymphadenopathy, and subcutaneous edema of face, legs, and feet. The acute phase of Chagas’ disease in immunosuppressed patients is manifested as acute myocarditis or acute encephalitis, with high mortality rates. Most acute cases resolve over a period of 2 to 3 months.
into an asymptomatic chronic stage (indeterminate phase or clinical latency period). Approximately 70% of the individuals with chronic Chagas’ disease remain asymptomatic (indeterminate phase); however, they are still capable of transmitting the infection. The remaining 30% of these individuals with chronic Chagas’ disease develop myocarditis or symptoms associated with denervation of the digestive tract. Chronic Chagas’ disease may develop years or decades after undetected infection or after the diagnosis of acute disease. The most frequent clinical sign of chronic Chagas’ disease is cardiomyopathy manifested by cardiomegaly and conduction changes. Some patients are more likely to develop megaesophagus or megacolon. Gastrointestinal Chagas’ disease is rare outside of Argentina, Bolivia, Brazil, Chile, and Paraguay (southern-cone countries). The “mega” condition has been associated with the destruction of ganglion cells, resulting in dysmotility and causing dysphagia, aspiration, and regurgitation in patients with megasphagus and severe constipation in patients with megacolon. In chronic Chagas’ disease, autoimmunity may also be responsible for tissue destruction in addition to the tissue destruction caused by the parasite. Reactivation of Chagas’ disease in HIV-positive patients usually leads to very high parasitemia and can occur in other immunosuppressed patients (86). Central nervous system (CNS) involvement is seldom observed, but in HIV-coinfected individuals, CNS involvement is frequently noted and acute fatal encephalitis and granulomatous encephalitis have been described for these patients. Congenital transmission from mother to fetus can occur in both the acute and chronic phases of the disease. Congenital infections can cause abortion, prematurity, neurological sequelae, and mental deficiency (71). Infants of seropositive mothers should be monitored for up to a year after birth to rule out infection. Transmission of the infection during transplantation of solid organs and other tissues from seropositive donors has become a significant problem (70). Although transplantation of any organ or tissue from a seropositive donor should be regarded as infectious, the risk of transmission of the infection is dependent on other factors. Some recipients do not develop infections.
however, all should be serially monitored for signs of infection.

**Diagnosis**

Health care personnel working with specimens from patients suspected of having Chagas’ disease should follow the bloodborne-pathogen guidelines using universal precautions. Trypomastigotes are highly infectious.

**Collection of Specimens**

A definitive diagnosis depends on demonstration of trypomastigotes in the blood, amastigote stages in tissues, or positive PCR and serologic tests (Table 3). Aspirates from chagomas and enlarged lymph nodes can be examined for amastigotes and trypomastigotes. Histological examination of biopsy specimens may also be done. Trypomastigotes may easily be detected in the blood in acute disease; however, in chronic disease, this stage is rare or absent, except during febrile episodes. Trypomastigotes appear in the blood about 10 days after infection and persist through the acute phase.

*IFLA, indirect fluorescent-antibody assay; EIA, enzyme immunosassay; IHA, indirect hemagglutinin assay; RIPA, radioimmunoprecipitation assay; WB, Western blotting.*
can be differentiated from fungal organisms because they will not stain positive with periodic acid-Schiff, mucicarmine, or silver stain. In areas where kala-azar occurs, amastigote stages look similar, and infections of L. donovani and T. cruzi must be differentiated by PCR, immunoassay, culture (epimastigote for T. cruzi versus promastigote for L. dono-
van'i), serologic tests, animal inoculation, or xenodiagnosis techniques (88). Patient history, including geographic and/ or travel history, and confirmation of organisms in striated muscle rather than reticuloendothelial tissues are very strong evidence for T. cruzi rather than L. donovani as the causative agent.

PCR Detection
Although not routinely available except in specialized cen-
ters, PCR (not FDA approved) has been used to detect as few as one trypomastigote in 20 ml of blood and has been useful in treatment follow-up (20, 88–90). To improve on detection of positive patients, real-time PCR using multiple gene targets has been advocated (91, 92). Multiple targets are needed due to polymorphism within the gene targets. The PCR-based methods have not been standardized, and multicenter studies to validate these tests have not been done. There have been few studies where various PCR methods used for diagnostic purposes have been compared.

Culture and Animal Inoculation
Aspirates, blood, and tissues can also be cultured. The me-
dium of choice is NNN (48). Cultures, incubated at 23°C, should be examined for epimastigote stages twice weekly during the first 2 weeks and once per week thereafter for up to 4 weeks before they are considered negative. If available, laboratory animals (rats or mice) can be inoculated and the blood can be observed for trypomastigotes.

Xenodiagnosis
Although xenodiagnosis is used less frequently for clinical diagnosis in areas of endemicity, trypanosome-free reduviid bugs are allowed to feed on individuals suspected of having Chagas' disease. The feces, hemolymph, hindgut, and sali-
vary glands can be examined microscopically for flagellated forms over a period of 3 months, or PCR methods can be used to detect infected bugs and provide a rapid diagnosis (93). Xenodiagnosis is positive in less than 50% of the seropositive patients. Some patients may develop a severe anaphylactic reaction to the reduviid bug's salivary secretion.

Serologic Tests
Serologic tests using blood and saliva for the diagnosis of Chagas' disease include complement fixation (Guerrero-
Machado test), chemiluminescence, IFA, indirect hemag-
 glutination, and ELISA (94, 95). Most of these tests use an epimastigote antigen, and cross-reactions have been noted for patients infected with Trypanosoma rangeli, Leishmania spp., Toxoplama gondii, and hepatitis (4, 96). The use of synthetic peptides and recombinant proteins has improved the sensitivity and specificity of the serodiagnostic tech-
niques; however, their reliability for diagnosis is questionable (81, 97–102). Several diagnostic enzyme immunoassay (ELA) methods using parasite lysate and recombinant antig-
gen's have been approved by the FDA for screening blood donors. The sensitivity and specificity of these serologic tests for screening blood donors have improved so that single-assay screening may be justified rather than the two-
assay screening method previously recommended. The FDA and AABB (American Association of Blood Banks) require

donated blood be screened for Chagas' antibodies, and it is recommended that UNOS (United Network Organ Shar-
ing) test tissue donors for the presence of Chagas' antibodies. Alternative diagnostic methods to confirm serology-positive tests are recommended. Follow-up blood specimens should be reexamined 1 to 2 months after therapy by the techniques described above. A difficult problem using serology has been determining whether a patient has been reinfected or if treatment has been unsuccessful. Changes in T. cruzi-
specific T cell and antibody responses were determined to be an excellent marker for therapeutic response. Serologic testing is available at referral laboratories and the CDC.

Treatment and Prevention
Nifurtimox (Lampit) and benznidazole (Radamil) reduce the severity of acute Chagas' disease. Other drugs, namely, allopurinol, flucnazole, itraconazole, and ketoconazole, have been used to treat a limited number of patients. Treatment of individuals with chronic Chagas' disease slowed the development of cardiomyopathy and decreased mortality. Response to therapy can be monitored by measuring the reduction in antibody response or the reduction in parasite load by PCR (76, 90, 103). Surgery has been successfully used to treat cases of chagasic heart disease, megaesophagus, and megacolon.

Until recently, control of Chagas' disease has been mainly through the use of insecticides to eliminate the reduviid vector. Construction of reduviid-proof dwellings and health education are essential for effective control pro-
grams. Bed nets are also effective in preventing infections. Serologic screening of blood products for transfusion from areas in which the disease is endemic is highly recommended (95, 103, 104). An alternative approach to serologic testing for blood donors is the use of questionnaires to defer prospective donors from areas of endemicity.

Trypanosoma rangeli
T. rangeli infects humans and other vertebrates in both Central and South America and is often found in areas where T. cruzi is also present (105, 106). Human infections are asymptomatic, and trypanosomastigotes have been noted to persist in the blood for longer than a year. T. rangeli and T. cruzi can use the same triatomid vector to transmit infec-
tions. T. rangeli infections can be transmitted by inoculation of triatomid saliva during feeding or by the vector's feces (107). In some areas, T. rangeli infections are five to six times more frequent than infections with T. cruzi. Trypo-
mastigotes can be detected from the blood of infected patients by using thin and thick blood smears and buffy coat concentration techniques. The parasites can be stained with Giemsa or Wright stain. Microscopically, the try-
ompastigote cannot be differentiated from African trypano-
somes, which do not occur in the Americas. T. rangeli trypanomastigotes can be differentiated from T. cruzi try-
ompastigotes based on the smaller size of the kinetoplast. PCR methods have been used to detect infections in humans and vectors (107, 108). Infections can also be detected by xenodiagnosis. In addition, blood can be cultured (Tobie's medium or NNN) (48) or injected into laboratory animals (mice) and examined for epimastigotes and trypanomastigotes, respectively. Although there are no serologic tests to detect T. rangeli infections, serologic cross-reactions have been noted to occur with tests for T. cruzi (109). To differentiate between the two infections, a clinical history should be obtained and acute- and convalescent-phase sera should be tested by serology or different test methods, namely, PCR and microscopic analysis of blood. There are no treatment recommendations for T. rangeli infections.
AFRICAN TRYPANOSOMIASIS

African trypanosomiasis is limited to the tsetse fly belt of Central Africa, where there are over 60 million people at risk for African trypanosomiasis (110). Fewer than 10,000 cases are reported per annum. The West African (Gambian) form of sleeping sickness, noted for its chronicity and responsible for 99% of the sleeping sickness cases, is caused by T. brucei gambiense, whereas the East African (Rhodesian) form, noted for its acute morbidity and mortality within months of infection, is caused by T. brucei rhodesiense (111). T. brucei gambiense infections can last for months to years, with slow CNS involvement. In some areas of endemicity, civil strife has disrupted both the health care infrastructure and vector control, which has led to a resurgence of this disease.

Life Cycle and Morphology

T. brucei rhodesiense and T. brucei gambiense are closely related and morphologically indistinguishable. In the past, differentiation was based on clinical signs and geographic area; however, differentiation can now be accomplished using isoenzyme characteristics and DNA and RNA methods.

Trypomastigote forms are the infective stages for the tsetse fly (Fig. 4 and 6) in the blood range from long, slender-bodied organisms with a long flagellum to short, fat, stumpy forms without a free flagellum (14 to 33 μm long and 1.5 to 3.5 μm wide). The short, stumpy forms are the infective stage for the tsetse fly. Using Giemsa or Wright stain, the granular cytoplasm stains pale blue and contains dark-blue granules and possibly vacuoles. The centrally located nucleus stains reddish; the remaining intracytoplasmic flagellum forms are the infective stage for the tsetse fly. The kinetoplast, as does the undulating membrane, the flagellum runs along the edge of the undulating membrane until the undulating membrane merges with the trypomastigote body at the organism's anterior end. At this point, the flagellum becomes free to extend beyond the body. Trypanosomal forms are ingested by the tsetse fly when a blood meal is taken and transformed to epimastigotes (Fig. 4).

The organisms multiply in the gut of the fly, and after approximately 2 weeks, the organisms migrate back to the salivary glands. Human are infected when metacyclic forms from the salivary glands are introduced into the bite site as the blood meal is taken by the tsetse fly. The epimastigote has the ability to change the surface coat of the outer membrane, helping the organism evade the host's humoral immune response (112).

Epidemiology and Transmission

The development cycle in the tsetse fly varies from 12 to 30 days and averages 20 days. Fewer than 10% of tsetse flies become infective after obtaining blood from infected patients. Both female and male tsetse flies can transmit the infection. Infections can also occur through placental transfer from mother to fetus and by needle sticks.

Although there is no evidence of animal-to-human transmission of T. brucei gambiense, trypanosomal strains isolated from hartebeest, kob, chickens, dogs, cows, and domestic pigs in West Africa are identical to those isolated from humans in the same area. Evidence suggests that transmission may be entirely interpersonal. The tsetse fly vectors of Rhodesian trypanosomiasis are game feeders (including cattle) that may transmit the disease from human to human or from animal to human.

There is molecular evidence of multistrain introduction of the infection with parasites of the T. brucei complex that can have epidemiological implications as to virulence, pathogenicity, and response to therapy (113). This phenomenon has not received much attention.

Clinical Significance

After a bite by an infected tsetse fly, a local inflammatory reaction that resolves spontaneously within 1 to 2 weeks can be detected at the bite site. The bite site chancre can be painful, presenting as an erythematous indurated nodule that may ulcerate. The trypomastigotes gain entrance to the bloodstream, causing a symptom-free low-grade parasitemia that may continue for many months. The infection may self-cure during this period without development of symptoms or lymph node invasion. Chancres may be confused with insect bites and bacterial skin infections, with resolution occurring within a few weeks.

The clinical course and disease progression are more acute with T. brucei rhodesiense than with T. brucei gambiense infections. Diagnostic symptoms include irregular fever, lymph node enlargement (particularly those of the posterior triangle of the neck, known as Winterbottom's sign, which is prominent in T. brucei gambiense infections), delayed sensation to pain (Kerandel's sign), and erythematous skin rashes. In addition to lymph node involvement, the spleen and liver become enlarged. Stage I of African trypanosomiasis is when the trypomastigotes multiply in the subcutaneous tissues, blood, and lymph (hemolymphatic phase). Stage II occurs when the trypomastigotes cross the blood-brain barrier to initiate infection of the central nervous system (neurologic phase). With Gambian trypanosomiasis, the blood lymphatic stage (stage I) may last for years before the sleeping sickness syndrome occurs (CNS involvement, meningoencephalitis stage, stage II). When symptoms occur in a patient infected with Gambian trypanosomiasis, the patient is already in the advanced stages of disease, with CNS involvement.

Laboratory findings include anemia, granulocytopenia, increased sedimentation rate, and marked increases in serum IgM. The sustained high IgM levels are a result of the parasite producing variable antigen types to evade the patient's defense system (112). In an immunocompetent host, the lack of elevated serum IgM rules out African trypanosomiasis. A diagnostic differential may include brucellosis, HIV infection, leishmaniasis, malaria, relapsing fever, tuberculosis, and typhoid fever.

Upon trypomastigote invasion of the CNS, the sleeping sickness stage of the infection is initiated (stage II). Gambian trypanosomiasis is characterized by steady, progressive meningoencephalitis, behavioral changes, apathy, confusion, coordination loss, and somnolence. T. brucei rhodesiense produces a more rapid, fulminating disease, and death may occur before there is extensive CNS involvement. In the terminal phase of the disease, the patient becomes emaciated, leading to profound coma and death, usually from secondary infections. Cerebrospinal fluid (CSF) findings include increased protein and IgM levels, lymphocytosis, and morular cells of Mott. Morular (mulberry) cells are altered plasma cells whose cytoplasm is filled with proteinaceous droplets. Morular cells are not seen in all patients; however, they are characteristic of African trypanosomiasis. World Health Organization criteria for CNS involvement, besides findings of trypomastigotes in the CSF, include a white blood cell count of greater than 5 cells and increased protein levels in the CNS fluid. The diagnostic differential may include cryptococcosis, HIV, meningitis, Parkinson's disease, psychiatric disorders, viral encephalitis, and space-occupying lesions.
Diagnosis

Because most of the infections occur in rural areas, sophisticated diagnostic techniques are not readily available and diagnosis is dependent on simple direct detection methods. Definitive diagnosis depends upon demonstration of trypomastigotes in blood, lymph node aspirate, sternum bone marrow, chancre fluid, and CSF. Trypomastigotes can be more readily detected in body fluids in infections due to T. brucei rhodesiense than in those due to T. brucei gambiense because of substantially higher parasitemias. Due to periodicity, parasite numbers in the blood vary, and a number of techniques must be used to detect the trypomastigotes. Laboratorians may want to contact their state public health laboratory or the CDC for diagnostic information and help with specimen selection and available tests.

Collection of Specimens

Trypomastigotes are highly infectious, and health care personnel must be cautious and adhere to blood-borne-pathogen guidelines using universal precautions when handling blood, CSF, or aspirates. Microscopic specimens should be examined as rapidly as possible due to potential lysis of trypomastigotes. Serial exams of fluids may be necessary to detect trypomastigotes especially with Gambian trypanosomiasis. Blood can be collected from either finger stick or venipuncture. Venous blood should be collected in a tube containing EDTA. Multiple blood exams should be performed before trypanosomiasis is ruled out. Parasites are found in high numbers in the blood during the febrile period and in low numbers in the afebrile periods. If CSF is examined, a volume greater than 1 ml, preferably 5 ml or more, should be collected. In cases in which trypomastigotes are in undetectable numbers in the blood, they may be seen in aspirates of inflamed lymph nodes; however, attempts to demonstrate them in tissue are not practical. Blood and CSF specimens should be examined every 6 months during therapy to evaluate the clinical response and up to 2 years after therapy.

Direct Examination

Microscopic Detection

In addition to taking thin and thick blood films, determining the buffy coat concentration is recommended to detect the parasites. Parasites can be detected (i) on thick blood smears when numbers are greater than 2,000/ml, (ii) by determining the hematocrit concentration in a capillary tube or by quantifying buffy coats (QBC) when numbers are greater than 100/ml, and (iii) by anion-exchange chromatography when numbers are greater than 4/ml (114). Unfortunately, anion exchange is not easily adapted to clinical laboratories or field studies (115). In suspected and confirmed cases of trypanosomiasis, a lumbar puncture is mandatory to rule out CNS involvement (stage II). CSF examination must be conducted by using centrifuged sediments (116). The CSF should be examined immediately because the trypomastigotes begin to autolyze within 10 min. Detection of trypomastigotes in the CSF allows immediate classification of stage II illness (CNS involvement).

PCR Detection

Referral laboratories have used molecular methods (PCR, not FDA approved) to detect infections and differentiate species, but these methods are not routinely used in the field (21, 48, 115, 117). The PCR-based methods have not been standardized, and multicenter institutional studies to validate these tests have not been done. There have been few studies where the various PCR methods used for diagnostic purposes have been compared.

Culture and Animal Inoculation

Small laboratory animals (rats and guinea pigs) have been used to detect infections. T. brucei rhodesiense is more adaptable to cultivation (Tobie’s medium [48]) and animal infection than T. brucei gambiense; however, cultivation is not practical for most diagnostic laboratories.

Serologic Tests

Serologic techniques (not FDA approved) that have been used for epidemiologic screening include IFA, ELISA, indirect hemagglutination assay, the card agglutination trypanosomiasis test (CATT), and LATEX/T. b. gambiense. Serologic tests are normally used for screening, with the definitive diagnosis of infection dependent on microscopic observation of trypomastigotes. The CATT is effective in screening the population for suspected cases of T. brucei gambiense but not T. brucei rhodesiense. Major serodiagnostic problems with the CATT include false-positive results due to malarial infections and the fact that many in the population have elevated antibody levels due to exposure to animal trypanosomes that are noninfectious to humans. The CATT does not differentiate between current and past infections (115, 118, 119). Both the CATT and LATEX/T. b. gambiense have good negative predictive values. Markedly elevated serum and CSF IgM concentrations are of diagnostic value. CSF antibody titers should be interpreted with caution because of the lack of reference values and the possibility of CSF containing serum due to a traumatic tap. Intrathecal production of immunoglobulins can be found in a number of neuroinflammatory diseases. LATEX/IgM has been developed for field use to measure CSF concentrations of IgM (115).

Antibodies to galactocerebrosides and neurofilaments as well as elevated concentrations of interleukin-10 and CSF protein levels may be markers for CNS involvement; all of these have been used to monitor CNS infections (115, 120). ELISA has been used to detect antigen in serum and CSF. These biomarker tests (antigen detection) are not widely used due to the limited sensitivity of the test when there are limited numbers of trypomastigotes in the blood or CSF (121, 122). This method can also be used for clinical staging of the disease to determine whether there was CNS infection and as a follow-up to therapy.

Treatment and Prevention

All patients determined to have active infections should be treated. The drugs used and the course of treatment are dependent on the trypanosomal species and the clinical staging of the disease (123). Suramin (Bayer 205; Naphuride or Anthrapol) is the drug of choice for treating the early blood or lymphatic stage of T. brucei rhodesiense infections, whereas pentamidine isethionate (Lomidine) is the drug of choice for treating the early stages of T. brucei gambiense infections (111, 124, 125). Melarsoprol (mel B or Arsobal) is the drug of choice when CNS involvement is suspected with T. brucei rhodesiense infections (111, 125). This drug may be given with a corticosteroid to reduce possible encephalopathy.

Difluoromethylornithine (DFMO; efomithine or Ormi- dy) is a cytostatic drug effective against the acute and late stages of T. brucei gambiense infections (123). It can be used alone or with oral nitfurimox. The effectiveness of therapy can be judged microscopically by the absence of trypomasti-
gotes in the blood, lymph fluid, or CSF and by a decrease in CSF white blood cells (126). CSF antibodies (IgM) decrease, as do levels of interleukin-10, after successful therapy (127). Any individual treated for African trypanosomiasis should be monitored every 6 months for 2 years after completion of therapy (128).

Population-screening programs have been used to control T. brucei gambiense infections. The use of vector control measures has met with limited success (75). The most effective control measures include an integrated approach to reduce the human reservoir of infection and the use of insecticide and fly traps. Use of N,N-diethyl-meta-toluamide (DEET) and permethrin-impregnated clothing or another insect repellent has not been proved to be particularly effective against tsetse flies, but it prevents other insect bites. Tsetse flies are attracted to clothing with bright and dark colors. Persons visiting areas in which the infection is endemic should wear protective clothing (long-sleeved shirts and long trousers). Vaccines are not available.

OTHER TRYPANOSOMES INFECTING HUMANS

Trypanosoma congolense

Only one case of human infection with this parasite has been reported and confirmed by DNA identification (128). The patient had a mixed infection with T. brucei and was successfully treated with pentamidine.

Trypanosoma evansi

The first human case of T. evansi was diagnosed in India (3). This organism is normally considered a parasite of animals (buffalo, camels, cattle, horses, and rats) and has a very wide geographic distribution (Africa, Asia, and Central and South America). The infection is transmitted mechanically by blood-sucking insects, such as stable flies or horseflies. In animals, the incubation period is 5 to 60 days, and the severity of the disease varies from no symptoms to weakness, weight loss, anemia, abortions, and death. In the above-mentioned human case, the patient complained of transient fevers and sensory disorders. Fever peaks were noted every 7 to 10 days, and large numbers of parasites were detected in the blood at the time of fevers. No parasites were observed in the CSF. The patient was treated with suramin. Normally, human serum has natural trypanolytic activity, but this patient was determined to have a mutation in apolipoprotein L-1 (APOL1), which has trypanolytic activity (129). Laboratory diagnosis is usually done by examination of blood and lymph node aspirates or biopsy specimens. T. evansi can be cultured in mice and rats (130).

T. evansi cannot be differentiated from T. brucei gambiense, T. brucei rhodesiense, or T. rangeli microscopically.

Trypanosoma lewisi

Human cases of T. lewisi infections have been described in India and Thailand in pediatric patients (130–132). Trypanastigotes were detected in the blood of these patients. In these cases, the patients fully recovered from the infection with no therapy. Symptoms included prolonged fever, thrombocytopenia hepatosplenomegaly, and elevated liver enzymes.

The kinetoplast is subterminal to the posterior end of the trypanastigote, and the nucleus is found at the anterior end, terminating where the flagellum is free of the trypanastigote body. T. lewisi is a natural infection of wild rats and is considered nonpathogenic. The intermediate host is the flea, in whose gut the parasite multiplies and gives rise to epimastigotes that are found in the rectum and feces. The infection is passed to susceptible rats by ingestion of fleas or their feces. Human infections are thought to be transmitted in a similar fashion.

REFERENCES

32. Janjoom MB, Ashford RW, Bates PA, Chance ML, Kemp SJ, Watts PC, Noyes HA. 2004. *Leishmania donovani* is the only cause of visceral leishmaniasis in East Africa; previous descriptions of *L.* infantum and “*L.* archibaldi” from this region are a consequence of convergent evolution in the isoenzyme data. Parasitology 129:399–409.

Toxoplasmosis is caused by infection with the parasite *Toxoplasma gondii*. It is one of the most common parasitic infections in humans and is most typically asymptomatic. However, in select clinical situations it can cause severe and disabling disease, making accurate and timely diagnosis vital.

**TAXONOMY**

*Toxoplasma gondii* is included in the phylum Apicomplexa, class Coccidea, subclass Coccidiasina, order Eimeriida, suborder Eimeriorina, family Sarcocystidae (*Sarcocystis* class Coccidea, subclass Coccidiasina, order Eimeriida, subfamily Toxoplasmatinae, and genus *Toxoplasma*).

**LIFE CYCLE**

*Toxoplasma gondii* is a protozoan parasite that infects most species of warm-blooded animals, including humans. Members of the cat family Felidae are the only known definitive hosts for the sexual stages of *T. gondii* and thus are the main reservoirs of infection. The three stages of this obligate intracellular parasite are (i) tachyzoites (trophozoites), which rapidly proliferate and destroy infected cells during acute infection; (ii) bradyzoites, which slowly multiply in tissue cysts; and (iii) sporozoites in oocysts (Fig. 1). Tachyzoites and bradyzoites occur in body tissues; oocysts are excreted in cat feces (Fig. 2). Cats become infected with *T. gondii* by carnivorism or by ingestion of oocysts. Cats that are allowed to roam outside are much more likely to become infected than domestic cats that are confined indoors. After tissue cysts or oocysts are ingested by the cat, viable organisms are released and invade epithelial cells of the small intestine, where they undergo an asexual cycle followed by a sexual cycle and then form oocysts, which are then excreted. The unsporulated (i.e., noninfective) oocyst takes 1 to 5 days after excretion to become sporulated (infective). Although cats shed oocysts for only 1 to 2 weeks, large numbers may be shed, often exceeding 100,000 per g of feces. Oocysts can survive in the environment for several months to more than a year and are remarkably resistant to disinfectants, freezing, and drying but are killed by heating to 70°C for 10 min (1).

**EPIDEMIOLOGY AND TRANSMISSION**

Sero logic prevalence data indicate that toxoplasmosis is one of the most common infections of humans throughout the world (2). Because *T. gondii* organisms are rarely detected in humans with toxoplasmosis, serologic examination is used to indicate the presence of the infection by detecting *Toxoplasma*-specific antibodies. The prevalence of positive serologic titers increases with age. In many areas of the world, infection is more common in warm climates and at lower altitudes than in cold climates and mountainous regions. This distribution is probably related to conditions favoring the sporulation and survival of oocysts. Variations in prevalences of infection between geographic areas and between population groups within the same locale are also probably due to differences in exposure. A high prevalence of infection in France (50 to 85%) has been related to a preference for eating raw or undercooked meat. However, a high prevalence in Central America has been related to the frequency of stray cats in a climate favoring the survival of oocysts. In U.S. military recruits in 1962, seroprevalence rates of up to 30% were found in people living along the sea coast, with rates of less than 1% in the Rocky Mountains and the desert Southwest. More-recent data comparing antibody prevalences in U.S. military recruits in 1962 and 1989 indicated a one-third decrease in seropositivity (3). The overall seroprevalence in the United States as determined with specimens collected by the Third National Health and Nutritional Assessment Survey (NHANES III) between 1988 and 1994 among persons 12 or more years of age was found to be 22.5%, with seroprevalence among women of childbearing age (15 to 44 years) of 15% (4). More recently, in analysis of NHANES data, *T. gondii* seroprevalence was shown to have declined in U.S.-born persons 12 to 49 years old, from 14.1% in 1988 to 1994 to 9.0% in 1999 to 2004 (5).

Human infection may be acquired in several ways: (i) ingestion of undercooked contaminated meat containing *T. gondii* cysts; (ii) ingestion of oocysts from hands, food, soil, or water contaminated with cat feces; (iii) organ transplantation or blood transfusion; (iv) transplacental transmission; and (v) accidental inoculation of tachyzoites. The two major routes of transmission of *Toxoplasma* to humans are oral and congenital. In humans, ingesting either the tissue cyst or the oocyst results in the rupture of the cyst wall (6), which releases organisms that invade the intestinal epithelium, disseminate throughout the body, and multiply intracellularly. The host cell dies and releases tachyzoites, which invade adjacent cells and continue the process. The tachyzoites are pressured by the host’s immune response to transform into bradyzoites and form tissue cysts, most commonly in skeletal muscle, myocar-
FIGURE 1 Three life stages of *T. gondii*. (A) Tachyzoites (Giemsa stain); (B) cyst with bradyzoites in brain tissue (Giemsa stain); (C) sporulated oocysts, unstained. (Photographs courtesy of J. P. Dubey, U.S. Department of Agriculture, Beltsville, MD). doi:10.1128/9781555817381.ch138.f1

...dium, and brain; these cysts may remain throughout the life of the host. Recrudescence of clinical disease may occur if the host becomes immunosuppressed and the cysts rupture, releasing the parasites.

Recently, researchers have begun to appreciate that differences in transmission, reactivation, and disease severity may also be explained by the different genotypes of *T. gondii* that occur in different parts of the world (7).

**Prevention**

Risk factors for *T. gondii* infection identified in epidemiologic studies include eating raw or undercooked pork, mutton, lamb, beef, ground meat products, oysters, clams, mussels, and wild-game meat, kitten ownership, cleaning a cat litter box, contact with soil (gardening and yard work), and eating raw or unwashed vegetables or fruits (1, 4, 8–10). Recommendations for prevention of toxoplasmosis for all persons, including pregnant women, were originally discussed at a conference at the Centers for Disease Control and Prevention and published (1), and now have been updated (see the Division of Parasitic Diseases [DPDM] Web page http://www.cdc.gov/parasites/toxoplasmosis/prevent.html). These recommendations included the following: (i) food should be cooked to safe temperatures (beef, lamb, and veal roasts and steaks to at least 145°F, with a 3-min rest; pork, ground meat, and wild game to 160°F; and poultry to at least 165°F, with a 3-min rest); (ii) fruits and vegetables should be peeled or washed thoroughly before being eaten; (iii) cutting boards, dishes, counters, utensils, and hands should always be washed with hot soapy water after they have come into contact with raw meat, poultry, seafood, or unwashed fruits or vegetables; (iv) individuals should wear gloves when gardening and during any contact with soil or sand, because cat waste might be in soil or sand, and wash hands afterwards; and (v) pregnant women should avoid changing cat litter, if possible. Pregnant women who must change cat litter should use gloves and then wash their hands thoroughly. The litter box should

be changed daily because *T. gondii* oocysts require more than 1 day to become infectious. Pregnant women should be encouraged to keep their cats inside and not adopt or handle stray cats. Cats should be fed only canned or dried commercial food or well-cooked table food, not raw or undercooked meats. Several outbreaks have been reported in association with drinking untreated water contaminated by oocysts. Freezing for several days at subzero temperatures (<0°F) greatly reduces the risk of infection.

**CLINICAL SIGNIFICANCE**

Toxoplasmosis can be categorized into four groups: (i) acquired by an immunocompetent patient, (ii) acquired or reactivated by an immunodeficient patient, (iii) congenital, and (iv) ocular. Methods of diagnosis and their interpretations may differ for each clinical category.

*Toxoplasma* infection acquired by immunocompetent individuals is generally an asymptomatic infection. However, 10 to 20% of patients with acute infection may develop cervical lymphadenopathy and/or a flu-like illness. The clinical course is benign and self-limited; symptoms usually resolve within weeks to months.

Immunodeficient patients often have central nervous system (CNS) disease but may have myocarditis or pneumonitis. In patients with AIDS, toxoplasmic encephalitis is the most common cause of intracerebral mass lesions and is thought to be due to reactivation of chronic infection. Toxoplasmosis in patients being treated with immunosuppressive drugs may be due to either newly acquired or reactivated latent infection (11, 12).

Congenital toxoplasmosis results from an acute primary infection acquired by the mother during pregnancy. The incidence and severity of congenital toxoplasmosis vary with the trimester during which infection was acquired. Because treatment of the mother may reduce the severity of manifestations in the infant due to congenital infection, prompt and accurate diagnosis is extremely important. Many infants with subclinical infection at birth will subsequently develop signs or symptoms of congenital toxoplasmosis; however, prompt treatment may help prevent subsequent symptoms.

Ocular toxoplasmosis, an important cause of chorioretinitis in the United States, may be the result of congenital or acquired infection (13). Acquired infection is now thought to be more common than congenital infection. Congenitally infected patients can be asymptomatic until the second or third decade of life, when lesions develop in the retina, presumably due to cyst rupture and subsequent release of tachyzoites and bradyzoites. Chorioretinitis is characteristically bilateral in patients with congenital infection but is often unilateral in individuals with acute acquired *T. gondii* infection.

Recent data have suggested an association between *T. gondii* infection and various neurologic or psychiatric syndromes, including schizophrenia, Alzheimer disease, and even suicide (14–16). These findings are intriguing but require further study to validate.

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

Serum, plasma, cerebrospinal fluid (CSF), ocular fluid, and amniotic fluid may be tested for antibodies and/or parasite DNA (2).

**Collection for Determination of Parasite DNA**

Blood samples should be collected with an anticoagulant; CSF, ocular fluid, and amniotic fluids do not need an anticoagulant. All samples should be shipped and stored at 4°C prior to testing.

**Collection for Antibody Determination**

Blood specimens to be tested for the presence of antibodies should be allowed to clot and be centrifuged, and the serum should be removed and shipped to a reference laboratory. Hemolysis does not seem to interfere with the antibody reaction in most tests. Serum and CSF specimens may be stored for several days at 4°C or frozen for longer storage. Specimens may be shipped at ambient temperature unless they will be in transit for more than 1 week or will be subjected to temperatures above 30°C. To avoid evaporation of small volumes, ocular fluids should be stored and shipped frozen. CSF and ocular fluid should be tested in parallel with a serum sample drawn on the same date. Long-term storage should take place at −20°C or below.

If the determination of immune status is the reason for testing, a single serum specimen is satisfactory; acute- and convalescent-phase specimens are not necessary. In situations in which determining the time of infection is important, specimens drawn at least 3 weeks apart may or may not be useful. In most cases, detection of an increasing immunoglobulin G (IgG) or IgM titer is not possible because the titers have already reached a plateau by the time the initial sample is drawn. If two specimens are to be compared, they should be tested in parallel. Results from tests done at different times, in different laboratories, or with different procedures should not be compared quantitatively, only qualitatively as positive or negative.

For tests other than serology, contact a reference laboratory for instructions before collecting specimens to ensure proper collection and handling.

**DIRECT EXAMINATION**

**Microscopy**

Only very rarely can the diagnosis of toxoplasmosis be documented by the observation of parasites in patient specimens (17, 18). Secretions, excretions, body fluids, and tissues are potential specimens for direct observation of parasites but are generally unrewarding. Fluid specimens, such as heparinized blood or CSF, should be centrifuged, and the sediment should be smeared on a microscope slide. The slides should be air dried, fixed in methanol, and stained with Giemsa stain for microscopic examination. Tachyzoites may be observed as free organisms or within host cells, such as leukocytes. Well-preserved tachyzoites are crescent shaped and stain well, but degenerating organisms may be oval and stain poorly. Tissue imprints stained with Giemsa stain may reveal *T. gondii* cysts.

**Antigen Detection**

Immunologic techniques have been used to identify parasites in tissue sections or tissue cultures; fluorescein isothiocyanate- or peroxidase-labeled antisera may be useful in detecting tachyzoites in tissue sections. Enzyme immunoassay (ELA) antigen detection techniques lack sensitivity for human samples and are not recommended.

**Nucleic Acid Detection Techniques**

PCR technology for *Toxoplasma* has been used to detect congenital infections, toxoplasmic encephalitis in AIDS patients, and ocular disease, with various degrees of success (19–26). The most important use of PCR is for prenatal diagnosis of congenital toxoplasmosis using amniotic fluid. When ma-
ternal serological results indicate potential infection during pregnancy, PCR of amniotic fluid has been shown to be more sensitive for the confirmation of fetal infection than the conventional methods of inoculation of mice and tissue culture cells and fetal blood testing for IgM (27, 28). PCR technology for Toxoplasma is offered at the Toxoplasma Serology Laboratory, Palo Alto, CA, and by a few commercial laboratories. Commercial kits are not yet available. The most common PCR targets include the 18S ribosomal DNA, B1, and AFI46257 genes. The requestor should be aware that the levels of reliability of PCR tests may vary widely (19, 29–32). PCR testing by low-density microarrays has been used successfully in the evaluation of granulomatous lymphadenitis (33). Recently, loop-mediated isothermal amplification has been used to detect Toxoplasma DNA in blood (34).

Cell-Mediated Immune Responses

T-cell response has been studied in newborns with congenital toxoplasmosis, and a recent study has suggested that measurement of interferon gamma production by T cells in response to stimulation by specific Toxoplasma antigens may add to the diagnosis of congenital infection (35). The interferon gamma release assay has been used successfully to detect cell-mediated responses in congenitally infected infants (36).

ISOLATION PROCEDURES

Parasites can be isolated with limited success by inoculating patient tissue or body fluids into either mice or tissue culture cells (37). Fresh tissue samples are ground in saline with a mortar and pestle and inoculated intraperitoneally into mice or directly into tissue culture flasks. The mice should be monitored for 4 to 6 weeks; if the organism is virulent for mice, the parasites can often be demonstrated in the peritoneal fluid after 5 to 10 days. However, if the organism is relatively avirulent for mice, as is usually the case, the mice may not be killed by the infection. If they survive for 6 weeks, serum samples should be obtained for serologic testing. If antibodies are present, the mouse brains should be examined for the presence of T. gondii cysts. If cysts are not observed, the murine host may not have been the ideal host. Inoculate additional mice with brain homogenate from the initially inoculated mice and observe and recheck after 6 weeks. T. gondii grows in a variety of tissue culture cells. A cytopathic effect may be detected on direct examination after 24 to 96 h in culture. Giemsa staining may reveal parasite structure, but parasitized cells may be difficult to detect. Immunofluorescence allows more-sensitive detection of the organisms. The following procedure has been used with some success for parasite isolation from amniotic fluids (2, 38). Centrifuge a 10-ml sample of amniotic fluid at 1,000 × g. Resuspend the sediment in 8 ml of minimum essential medium. Inoculate 1 ml into coverslip cultures of the human embryonic fibroblast cell line MRC5 in 24-well plates. Incubate the cultures for 96 h with one change of medium at 24 h; fix the cultures with cold acetone. Examine the coverslips by indirect immunofluorescence for the presence of T. gondii. The use of tissue culture cells for isolation permits a more rapid diagnosis than mouse inoculation; both methods can be useful for diagnosing congenital toxoplasmosis.

SEROLOGIC TESTS

Serologic testing for T. gondii-specific antibodies is the most commonly used method for diagnosis of toxoplasmosis. Many tests for the detection of antibodies to Toxoplasma have been used since Sabin and Feldman developed the methylene blue dye test (DT) (2, 32, 39). Commercial kits for agglutination tests, indirect fluorescent-antibody (IFA) tests, and EIAs are available worldwide. Because of difficulties in obtaining specimens from patients with clinically documented toxoplasmosis, commercial kit sensitivity and specificity may not be based on documented case specimens but rather on a comparison of results obtained with another kit. Consequently, the true sensitivity and specificity of a kit are generally not known or determined. The rates stated by the manufacturer or published in articles may vary depending upon the samples chosen for testing. Sensitivity and specificity rates determined in prospective studies when random samples are tested as received for Toxoplasma testing, will usually differ from those determined in retrospective studies, when the samples have been chosen as potential problem samples to increase the probability of detecting false-positive or false-negative reactions.

When laboratory personnel decide to initiate Toxoplasma-specific antibody testing when they have not yet purchased a commercial kit, they must carefully review the manufacturer’s package insert and published literature for information on the sensitivity and specificity of the test. The user should perform a laboratory comparison of kits by using positive and negative samples confirmed by a toxoplasmosis reference laboratory. Tables 1 and 2 list commercial kits available in the United States and references to published evaluations. However, the test kit industry is in a great deal of flux; company and kit names may change.

In the United States, initial testing for the presence of IgG antibodies in most laboratories is usually performed with an EIA or IFA commercial kit. Results may be stated in international units (based on the WHO international standard reference serum for Toxoplasma [32, 40] distributed by Public Health Wales, Singleton Hospital, Swansea, Wales, United Kingdom) as an index (specific to each kit), as an optical density value (specific to each kit), or as a geometric mean titer. Numerical results are not comparable from kit to kit; comparison may be made only qualitatively as negative (nonreactive or not infected) or positive (reactive or infected). Although elevated Toxoplasma-specific IgG levels have been suggested as an indicator of congenital infection, high IgG levels may last for many years after primary infection and should not be relied upon for this purpose.

To more definitely distinguish acute and chronic infections, detection of Toxoplasma-specific IgM antibodies has been used. The most important use of IgM test results is that a negative reaction essentially excludes recent infection. A guide to the general interpretation of Toxoplasma IgG and IgM serology results is presented in Table 3. IgM test IgM titers generally increase within 1 week of the onset of symptoms and revert to negative within 6 to 9 months of infection. False-positive reactions caused by rheumatoid factor and false-negative reactions caused by blockage by Toxoplasma-specific IgM may occur in IFA IgM tests and indirect EIAs for IgM when whole serum samples are tested. To decrease the effects of these interfering factors, specimens should be treated to obtain only the IgM fraction for testing.

The IgM capture EIA eliminates potential interference by IgG and other isotypes by binding only IgM antibodies; unbound antibodies are removed by washing the plate, which eliminates the need for serum fractionation. The most important advantage of the IgM capture EIA compared to other IFA tests is the increased detection of congenital infections: the IgM enzyme-linked immunosorbent assay

Multiple commercial kits are available from companies outside the United States: Ani Labsystems (48), bioMérieux (23, 49), and DiaSorin (50).

Other tests may be of assistance in determining current infection. Assays for Toxoplasma-specific IgA antibodies should always be performed in addition to IgM assays for newborns suspected of having congenital infection (51–53). Results of IgA testing in adults have been less consistent (54). The presence of Toxoplasma-specific IgA antibodies may also contribute to the determination of acute infections, although reports of the utility of IgA antibody detection have been mixed (55, 56). Immunoblot assays may be useful in determining congenital infections (57, 58) and ocular infections (59). These and other assays (30, 32, 60) are available in the United States at the Toxoplasma Serology Laboratory, Palo Alto Medical Foundation, Palo Alto, CA (http://www.pamf.org/serology/; phone, 650-853-4828) and at many of the Toxoplasma Reference Laboratories in Europe (for example, the National Reference Centre for Toxoplasmosis, Maison Blanche Hospital, University Reims Champagne, Ardenne, France).

A guideline for the clinical use and interpretation of serologic tests for Toxoplasma gondii was published (61) by the Clinical and Laboratory Standards Institute (formerly called the National Committee for Clinical Laboratory

CLINICAL USE OF IMMUNODIAGNOSTIC TESTS

There are four groups of patients for whom diagnosis of toxoplasmosis is critical: pregnant women with infection during gestation, congenitally infected newborns, patients with chorioretinitis, and immunocompromised individuals.

Determination of Immune Status

An algorithm for serological testing for immune status and acute acquired infection is shown in Fig. 3. Three times at which baseline information about an individual’s immune status would be useful include the following: (i) before con-

ception; (ii) before receiving immunosuppressive therapy; and (iii) after the initial determination of positive HIV-1 status. Screening one serum specimen with a sensitive test for IgG antibodies, such as the DT, the IFA test, or EIA, is sufficient. A negative test result indicates that the patient has not been infected. A positive result of any degree indicates infection with *T. gondii* at some undetermined time.

### Diagnosis of Acute Acquired Infections

If an acute acquired infection is suspected, the patient’s serum specimen should be tested for the presence of *Toxoplasma*-specific antibodies (Fig. 3). A negative result in the DT, IgG IFA test, or IgG EIA essentially excludes a diagnosis of acute *Toxoplasma* infection in an immunocompetent person. Very rarely, early after infection, a person may present with a positive IgM and a negative IgG result, which will soon turn positive. Demonstration of seroconversion from a negative titer to a positive titer or a >4-fold increase in titer confirms the diagnosis of recent infection when specimens drawn several weeks apart are tested in parallel with the same test. However, such situations are rare because specimens are usually drawn after titers have peaked, too late to observe titer changes after initial infection. The presence of typical lymphadenopathy suggestive of acute toxoplasmosis, the presence of a high DT or IgG IFA titer (≥300 IU/ml or ≥1:1,000), and the presence of specific IgM are indicative of acute infection (49, 62, 63). If the patient has clinical illness compatible with toxoplasmosis, but the IgG titer is low, a follow-up test 3 weeks later should show an increase in the antibody titer if the illness is due to acute toxoplasmosis and the host is not severely immunosuppressed.

Results of an EIA for IgM and an IgG avidity assay can provide additional evidence for or against acute infection when IgG antibodies are present (2, 32, 64). A negative IgM test essentially rules out infection in the previous 6 months. A positive IgM titer combined with a positive IgG titer may be suggestive of acute infection (due to persistent IgM antibodies) or may be a false-positive reaction.

### Diagnosis during Pregnancy

Congenital toxoplasmosis occurs when a woman passes the infection to her fetus after acquiring a primary infection during pregnancy or, more rarely, when a pregnant woman is immunocompromised and a previously acquired infection is reactivated. Congenital toxoplasmosis can also occur, as more recently described, when secondary infection with a different genotype occurs (7, 39, 65). The rate of transmission of infection to the fetus ranges from 11% in the first trimester to 90% in the late third trimester, with an overall transmission rate of approximately 30 to 50%. In France and Austria, the prevention, diagnosis, and treatment of congenital toxoplasmosis begin with mandatory serologic testing of all women before or soon after conception. The cost-effectiveness of adopting this approach for all pregnant women in the United States is controversial, although modeling suggests that it may be cost-effective; this approach does serve as a model for managing individual pregnant patients (30, 66, 67).
Immunocompetent women who have IgG antibody before conception are generally considered immune and so at very little risk for transmission of infection to the fetus. As noted above, newer research suggests that infection with a second genotype may occasionally lead to congenital transmission. Women who are seronegative are considered at risk for infection and in France are tested monthly during pregnancy for IgG antibody. If a woman is first tested after conception and has a low IgG avidity for many months after infection. Immunodiagnosis of acute infection in a pregnant woman should be confirmed by a toxoplasmosis reference laboratory prior to intervention (30, 31, 35, 39).

When the diagnosis of acute toxoplasmosis has been made in a pregnant woman, she can be treated and the fetus can be tested for evidence of infection. The strategy used by Daffos et al. (68) involved initiating treatment with spiramycin once acute maternal infection was indicated. When the diagnosis of acute toxoplasmosis has been established (Fig. 4). Amniotic fluid PCR (at 18 weeks of gestation or later) is the test of choice to establish the intrauterine diagnosis of congenital toxoplasmosis (44, 69–72). In addition, fetal ultrasound examinations were performed every 2 to 4 weeks until delivery to search for several nonspecific signs of infection: cerebral or hepatic calcifications, hydrocephalus, hepatomegaly, or ascites.

If collected, fetal blood should be tested for Toxoplasma-specific IgG, IgM, and IgA antibodies. Clotted blood should be inoculated into mice or tissue culture cells to demonstrate parasitism. Nonspecific markers of infection should be evaluated; these include leukocytes, eosinophils, platelets, total IgM, gamma-glutamyltransferase, and lactate dehydrogenase (69). Most infected fetuses have one or more abnormal nonspecific tests, most commonly an elevated total IgM level or an elevated gamma-glutamyltransferase level (58, 67, 69, 73). Demonstrating Toxoplasma-specific IgM or IgA antibodies in fetal serum or isolating the parasite from fetal leukocytes is a definitive diagnosis of fetal infection.

**Diagnosis in Newborns**

Diagnosis of Toxoplasma infection in newborns is made through a combination of serologic testing, parasite isolation, and nonspecific findings (58, 69, 74–76). An attempt should be made to isolate *T. gondii* from the placenta, amniotic fluid, and cord blood if the diagnosis has not already been established (Fig. 5). *T. gondii* has been isolated from 95% of the placentas of congenitally infected newborns when the mother has not been treated and from approximately 81% when the mother has been treated. However, *T. gondii* can be isolated from the placentas of uninfected newborns as well. The child’s serum should be tested for total IgG and IgM antibody levels and Toxoplasma-specific IgG, IgM, and IgA antibodies. CSF should be analyzed for cells, glucose, protein, total IgG antibody, and Toxoplasma-specific IgG and IgM antibodies and directly examined for *T. gondii* tachyzoites. A child suspected of having congenital toxoplasmosis should have a thorough general, neurologic, and ophthalmologic examination and a computed tomographic scan of the head (magnetic resonance imaging does not demonstrate calcifications). Because the diagnosis can take several months to confirm, clinicians may have to treat patients based upon early signs, symptoms, and serology while awaiting definitive confirmation. Although the complexity of diagnosing congenital infection necessitates the use of multiple costly laboratory tests, the benefit of early diagnosis and treatment and the cost of unnecessary treatment justify establishing the correct diagnosis.

Persistent or increasing IgG antibody levels in the infant compared with the mother as measured by the DT or IFA test and/or a positive result for *Toxoplasma*-specific IgM or IgA are diagnostic of congenital infection. Demonstration by IgG and IgM Western blotting of serum antibodies in the newborn that are directed against unique *Toxoplasma* epitopes not found in the mother’s serum is also evidence of congenital infection (31, 32, 39, 46, 77).

Placental leak may occasionally lead to false-positive IgM or IgA measurements in newborns. Positive tests for these antibodies usually must be confirmed by repeat testing for IgM at 2 to 4 days of life and repeat testing for IgA at 10 days of life. Passively transferred maternal IgG has a half-life of approximately 1 month. Maternal antibodies can be detected for several months and have been reported at up to 1 year of age. Pathologic findings in newborns with congenital toxoplasmosis may include significant hepatomegaly and splenomegaly, severe anemia, generalized lymphadenopathy, low birth weight, seizures, growth retardation, and visual abnormalities.

**FIGURE 5** Algorithm for the diagnosis of neonatal congenital toxoplasmosis. doi:10.1128/9781555817381.ch138.f5

### Algorithm for the diagnosis of antenatal congenital toxoplasmosis

- **Acute infection documented in a pregnant woman**
  - Perform fetal ultrasound every 2 to 4 weeks.
  - Obtain amniotic fluid sample.

- **Amniotic fluid pellet**
  - PCR
  - Mouse or tissue culture inoculation

- Either both positive; infected; both negative; perhaps infected; evaluate neonate

---

**FIGURE 4** Algorithm for the diagnosis of antenatal congenital toxoplasmosis. doi:10.1128/9781555817381.ch138.f4

| If diagnosis has not been established antenatally, attempt isolation of parasites from amniotic fluid, placenta, and cord leukocytes. |
| Perform *Toxoplasma*-specific laboratory tests on newborn and maternal serum samples: IgG, IgM, IgA, IgE, and PCR |
| Perform general, neurologic, and ophthalmologic examinations of the newborn, including complete blood count with differential and platelet count, serum bilirubin, gamma-glutamyltransferase, creatinine, and quantitative immunoglobulin, urinalysis, brain computed tomography, and auditory brain stem response to 20 dB of sound. |
to 1 year of age. Untreated congenitally infected newborns will begin to produce Toxoplasma-specific IgG antibody within approximately 3 months. Treatment of an infected child may delay antibody production until 9 months of age and on rare occasion may prevent production altogether. The persistence of a positive IgG result at 12 months of life in the child confirms infection. Demonstration of a decrease in antibody load (Toxoplasma-specific IgG antibody divided by total IgG) can be helpful in differentiating maternal antibody from fetal antibody. Although rarely performed, demonstration of IgM antibody or local Toxoplasma-specific IgG antibody production in CSF not contaminated with peripheral blood can help confirm the diagnosis of congenital toxoplasmosis. The calculation is made by dividing the Toxoplasma-specific antibody titer in the body fluid by the Toxoplasma-specific antibody titer in the serum and multiplying the result by the concentration of gamma globulin in serum divided by the concentration of gamma globulin in the body fluid. Absence of 4 or greater suggests corresponding to significant antibody production.

A long-term prospective study is under way in the United States to define optimal therapeutic regimens for the treatment of congenital toxoplasmosis (8, 78). Clinicians should contact Rima McLeod, University of Chicago Hospitals, Chicago, IL (phone, 773-834-4152) regarding the treatment of infected children.

**Diagnosis of Ocular Infection**

Toxoplasma chorioretinitis results from both acute infection and congenital infection (79, 80). In addition to demonstration of IgG antibody to Toxoplasma in the serum of a person with compatible eye lesions, demonstration of the local production of antibody and detection of parasite DNA in aqueous humor have been used to document active ocular toxoplasmosis (2, 20, 23, 81). When the formula described in the section above is used to calculate results obtained in eye fluids and results obtained in serum, a value of 8 or greater suggests acute ocular toxoplasmosis. If the serum DT titer is greater than 1:1,000, it is usually not possible to calculate local antibody production.

**Diagnosis in Immunocompromised Hosts**

A wide variety of immunosuppressed hosts, including patients with hematologic and solid-tumor malignancies, transplant recipients, and those with autoimmune disorders, have been described as having severe, often fatal, toxoplasmosis. The disease is most often related to reactivation of latent infection and commonly involves the CNS, although a wide spectrum of clinical manifestations has been reported. Diagnosis can be very difficult for these patients, as IgM antibody is usually not detectable, and the presence of IgG antibody only confirms chronic infection. In the absence of serologic evidence of acute infection, diagnosis can be confirmed by demonstration of the organism histologically or cytologically as replicating within tissue or by isolation or identification of its nucleic acids in a site such as amniotic fluid, CSF, bronchoalveolar fluid, or placenta, in which the encysted organism would not be present as part of a latent infection.

Persons undergoing organ or bone marrow transplantation can benefit from pretransplant testing for Toxoplasma-specific IgG antibodies to determine immune status because they are either at risk for acute acquired infection if they are seronegative before transplantation or at risk for reactivation if they are seropositive before transplantation (2, 82). Those with acute acquired infection will usually develop detectable Toxoplasma-specific IgG and IgM antibodies, while those with reactivation will not have a detectable Toxoplasma-specific IgM response. Serial measurement of Toxoplasma DNA in peripheral blood by PCR has been advocated by some as a supplement to serology for monitoring for development of toxoplasmosis in bone marrow transplant patients (21, 22). Seronegative transplant recipients of hearts from seropositive donors can develop toxoplasmic myocarditis that mimics organ rejection.

Toxoplasmic encephalitis is the most frequent CNS opportunistic infection of AIDS patients and is uniformly fatal if untreated. Among people who died with AIDS from 1992 through 1997 in the United States, 7.2% developed toxoplasmic encephalitis during the course of their AIDS (11, 83). It is recommended that all HIV-infected persons be tested for Toxoplasma-specific IgG antibodies soon after the diagnosis of HIV infection to detect latent infection (11, 83). If Toxoplasma-seropositive, adult/adolescent patients who have a CD4+ T-lymphocyte count of <100/µl should be administered treatment as described in the treatment section. Most AIDS patients with toxoplasmic encephalitis have demonstrable IgG antibodies to T. gondii. However, approximately 3% of AIDS patients with toxoplasmic encephalitis do not have Toxoplasma-specific antibody in their serum. Local production of Toxoplasma-specific IgG antibody in CSF has been demonstrated for persons with AIDS and with toxoplasmic encephalitis (31, 32). When the formula described above for toxoplasmosis in the newborn is used, a result of greater than 1 corresponds to significant antibody production.

**TREATMENT**

In general, physicians treat four types of patients with T. gondii infection: (i) pregnant women with acute infection to prevent fetal infection (30, 67, 68, 76, 84, 85); (ii) congenitally infected infants (74, 78, 86–88); (iii) immunosuppressed persons, usually with reactivated disease (11, 21, 22, 31, 83, 89–91); and (iv) patients with acute and recurrent ocular disease (79, 80, 92–95). Drugs are also prescribed for preventive or suppressive treatment of HIV-infected individuals (74, 78, 92–95). The currently recommended drugs work primarily against the actively dividing tachyzoite form of T. gondii and do not eradicate encysted organisms (bradyzoites).

The most common drug combination used to treat congenital toxoplasmosis consists of pyrimethamine and a sulfonamide (sulfadiazine is recommended in the United States) plus folinic acid in the form of leucovorin calcium to protect the bone marrow from the toxic effects of pyrimethamine. Pyrimethamine inhibits dihydrofolate reductase, which is important in the synthesis of folic acid and produces a reversible depression of the bone marrow. Sulfonamides inhibit synthesis of dihydrofolic acid, also important in the synthesis of folic acid. The two drugs work synergistically against T. gondii. Due to toxicity in early pregnancy, pyrimethamine and sulfadiazine therapy is generally recommended for use in pregnant women at 218 weeks of gestation (39, 60). After the 18th week, pyrimethamine and sulfadiazine may be given if fetal infection is confirmed by amniocentesis or cordocentesis. Spiramycin (available through the FDA [phone, 301-796-0563 or 301-796-1400; if no response, then 301-796-3763]) is recommended for pregnant women with acute toxoplasmosis when fetal infection has not been confirmed in an attempt to prevent the
transmission of *Toxoplasma gondii* from the mother to the fetus (39, 60). Randomized prospective studies of treatment during acute infection in pregnant women have not been performed. Some researchers have questioned, or been unable to demonstrate, the effectiveness of treatment during pregnancy in preventing congenital infection (76, 96) or sequelae in infants (96). One hypothesis for the lack of effectiveness is that *T. gondii* tachyzoites transform into bradyzoites within days of infection, probably coinciding with the serological and cell-mediated responses (96). Therefore, by the time an infection is detected in a pregnant woman, tachyzoites already may have been transmitted to the fetus, inflicted damage, and converted to encysted bradyzoites that do not respond to therapy. Nevertheless, a multicenter observational study found that the treatment of acute *T. gondii* infection in pregnancy was associated with a reduction of sequelae in infants but not a reduction in maternal-fetal transmission (68). Pyrimethamine and sulfadiazine (plus leucovorin) are the drugs generally used to treat infants with congenital toxoplasmosis and have led to improved outcomes compared with those of historic controls (39, 74, 78).

In immunosuppressed persons with toxoplasmosis, a regimen of pyrimethamine and sulfadiazine plus leucovorin is the preferred treatment (11, 31, 60, 83). Clindamycin is a second alternative for use in combination with pyrimethamine and leucovorin in those who cannot tolerate sulfonamides (11, 60, 83, 91, 97). Leucovorin prevents the hematologic toxicities associated with pyrimethamine therapy. Atovaquone in combination with either pyrimethamine or sulfadiazine has sufficient activity to be considered for treatment in some less severely affected adult patients (60, 98). The role of other drugs in the treatment of systemic toxoplasmosis has not been defined by controlled trials. In general, alternative drugs, such as azithromycin, clarithromycin, and dapsone, should be used in combination with another drug, preferably pyrimethamine (31).

Because relapse often occurs after toxoplasmosis in HIV-infected patients, maintenance therapy (secondary prophylaxis) with pyrimethamine plus sulfadiazine (first choice) or pyrimethamine plus clindamycin (alternative) is recommended (10, 82). Secondary prophylaxis for toxoplasmosis may be discontinued in patients with a sustained increase in CD4+ counts (e.g., 6 months) to >200 cells/μl in response to highly active antiretroviral therapy if the patient has completed the initial therapy and has no symptoms or signs attributable to toxoplasmosis. For prophylaxis to prevent an initial episode of *T. gondii* in *Toxoplasma*-seropositive persons with a CD4+ T-lymphocyte count of less than 100 cells/μl, trimethoprim-sulfamethoxazole is recommended as the first choice, with alternatives consisting of dapsone plus pyrimethamine, or atovaquone with or without pyrimethamine. Leucovorin is given with all regimens, including pyrimethamine (11, 83).

Pyrimethamine and sulfadiazine are often used for persons with ocular disease (80). Clindamycin, in combination with other antiparasitic medications, is also frequently prescribed for ocular disease (93). A variety of newer agents have been tried in the treatment of ocular toxoplasmosis, including atovaquone (99), rifabutin, trovafloxacin, azithromycin, and clarithromycin (100). In addition to prescribing antiparasitic drugs, physicians may add corticosteroids to reduce ocular inflammation. However, the optimal treatment for ocular toxoplasmosis remains to be defined by controlled trials.

Small, free-living amebae belonging to the genera *Naegleria*, *Acanthamoeba*, and *Balamuthia* have been identified as agents of central nervous system (CNS) infections of humans and other animals (1–37). Only one species of *Naegleria* (N. *fowleri*), several species of *Acanthamoeba* (e.g., *A. castellanii*, *A. culbertsoni*, *A. hatchetti*, *A. healyi*, *A. polyphaga*, *A. rhysoides*, *A. astronyxis*, *A. lenticulata*, and *A. divationis*), and the only known species of *Balamuthia* (*B. mandrillaris*), are known to cause disease. *Acanthamoeba* spp. also cause infection of the human cornea, *Acanthamoeba* keratitis (38–44). Further, both *Acanthamoeba* spp. and *B. mandrillaris* have been identified as agents of cutaneous infections in humans (7, 12, 17, 19, 22, 33, 34, 45). *Sappinia diploidea*, a free-living ameba normally found in soil contaminated with the feces of elk and buffalo, was identified in an excited brain lesion from a 38-year-old immunocompetent man who developed a bifrontal headache, blurry vision, and loss of consciousness following a sinus infection (46). This ameba was recently identified as *Sappinia pedata* based on a real-time PCR assay (47). Additionally, *Paravahlkampfia francinae*, a new species of the free-living ameba genus *Paravahlkampfia*, was recently isolated from the cerebrospinal fluid (CSF) of a patient with a headache, sore throat, and vomiting, symptoms typical of primary amebic meningoencephalitis (PAM) caused by *Naegleria fowleri*. The patient recovered within a few days, indicating that some of the previously reported patients with PAM who survived may have been infected with *P. francinae* (48). These findings clearly indicate that there are probably other small amebae that may also cause encephalitis in humans.

The concept that these small, free-living amebae may occur as human pathogens was proposed by Culbertson and colleagues, who isolated *Acanthamoeba* sp. strain A-1 (now designated *A. culbertsoni*) from tissue culture medium thought to contain an unknown virus (49). They also demonstrated the presence of amebae in brain lesions of mice and monkeys that died within a week after intracerebral inoculation with *A. culbertsoni*. Culbertson et al. hypothesized that similar infections might exist in nature in humans. In 1965, Fowler and Carter were the first to describe a fatal infection due to free-living amebae in the brain of an Australian patient (50). The infection is now believed to have been due to *N. fowleri*, as reported in reference 50.

**TAXONOMY**

Until recently, the classical taxonomic classification was based largely on morphologic, ecologic, and physiologic criteria. According to this system, *Acanthamoeba* and *Balamuthia*, along with a heterogeneous group of amebae that include both free-living (e.g., *Hartmannella*, *Vahlkampfia*, and *Vanrellia*) and parasitic (e.g., *Entamoeba histolytica*) amebae, were classified under the phylum *Protozoa*, subphylum *Sarcodina*, class *Lobosea*, order *Amebida*, and family *Vahlkampfiidae*. Additional species of *Balamuthia* were classified under the class *Heterolobosea*, order *Amoebida*, and family *Vahlkampfiidae*. *Naegleria* was classified under the class *Heterolobosea*, order *Amoebida*, and family *Heterolobosea*. Recent information based on modern morphological approaches, biochemical pathways, and molecular phylogenetics has led to the abandonment of the traditional classification system and replacement with a new classification system. According to this new schema, the eukaryotes have been classified into six clusters or “superclusters,” namely, *Amoebozoa*, *Opisthokonta*, *Rhizaria*, *Archaeplastida*, *Chromalveolata*, and *Excavata*. *Acanthamoeba* and *Balamuthia* are included under the supergroup *Amoebozoa*: *Acanthamoebidae*; *Naegleria* is included under the supergroup *Amoebozoa*: *Vahlkampfiidae*; *Sappinia* is included under the supergroup *Amoebozoa*: *Flabellinea*: *Thecamoebidae*; and *Naegleria* is included under the supergroup *Excavata*: *Heterolobosidae* (51). The classification of amebae presented here is supported by the International Society of Protistologists. However, other classification schemes may also be used.

**DESCRIPTION OF THE AGENTS**

*Acanthamoeba* spp.

*Acanthamoeba* has two stages in its life cycle, a feeding and multiplying stage, the trophozoite and the cyst (a dormant, resistant stage). The trophozoite measures 15 to 45 μm in length and produces from the surface of its body fine, tapering, hyaline projections called acanthopodia (see Fig. 5). The trophozoite is uninucleate, although binucleate forms are occasionally seen. The nucleus is characterized by a centrally located, large, dense nucleolus. It feeds on *Escherichia coli* or other Gram-negative bacteria and divides by binary fission. During cell division, the nucleus divides by conventional mitosis, in which the nucleolus and the nuclear membrane disappear. It has no flagellate stage but produces a double-walled cyst (10 to 25 μm) (see Fig. 6) with a wrinkled outer wall (the ectocyst) and a stellate, polygonal, or even round inner wall (the endocyst) (52).
Cysts are resistant to many physical and chemical environmental pressures, including desiccation (53).

The genus *Acanthamoeba* contains as many as 24 species in three groups, with groupings based largely on morphologic characteristics. In group I are included those species that have large trophozoites and cysts that measure more than 18 μm. Group II is the largest group, and its members are the most widespread; the endocysts are usually stellate, polygonal, triangular, and oval and measure less than 18 μm. Group III includes those species with cysts that measure less than 18 μm, and the endocysts are either round or oval. Because such morphological characters may change with environmental pressures and culture conditions, efforts were made to utilize nonmorphologic characters for use in taxonomic classification. Therefore, the 18S rRNA gene was considered a good target for the classification and diagnosis of *Acanthamoeba* infection since it has multiple copies and is evolutionarily stable. In the case of *Acanthamoeba*, a substantial sequence variation was seen not only between the species but also within the same species, identified based on morphological features. *Acanthamoeba* is therefore classified into 18 genotypes known as T1 to T18 (54–56).

**Naegleria**

*N. fowleri* has three stages, a trophozoite, a flagellate, and a cyst, in its life cycle. The trophozoite is a small, slug-like ameba measuring 10 to 25 μm long that exhibits an eruptive locomotion by producing smooth hemispherical bulges. The posterior end, termed the uroid, appears to be sticky and often has several trailing filaments. It is uninucleate and is characterized by a centrally located, large, dense nucleolus. It feeds on *Escherichia coli* or other Gram-negative bacteria and divides by binary fission. During cell division, the nucleus divides by promitosis, in which the nucleus elongates and divides into two polar bodies, and the nuclear membrane...
persists. During its life cycle, this ameba produces a transient pear-shaped biflagellate stage, resulting from altered environmental conditions, and smooth-walled cysts (Fig. 1 to 4). The flagellates do not have cytostomes (mouths). Cysts are usually spherical and measure 7 to 15 μm, and the cyst wall may have one or more pores plugged with a mucoid material (52).

**Balamuthia**

*Balamuthia* trophozoites are in general irregular in shape; a few, however, may be slug-like. They are uninucleate, but binucleate forms may occasionally be seen. The nucleus has a large centrally located nucleolus. The pattern of nuclear division in *Balamuthia* is termed mitosis, in which the nuclear membrane breaks down and the nucleus eventually disappears (32, 33). Occasionally, the nucleus of *Balamuthia*, especially in tissue sections, may have more than one nucleolus. Unlike *Acanthamoeba* and Naegleria fowleri, *Balamuthia* is not known to feed on bacteria. In the laboratory, it feeds on mammalian tissue culture cells, such as monkey kidney cells, human lung fibroblasts, or human brain microvascular endothelial cells. Actively feeding amebae may be 12 to 60 μm long, with a mean length of 30 μm (Fig. 7). The trophic forms while feeding on tissue culture cells produce broad pseudopodia without any clearly discernible movement. However, when tissue culture cells are destroyed, the trophozoites resort to a spider-like walking movement by producing finger-like determinate pseudopodia (33). Like *Acanthamoeba*, *Balamuthia* does not have a flagellate stage. Cysts are generally uninucleate and spherical and measure 6 to 30 μm in diameter (Fig. 8). Under a light microscope, each cyst appears to have an irregular and slightly wavy outer wall and a round inner wall. A layer of refractile granules immediately below the inner cyst wall is often seen in mature cysts. Under an electron microscope, the cyst wall can be seen to consist of three walls: a thin, irregular outer ectocyst; a thick, electron-dense inner endocyst; and a middle amorphous layer, the mesocyst (32, 33).

**EPIDEMIOLOGY**

Infection with *N. fowleri* was first described in 1965 in Australia and has now been identified virtually all over the world. In the United States, PAM has been reported from 1931 to 2012 and is known to affect primarily young males who frequently dive and jump into warm freshwater in the summer, when the temperature of the water in lakes and ponds, especially in the southern tier of the United States, is expected to be high. Recent occurrences of PAM in northern states such as Minnesota (13) and Kansas (37) indicate that the geographic range of *N. fowleri* is changing. It has been postulated that higher temperatures due to climate change might be responsible for increases in ambient water temperatures and, therefore, for increases in the chances of contracting *N. fowleri* infections in areas that had been free of this infection (6, 13). Poorly treated municipal water systems have been implicated in the acquisition of PAM (24, 37). However, the fact that two recent cases of PAM in Louisiana were associated with disinfected municipal water underscores the changing epidemiology of PAM (37). It is, however, believed that the risk for infection might be reduced if appropriate measures, such as holding the nose shut by using nose clips and/or not stirring up sediments while swimming or doing water sports in freshwater lakes and other bodies of water, are taken (36).

Both *Acanthamoeba* and *Balamuthia* infections have been identified from many parts of the world. However, they are not associated with a particular time of the year. *Acanthamoeba* infections are found mostly in people with immunosuppression either because of other underlying infections or because of transplantation (2, 7, 9, 12, 17–19, 21, 22, 25, 30), whereas infections with *Balamuthia* are found in both immunocompromised and immunocompetent individuals (8, 11, 20, 22, 26, 27, 29, 33, 34, 45). Recently, *B. mandrillaris* has been identified as an agent of encephalitis in solid organ transplant recipients (4, 5).

*N. fowleri* and *Acanthamoeba* spp. are commonly found in soil, freshwater, sewage, and sludge and even on dust in the air. Several species of *Acanthamoeba* have also been isolated from brackish water and seawater and from ear discharges, pulmonary secretions, nasopharyngeal mucosa samples, maxillary sinus samples, mandibular autografts, and stool samples (19, 22, 27, 34). These amebae normally feed on bacteria and multiply in their environmental niche as free-living organisms. *Acanthamoeba* spp. have also been known to harbor *Legionella* spp., *Mycobacterium avium*, and other bacterial pathogens, such as *Listeria monocytogenes*, *Burkholderia pseudomallei*, *Vibrio cholerae*, and *Escherichia coli* serotype O157, which signifies a potential expansion of the public health importance of these organisms (57, 58). Additionally, pure cultures of *A. polyphaga* have been used to isolate *Legionella pneumophila* (59), *Legionella anisa* (60), and, recently, *Mycobacterium massiliense* (61) from human clinical specimens, such as sputa, liver, and lung abscess specimens, and even from human feces. Obligate intracellular pathogens, such as *Chlamydia*, *Chlamydomphila*, and *Chlamydia*-like bacteria, have been found in ~5% of *Acanthamoeba* isolates, and *Chlamydomphila pneumophila*, a respiratory pathogen, can survive and grow within *Acanthamoeba* (57). Whether endosymbiont-bearing *Acanthamoeba* strains serve as reservoirs for these bacteria, some of which are potential pathogens for humans, is unknown.

Although *B. mandrillaris* has been isolated from soil and dust (62–64) and its DNA found in the environment (65), not much is known about the environmental niche of *B. mandrillaris* and its feeding habits. It is, however, believed that its habitat is similar to those of *Acanthamoeba* and *Naegleria* and that it feeds on small amebae and possibly flagellates (66).

**CLINICAL SIGNIFICANCE**

**Naegleria Meningoencephalitis**

In 1966, Butt (3) described the first case of CNS infection caused by *N. fowleri* in the United States and coined the term “primary amebic meningoencephalitis” (PAM). PAM is an acute fulminating disease with an abrupt onset that occurs generally in previously healthy children and young adults who had contact with freshwater an average of 5 days before the onset of symptoms. It is characterized by a severe headache, spiking fever, a stiff neck, photophobia, and a coma, leading to death within an average of 5.3 days (range, 1 to 12 days) after the onset of symptoms (3, 6, 19, 22, 24, 27, 28, 34, 36, 37, 50). The portal of entry of the *N. fowleri* amebae is the nasal passages. When people swim in lakes and other bodies of freshwater that harbor these amebae, the amebae may enter the nostrils of the swimmers, make their way into the olfactory lobes via the cribiform plate, and cause acute hemorrhagic necrosis, leading to destruction of the olfactory bulbs and the cerebral cortex. Only a few patients have survived. Upon autopsy, large numbers of amebic trophozoites, many with ingested erythrocytes and brain tissue, are usually seen interspersed with brain tissue.
(Fig. 9). It is believed that *N. fowleri* directly ingests brain tissue by producing food cups, or amebostomes, as well as by exerting contact-dependent cytolysis, possibly mediated by a multicomponent system consisting of a heat-stable hemolytic protein, a heat-labile cytolysin, and/or phospholipase enzymes (67). Cysts of *N. fowleri* are not usually seen in brain tissue. It was believed until recently that *N. fowleri* infects only humans. In March 1997, however, a report of the first case of PAM in a South American tapir was published, indicating that PAM can occur in animals other than humans (16). Additionally, a report of PAM in Holstein cattle, associated with drinking of surface waters, indicates that this disease is probably more common than is currently appreciated (31).

**Acanthamoeba Encephalitis**

cases, spp. in tissue sections under a light microscope. In some Balamuthia it is difficult to differentiate they are also surrounded by polymorphonuclear leukocytes, blood vessels are thrombotic and exhibit fibrinoid necrosis; tous, with extensive hemorrhagic necrosis involving the most heavily affected CNS tissue. They are often edema-

A headache, confusion, dizziness, drowsiness, seizures, and even for months (17, 22, 27, 34). It is characterized by usually chronic, lasting for more than a week and sometimes even for months (17, 22, 27, 34). It is believed that the route of invasion of and penetra-

Acanthamoeba spp. Although a number of these cases were confirmed Balamuthia organisms. Since cysts were found in the brain of patient (17). It is believed that the route of invasion of and penetra-

Acanthamoeba spp. also cause infections of the CNS in the lower respiratory tract or the skin (17, 19, 22, 27, 34). Acanthamoeba spp. also cause infections of the CNS of animals other than humans. Such infections have been recorded in gorillas, monkeys, dogs, ovines, bovines, horses, and kangaroos (10, 19, 22, 23, 27, 34).

Balamuthia (Leptomycid) Encephalitis

It was believed that all cases of GAE were caused by Acanthamoeba spp. Although a number of these cases were confirmed by serologic techniques as being caused by Acanthamoeba spp., the causative organisms in a few cases could not be definitively identified. Since cysts were found in the brain tissues of the patients, it was believed that the infections were caused by some other species of Acanthamoeba that did not cross-react with the anti-Acanthamoeba sera used in the serologic test (19, 22, 27, 34). B. mandrillaris (leptomycid ameba) was definitively identified by an indirect immunofluorescence test as the causal agent in these and many other cases (4, 5, 8, 10, 11, 19, 22, 23, 26, 29, 33–35). The rabbit anti-B. mandrillaris serum used in the indirect immunofluorescence test was made by using culture-

e of specimens.

The pathology and pathogenesis of B. mandrillaris-induced GAE are similar to those of Acanthamoeba-induced GAE. Both trophozoites and cysts are found in CNS tissue (Fig. 11), and their sizes overlap those of Acanthamoeba trophozoites and cysts (19, 20, 22, 27, 32, 34, 69). Hence, it is difficult to differentiate Balamuthia from Acanthamoeba spp. in tissue sections under a light microscope. In some cases, Balamuthia trophozoites in tissue sections appear to have more than one nucleolus in the nucleus (Fig. 11). In such cases, it may be possible to distinguish Balamuthia ameba from Acanthamoeba organisms on the basis of nuclear morphology, since Acanthamoeba trophozoites have only one nucleolus. In most cases, electron microscopy, immunohistochemical techniques, or both are necessary to identify Balamuthia organisms. Ultrastructurally, the cysts are characterized by three layers in the cyst wall: an outer wrinkled ectocyst, a middle structureless mesocyst, and an inner thin endocyst (32–34). Balamuthia ameba are anti-

Acanthamoeba Keratitis

Acanthamoeba spp. also cause a painful vision-threatening disease of the human cornea, Acanthamoeba keratitis. If the infection is not treated promptly, it may lead to ulceration of the cornea, loss of visual acuity, and eventually blindness and enucleation (17, 19, 21, 22, 27, 38–44). Acanthamoeba keratitis is characterized by severe ocular pain, a 360° or partial paracentral stromal ring infiltrate, recurrent corneal epithelial breakdown, and a corneal lesion refractory to the commonly used ophthalmic antibacterial medications. Acanthamoeba keratitis in the early stages is frequently misdiagnosed as herpes simplex virus keratitis because of the irregular epithelial lesions, stromal infiltrative keratitis, and edema that are commonly seen in herpes simplex virus keratitis (38–44). A nonhealing corneal ulcer is often the first clue that Acanthamoeba keratitis may be the problem.

The first case of Acanthamoeba keratitis in the United States was reported in 1973 in a south Texas rancher with a history of trauma to his right eye (40). Both the trophozoite and cyst stages of A. polyphaga were demonstrated to be present in corneal sections and were repeatedly cultured from corneal scrapings and biopsy specimens. Between 1973 and July 1986, 208 cases were diagnosed and reported to the Centers for Disease Control (CDC) (43). The numbers of cases increased gradually between 1973 and 1984, and a dramatic increase began in 1985. An in-depth epidemiologic and case-control study (43) revealed that a major risk factor was the use of contact lenses, predominantly daily-wear or extended-wear soft lenses, and that patients with Acanthamoeba keratitis were significantly more likely than controls to use homemade saline solution instead of commercially prepared saline (78 and 30%, respectively), to disinfect their lenses less frequently than recommended by the lens manufacturers (72 and 32%), and to wear their lenses while swimming (63 and 30%). Based on a case-control study conducted by the CDC to investigate a recent increase in the Acanthamoeba keratitis cases during 2004 to 2007, it was revealed that a national increase in the number of such cases was associated with the use of Advanced Medical Optics Complete MoisturePlus multipurpose contact lens solution (44). Further, another study revealed that most contact lens solutions marketed in the United States do not have sufficient disinfection activity against Acanthamoeba spp. (70).

COLLECTION, HANDLING, AND STORAGE OF SPECIMENS

For isolation of N. fowleri, CSF, and brain tissue (especially surrounding the nasal olfactory bulbs) should be obtained aseptically. For Acanthamoeba and Balamuthia, CSF, brain, lungs, and ulcerated skin tissues, and for Acanthamoeba in the case of Acanthamoeba keratitis, corneal scrapings or corneal biopsy tissue should be obtained aseptically. The
specimens should be kept at room temperature (24 to 28°C) and should never be frozen. Personnel handling the specimens must take appropriate precautions, such as wearing surgical masks and gloves and working in a biological safety cabinet. Remaining tissues must be preserved in 10% neutral buffered Formalin so that they can be examined histologically for amebae (69).

CLINICAL AND LABORATORY DIAGNOSIS

Methods of Examination

Direct Examination
Since no distinctive clinical features differentiate PAM from pyogenic or bacterial meningitis, direct examination of the sample as a wet mount preparation is of paramount importance in the diagnosis of PAM and other diseases caused by these amebae. In PAM, the CSF is usually pleocytotic, with a preponderance of polymorphonuclear leukocytes and no bacteria. The CSF pressure may be elevated. The CSF glucose level may be normal or slightly reduced, but the CSF protein level is increased, ranging from 1 to 10 mg/ml. Microscopic detection of amebic organisms in the CSF is the only means of diagnosing PAM. CSF should be examined in situ microscopically for the presence of *N. fowleri* amebae with directional movement. Since the amebae tend to attach to the surface of the container, the container should be shaken gently; then, a small drop of fluid should be placed on a clean microscope slide and covered with a no. 1 coverslip. The CSF may have to be centrifuged at 500 × g for 5 min to concentrate the amebae. After the specimen has been centrifuged, most of the supernatant is carefully aspirated and the sediment is gently suspended in the remaining fluid. A drop of this suspension is prepared as described above for microscopic observation. Giemsa or trichrome staining should be performed on CSF smears to visualize the nuclear morphology of the amebae. The slide preparation should be examined under a compound microscope with 10× and 40× lens objectives. Phase-contrast optics is preferable. If regular bright-field illumination is used, the slide should be examined under diminished light. The slide may be warmed to 35°C (to promote amebic division of EM Industries, Inc.) (27, 34). CSF can also be processed via cytospinning whenever possible and stained with Wright-Giemsa stain. Amebae, if present, can be distinguished based on their nuclear morphology (13), and the result should be reported to the clinician so that the patient can be treated with appropriate medication. This is especially important in the case of PAM caused by *N. fowleri*. Gram staining is not useful in the detection of amebae. Further, a false-positive Gram stain may lead to inaccurate diagnosis and hence to inappropriate therapy, which may result in patient death. A recent report suggests the possibility of extra CNS dissemination of *N. fowleri*, and therefore, the organism might pose a risk of transmission of PAM via organ transplantation (15). A few reports describing the transplantation of solid organs from donors infected with *B. mandrillaris* (4, 5, 15) underscores the importance of a correct and timely diagnosis.

Antigen Detection
Pathogenic *N. fowleri* is morphologically indistinguishable from nonpathogenic *Naegleria* at the trophic stage. Differences between these amebae, however, have been demonstrated antigenically by the gel diffusion, immunoelectrophoretic, and immunofluorescence techniques, as well as by their isoenzyme patterns, and these techniques have been utilized to identify the amebae isolated in culture (22, 27, 34). Similarly, antigenic differences have also been shown among various species of *Acanthamoeba* (17, 19, 22, 27, 34). Additionally, *N. fowleri*, *Acanthamoeba* sp., and *B. mandrillaris* have been identified in tissue sections by histochmical methods (2–13, 15, 16, 21–23, 25–27, 29, 30, 32–35, 69).

Nucleic Acid Detection in Clinical Materials
*Acanthamoeba* genotypes have been identified in corneal tissue, tear fluid, and brain and lung tissue, as well as in the environment. A number of studies have analyzed the mitochondrial DNA and 18S rRNA gene to understand the inter- and intraspecies diversity and phylogeny of *Acanthamoeba* spp. (17, 22, 27, 34). However, only a few studies have used this technique to identify *Acanthamoeba* keratitis or *Acanthamoeba* GAE by using patient specimens (1, 2, 7, 17, 22, 27, 29, 33, 54, 55, 71). This is probably because of the lack of reagents from commercial sources.

For the detection of *Acanthamoeba*, Booton et al. (54) used nuclear single-subunit ribosomal DNA (rDNA) sequences and the genus-specific primers JDP1 (5′-GGCCCGAGTCGTTTACCGTGA-3′) and JDP2 (5′-TCTCACAAGCTGCTAGGGGAGTCA-3′), which amplify a region of the single-subunit rDNA that permits genotypic identification of an *Acanthamoeba* isolate following sequence analysis. In the case of *Balamuthia*, all isolates analyzed so far seem to be largely similar on the basis of their 18S rRNA gene sequences, whereas mitochondrial 16S rRNA gene sequences show variability of about 1.8%, in contrast to those of *Acanthamoeba* isolates (72). A PCR assay for the detection of *B. mandrillaris* has been described (72). A PCR assay to detect *B. mandrillaris* in Formalin-fixed archival tissue specimens has also been described (73). In the case of *N. fowleri*, however, different isolates show similar nuclear 18S rRNA sequences, but variation in the internal transcribed spacer (ITS) sequences has been used to identify six different genotypes (I, II, III, IV, V, VI) (74), although only three genotypes (genotypes I, II, and III) circulate in North America (75). Sequencing of the 5.8S rRNA gene and ITS1 and ITS2 of *N. fowleri* not only can differentiate *N. fowleri* from other *Naegleria* spp. and *Paravahlkampfia* spp. but also can be used in the genotypic analysis of *N. fowleri* strains (6, 13, 22, 24, 27, 34, 37, 48, 71, 74, 75). The recently unraveled genome of *N. fowleri* (76) offers great promise not only in elucidating the pathogenic mechanisms but also in the development of better
drug targeting and thus help in the survival of patients infected with this deadly pathogen.

A real-time multiplex PCR test that simultaneously identifies Acanthamoeba, Balamuthia, and N. fowleri in CSF specimens has been developed at the CDC (71). In this assay, PCR primers and TaqMan probes targeting three regions of the 18S rRNA gene are used. The real-time multiplex PCR assay is a fast, sensitive, and robust assay that detects all three pathogenic free-living amebeae, Acanthamoeba spp., Balamuthia mandrillaris, and Naegleria fowleri, simultaneously in a single specimen and has many advantages over conventional PCR. This test is being used at the CDC to identify Acanthamoeba, Balamuthia, and N. fowleri in patient specimens with great success. Based on its limited sensitivity and specificity, this assay can identify a single ameba in a specimen. Unfortunately, these molecularly based tests are not routinely available in clinical laboratories because of the lack of commercially available reagents.

**ISOLATION**

The recommended procedure for isolating free-living pathogenic amebeae from biological specimens is as follows.

**Materials**

1. Page’s ameba saline (52). Physiological saline or phosphate-buffered saline solutions that are normally available in clinical laboratories are not suitable, as the sodium chloride concentrations in these solutions will prevent the growth of amebeae, especially N. fowleri.

2. Petri dishes containing 1.5% Difco agar made with Page’s ameba saline (nonnutrient agar plate) (52). These plates can be stored at 4°C for up to 3 months. Chocolate agar with blood, Trypticase soy agar, and Lowenstein-Jensen agar have been used sometimes. These are not suitable because bacteria that coat the plates or bacteria from the clinical sample may overgrow and either prevent the growth of amebeae, especially when they are in small numbers, or obscure their presence.

3. Eighteen- to 24-h-old cultures of E. coli or Enterobacter aerogenes.

**Preparation of Agar Plates**

1. Remove the plates from the refrigerator and place them in a 37°C incubator for 30 min.

2. Add 0.5 ml of ameba saline to a slant culture of E. coli or Enterobacter aerogenes. Gently scrape the surface of the slant with a sterile bacteriologic loop (do not break the agar surface). Using a sterile Pasteur pipette, gently and uniformly suspend the bacteria. Add 2 or 3 drops of this suspension to the middle of a warmed (37°C) agar plate, and spread the bacteria over the surface of the agar with a bacteriologic loop. The plate is then ready for inoculation.

**Inoculation of Plates with Specimens**

1. For CSF samples, centrifuge the CSF at 500 × g for 5 to 8 min. With a sterile serologic pipette, carefully transfer all but 0.5 ml of the supernatant to a sterile tube, and store the tube at 4°C for possible future use. Mix the sediment with the remaining fluid. With a sterile Pasteur pipette, place 2 or 3 drops in the center of the agar plate precoated with bacteria, and incubate in room air at 37°C.

2. For tissue samples, gently grind a small piece of the tissue in a small amount of ameba saline. With a sterile Pasteur pipette, place 2 or 3 drops of the mixture in the center of the agar plate. Incubate the plate in room air at 37°C for CNS and lung tissues and at 30°C for tissues from other sites (e.g., skin and cornea).

3. Handle water and soil samples in the same manner as CSF and tissue specimens, respectively.

4. Control cultures are recommended for comparative purposes, although care should be exercised to prevent cross-contamination of patient cultures.

**Examination of Plates**

1. Using the low-power (10×) lens objective of a microscope, observe the plates daily for 7 days for amebeae.

2. If you see amebeae anywhere, circle that area with a wax pencil. With a fine spatula, cut a small piece of agar from the circled area and place it face down on the surface of a fresh agar plate precoated with bacteria; incubate as described above. Both N. fowleri and Acanthamoeba spp. can easily be cultivated in this way and, with periodic transfers, maintained indefinitely. When the plate is examined under a microscope, the amebeae will look like small blatches, and if they are observed carefully, their movement can be discerned. After 2 to 3 days of incubation, the amebeae will start to encyst. If a plate is examined after 4 to 5 days of incubation, trophozoites as well as cysts will be visible. B. mandrillaris, however, will not grow on agar plates seeded with bacteria. While B. mandrillaris can be grown on monkey kidney or lung fibroblast cell lines, on human brain microvascular endothelial cells, and axenically in a complex medium (32, 33, 77–80), such techniques are not routinely available.

**Identification and Culture**

Identification of living organisms to the genus level is based on characteristic patterns of locomotion, morphologic features of the trophozoite and cyst forms, and results of enflagellation experiments. Immunofluorescence or immunoperoxidase tests using monoclonal or polyclonal antibodies (available at the Centers for Disease Control and Prevention) will be helpful in differentiating Acanthamoeba spp. from B. mandrillaris in fixed tissue (4, 7–12, 19–23, 25, 27, 29, 32–35, 69).

**Enflagellation Experiment**

1. Mix 1 drop of the sedimented CSF containing amebeae with about 1 ml of sterile distilled water in a sterile tube, or with a bacteriologic loop scrape the surface of a plate that is positive for amebeae, transferring a loopful of scraping to a sterile tube that contains approximately 1 ml of distilled water.

2. Gently shake the tube and transfer a drop of this suspension to the center of a coverslip whose edges have been coated thinly with petroleum jelly. Place a microscope slide over the coverslip and invert the slide. Seal the edges of the coverslip with Vaspal. Place the slide in a moist chamber and incubate as before for 2 to 3 h. In addition, incubate the tube as described above.

3. Periodically examine the tube and the slide preparation microscopically for free-swimming flagellates. N. fowleri has a flagellate stage; Acanthamoeba spp. and B. mandrillaris do not. If the sample contains N. fowleri, about 30 to 50% of the amebeae will have undergone transformation into pear-shaped biflagellate organisms (Fig. 3).

**Other Culture Methods**

**Axenic Culture**

Acanthamoeba spp. can easily be cultivated axenically, without the addition of serum or host tissue, in many different
types of nutrient media, e.g., proteose peptone-yeast extract-glucose medium, Trypticase soy broth medium, and chemically defined medium (78). *N. fowleri*, however, requires media containing fetal calf serum or brain extract, e.g., Nelson's medium. A chemically defined medium has only recently been developed for *N. fowleri* (78). *B. mandrillaris* cannot be cultivated on agar plates with bacteria. It can, however, be cultivated on mammalian cell lines or a complex axenic medium (78).

Axenic cultures of *Acanthamoeba* spp. and *N. fowleri* can be established as follows. An actively growing 24- to 36-h-old ameba culture is scraped from the surface of the plate, suspended in 50 ml of ameba saline, and centrifuged at 500 × g for 5 min. The supernatant is aspirated, and the sediment is inoculated into proteose peptone-yeast extract-glucose medium or Nelson's medium, depending on the ameba isolate, and incubated at 37°C. Gentamicin, to a final concentration of 50 μg/ml, is added aseptically to the medium before the amebae are inoculated. Three subcultures into the antibiotic-containing medium at weekly intervals are usually sufficient to eliminate the associated bacteria (*E. coli* or *Enterobacter aerogenes*).

Cell Culture
*Acanthamoeba* spp., *B. mandrillaris*, and *N. fowleri* can also be inoculated onto many types of mammalian cell cultures. Shell vial cultures normally used in the isolation of viruses are suitable for the isolation of the amebae provided that antifungal agents (amphotericin B) are not included in the antibiotic mix. The amebae grow vigorously in these cell cultures and produce cytopathic effects somewhat similar to those caused by viruses (78–80). Because of such cytopathic effects, *Acanthamoeba* organisms were mistaken for transformed cell types presumed to contain viruses and were erroneously termed lipovirus and Ryan virus (17, 22, 27, 34).

Animal Inoculation
Two-week-old Swiss Webster mice weighing 12 to 15 g can be infected with these amebae. The mice are anesthetized with ether, and a drop of ameba suspension is instilled into their nostrils. Mice infected with *N. fowleri* die within 5 to 7 days after developing characteristic signs, such as ruffled fur, aimless wandering, partial paralysis, and finally coma and death. Mice infected with *Acanthamoeba* spp., and *B. mandrillaris* may die of acute disease within 5 to 7 days or may die of chronic disease after several weeks. In all cases, the presence of amebae in the mouse brain can be demonstrated either by culture or by histologic examination.

Serology
The serologic techniques discussed here have been developed as research tools and are not routinely available to clinical laboratories. Antibodies (detected by complement fixation, indirect fluorescent-antibody assay [IFA], precipitin, etc.) to *Acanthamoeba* spp. have been shown to be present in the sera of patients with GAE, upper respiratory tract distress, optic neuritis, macular disease, and keratitis (1, 17, 19, 22, 27, 30, 34, 37, 39, 40, 81).

An antibody response to *N. fowleri*, however, has not yet been defined. Most of the patients with *N. fowleri* PAM die very shortly after infection (5 to 10 days), before they have time to produce detectable levels of antibody. In one case, however, in which the patient survived PAM, an antibody response was detected by 10 days after hospitalization, ultimately reaching a titer of 1:4,096 (22, 27, 28, 34, 67).

Since the recognition of *Balamuthia* GAE is relatively new, not much information is available on the serologic responses of patients infected with *Balamuthia*. According to a recent report, four patients with confirmed *Balamuthia* GAE infection had high titers of antibody to *Balamuthia*, whereas six serum specimens from patients with encephalitis of unknown causes (10% of the sera) had titers of 64 and above and none of the control sera had titers of 64 or above (26). It is therefore possible that patients with *Balamuthia* GAE may be diagnosed premortem by using this serologic test (4, 22, 26, 27, 34). According to Schuster et al. (81), IFA can be successfully used to screen GAE due to *Acanthamoeba* and *Balamuthia* in patients whose clinical presentation, laboratory results, and neuroimaging findings are suggestive of amoebic encephalitis, thus enabling an earlier diagnosis and earlier start of antimicrobial therapy. Recently, Kucerova et al. showed by SDS-PAGE and Western blot assay that several isolates irrespective of their isolation from humans or animals or from different geographic locales are basically similar, underscoring the similarity of the isolates (82).

TREATMENT
There is no single drug that is effective against systemic acanthamebiasis. A number of antimicrobials have shown efficacy against amebae in vitro, but there is no assurance that these same drugs will be effective clinically. An important consideration in corneal infections is using drugs that are not only amebicidal but also cysticidal. As long as cysts remain viable, the infection can recur. Jones et al. (40) found that paromomycin, clotrimazole, and hydroxystilbamidine isethionate were active against *A. polyphaga* in vitro. In a recent study, azithromycin and several phenothiazine compounds protected rat glioma cells from destruction by *Acanthamoeba* (27). Colbert et al. and others found sulfadiazine to be active against experimental *Acanthamoeba* infections in mice (17, 27, 49). In vitro studies indicate that chlorhexidine gluconate and polyhexamethyl biguanide have excellent amebicidal and cysticidal properties, and they have been used topically in the treatment of *Acanthamoeba* keratitis with success. Several patients with *Acanthamoeba* keratitis have been successfully treated with different drug combinations administered over a long period (22, 27, 38–41). For example, in one study, treatment with 0.1% propamidine isethionate (Brolene) eye drops and 0.15% dibromopropamidine ointment together with topical neomycin sulfate was successful in the management of *Acanthamoeba* keratitis (39). Although a few patients with *Acanthamoeba* sp. GAE have survived, most have died in spite of treatment with several drug combinations. The prognoses of patients without CNS infection but with disseminated cutaneous ulcers due to *Acanthamoeba* spp. are good. For example, a patient with Down’s syndrome and an immunoglobulin A deficiency who also had undergone cadaveric renal transplantation developed a biopsy specimen-confirmed *Acanthamoeba* skin ulcer. The patient was successfully cured of the infection after prolonged therapy (more than 8 months) with a regimen that included topical as well as systemic administration of a combination of drugs, including topical application of chlorhexidine gluconate solution followed by 2% ketoconazole cream. He also received pentamidine isethionate intravenously for 1 month and thereafter was given oral itraconazole therapy for 8 months; this regimen resulted in complete healing of the cutaneous ulcers.
(30). Recently, several patients with *Acanthamoeba* CNS infections have also been cured with a combination of pharmacueticals that included amikacin, voriconazole, sulfa drugs, and miltefosine (1, 22, 34, 35).

Pathogenic *N. fowleri* is exquisitely susceptible to amphotericin B *in vitro*, and the minimum amebicidal concentrations were determined to be 0.02 to 0.078 µg/ml for three different clinical isolates of *N. fowleri* (22, 27, 28, 34, 50). Although many patients with PAM have been treated with amphotericin B, only two patients have survived after receiving intrathecal and intravenous injections of amphotericin B alone or in combination with miconazole (22, 27, 28, 34).

In *in vitro* studies indicate that *B. mandrillaris* is susceptible to *in vitro* to pentamidine isothiocyanate and that patients with *B. mandrillaris* infection may benefit from treatment with this drug (4, 5, 45). Although most patients with *B. mandrillaris* GAE have died of this disease, several patients have survived after treatment initially with pentamidine isethionate and subsequently with a combination of sulfadiazine, clathromycin, and flucloxacin. The antiasthma and antiasthmatic drug miltefosine and the antifungal drug voriconazole were tested in *in vitro* against *Balamuthia mandrillaris*, *Acanthamoeba* spp., and *Naegleria fowleri*. *Balamuthia* organisms exposed to <40 µM concentrations of miltefosine survived, while concentrations of ≥240 µM were amebicidal. *Acanthamoeba* spp. recovered from exposure to 40 µM but not 80 µM miltefosine. The inhibitory and amebicidal concentrations for *N. fowleri* were 40 and 55 µM, respectively. Voriconazole had little or no inhibitory effect on *Balamuthia* at concentrations up to 40 µg/ml but had a strong inhibitory effect upon *Acanthamoeba* spp. and *N. fowleri* at all drug concentrations through 40 µg/ml. The ability of miltefosine and voriconazole to penetrate into brain tissue and CSF and their low toxicity make them attractive possibilities in the treatment of the amebic encephalitides. In combination with other antimicrobials, these two drugs may form the basis of an optimal therapy for treatment of *Acanthamoeba*, *Balamuthia*, and *Naegleria* infections (79). For example, miltefosine in conjunction with other pharmaceuticals has been used in the successful treatment of *Acanthamoeba* (1), *Balamuthia* (4, 15, 83), and *N. fowleri* (84).

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

Most clinical laboratories rely on the agar plate technique for the isolation and identification of small, free-living, and pathogenic *N. fowleri* and *Acanthamoeba* spp. An agar plate inoculated with patient CSF should be microscopically examined every day for the presence of amebae. If amebae are seen, an area with amebae should be scraped and inoculated into ~1 ml of distilled water and incubated at 37°C and examined every 10 min for 1 h. If flagellates are seen, the clinician should be informed that the CSF is positive for *Naegleria* (possibly *N. fowleri*) amebae. If no flagellates are seen, even after 2 h, then the amebae should be examined under high magnification (>400X) for the presence of fine thorn-like processes (*acanthopodia*). The clinician should then be informed of the presence of ameba, probably *Acanthamoeba*. Wet mount preparations should always be confirmed with permanently stained smears (trichrome, hematoxylin, Giemsa-Wright). If other techniques, like PCR or IFA, are available, then the identity of the ameba should be confirmed. Since many clinical laboratories may not have the necessary expertise and/or equipment, they usually send the specimens to an outside laboratory like the CDC for identification and interpretation. Also, antimicrobial testing is currently not available in most clinical laboratories. Further, it is well known, at least for these free-living amebae, that what works *in vitro* may not always work *in vivo*. For example, voriconazole has no activity *in vitro* against *Balamuthia* but is one of the drugs of choice for treatment. Several patients have survived after receiving fluconazole given along with other drugs; this approach may represent synergistic activities.

Use of trade names is for identification only and does not imply endorsement by the Public Health Service or by the U.S. Department of Health and Human Services.

**REFERENCES**

Entamoeba histolytica and Giardia duodenalis infections are two of the most common protozoal infections seen worldwide and are of serious concern on a global scale due to their prevalence and the pathogenicity of their causative agents. Most of the other protozoa described in this chapter are nonpathogenic organisms. Nevertheless, detection and differentiation of nonpathogens from true pathogens in clinical specimens is useful in that their presence indicates exposure to fecal contamination and examination of additional specimens may reveal pathogenic protozoa. The pathogenic and nonpathogenic organisms are categorized as indicated in Table 1; however, reports of disease in patients infected with those organisms considered nonpathogenic are found in the literature.

Microscopic examination of stool specimens continues to be one of the main tools used in the laboratory diagnosis of intestinal amebic, flagellate, and ciliate infections. The goal of microscopy is to identify pathogenic protozoa, differentiate between these and nonpathogenic species, and properly discriminate among various artifacts that may be present. Antigen detection methods such as enzyme immunoassays (EIAs), immunochromatographic assays, and direct fluorescent-antibody (DFA) assays are available for the detection of pathogens such as E. histolytica/Entamoeba dispar group, E. histolytica, and G. duodenalis. Culture for the intestinal ameba is generally not feasible, readily available, or clinically relevant except in certain limited situations but is useful still in the diagnosis of Trichomonas vaginalis. Nucleic acid-based techniques have been developed, and reports in the literature for select pathogens are increasing. One of the most important developments related to the molecular detection of parasites is the advent of panels for detection of multiple agents of gastrointestinal disease, including combinations of bacterial, viral, and parasitic agents (1). More data from clinical evaluations, particularly related to detection of intestinal parasites, is needed to assess the performance of these systems, but on the whole they appear more sensitive than conventional methods. Multiplex molecular testing is not yet widely available for intestinal parasites, but as more kits are approved by the U.S. Food and Drug Administration (FDA), they will be a viable alternative for many laboratory settings. These assays will be particularly useful to diagnose diseases like amebiasis, for which microscopy does not allow differentiation of pathogenic versus nonpathogenic Entamoeba species. See the sections below and refer to chapters 6, 7, and 135 for additional information.

**AMEBAE**

**Taxonomy**

The amebae that parasitize the intestinal tracts of humans belong to three genera: Entamoeba, Endolimax, and Iodamoeba. They all belong to the phylum Amoebozoa, class Archamoebae, and order Entamoebida. These organisms move by means of cytoplasmic protrusions called pseudopodia (see chapter 132 of this Manual). While Dientamoeba fragilis was once classified as an ameba, it is now grouped with the flagellates; however, it is still identified microscopically on the basis of morphologic comparison to amebae.

**Description of the Agents**

Of the 11 species of intestinal amebae, E. dispar, Entamoeba hartmanni, Entamoeba coli, Entamoeba polecki, Entamoeba gingivalis, Endolimax nana, and Iodamoeba bütschlii are nonpathogenic for humans. Blastocystis hominis is also considered pathogenic, although there is still some debate Little is known about the pathogenicity of Entamoeba moshkovskii and Entamoeba bangladeshii. E. histolytica is pathogenic for humans, causing invasive intestinal and extraintestinal amebiasis.

**Epidemiology, Transmission, and Prevention**

All amebae have a common and relatively simple life cycle. The cyst is the infectious form and is acquired by ingestion of contaminated material such as water and food or by direct fecal-oral transmission. Once the cyst reaches the intestinal tract, excystation occurs, releasing trophozoites. Encystment occurs in the colon, presumably when conditions become unfavorable for the trophozoites. Cysts are passed in the feces and remain viable in the environment for days to weeks in water and soil if protected from desiccation. Improvements in sanitary conditions are necessary to prevent infections in areas where the organisms are endemic. Research to develop a vaccine against E. histolytica is ongoing, but none is currently available.

**Collection, Transport, and Storage of Specimens**

For detection of the amebae, laboratories predominantly receive stool specimens for examination. Both fresh and

A: A distinction between E. histolytica, E. dispar, E. moshkovskii, and E. bangladeshi cannot be made on the basis of morphology unless ingested RBCs are seen in the cytoplasm of the trophozoite, indicative of E. histolytica.
B: E. moshkovskii may be found in human stool specimens more predominantly in certain areas of endemicity. A free-living ameba, it is nonpathogenic and morphologically identical to E. histolytica/E. dispar (7, 30).
C: E. bangladeshi has been recently identified from human stool specimens of both symptomatic and asymptomatic individuals. It is morphologically identical to E. histolytica/E. dispar (11).
D: E. gingivalis and T. tenax are found in the oral cavity and related specimens.

Table 1: Intestinal and urogenital amebae, flagellates, and ciliates of humans

Preserved specimens are useful for the diagnosis of infection, depending on the methodology employed and the circumstances of the laboratory. If fresh specimens are received for the detection of organism motility, they must be examined quickly; wet mounts for the detection of motility cannot be performed on preserved specimens. Other sample types, such as aspirates and tissue samples, may be received and are appropriate for testing depending on the organism suspected. For a more detailed description of collection, refer to chapter 133 of this Manual.

Direct Examination

Microscopy

All diagnostic stages of the amebae (trophozoite and cyst) can be detected in fecal specimens. The key morphologic features of amebae must be used to differentiate among the various species and to distinguish between somatic cells and other material. Trophozoites must be distinguished from epithelial cells and macrophages. Cysts must be distinguished from polymorphonuclear cells. Also, yeast, pollen, molds, food particles, and other debris present in feces may cause confusion (Table 2; Fig. 1 and 2).

Morphologic examination of fecal specimens can be accomplished with fresh wet mount preparations, wet mounts of concentrated material, and permanent-stained smears. Each of these three types of preparations may be useful for visualizing certain key characteristics. Stained and unstained wet mounts of concentrated material may also be useful for identification, particularly for certain cysts such as those of E. coli and I. bütschlii. Iodine provides color and contrast, both of which may aid in the identification of organisms in wet preparations. However, morphologic examination with permanent-stained smears by oil immersion microscopy (magnification, ×1,000) is the most useful procedure (2).

Trophozoite motility is visible only in saline wet mounts of fresh feces and is often difficult to detect. The arrangement, size, and pattern of nuclear chromatid help differentiate species within the genus Entamoeba from other intestinal amebae. The size and position of the nuclear karyosome are also important morphologic features. A ring of nuclear chromatin surrounding the karyosome, resembling a bull’s-eye, is characteristic of Entamoeba. Endolimax, Iodamoeba, and the flagellate Dientamoeba lack peripheral chromatin. The cytoplasm of the trophozoites may contain granules and ingested material such as red blood cells (RBCs), bacteria, yeasts, and molds. It is important to note that it is very difficult to differentiate trophozoites of I. bütschlii from E. nana trophozoites. This is true even on the permanent-stained smear (3). The characteristics of cysts are less variable than those of trophozoites. To aid in differentiation among the genera, the cytoplasm should be examined for the presence of chromatoidal bodies and vacuoles, particularly the large glycogen vacuole seen in I. bütschlii.

Evaluation, Interpretation, and Reporting of Results

It is important to remember that identification may not be possible on the basis of one morphologic feature or the characteristics of a single organism in the preparation. Nuclear and cytoplasmic features can vary within species and may overlap between species, making identification challenging. Mixed infections are not uncommon and can be missed in a cursory examination. A complete, overall assessment of the slide is necessary for correct identification. It is important to use an accurate micrometer to measure life cycle stages. Size is reliable only for the differentiation of E. histolytica/E. dispar from E. hartmanni. Also, on permanent-stained smears, shrinkage may occur, affecting the apparent size of the organism. Results of microscopy should clearly indicate the full taxonomic name of the organisms detected along with the forms of the organisms seen (trophozoites versus cysts). Quantitation of the amebae on the final report is not appropriate.

E. histolytica

Description of the Agent

The development of axenic culture methods was a key step in confirming the existence of two species among organisms that had been identified as E. histolytica based solely on microscopic findings. Using organisms obtained by such

cultures, Sargeaunt and Williams (4) performed isoenzyme analysis of several glycolytic enzymes and identified electrophoretic banding patterns, or zymodemes. Two groups were identified on the basis of these patterns: pathogenic zymodemes (invasive isolates) and nonpathogenic zymodemes (noninvasive isolates). The zymodeme patterns represent stable genetic differences and do not interconvert (5). Additional genetic, biochemical, and immunologic evidence has supported the existence of two distinct species. Diamond and Clark (6) redescribed the two species as *E. histolytica* Schaudinn 1903, which is the invasive human pathogen, and *E. dispar* Brumpt 1925, which is noninvasive and does not cause disease.

A third species of *Entamoeba*, *E. moshkovskii*, has been recognized and is generally considered a free-living ameba that may be detected in human stool specimens. It is morphologically indistinguishable from *E. histolytica/E. dispar*. The epidemiology of *E. moshkovskii* is not well understood. The prevalence varies depending on the population studied from relatively rare up to nearly 50% of the identified *Entamoeba* species found in stool (7), and coinfections with *E. histolytica* and *E. dispar* are not uncommon (8). It has been reported as an agent associated with gastrointestinal disease in the absence of other known causes (9–11), and newly documented acquisition of *E. moshkovskii* in children has been associated with diarrhea (12). Most recently, Royer et al. (13) reported a fourth species, *E. bangladeshi* nov. sp., Bangladesh, which is also morphologically indistinguishable from *E. histolytica/E. dispar*. It was identified in stool specimens from symptomatic and asymptomatic children in Bangladesh; specimens were positive for *E. histolytica/E. dispar* by microscopy but negative by PCR targeting *E. histolytica*, *E. dispar*, and *E. moshkovskii*. More research is needed to understand the role of both *E. moshkovskii* and *E. bangladeshi* in human disease and the importance of laboratory diagnosis (7, 13, 14).

**Epidemiology, Transmission, and Prevention**

*E. histolytica* can be found worldwide but is more prevalent in tropical and subtropical regions. In areas where the organism is endemic, up to 50% of people may be infected. In temperate climates with poor sanitation, infection rates can approach those seen in tropical regions. Humans are the primary reservoir; infection occurs by ingestion of cysts from material contaminated with feces such as water and food. Sexual transmission also occurs.

Asymptomatic *E. histolytica* infection is equally distributed between the genders, while invasive amebiasis affects men predominantly. In the United States, groups with a higher incidence of amebiasis include immigrants from South and Central America and Southeast Asia. Also, residents of the southern United States and institutionalized individuals are more likely than others to be infected. In one study, short-term travelers to areas where *E. histolytica* and *E. dispar* are endemic were found to be at higher risk of infection with the pathogenic species, *E. histolytica*, than...
one capable of producing disease (E. histolytica) and the other not (E. dispar). E. dispar appears to be at least 10 times more common than E. histolytica (14). A more precise determination of prevalence is possible using newer molecular methods to detect and differentiate among the species of Entamoeba and may change our understanding of the epidemiology of these infections (22).

Infection with E. histolytica/E. dispar can result in different clinical presentations: asymptomatic infection, symptomatic infection without tissue invasion, and symptomatic infection with tissue invasion. The majority of infections with E. histolytica/E. dispar are asymptomatic. Individuals with such infections will have a negative or weak serologic response and will primarily pass cysts in their stools. Zymodeme analysis shows that most asymptomatic individuals are infected with the noninvasive species E. dispar (21, 23). However, it appears that infection with both E. histolytica and E. dispar can be asymptomatic, with cyst stages being passed in the stool (24). Asymptomatic E. histolytica infection may be due to the existence of genetically distinct invasive and noninvasive strains of E. histolytica (25).

Intestinal disease results from the penetration of the amebic trophozoites into the intestinal tissues. Approximately 10% of infected individuals have clinical symptoms, presenting as dysentery, colitis, or, rarely, ameboma. The incubation period varies from a few days to several months. Various molecules such as adhesins, amebapores, and proteases have been associated with lysis of the colonic mucosa in intestinal amebiasis (26), and evidence supports the role of caspase-3-dependent apoptotic death as a major mechanism of host cell destruction (27). The 260-kDa galactose-or N-acetylgalactosamine-specific lectin of E. histolytica is an important virulence factor, mediating the attachment of the ameba to the intestinal epithelium and contact-dependent cytolysis (28). Symptoms of amebic dysentery include diarrhea with cramping, lower abdominal pain, low-grade fever, and the presence of blood and mucus in stool. The ulcers produced by intestinal invasion by trophozoites start as superficial localized lesions that deepen into the classic flask-shaped ulcers of amebic colitis. The ulcers are separated by segments of normal tissue but can coalesce. Amebae can be found at the advancing edges of the ulcer but usually not in the necrotic areas. Abdominal perforation and peritonitis are rare but serious complications. A more chronic presentation occurs with amebic colitis. It is characterized by intermittent diarrhea over a long period and can be misdiagnosed as ulcerative colitis or irritable bowel syndrome. Ameboma, a localized tumor-like lesion, results from chronic ulceration and may be mistaken for malignancy. Histologically, it consists of granulomatous tissue.

Extraintestinal disease occurs with the hematogenous spread of the organism. It can occur with or without previous symptomatic intestinal infection. The liver is the most common site of extraintestinal disease, followed by the lungs, pericardium, brain, and other organs including skin. Symptoms can be acute or gradual and may include low-grade fever, right-upper-quadrant pain, and weight loss. Up to 5% of individuals with intestinal symptoms develop liver abscess. However, up to 50% of individuals with liver abscess have no history of gastrointestinal disease.

Direct Examination
The laboratory diagnosis of amebiasis can be made by the examination of feces, material obtained from sigmoidoscopy, tissue biopsy specimens, and abscess aspirates. Serologic testing is also useful for the diagnosis of extraintestinal amebiasis. The choice of methods used by each laboratory is

FIGURE 2 (Top row) Entamoeba histolytica trophozoites. Note the ingested RBCs in the cytoplasm. (Middle row) E. histolytica/Entamoeba dispar trophozoites. Note the absence of RBCs in the cytoplasm. (Bottom row) E. histolytica/E. dispar cysts. These cysts cannot be identified to the species level on the basis of morphology. Organisms are stained with Wheatley’s trichrome stain. Courtesy of L. Garcia. doi:10.1128/9781555817381.ch140.f2

Clinical Significance
Among the estimated 500 million people infected each year with E. histolytica, there are ~50 million cases of colitis and liver abscess and ~100,000 deaths (21). The discrepancy between the number of people infected with E. histolytica and the morbidity and mortality rates is explained by the existence of two morphologically similar yet distinct species:
dependent on the available resources, funding, and clinical need. A summary of the laboratory techniques and their performance characteristics is presented in Table 3.

### Microscopy

As discussed above, the most important part of the standard microscopic examination of stool and other specimens is the permanent-stained smear. Direct wet preparations and concentration procedures may also be useful (Fig. 1 and Table 2; see also chapter 135). Detection of trophozoites and cysts does not, however, allow differentiation of the pathogenic species, *E. histolytica*, from the nonpathogenic species, *E. dispar* (Fig. 1 and 2). The presence of ingested RBCs in the cytoplasm of the trophozoites is commonly regarded as diagnostic of *E. histolytica* infection. However, the majority of patient samples do not contain trophozoites with ingested RBCs (14). In addition to concerns about sensitivity, Haque et al. (29) found that 16% of *E. dispar* isolates had ingested RBCs; thus, this distinction between the two species is not absolute and may affect specificity (30, 31). In tissue specimens, only the trophozoite is found, and its presence is considered diagnostic of invasive *E. histolytica* disease.

### Antigen Detection

For a more definitive differentiation of *E. histolytica* and *E. dispar*, methods other than microscopy are necessary. Zymodeme analysis can accomplish this differentiation, but it requires culture of the organisms from the specimen and is too expensive and complex for routine laboratory use. Antigen-based methods for the detection of *E. histolytica* and *E. dispar* are commercially available in the United States, including one that detects *E. histolytica*/*E. dispar*, *G. duodenalis*, and *Cryptosporidium parvum* in an immunochromatographic cartridge format (32). The antigen assays offer a more sensitive method for detection than microscopy and, depending on the kit used, allow specific detection of *E. histolytica* (14). A listing of commercially available parasite antigen detection kits is given in chapter 133 and has been recently reviewed (14).

The antigen detection assays are designed for use with fresh, fresh-frozen, or unfixed human fecal specimens. As mentioned previously, depending on the kit used, the group *E. histolytica*/*E. dispar* or the individual species can be detected in the feces. Of the available kits, only TechLab (Blacksburg, VA) offers an *E. histolytica*-specific EIA kit, *E. histolytica* II, which detects the Gal- or GalNAc-binding lectin specific to the pathogenic species (29, 33). A rapid point-of-care test that is specific for *E. histolytica* adherence lectin (*E. histolytica* Quik Chek; TechLab) has been reported and would be useful particularly in the developing world; this test is not yet available commercially either in or outside the United States (34, 35). All the antigen detection methods are relatively simple and are more sensitive and specific than microscopy (Table 3) (29, 32, 36). In comparison to amplified methods such as PCR, antigen detection using stool specimens may be less sensitive and specific for detection of *E. histolytica*/*E. dispar*, depending on the population studied (37, 38). To date, none of the available products can be used with preserved stool (i.e., formalin), as the fixative appears to denature the antigens. Although some reports of the use of preserved stool have appeared (39), more work is needed to identify additional antigens that withstand fixation before it would be practical to offer antigen tests in laboratories that receive only preserved stool specimens. Antigen assays have been used to test a number of other sample types such as serum, pus, and saliva (40, 41); the detection of antigen in serum may prove to be a sensitive means of diagnosing amebic liver abscess and intestinal disease (30, 41). Because <10% of patients with amebic liver abscesses have concurrent intestinal disease with amebae detectable in the stool, methods such as routine ova and parasite examination are not useful. Microscopic examination or culture of pus from liver abscesses likewise lacks sensitivity. In a study by Haque et al. (41), serum antigen detection by using the TechLab *E. histolytica* II kit was a sensitive method for diagnosis with samples collected prior to treatment with metronidazole. Serum antigennemia appears to clear after treatment, suggesting possible utility to monitor therapy; however, this use is still experimental (30, 41).

ELISA, enzyme-linked immunosorbent assay.
*Sensitivities of PCR assays are dependent on comparator methods and PCR techniques, with real-time PCR demonstrating increased sensitivity over conventional PCR.
Nucleic Acid Detection Techniques

Nucleic acid amplification techniques, such as PCR, have been developed for the detection and differentiation of *E. histolytica* and *E. dispar*. The most common genomic targets include the rRNA- or species-specific episomal repeats. Conventional PCR has been applied to specimens such as stool, liver, or brain aspirates and can detect both trophozoite and cyst DNA (42–46). More recently, real-time PCR has been used for the detection of *E. histolytica* and *E. dispar* (37, 47). Haque et al. (48) recently reported on the use of *E. histolytica* real-time PCR on blood, saliva, and urine samples for detection of amebic liver abscess and amebic colitis, finding that a combination of testing both urine and saliva increased diagnostic sensitivity, with 97 and 89% of amebic liver abscess and colitis cases detected, respectively; blood was less sensitive, being positive in 49% of amebic liver abscess cases and 36% of colitis cases examined. Several researchers have reported methods for multiplex molecular detection of and differentiation among the Entamoeba species, including *E. histolytica*, *E. dispar*, and *E. moshkovskii* (14, 42, 49, 50). Use of such a multiplex assay would permit a more accurate diagnosis than microscopy and allow targeted therapy for only true *E. histolytica* infections. As mentioned previously, simultaneous detection from stool of multiple intestinal parasites or multiple organisms, including bacteria and viruses, is of interest as there is significant overlap in the clinical presentations. Reports include detection of various combinations, including *E. histolytica*, *G. duodenalis*, and Cryptosporidium spp., and *D. fragilis* using tandem multiplex real-time PCR (51). At the time of writing, there is one FDA-cleared multiplex molecular test, XTAG Gastrointestinal Panel (Luminex Molecular Diagnostics, Austin, TX), for testing on fresh or frozen stool samples, which detects 11 agents of gastroenteritis, including the parasites *E. histolytica*, *G. duodenalis*, and *Cryptosporidium* spp. It is a bead-based assay utilizing nucleic acid extraction followed by endpoint PCR amplification and bead-based detection. Initial reports demonstrate the utility of the test, but the numbers of *E. histolytica* infections detected is low (1, 53). As more data are generated and other FDA-cleared multiplex molecular tests are made available, this approach will have a significant impact on many aspects of laboratory diagnosis of amebiasis.

PCR on stool specimens has proven to be more sensitive and specific than microscopy and at least as sensitive as antigen detection, depending on the study (Table 3) (30, 37, 54). For routine use in clinical laboratories, a PCR method would ideally involve a relatively simple sample preparation procedure and allow the use of preserved material. Different extraction techniques, some of which are relatively simple, and the use of fresh and preserved materials have been reported (55–57). Stool can present challenges due to the presence of PCR inhibitors (58), so the inclusion of an amplification control is useful (51).

Serologic Tests

Serologic testing is a valuable aid, in conjunction with antigen detection or PCR, for the diagnosis of symptomatic, invasive disease. Multiple serologic methods have been used, including indirect hemagglutination, complement fixation, latex agglutination, and EIA (14, 30). These methods are most useful in populations where *E. histolytica* is not endemic. In patients with biopsy-proven intestinal amebiasis, 85% have serum antibodies. For patients with extraintestinal disease, serologic tests have a sensitivity approaching 99%. For asymptomatic intestinal diseases, serology is generally not useful unless the patient has invasive infection. Persons infected with *E. dispar* do not produce detectable antibodies. After cure of invasive amebiasis, serum antibodies may persist for up to 10 years; this can complicate diagnosis in areas where infection is endemic (59).

EIAs for the detection of IgM and IgG are widely used, and most are based on the detection of antilectin antibodies, which appear after 1 week after symptoms of *E. histolytica* infection (30). Indirect hemagglutination is useful and highly specific but may lack sensitivity compared to EIAs (30). Several investigators have reported the utility of IgA antibody testing and a link to partial immunity in individuals with detectable antilectin IgA (41, 60, 61). There are several commercially available serologic kits for diagnosis of amebiasis, some of which are available in the United States. For a review of serologic testing, see the article by Foredar et al. (14) and also refer to chapter 7 in this Manual.

Treatment

On the basis of the 1997 World Health Organization conference, treatment is not recommended for *E. dispar* infections; if *E. histolytica*/E. dispar is detected (no differentiation of species) in symptomatic patients, the physician must evaluate the total clinical presentation to decide whether treatment is indicated. The detection of *E. histolytica* requires treatment of the patient regardless of the symptoms. The use of diagnostics that are species specific (i.e., antigen detection or PCR) allows for targeted chemotherapy.

The drugs used for the treatment of amebiasis are of two classes: luminal amebicides for cysts (paromomycin, iodoquinol, and diloxanide furoate) and tissue amebicides for trophozoites (metronidazole, tinidazole, and dehydroemetine) (62). Invasive disease should be treated with a tissue amebicide followed by a luminal amebicide. Tissue amebicides are not appropriate for treatment of asymptomatic infections (cysts). Not all strains of *E. histolytica* have been tested for tissue amebicides has been detected to date. Follow-up stool examination is always necessary because of potential treatment failures. Chemophrophylaxis is never appropriate because it may lead to drug resistance and limit the utility of drugs such as metronidazole (21, 63).

Evaluation, Interpretation, and Reporting of Results

Laboratory reporting of *Entamoeba* infection must account for the ability of a particular methodology to detect and differentiate pathogenic and nonpathogenic species. This is based on the report of a World Health Organization panel of experts that made recommendations concerning the reporting and treatment of amebiasis (21). If a microscopic diagnosis is made on the basis of the detection of trophozoites and/or cysts and no method is used to differentiate the two species, the report should indicate “*E. histolytica*/E. dispar detected.” Laboratory reports must indicate whether trophozoites and/or cysts are present, due to differences in therapy (3).

With the increasing awareness of other Entamoeba species, reporting as *E. histolytica*/E. dispar complex (*E. histolytica*, *E. dispar*, *E. moshkovskii*, and *E. bangladensis*) might be considered, but care must be taken to convey the proper interpretation of these results, reflecting the lack of differentiation of the pathogenic and nonpathogenic species. Laboratories may also choose to further test stools with *E. histolytica*/E. dispar detected with an *E. histolytica*-specific test such as antigen or PCR. This reflexive testing could allow more specific and appropriate treatment and be a cost-effective testing algorithm.
Antigen detection methods may or may not allow species differentiation, and the laboratory report should accurately reflect these facts. Reporting of PCR results that are specific for *E. histolytica* or other *Entamoeba* species such as *E. dispar* should state that nucleic acid was detected or not detected. Due to the ability of amplified methods to detect nonviable organisms, the use of PCR for determination of treatment failure should be interpreted cautiously. PCR does not allow for the determination of the parasite forms present, in contrast to the TechLab *E. histolytica* II.

**Blastocystis hominis**

**Taxonomy**

Since its first description in 1912, the taxonomic classification of *B. hominis* has changed and is still somewhat unclear (64, 65). Current classification of *Blastocystis* is as follows: kingdom Chromista, phylum Bigynia, class Blastocystea, and order Blastocystida (see chapter 132). Molecular studies indicate that *Blastocystis* is closely related to *Proteromonas lacertae* (66–68). Though *P. lacertae* is a flagellate, interestingly, *B. hominis* does not possess a flagellum and is nonmotile. Genetic, biochemical, and immunologic analyses have revealed that great diversity exists within the species (69–71). Recent studies have shown that *Blastocystis* spp. in humans and animals can be divided into 12 or more species (71).

**Description of the Agent**

The life cycle of *B. hominis* includes vacuolar and fecal cyst forms, granular forms, and ameboid forms. *B. hominis* is capable of pseudopod extension and retraction. The exact nature of the life cycle of this organism and the infective form has yet to be confirmed experimentally. The cyst form can be varied depending on whether the cyst is observed in fresh stool or in culture (68). *B. hominis* produces pseudopods and reproduces by binary fission or sporulation. It is strictly anaerobic and is capable of ingesting bacteria and other debris. The membrane-bound central body occupies up to 90% of the cell and may function in reproduction. Both thin- and thick-walled cysts have been observed. The classic form is usually seen in human stool specimens; it characteristically contains a large central body or vacuole. The more amebic form is more difficult to see in human specimens and has been seen in diarrheal stool specimens (3).

**Epidemiology, Transmission, and Prevention**

*B. hominis* is a common intestinal parasite of humans and animals, with a worldwide distribution (68). Depending on the geographic location, it may be detected in 1 to 40% of fecal specimens. Human-to-human, animal-to-human, and waterborne modes of transmission have been proposed (68, 71–73). The organism is polymorphic, consisting of four major forms. The thick-walled cysts are thought to be responsible for external transmission via the fecal-oral route; the thin-walled cysts are thought to cause autoinfection (74). The cyst form is the most recently described form of the life cycle stages. The cysts can vary in shape but are mostly ovoid or spherical. The central vacuole form (also referred to as the central body form) is the most common form found in clinical stool samples. The large central vacuole can occupy the majority of the cellular volume. The ameboid form is rarely reported, and the granular form can be seen when culturing the parasite.

Clinical Significance

The role of *B. hominis* in human disease is still controversial, and studies supporting and refuting its pathogenicity have been published (75–77). Most recent epidemiological studies point to the fact that *B. hominis* is a pathogen. Since many genotypes appear to exist, there is strong evidence that there are pathogenic and nonpathogenic species (68). Regardless of the number of publications on each side of this debate, clinicians may decide to treat patients with *B. hominis* infection. When *B. hominis* is present in large numbers in the absence of other pathogens, it may be the cause of gastrointestinal disease. The most common symptoms cited include recurrent diarrhea without fever, vomiting, and abdominal pain. The symptoms may be more pronounced and prolonged in patients with underlying conditions such as HIV infection, neoplasia, and abnormal intestinal tract function (78, 79). Other studies suggest that symptomatic patients receiving treatment for *B. hominis* infection may improve due to the elimination of another, undetected pathogen (75). In a study of HIV-infected individuals, Albrecht et al. (80) concluded that, even in patients with severe underlying immunodeficiencies, *B. hominis* is not pathogenic and its detection does not justify treatment.

**Direct Examination**

**Microscopy**

Diagnosis of infection is made by detection of the organism, typically the central body form, by routine microscopic stool examination (Table 2; Fig. 1 and 3). The size of the central body form can vary tremendously, from 2 to 200 μm. Extensive size variation exists within and between isolates. The vacuolar form contains a large central vacuole that occupies ~90% of the cell (68, 81). Examination of permanent-stained smears is the procedure of choice. Exposure to water before fixation (for the concentration method) will lyse the trophozoites and central body forms, yielding false-negative results. Some type of quantitation (few, moderate, or many) should be included in the laboratory report. Direct wet mounts using iodine as a stain are not recommended, as trichrome staining is more sensitive (68).

**Other Diagnostic Methods**

Culture of the organism from stool is possible and has been reported to be more sensitive than microscopy but is not routinely available (82). A serologic response to *B. hominis* has been detected using techniques such as ELA and fluorescent-antibody testing (68, 83, 84). It is suggested that this antibody response supports the role of *B. hominis* as a human pathogen but is not useful for diagnosis and should be limited to

![FIGURE 3 Blastocystis hominis on an iodine wet mount preparation. Note the peripheral nuclei and the central body form. Courtesy of L. Garcia. doi:10.1128/9781555817381.ch140.f3](image-url)
epidemiological and serologic studies. In asymptomatic individuals, a serologic response may require exposure of up to 2 years before it is detectable (85). A review by Tan (68) describes in detail molecular approaches to the diagnosis and characterization of B. hominis. Molecular approaches to organism detection might be more sensitive based on some studies but are still not routinely available in the clinical laboratory setting (86–88).

Treatment

Until the role of B. hominis as an intestinal pathogen is clearly established, treatment decisions must be based on the overall clinical presentation. Current recommendations for treatment include the use of metronidazole, iodoquinol, or trimethoprim-sulfamethoxazole (62). Metronidazole appears to be the most appropriate choice at present. In vitro data on the susceptibility of B. hominis to various drugs are limited (77), but resistance to metronidazole has been reported (89). A failure to clear organisms from the stool has been demonstrated in patients treated with metronidazole and trimethoprim-sulfamethoxazole.

Evaluation, Interpretation, and Reporting of Results

For most laboratories, testing and reporting for B. hominis is limited to detection of the organism by microscopic means. There can be confusion in identifying Blastocystis correctly, since the organism can be confused with yeast, fat globules, and even Cyclospora spp. It is not necessary to state the form of the organism present (e.g., central body form). This is the sole intestinal parasite that should be routinely reported with quantitation to aid clinicians in determining its clinical significance. Additional commentary may be added to the laboratory report explaining the role of B. hominis in disease and the need to exclude other causes for the clinical condition.

NONPATHOGENIC AMEBAE

The other species of intestinal amebae are considered nonpathogenic; except for E. polecki, they have a worldwide distribution and are more prevalent in warmer climates. They must, however, be differentiated from the pathogenic species, E. histolytica. A permanently stained smear is often essential to accomplish this goal (Table 2; Fig. 1).

E. hartmanni is a separate species that is morphologically similar to E. histolytica/E. dispar (Fig. 4). Size is the key differentiating characteristic. Entamoeba coli trophozoites may be difficult to differentiate from E. histolytica/E. dispar trophozoites on wet preparations. The mature cyst of Entamoeba coli may be refractory to fixation, making it less visible in permanent-stained smears but still detectable by the wet mount method (Fig. 5). It has been reported as the most common ameba isolated from human stool specimens. E. polecki is associated with pigs, and in certain areas of the world, such as Papua New Guinea, it is the most common human intestinal parasite. The trophozoite shares characteristics with both E. histolytica/E. dispar and Entamoeba coli; the cyst normally has one nucleus. E. gingivalis was the first parasitic ameba of humans to be described. It is found in the soft tartar between teeth and can be recovered from sputum. In the trophozoite, the cytoplasm often contains ingested leukocytes. A cyst form has not been observed. E. nana, like E. hartmanni, is one of the smaller intestinal amebae. It is seen in most populations as frequently as Entamoeba coli. There is a great deal of nuclear variation, and it can mimic D. fragilis and E. hartmanni (Fig. 6). The cysts of E. nana are usually oval, and both the trophozoites and the cysts are commonly present in fecal material. I.

FIGURE 4 Entamoeba hartmanni trophozoite (left) and cyst (right). Note the “bull’s-eye” nucleus in the trophozoite and the numerous chromatoidal bars within the cyst. Organisms are stained with Wheatley’s trichrome stain. Courtesy of L. Garcia. doi:10.1128/9781555817381.ch140.f4

FIGURE 5 (Top row) Entamoeba coli trophozoite (left; trichrome) and cyst (right; trichrome). Note the large eccentric karyosome in the trophozoite and the chromatoidal bars with sharp pointed ends in the cyst. (Middle row) Entamoeba coli cyst in iodine (left) and in saline (right). The nuclei are visible; the presence of five or more nuclei is confirmatory for Entamoeba coli. (Bottom row) Entamoeba coli cyst (left; trichrome) and cyst (right; trichrome). Both cysts are very distorted and shrunken, although the nuclei can be seen in the cyst on the right. This type of shrinkage is typical of Entamoeba coli cysts on permanent-stained smears. Courtesy of L. Garcia. doi:10.1128/9781555817381.ch140.f5
contain a large glycogen vacuole. The cyst is very characteristic; it is round to oval and may be similar to that of *E. nana* and *I. bütschlii*. The trophozoite of *Entamoeba coli* ameba but is less common than *G. duodenalis* has the same distribution as other nonpathogenic amebae but is less common than *E. nana* and *I. bütschlii*. The trophozoite of *I. bütschlii* may be similar to that of *E. nana*, and differentiation between them is difficult. The cyst is very characteristic; it is round to oval and may contain a large glycogen vacuole (Fig. 6).

Treatment is not recommended for infections with any of the nonpathogenic amebae. Methods of prevention of infection with all these amebae include improved personal hygiene and improved sanitary conditions.

### FLAGELLATES

#### Taxonomy

There are six genera of flagellates that parasitize the intestinal tracts of humans; they belong to phylum *Metamonada*, class *Trichomonadacea* (*Dientamoeba* and *Trichomonas*), class *Trepomonadacea* (*Giardia* and *Enteromonas*), and class *Retortamonadacea* (*Chilomastix* and *Retortamonas*) (Fig. 7; see chapter 132).

#### Description of the Agents

Some flagellates are commensals that reside in the intestinal tract and are harmless to the individual. The flagellates that are pathogenic to humans include *G. duodenalis*, *D. fragilis*, and *T. vaginalis*. The nonpathogenic organisms are *Chilomastix mesnili*, *Enteromonas hominis*, *Retortamonas intestinalis*, and *Pentatrichomonas* (*Trichomonas*) *hominis*. As mentioned above, *D. fragilis* has been reclassified as a flagellate and appears to be closely related to the trichomonads.

#### Epidemiology, Transmission, and Prevention

Transmission of flagellates, with the exception of *T. vaginalis*, is initiated via the ingestion of contaminated food or water. Of the members of the six genera, all except *D. fragilis* and *Trichomonas* spp. are transmitted in a cyst form. To date, only a trophozoite form has been observed for *D. fragilis* and *Trichomonas* spp., though for *D. fragilis* the presence of a cyst form is being challenged. Once in the intestine, the organism excysts, releasing trophozoites that attach to the intestinal epithelium. Completion of the life cycle in humans culminates in the release of viable cysts into the environment via the feces. Infection with any of the flagellates indicates exposure to feces regardless of the pathogenicity of the organism; preventing this exposure is the key. Measures to improve sanitary conditions are necessary to prevent the spread of infection. As yet, there are no human flagellate vaccines available.

#### Collection, Transport, and Storage of Specimens

For the detection of flagellates and ciliates, laboratories predominantly receive stool specimens for microscopic examination. String test samples (Entero-Test; Nutri-Link Ltd., Newton Abbot, United Kingdom) can be submitted for *Giardia* as well, which is described in detail below. Fresh or preserved specimens can be submitted, but preserved stool is the specimen of choice for most routine clinical laboratories. If fresh specimens are submitted and observed for motility, they must be examined within a specific time period depending on the consistency of the stool. Stool specimens for immunoassay or DFA assay can be fixed in formalin, which can also be used for an ova and parasite exam if immunoassays are negative for *G. duodenalis*. Additional information on specimen collection and transport can be found in chapter 133 of this Manual.

#### Direct Examination

**Microscopy**

In the clinical laboratory, wet preparations and permanent-stained smears of fecal material are still the predominant specimens used to diagnose infections with flagellates. The flagellates have greater morphologic diversity relative to one another than do the amebae (described above), making determination of the genus easier (Table 4; Fig. 7). To aid in the identification of the trophozoite, key features to be noted are the shape, size, number, and position of flagella; the number of nuclei; and the presence of a spiral groove, cytostome, and characteristic features such as a sucking disk or undulating membrane. Typically, the size, shape, and number of nuclei are diagnostic characteristics used to identify cysts. Examination of permanent-stained smears is always recommended for diagnosis of infection because the wet mount may not be reflective of all organisms and stages present in the specimen.

**Other Diagnostic Methods**

Antigen-based tests for organisms such as *G. duodenalis* have increased in popularity over the years due to the ease of
Intestinal and Urogenital Parasites

FIGURE 7 Intestinal and urogenital flagellates of humans. (Top row) Trophozoites. *T. vaginalis* is found in urogenital sites; all other flagellates are intestinal. (Bottom row) Cysts. *D. fragilis* trophozoite is shown; no cyst stage. doi:10.1128/9781555817381.ch140.f7

use and increased throughput compared to microscopy. In addition, nucleic acid amplification methods have been developed to detect *T. vaginalis* in clinical samples and *G. duodenalis* in water and clinical samples but are not yet routinely available in the clinical laboratory. Both antigen and amplification tests for the flagellates are discussed in more detail below. Serologic assays are available for the diagnosis of *G. duodenalis* infection but are not routinely used in the clinical setting.

Evaluation, Interpretation, and Reporting of Results

It is important that a representative portion of the slide, either a wet mount or a permanent smear, be scanned before a final opinion on a specimen is given. It is also important to use an accurate micrometer to measure life cycle stages. Reports of microscopy results should clearly indicate the full taxonomic names of the organisms detected along with the forms of the organisms seen (trophozoites versus cysts) (2). Quantitation of the number of organisms seen is not appropriate for the flagellates.

**Giardia duodenalis**

**Taxonomy**

*G. duodenalis* and the other *Giardia* spp. are classified as belonging to the phylum *Metamonada* (flagellates), subphylum *Conosa*, class *Trepomonadea* (intestinal flagellates), order *Diplomonadida* (see chapter 132 of this Manual).

**Description of the Agent**

*G. duodenalis* is an intestinal flagellate that infects both humans and animals and is the most common cause of intestinal parasitosis in humans worldwide. Because the literature refers to this organism as *Giardia lamblia*, *Giardia intestinalis*, and *G. duodenalis*, it is evident that there has been debate about the classification and nomenclature of this flagellate. There is an extensive review of taxonomy related to *Giardia* that explores in depth the taxonomy of this genus. Currently *G. duodenalis* is the accepted species name in regards to human infections. According to Feng and Xiao (90), there are six species: *G. agilis*, *G. ardeae*, *G. muris*, *G. microti*, *G. psittaci*, and *G. duodenalis*.

It is now accepted that there is considerable genetic diversity within *G. duodenalis*. Based on molecular biology, the genus *Giardia* is subdivided into major genotypes containing subgenotypes. The major genotypes of *G. duodenalis* that are associated with human infections are assemblages A and B. Assemblage A is associated with a mixture of both human and animal isolates, whereas assemblage B is typically associated with human isolates only. Most zoonotic animal-to-human infections occur with assemblage A (91).

**Epidemiology, Transmission, and Prevention**

Infection with *G. duodenalis* occurs through fecal-oral transmission or the ingestion of cysts in contaminated food or water, and an inoculum of only 10 to 100 cysts is sufficient for human infection (92). Individuals more commonly infected in developed countries are children in day care centers, hikers, and immunocompromised individuals. Among immunocompromised individuals, infections have been documented in people with AIDS and hypogammaglobulinemia and those affected by malnutrition. Prevalence rates for this pathogen range from 1 to 7% in industrialized countries and from 5 to 50% in developing countries. Of the intestinal flagellates, *G. duodenalis* is the flagellate most frequently isolated in the United States. In high-risk domestic settings,

aSize ranges are based on wet preparations (with permanent stains, organisms usually measure 1 to 2 μm less).

bNuclear and cytoplasmic descriptions are based on permanent-stained smears.

cNuclear and cytoplasmic descriptions are based on permanent-stained smears.
such as day care centers, prevalence rates can reach 90% (93). A Giardia vaccine is available for dogs and cats; this may affect the prevalence of infections in humans (94).

Infection occurs when viable cysts are ingested, excyst, and transform into trophozoites. After excystation, the trophozoite, which appears to have a propensity for the duodenum, attaches to the mucosal epithelium. Trophozoites attach to the epithelium via a sucking disk located on the ventral side of the parasite. During the course of infection, the parasites remain attached to the epithelium and do not invade the mucosa. In the intestine, trophozoites divide by binary fission to produce two identical daughter trophozoites. As they move down toward the large intestine, the trophozoites encyst, and infective cysts are excreted into the environment (3).

Clinical Significance
The majority of individuals infected with G. duodenalis are asymptomatic. Asymptomatic versus symptomatic infection may be due to the existence of two different strains of Giardia with different levels of virulence. Preliminary studies have grouped G. duodenalis into two groups, group A and group B. Group A appears to be more pathogenic and is associated with symptomatic infection. Isoenzyme and molecular studies show that group A and group B differ from one another and appear to be no more related than E. histolytica and E. dispar. The genes homologous between group A and group B Giardia isolates show an identity of approximately 81 to 89% (95–97). In symptomatic individuals, acute G. duodenalis infections can mimic infections with other protozoal, viral, and bacterial pathogens. After an incubation period of 12 to 20 days, patients can experience nausea, chills, low-grade fever, epigastric pain, and a sudden onset of watery diarrhea. Diarrhea is often explosive and presents as foul-smelling without the presence of blood, cellular exudate, or mucus. Individuals can develop subacute or chronic infections with symptoms such as recurrent diarrhea, abdominal discomfort and distention, belching, and heartburn. In patients with chronic cases of giardiasis, diarrhea can lead to dehydration, malabsorption, and impairment of pancreatic function (98).

Direct Examination

**Microscopy**

Diagnosis of G. duodenalis infection is often established by the microscopic examination of stool for the presence of cysts and/or trophozoites, although many laboratories have migrated to antigen-based assays. Stained smears are more helpful in identifying the trophozoite stage of the infection, although this stage can be identified in wet mount preparations (Table 4; Fig. 7 and 8). Examination of stool specimens may not be diagnostic because cyst forms can be trapped in mucus, making them difficult to detect on smears. Also, the excretion pattern of cysts can be cyclical. In these instances, other methods, such as the string test (Entero-Test), should be used to obtain clinical samples. The string test procedure consists of a patient swallowing a weighted capsule containing gelatin and a tightly wound string. After ~5 h, the string is removed from the patient and the adherent material is examined as a wet mount or permanent smear (3). Endoscopy can also be used to collect clinical specimens. Because this procedure is invasive, it is used only for diagnosis of disease in patients with perplexing clinical presentations (93).

**Antigen Detection**

Other assays that have gained wide acceptance for the detection of G. duodenalis in stool specimens are EIAs, DFA assays, and immunochromatographic assays. These methods have very high specificities (90 to 100%) and sensitivities that range from 63 to 100% (99–104). Although these methods have proven to be fairly sensitive and specific compared to the routine staining of fecal smears (trichrome staining), other important pathogens may be missed if a wet mount and permanent-stained smear are not examined. The DFA assay widely used is the Merifluor reagent assay (Meridian Bioscience, Inc., Cincinnati, OH), but it does require the availability of a fluorescent microscope. DFA assays have a sensitivity and specificity of >95%.

Immunoassays are available and are useful for testing large numbers of patient specimens, and some studies have shown the performance of the EIA to be excellent compared to that of the ova and parasite exam (100, 102, 105). Four available immunoassays are the ProSpecT Giardia EZ (Remel, Lenexa, KS), the ColorPAC Giardia assay (Becton Dickinson and Co., Sparks, MD) (101), the TechLab Giardia II assay, and the Giardia/Cryptosporidium Chek from TechLab. The Tri-Combo parasite screen (TechLab) is another immunoassay for Giardia, Cryptosporidium, and E. histolytica but is not yet approved by the FDA (106). These assays have very good sensitivity and specificity, often >90% (103, 106, 107).

It is very important to note that if a patient is immunocompromised, has traveled, or is suspected of coming into contact with an unusual pathogen, the ova and parasite examination should be performed. Some studies suggest that the use of an immunoassay does not necessarily eliminate the need for more than one stool specimen. Positive specimens from asymptomatic patients may be missed if only one stool specimen is tested using an immunoassay (108). Some immunoassays are affected by specimens contami-
nated with blood. It was documented in one study that blood can interfere with the performance of the ProSpecT assay and potentially cause false-positive results (101).

Immunochromatographic detection methods have also been developed for use in the clinical laboratory (32, 105, 109, 110). The ImmunoCard STAT (Meridian Bioscience) has been developed to detect G. duodenalis antigens in stool specimens by using rapid solid-phase qualitative immunochromatography. It is recommended that patients negative by the ImmunoCard STAT who remain symptomatic be tested using a routine ova and parasite exam (109). The Triage Micro parasite panel (Alere, Waltham, MA) is a rapid immunassay that can detect not only G. duodenalis antigens but also those of E. histolytica/E. dispar and C. parvum in stool specimens (111). Antigens in stool specimens are immobilized on a membrane containing specific antibodies to the respective intestinal parasites. The formation of color bars occurs on a specific area of the membrane depending on the parasite present in the stool. Laboratories should check with the manufacturer's package insert to determine what specimens, formalin-fixed or fresh, are compatible with each assay. The Quik Chek (TechLab) is also available for rapid diagnosis of Giardia and Cryptosporidium infections. Although there are several methods now available for the detection of G. duodenalis, parameters such as workload, skill levels of technologists, and the availability of necessary equipment should be considered in choosing a specific method, along with performance characteristics of the test (112). Refer to chapter 133 for a complete list of current available assays for Giardia detection in the clinical laboratory.

**Nucleic Acid Detection Techniques**

Some investigators are now using molecular tools to diagnose G. duodenalis infection with clinical samples (51–53, 91, 113, 114). One group has developed an oligonucleotide microarray with excellent sensitivity and specificity for the detection of G. duodenalis and other intestinal parasites in stool specimens. The assay was also able to discriminate between Giardia assemblages A and B (115). A multiplex PCR assay to detect specific genotypes of G. duodenalis has also been developed that may potentially aid in epidemiologic investigations of outbreaks (116). It is important to note that molecular detection of G. duodenalis has not been widely implemented; to date there is one FDA-approved assay, as mentioned above (1, 53).

Because of the potential for contamination of municipal water supplies, routine monitoring of water for parasitic protozoa is recommended as a public health control measure. G. duodenalis cysts can remain viable for 2 to 3 months in cold water and are fairly resistant to killing by routine chlorine treatments. DFA assays are commonly used to detect G. duodenalis cysts in water samples, but PCR is also being used for this purpose (117). The advantage of PCR is the increased sensitivity compared to those of fluorescence assays or assays that use special stains. Research continues to enhance the ability of investigators to detect viable organisms, which is a better indication of poor water quality (118).

**Treatment**

For individuals diagnosed with giardiasis, the treatment of choice is metronidazole, tinidazole, or nitazoxanide (62). Alternatives include paromomycin, furazolidone, and quinacrine or other nitroimidazoles such as ornidazole and secnidazole (119). In most immunocompetent hosts, infection is self-limiting; however, treatment lessens the duration of symptoms and prevents transmission. Other drugs that have been used to treat giardiasis are albendazole, mebendazole, and bacitracin (120), and there are other therapeutics on the horizon. Albendazole, mebendazole, and paromomycin have lower activity against Giardia than do the nitroimidazoles (119). Resistance to metronidazole and other agents has been observed clinically and in vitro (63). In vitro resistance-testing assays are available but lack the standardization required for the clinical laboratory (121).

**Evaluation, Interpretation, and Reporting of Results**

As with any of the organisms mentioned in this chapter, it is important to evaluate more than one stool specimen for the presence of G. duodenalis. For Giardia, this could include up to five or six stool specimens to increase the chance of recovery. This is especially important for diagnosing G. duodenalis infection, since organisms can be passed in the stool intermittently on a more cyclical basis. During the staining procedure, the cysts can be shrunk or distorted, which may affect the ability of the clinical laboratory scientists to read the smear. There are several techniques available for the diagnosis of giardiasis in the clinical laboratory. Some methods might offer somewhat better sensitivity but need to fit into the overall workflow of the laboratory. EIAs offer somewhat enhanced sensitivity but cannot always replace the ova and parasite exam due to the prevalence of other pathogens in the patient population being tested. Adding assays, such as the EIA, might increase detection of Giardia but add to the bottom-line cost per testing if the physicians continue to order a routine ova and parasite exam as well.

**Dientamoeba fragilis**

**Taxonomy**

*D. fragilis* is currently grouped in the kingdom *Protozoa*, class *Trichomonadida*, and order *Trichomonadida* (see chapter 132).

**Description of the Agent**

Despite the lack of external flagella, this parasite is currently classified as a flagellate but has historically been grouped with the amebae. Electron microscopy and antigenic analysis have aided in the classification of this organism and have demonstrated that it is closely related to *Trichomonas* and *Histomonas* species. Phylogenetic analysis of small-subunit rRNA sequences has also confirmed the relationship between *D. fragilis* and *Histomonas* (122, 123).

**Epidemiology, Transmission, and Prevention**

*D. fragilis* is found worldwide and is known to cause a noninvasive diarrheal illness in humans. Colonization in humans is similar to that seen with other intestinal parasites; typically, the cecum and the proximal part of the colon are affected. The mode of transmission of *D. fragilis* is still uncertain; one hypothesis concerning the spread of *D. fragilis* is that transmission occurs within the eggs of *Enterobius vermicularis* or *Ascaris lumbricoides* (124). Several studies provide circumstantial evidence to support *E. vermicularis* as a vector, documenting a greater-than-expected coinfection rate with the two organisms (125). Recent animal studies suggest the possibility of a cyst form for *D. fragilis*, but this has not been definitively proven (126, 127).

Though *D. fragilis* has a worldwide distribution, prevalence rates for this organism vary quite substantially from 0% in Prague to 42% in Germany (125). There appears to be a higher prevalence in certain groups of individuals such as...
as missionaries, Native Americans living in Arizona, and institutionalized individuals (128). In the United States, the prevalence is reported to be quite low. This may be due to underreporting attributable to difficulties associated with identifying the organism in clinical samples. In addition, Johnson and Clark (129) identified the existence of two genetically distinct types of D. fragilis with a resulting sequence divergence of ∼2% (129, 130). The degree of divergence appears to be similar to that seen with E. histolytica and E. dispar. Since asymptomatic infections occur, this finding may lend support to the possibility that two distinct species exist, though there is no consensus on this matter (125, 129).

Clinical Significance
The frequency of symptomatic disease ranges from 15 to 25% in adults, and symptomatic disease is more common in children, in whom up to 90% of those infected have clinical signs (93, 131, 132). Symptoms include fatigue, insufficient weight gain, diarrhea (often intermittent), abdominal pain, anorexia, and nausea. Studies have linked D. fragilis infection to a variety of conditions (133), irritable bowel syndrome (26), allergic colitis (134), and diarrhea in HIV-infected patients (135). One case report describes a patient who presented in the emergency room with acute appendicitis that was attributed to D. fragilis infection (136). Some individuals, mainly children, also experience unexplained peripheral blood eosinophilia (3, 137). Diarrhea is seen predominantly during the first 1 to 2 weeks after the onset of disease. The number of D. fragilis organisms can vary greatly from day to day, which is similar to those of other intestinal protozoa. Abdominal pain can persist for 1 to 2 months (131). Although D. fragilis has been implicated in the above-mentioned clinical situations, the organism is isolated from patients with no apparent clinical symptoms. In addition, the lack of an animal model affects researchers’ ability to detect specific pathological manifestations (125).

Direct Detection

Microscopy
Diagnosis of D. fragilis infection is similar to that of infections with other intestinal protozoa, and detection of the trophozoite in fresh or preserved stool is warranted to establish infection. Laboratories using direct microscopy may be at a disadvantage, since the trophozoite can degenerate if not placed in fixative. Nonfixed trophozoites can appear rounded and refractile and are more difficult to identify microscopically. Morphologically, the trophozoite of D. fragilis contains one or two nuclei (binucleate), with two nuclei being more common. Well-trained laboratory personnel can identify D. fragilis trophozoites in stool specimens, but because no cyst stage exists, diagnosis from the wet mount can be difficult. Use of a permanent-stained smear is the recommended procedure for detection (Table 4; Fig. 7 and 9).

Other Diagnostic Methods
Culture has been shown to be more sensitive than microscopy; however, it is not recommended for the routine clinical laboratory (125). Antigen and antibody techniques have been used as diagnostic tools for the detection of D. fragilis but are not commercially available (138, 139). D. fragilis DNA has been detected using PCR with fresh, preserved stool. Molecular techniques have the promise of being more sensitive than microscopy (140–142). Multiplex PCR assays are being developed for the detection of D. fragilis (52).

Treatment
The treatment of choice for symptomatic individuals is iodoquinol (diiodohydroxyquin) (62). Alternate choices include paromomycin, tetracycline, or metronidazole (62). Metronidazole, iodoquinol, and tetracycline have been used to treat children (3). Additional therapeutic options include diphenoxylate, carbarsone, erythromycin, hydroxyquinoline, and secnidazole (125, 143). If E. vermicularis is detected concomitantly, the treatment regimen should also include mebendazole (131).

Evaluation, Interpretation, and Reporting of Results
The recovery of D. fragilis is greatly enhanced by the collection of at least three stool specimens (2, 93). Trophozoites have been recovered from soft and formed stools, indicating the need to evaluate all types of samples (131). Low incidence in a community setting for D. fragilis may be due to the inability of the laboratory to accurately identify the organism.

Trichomonas vaginalis

Taxonomy
T. vaginalis is a flagellate belonging to the kingdom Protozoa, class Trichomonadida, and order Trichomonadida (see chapter 132 of this Manual). Unlike the other members of the order, which inhabit the intestinal tract, T. vaginalis infects the urogenital tract.

Description of the Agent
The life cycle includes only the trophozoite stage; there is no cyst stage. The organism is similar in morphology to the other trichomonads and is characterized by a pear shape with a prominent axostyle and an undulating membrane that stops halfway down the side of the trophozoite (Table 4; Fig. 7 and 10). It is a facultative anaerobe that divides by binary fission, and it cannot survive long outside the host.

Epidemiology, Transmission, and Prevention
T. vaginalis is a pathogenic flagellate that infects the urogenital tracts of males and females. The infection is primarily a sexually transmitted infection and is thought to be the most common curable sexually transmitted infection among sexually active young women. Worldwide there are an estimated 250 million cases of Trichomonas infection each year, with an overall estimated prevalence of 4.5% (144). Prevalence is estimated to be higher in women (8%) than in

FIGURE 9 Dientamoeba fragilis trophozoites. The trophozoites can have one nucleus (left) or two nuclei (right). No cyst stage is known for this organism. Trophozoites are stained with Wheatley’s trichrome stain. Courtesy of L. Garcia. doi:10.1128/9781555817381.ch140.f9
men (1%) (144, 145). It is hypothesized that hormones in women may play a large role in infection and persistence of *Trichomonas* infections in women. The incidence of trichomoniasis differs depending on the population examined, varying from 5 to 60% in various studies. Factors such as lower socioeconomic status, multiple sex partners, and poor personal hygiene are linked to a higher incidence of infection. The prevalence of *Trichomonas* infections appears to be higher in older women, as shown by several studies (146–148). This is in contrast to other common sexually transmitted diseases, such as chlamydia, for which prevalence is typically higher in younger women. One study screened male patients to assess the prevalence in that population. The prevalence was ∼6.6%, but the average age of *T*. *vaginalis*-infected men was 39.9 years, which was much higher than those infected with *Chlamydia trachomatis* or *Neisseria gonorrhoeae* (146). This parallels what is seen in women, as described above. Several studies have described the relationship between *T*. *vaginalis* and the possibility of lethal prostate cancer (149–151). Some researchers are exploring the use of a serodiagnostic test that would identify those at risk for prostate cancer related to seropositivity for *T*. *vaginalis* (152).

The estimated infection rates cited in the literature may indeed be too low because (i) trichomoniasis is not a reportable disease in the United States and other countries; (ii) the infection, particularly in men, can be asymptomatic; and (iii) laboratory tests used for diagnosis vary in their sensitivities. Despite these rates of infection and their serious medical consequences, trichomoniasis has not received adequate attention from public health and sexually transmitted disease prevention programs (153).

Clinical Significance
Infection in females can result in vaginitis, cervicitis, and urethritis (153). The vaginal discharge is classically described as copious, liquid, greenish, frothy, and foul smelling. The onset of symptoms, such as intense vaginal and vulvar pruritus and discharge, is often sudden and occurs during or after menstruation. The vaginal pH is usually elevated above the normal pH of 4.5, and dysuria occurs in 20% of women with *T*. *vaginalis* infection. Infection has also been associated with premature rupture of membranes, premature birth, and posthysterectomy cuff infections (154–156). In men, the most common symptomatic presentation is urethritis. Up to 50% of infected women are asymptomatic carriers. In men, the majority of infections are asymptomatic.

Asymptomatic carriers serve as a reservoir for transmission and also remain at risk for developing disease. Trichomoniasis has been implicated as a cofactor in the transmission of HIV (157, 158). In one study, men with symptomatic *Trichomonas* urethritis were found to have increased HIV concentrations in seminal plasma compared to HIV-infected men without urethritis (159).

Neonates can acquire the organism during passage through the infected birth canal (153). Reports have also documented *T*. *vaginalis* as a cause of neonatal pneumonia (160). A recent report of bilateral conjunctivitis in a male without genital infection was reported (211). Multilocus sequence typing has been used to characterize different strains of *T*. *vaginalis*. Techniques such as this can be useful for population-based studies and perhaps strain selection for future vaccine development (161).

Direct Detection

Microscopy
The diagnosis of *T*. *vaginalis* infection is commonly based on the examination of wet preparations of vaginal and urethral discharges, prostatic secretions, and urine sediments. Permanent stains such as Papanicolaou and Giemsa stains can be used, but the organisms may be difficult to recognize (162). For wet preparations, vaginal specimens are routinely collected during a speculum examination, but studies suggest that self-collected or tampon-collected specimens may be used successfully (163, 164). Specimens should be mixed with a drop of physiologic saline and examined microscopically within 1 h under low power (magnification, ∼x100) with reduced illumination. Specimens should never be refrigerated. The presence of actively motile organisms with jerky motility is diagnostic. The movement of the undulating membrane may be seen as the motility of the trophozoite diminishes. Polymorphonuclear cells are often present. The sensitivity of the wet preparation test with vaginal specimens is between 50 and 70%, depending on the skill of the microscopist and other factors. The sensitivity of microscopy in males is low, and additional testing, such as culture of urethral swab, urine, and semen, is required for optimal sensitivity. Perhaps the most important factor affecting the sensitivity of wet mount testing is the time between collection and examination of the specimen. Viability of the organism is essential for the detection of motility on the wet mount and drops off precipitously with time. Amies gel agar transport medium can maintain the viability for culture of *T*. *vaginalis* on swabs held at room temperature for 24 ± 6 h before inoculation of the specimen into a culture pouch (165). Because the morphology of *P*. *hominis*, a nonpathogenic intestinal flagellate, is very similar to that of *T*. *vaginalis*, care must be taken to ensure that specimens are not contaminated with fecal material.

Culture
Culture has greater sensitivity (>80%) than the wet mount method and is considered the gold standard method for the detection of *T*. *vaginalis*. Specimens must be collected properly and inoculated immediately into the appropriate medium, such as modified Diamond’s, Trichosel, or Hollander’s medium. Due to cost and convenience, this approach is not routinely used. Culture systems (InPouchTV [BioMed Diagnostics, San Jose, CA] and the system of Empyrean Diagnostics, Inc. [Mountain View, CA]) that allow direct inoculation, transport, culture, and microscopic examination are commercially available (166, 167). In situations in which immediate transport of specimens is not...
feasible, the use of these transport/culture devices should be encouraged. Studies have also shown that a delayed inoculation protocol is as sensitive as immediate inoculation, allowing the results of microscopy to be used to determine whether further culture is necessary (168). Serologic testing is not useful for the diagnosis of trichomoniasis.

Antigen Detection
Several antigen detection methods have been developed for *T. vaginalis* and offer the advantage of being rapid and easy to perform. A latex agglutination test (TV Latex; Kalon Biological, Guildford, United Kingdom) has been shown to have excellent sensitivity (169) but is not available in the United States. An immunofluorescence assay (Light Diagnostics *T. vaginalis* DFA; Chemicon International, Temecula, CA) is available in the United States for testing directly from patient samples. An immunochromatographic capillary flow assay is available commercially for the qualitative detection of *T. vaginalis* antigens from vaginal swabs. The OSOM Trichomonas Rapid Test Kit (Sekisui Diagnostics, Tokyo, Japan) is a dipstick assay providing results in 10 min. In published studies, the OSOM test has demonstrated good sensitivity (67 to 94.7%) and specificity (98.8 to 100%) compared to various comparator assays, including wet mount, culture, and amplified testing (170–176). This assay would perhaps be more suitable for a clinic setting, where more-rapid results are desirable. A rapid point-of-care test is being developed for *T. vaginalis*. This assay features novel electrochemical endpoint detection and in initial studies appears to have high sensitivity and specificity (177).

Nucleic Acid Detection Techniques
The Affirm VPIII (Becton Dickinson) is a direct DNA probe test for the detection of organisms from vaginal swabs associated with vaginosis/vaginitis. It tests for the three most common syndromes associated with increased vaginal discharge: bacterial vaginosis (Gardnerella vaginalis), candidiasis (Candida albicans), and trichomoniasis (*T. vaginalis)*. According to the manufacturer’s package insert, the assay has a sensitivity and specificity of 90 and 98%, respectively, compared with wet mount and culture for *T. vaginalis* (package insert, Affirm VPIII, version no. 670160JAAG; Becton Dickinson). In a clinical evaluation of vaginal swab specimens from both symptomatic and asymptomatic females, the Affirm detected more *T. vaginalis*-positive samples than wet mount testing, although the difference was not statistically significant (178).

Nucleic acid-based amplification methods, such as PCR and transcription-mediated amplification (TMA), developed for the detection of *T. vaginalis* have been reported in the literature, though only one is currently FDA cleared. These amplification methods have demonstrated varying sensitivities depending on the genomic target, specimen type, and sex of the patient (172, 179–183). PCR has a sensitivity of 85 to 100% with vaginal swabs; its sensitivity with urine is lower, ranging from 60 to 80% (153, 184, 185). For men, PCR with urine and urethral swabs has been reported and appears to be more sensitive than conventional methods (186, 187). Several researchers have reported using TMA technology from Hologic/Gen-Probe (San Diego, CA) for detection of *T. vaginalis*, which is now FDA approved (148, 181, 182, 188, 189). Studies using the Trichomonas Aptima Combo 2 assay have shown the performance of the assay to be superior compared to other methodologies (147, 148, 189). The assay is approved for the detection of *T. vaginalis* infections from a wide variety of specimens such as clinician-collected vaginal specimens, endocervical swabs, ThinPrep liquid-based cytology samples, and urine samples (189). Samples can be automated for testing using either the Panther or the Tigris instrumentation. In addition to testing on adults, molecular testing is also being evaluated for the detection of *Trichomonas* in children (190). Some researchers have evaluated the Hologic/Gen-Probe assay for diagnosis of anorectal *T. vaginalis* using rectal swabs (146, 191). Another assay available outside the United States is the Seeplex STD 6 ACE Detection System (Seegene, Seoul, Korea), which detects *T. vaginalis* and other pathogens (192). This assay is a multiplex PCR assay. Detection employs six pairs of dual priming oligonucleotide primers targeted to unique genes of the specific pathogen. It is not clear if this assay will receive approval in the United States.

While the wet mount method provides a rapid result at a low cost, tests with the increased sensitivities, such as nucleic acid probes or amplification tests, may be indicated because of the impact of *T. vaginalis* infections on pregnancy and the link with HIV transmission (165, 187). The use of alternate specimen types such as urine makes amplified testing an important advancement for diagnosis of trichomoniasis. An algorithm to reflex specimens with negative wet mounts to culture or a more sensitive methodology may be a useful diagnostic approach (173). Because the true prevalence of *T. vaginalis* is unknown and the prevalence appears to be higher in older women, it is important for laboratories and clinicians to be aligned in regards to which patients should be tested (148).

Treatment
The recommended treatment for *T. vaginalis* infections is metronidazole or tinidazole (62, 193). For metronidazole, oral therapy is recommended over topical treatment. Tinidazole may be used as a first-line agent or for refractory cases previously treated with metronidazole (194). For treatment during pregnancy, metronidazole is the recommended therapy; however, it should be used cautiously, as data do not suggest that metronidazole treatment results in a reduction in perinatal morbidity (193, 195). All sexual partners of infected individuals should also receive treatment. Treatment failure with metronidazole is most often due to non-compliance or re-infection. True resistance to metronidazole has been documented and appears to be increasing (194, 196). While not routinely available, methods have been published for the *in vitro* determination of susceptibility. These methods have not been standardized, and the results can vary based on assay conditions (197, 198).

Evaluation, Interpretation, and Reporting of Results
A laboratory finding that is positive for *T. vaginalis* is considered diagnostic of trichomoniasis. As discussed above, both microscopy and culture are prone to lower sensitivities due to issues related to sampling and transport. Laboratories should have strict rejection criteria for *Trichomonas* culture and wet mount specimens that do not arrive within the specified time or transport conditions; such policies improve sensitivity, ensuring more-accurate results. In comparison to methods such as antigen detection and molecular methods, a negative result by these methods should be viewed cautiously and evaluated in conjunction with clinical symptoms.

With testing for *Trichomonas*, such as antigen detection and direct molecular probes or amplified tests, reported results should reflect the analyte that is detected. For example, a positive result for *T. vaginalis* by a direct DNA probe assay should state “*T. vaginalis* DNA detected.” If testing is
expanded to differing sample types, such as urine testing by amplified methods, the report should clearly state the specimen tested.

If a home-brew assay is used for the diagnosis of *Trichomonas*, it is required that the result be labeled to indicate its status as an in-house test in accordance with Clinical Laboratory Improvement Amendments regulations as follows: “This test was developed and its performance characteristics determined by [Laboratory Name]. It has not been cleared or approved by the U.S. Food and Drug Administration.”

**NONPATHOGENIC FLAGELLATES**

*C. mesnili* is found worldwide and is generally considered nonpathogenic. Unlike *D. fragilis*, *C. mesnili* has both a trophozoite and a cyst stage. The organism is acquired through the ingestion of contaminated food or water and resides in the cecum and/or colon of the infected human or animal. The trophozoite is 6 to 24 μm long and contains a characteristic spiral groove that runs longitudinally along the body (Table 4; Fig. 7 and 11). Motility of the organism can sometimes be seen in fresh preparations, and the spiral groove may be exposed as the organism turns. Flagella are difficult to see in stained preparations. The trophozoite contains one nucleus, with a cytostome or oral groove in close proximity. The pear-shaped cyst retains the cytoplasmic organelles of the trophozoite, with a single nucleus and curved cystostomal fibril. Observing the organism in permanent-stained preparations makes identification more definitive.

*P. hominis*, formerly referred to as *Trichomonas hominis*, is a nonpathogenic flagellate that is similar to *D. fragilis* in that only the trophozoite stage has been observed. Although the organism is cosmopolitan in nature and is recovered from individuals with diarrhea, it is still considered nonpathogenic. The trophozoites typically inhabit the cecum. They are pyriform and contain an undulating membrane that runs the length of the parasite. The use of permanent smears is recommended for observation of these organisms in clinical specimens. The trophozoites may stain weakly, making them difficult to detect on stained smears (3).

Two additional nonpathogenic intestinal flagellates are *E. hominis* and *R. intestinalis*. Both *E. hominis* and *R. intestinalis* are found in warm or temperate climates, and infection is acquired through the ingestion of cysts. When clinical specimens are examined, it is important to note that cysts of *E. hominis* can resemble those of *E. nana*, although *E. nana* cysts containing two nuclei are rare. Because of the small sizes of *E. hominis* and *R. intestinalis*, it is difficult to detect these organisms even when permanent-stained smears are examined. This may lead to the underreporting of both organisms. *R. intestinalis* has been recovered from the pancreatic juice of a patient with small lesions of the pancreatic duct (199).

In general, treatment is not recommended for infections with the nonpathogenic flagellates. Improved personal hygiene and sanitary conditions are key methods for the prevention of infection.

**CILIATES**

*Balantidium coli*

**Taxonomy**

*B. coli* is a ciliate belonging to the phylum Ciliophora, class Litostomata, order Trichomastia (see chapter 32 of this Manual). Members of the phylum Ciliophora are protozoa possessing cilia in at least one stage of their life cycles. They also have two different types of nuclei, one macronucleus and one or more micronuclei. Over the last several years, molecular analysis has aided in the characterization of the genus Balantium (200–202). Sequences of the genus are on file at GenBank based on the small-subunit rRNA. There is question as to whether the species isolated from humans, *B. coli*, and pigs, *B. suis*, are the same species (200).

**Description of the Agent**

This organism has both the trophozoite and cyst forms as part of its life cycle (Table 5; Fig. 12). The cyst form is the infective stage. After ingestion of the cysts and excystation, trophozoites secrete hyaluronidase, which aids in the invasion of the tissue. The trophozoite, which is oval and covered with cilia, is easily seen in wet mount preparations under
low-power magnification. The cytoplasm contains both a macronucleus and a micronucleus, in addition to two contractile vacuoles. Motile trophozoites can be observed in fresh wet preparations, but the specimen must be observed soon after collection. The trophozoite is somewhat pear shaped and also contains vacuoles that may harbor debris such as cell fragments and ingested bacteria. Cyst formation takes place as the trophozoite moves down the large intestine.

Epidemiology, Transmission, and Prevention

*B. coli* exists in animal reservoirs such as pigs and chimpanzees, with pigs being the primary reservoir (200). The organism is the only pathogenic ciliate and the largest pathogenic protozoan known to infect humans. Transmission occurs by the fecal-oral route following ingestion of the cysts in contaminated food or water. Infection is more common in warmer climates and in areas where humans are in close contact with pigs. As with other intestinal protozoa, poor sanitary conditions lead to a higher incidence of infection. Prevalence of *Balantidium* varies by geographic location but overall is estimated to be between 0.02 and 1% (203). High-prevalence areas include areas of the Middle East, Papua New Guinea and West Irian, Latin America, and the Philippines (204, 205).

Clinical Significance

Infection with *B. coli* is most often asymptomatic; however, symptomatic infection can occur, resulting in bouts of diarrhea similar to amebiasis (3, 206). Infection with *Balantidium* can be described in three ways: (i) asymptomatic host, carrying the disease; (ii) chronic infection, nonbloody diarrhea, including other symptoms such as cramping and abdominal pain; and (iii) fulminating disease consisting of mucoid and bloody stools (200). In addition, colitis caused by *B. coli* is often indistinguishable from that caused by *E. histolytica*. Symptoms typically include diarrhea, nausea, vomiting, headache, and anorexia. Fluid loss can be dramatic, as seen in some patients with cryptosporidiosis. The organism can invade the submucosa of the large bowel, and ulcerative abscesses and hemorrhagic lesions can occur. The shallow ulcers and submucosal lesions that result from invasion are prone to secondary infection by bacteria and can be problematic for the patient (207, 208). Death due to invasive *B. coli* infection has been reported (207). Infections associated with extraintestinal sites have been described (207–209). There have been several reports of *Balantidium* spreading from the intestine to the lung. Most of these cases have occurred in patients who are either elderly or immunocompromised. The disease presents as a pneumonia-like illness. In these documented cases, *Balantidium* has been recovered from specimens such as bronchial secretions and bronchial lavage specimens. It is hypothesized that extraintestinal colonization can occur between the lymphatic or circulatory system, by perforation through the colon, or through aspiration of fluid from the oral cavity (200). One case describes an individual with vertebral osteomyelitis and myelopathy, which is the first documented case of infection in the bone (210).

Direct Examination

Microscopy

Either ova and parasite examination of feces or histological examination of intestinal biopsy specimens establishes the diagnosis of *B. coli* infections. The diagnosis can be established only by demonstrating the presence of trophozoites in stool or tissue samples (209). It is very easy to identify these organisms in wet preparations and concentrated stool samples. Conversely, it can be challenging to identify *B. coli* from trichrome-stained permanent sections because the organisms are so large and have a tendency to overstain. This makes the organism less discernible and increases the chance of misidentification.

Treatment

The treatment of choice for *B. coli* infection is tetracycline, although it is considered an investigational drug when used in this context (62). Metronidazole and iodoquinol are therapeutic alternatives used in some cases (3). Nitazoxanide, which is a broad-spectrum antiparasitic drug, may be another alternative for treatment (200).

Evaluation, Interpretation, and Reporting of Results

The recovery of *B. coli* in humans is fairly uncommon despite its worldwide distribution. Pulmonary infections can occur, but the clinical laboratory scientist needs to make sure that this organism is not confused with motile ciliated epithelial cells that can be present in respiratory specimens. *Balantidium* spp. in wet mounts are very active parasites with uniform ciliation.

SUMMARY

Clinical laboratories are now given more choices for testing in diagnostic parasitology, with assays ranging from microscopy, culture, antigen detection, and nucleic acid amplification techniques for detection of the intestinal and urogenital amebae, flagellates, and ciliates. Molecular biology has the promise to deliver more sensitive and specific methods, with the availability of an FDA-cleared assay for detection of *T. vaginalis* from genital specimens and a multiplex assay for *E. histolytica*, *G. duodenalis*, and *Cryptosporidium* species detection from stool. There are other assays being designed and in clinical trials at the time of writing, and while these methods have not been fully adapted to the clinical diagnostic laboratory, their use in the coming years is certain to increase. In addition to these amplification tests, rapid point-of-care tests are available for organisms such as *T. vaginalis*. Results can now be available in real time for the clinician to manage patients directly in the exam setting. While these new test modalities are exciting, clinical laboratories are still faced with using microscopy for routine workup for stool specimens due to the lack of commercially
available testing for all the relevant organisms. Some laboratories have switched to antigen-based methods, but many still rely on microscopy because antigen-based methods cannot detect all potential pathogens in a given stool specimen. Microscopy, as we know, cannot differentiate between pathogenic and nonpathogenic amebae and the different genotypes of G. lamblia. Together these exciting new areas will help increase the options that the clinical parasitology laboratory has for the diagnosis of intestinal parasitic infections.

Cystoisospora, Cyclospora, and Sarcocystis

DAVID S. LINDSAY AND LOUIS M. WEISS

Cystoisospora, Cyclospora, and Sarcocystis are intestinal coccidia of humans (Fig. 1 to 5). They have varied life cycles, epidemiologies, treatment requirements, and diagnostic methods. Oocysts of these coccidia are found in the feces of humans (Table 1), and diagnosis is based ultimately on demonstrating oocysts (Cystoisospora or Cyclospora) or sporocysts (Sarcocystis) in human stool samples.

TAXONOMY

Cystoisospora, Cyclospora, and Sarcocystis are in the phylum Apicomplexa, class Coccidia, order Eimeriida. Cystoisospora belli, Sarcocystis hominis, and Sarcocystis suihominis are in the family Sarcocystidae, while Cyclospora cayetanensis is in the family Eimeriidae. Many people are familiar with the old name for Cystoisospora belli, Isospora belli, but life cycle (1) and molecular studies indicate that the parasite is a member of the genus Cystoisospora (2), not Isospora.

DESCRIPTION OF THE AGENTS

Life Cycles

Cystoisospora belli

The life cycle is direct (monoxenous), but evidence exists that it can be facultatively heteroxenous (use two hosts). C. belli oocysts are passed in the feces unsporulated or partially sporulated (Fig. 1C and D and 2A and B). Oocysts generally complete sporulation within 72 h, although sporulation time varies between 24 h and >5 days, depending on temperature and humidity. Sporulated oocysts contain two sporocysts, each with four sporozoites, although Caryospora-like oocysts of C. belli (containing one sporocyte with eight sporocysts) have been reported and can comprise up to 5% of the sporulated oocysts in a sample (3). The prepatent period, the time it takes for unsporulated oocysts to appear in the feces after sporulated oocysts are ingested, is 9 to 17 days (4). The patent period, the time from when oocysts are first excreted in the feces until they can no longer be observed in the feces, is quite variable and depends on the immune status of the infected individual. Oocysts can usually be found for 30 to 90 days in immunocompetent patients, while immunosuppressed patients may continue to shed oocysts for 6 months or more (5). Recurrence of oocyst shedding is common. This prolonged oocyst shedding in immunosuppressed patients is presumably due to recycling of one or more schizogenous stages or activation of dormant extraintestinal tissue cysts (Fig. 4).

Developmental stages of C. belli have been reported for intestinal biopsy specimens of the duodenum, jejunum, and occasionally ileum, and oocysts can be aspirated directly from the duodenal contents. Intestinal development occurs predominantly in epithelial cells, although schizonts (mero- nts) are occasionally reported from the lamina propria or submucosa (6). At least two generations of schizonts, as well as macroagamocytes (female sexual stage), microgamocytes (male sexual stage), and unsporulated oocysts, have been observed.

C. belli sporozoites/merozoites are capable of traveling extraintestinally and becoming dormant as single-organism-containing tissue cysts (Fig. 4) in a variety of tissues, including lamina propria, mesenteric lymph nodes, liver, and spleen (7–9). These cysts are commonly termed monozoic tissue cysts. Monozoic tissue cysts in histological sections are thick walled and measure 12 to 22 by 8 to 10 μm, and each contains a single dormant sporozoite/merozoite of about 8 to 10 by 5 μm (7, 8). Presumably, the monozoic tissue cysts are capable of reactivating patent infections once immunity wanes. Monozoic tissue cysts can be present in the lamina propria in the absence of oocysts in stool samples (9).

The existence of these monozoic tissue cysts has led to speculation that a paratenic (transport) host may be involved in the life cycle of C. belli (7). Paratenic hosts are known to occur in the Cystoisospora species that infect cats and dogs, and it is probable that they occur in the life cycle of C. belli.

Cystoisospora natalensis

The life cycle is unknown but presumably monoxenous (direct). The oocysts are smaller and more spherical than those of C. belli (Table 1). Oocysts are passed in the stool unsporulated. At ambient temperature, oocysts can complete sporulation within 24 h (10). The prepatent and patent periods of C. natalensis are unknown. One individual passed unsporulated oocysts for at least 4 days (11). The validity of this species is questionable because oocysts of C. natalensis have been reported only for patients from South Africa and no reports of C. natalensis appear in the literature after 1955 (10, 11).

2425
**Cyclospora cayetanensis**

The life cycle is monoxenous and involves only humans as hosts. Oocysts are passed in the stool unsporulated (Fig. 1A and 2C). At room temperature (23 to 25°C), small numbers of oocysts may sporulate within 10 to 12 days (3, 12) (Fig. 1B). However, many oocysts require 3 to 4 weeks for sporozoites to fully develop. Sporulated *C. cayetanensis* oocysts contain two sporocysts, each with two sporozoites. A structure termed a Stieda body is present in the end of each sporocyst. There are no Stieda bodies in the oocysts of *C. belli* or *Sarcocystis* species (Fig. 1). The precise prepatent period is not yet known. However, the onset of clinical signs following infection generally averages 7 to 8 days postinfection and lasts 2 to 3 weeks, but this may range from 1 to >100 days. The length of time that oocysts are shed in the feces is highly variable. Oocysts may be shed in the feces for anywhere from 7 days to several months. Relapse of diarrhea can occur in up to 25% of infected individuals (13). Indigenous infections are confined primarily to tropical, subtropical, or warm temperate regions of the world. Outbreaks occur in other areas of the world due to contaminated foodstuffs obtained from regions of endemcity (85).

Developmental stages of *C. cayetanensis* generally occur within epithelial cells of the lower duodenum and jejunum (14–16). There are two asexual generations followed by sexual stages and oocysts. Stages develop in a supranuclear location within enterocytes (16). An experimental attempt to infect seven healthy human volunteers by oral adminis-
demonstrating several monozoic tissue cysts (arrows) of *Cystoisospora* infection occurs, and the oocysts sporulate in the lamina propria of the intestine. Fermentation occurs when raw or undercooked meat containing sarcocysts is ingested. Known intermediate hosts include cattle (*Bos taurus*), American bison (*Bison bison*), water buffaloes (*Bubalus bubalis*), and wisents (European bison; *Bison bonasus*). These intermediate hosts harbor sarcocysts (muscle cysts) that are infective when ingested by humans. Infective bradyzoites (dormant merozoite-like stages) are present in the sarcocysts. The bradyzoites penetrate the human intestinal epithelium and develop as sexual stages (macrogametocytes and microgametocytes) in cells in the lamina propria of the intestine. Fertilization occurs, and the oocysts sporulate in the lamina propria. The oocysts are *Cystoisospora*-like and contain two sporocysts, each with four sporozoites. The oocyst wall often ruptures as the oocyst makes its way to the intestinal lumen. This results in the shedding of individual sporocysts in the feces (Fig. 3). Individual sporocysts contain four sporozoites. Both oocysts with two sporocysts and individual sporocysts can be seen in the feces of humans with intestinal *Sarcocystis* infection (Fig. 1E and F).

Oocysts and sporocysts are fully sporulated when passed in the feces. For human volunteers, the prepatent period has been reported to be 8 to 39 days, and patent infections can last as long as 18 months. *S. hominis* occurs on all continents, anywhere cattle or buffaloes have access to human feces and humans ingest raw or undercooked beef.

**Sarcocystis suihominis**

The life cycle is similar to that described above for *S. hominis*, except that pigs are the intermediate hosts. The prepatent period is 9 to 10 days, and patency is in excess of 36 days. *S. suihominis* presumably occurs on all continents, anywhere swine have access to human feces and humans ingest raw or undercooked pork.

**Human Muscular Sarcocystis Infection**

Sarcocystis have been reported as incidental findings from tissue sections of both skeletal and cardiac muscle of nearly 100 humans worldwide. Humans become infected after ingesting Sarcocystis species sporocysts in contaminated food or water. One to two generations of precystic schizogony presumably occur in endothelial cells in capillaries throughout the body. The final generation of merozoites penetrates striated muscle cells and transforms into metrocysts. Metrocysts divide by endodyogeny to produce bradyzoites within the sarcocyst. Clinical signs probably arise from schizogony occurring in endothelial cells of capillaries and the host reaction to developing sarcocysts in muscles (i.e., eosinophilic myositis). There are at least seven distinct types of sarcocysts (18) present in human muscles. This suggests that as many as seven definitive hosts may be able to produce sporocysts infective for humans. Many of these sarcocysts appear similar to sarcocysts found in nonhuman primates.

**EPIDEMIOLOGY, TRANSMISSION, AND PREVENTION**

**Cystoisospora belli**

*C. belli* is found primarily in tropical, subtropical, and warm temperate regions, but reports of indigenous infections have been published from temperate areas as well. Most cases of infection in temperate areas involve foreign travel or homosexual contact. Transmission is via ingestion of sporulated oocysts and possibly the ingestion of raw or undercooked tissues from unknown paratenic hosts. An outbreak of *C. belli* infections involving ~90 patients was reported in the city of Antofagasta, Chile, in 1977 (19). It was associated with ingestion of vegetables contaminated with irrigation water from a sewage treatment plant (19). Improving sanitation and water quality in areas of endemicity will decrease transmission of *C. belli*.

**Cyclospora cayetanensis**

*Cyclospora* is endemic in Central and South America, the Caribbean, Mexico, Indonesia, Asia, Nepal, Africa, India, southern Europe, and the Middle East. In areas of endemicity, there is an increased risk of *Cyclospora* infection with contact with soil (20) and water (21). Three outbreaks of

waterborne C. cayetanensis infections were reported in a study of waterborne protozoal disease outbreaks from 2004 and 2010 (22). Infections in most temperate areas are correlated with the consumption of imported, contaminated fruits and vegetables, such as basil, raspberries, lettuce, mesclun, and snow peas. Two large outbreaks of cyclosporiasis occurred during the summer of 2013 (85). One was concentrated in Iowa (153 cases) and Nebraska (86 cases) and linked to a restaurant-associated salad mix that contained iceberg lettuce, romaine lettuce, red cabbage, and carrots (85). The second was associated with fresh cilantro (85) and was associated with a restaurant (22 of 30 patrons) in a large outbreak in Texas (278 cases).

Individuals in areas of endemicity should wear gloves when gardening to prevent exposure to oocysts of C. cayetanensis. Better washing of produce may help to remove Cyclospora oocysts, but many fruits are delicate. Most of the produce items implicated as transmitting Cyclospora are consumed raw, which does not lend itself to prevention by thermal means. Nonthermal treatments such as high hydrostatic pressure (23) have been shown to inactivate Toxoplasma gondii oocysts, and these methods may be effective in inactivating Cyclospora on produce.

**Sarcocystis Species**

Human intestinal Sarcocystis species are potentially present in any region in the world where cattle, buffaloes, and swine have access to human feces and the life cycle can be maintained. The cycle has not been detected in the United States. Cultural habits that include ingestion of raw meat or undercooked meat products help to maintain this life cycle in areas where Sarcocystis species are endemic. Cooking meat to an internal temperature of >67°C kills T. gondii tissue cysts in the meat (24), and this temperature should also kill tissue cysts of human-infective Sarcocystis species in meat products. Preventing cattle, buffaloes, and swine from consuming human feces will also break the cycle in areas of endemicity.

Most cases of human muscular Sarcocystis infection (Fig. 3) have been reported from the Far East, particularly Malaysia (25–27). One study of 100 consecutive autopsy cases from Malaysia found that 21% of tongue sections were positive for sarcocysts (27). This is probably an underrepresentation of the true prevalence because only a small amount of muscle can be examined histologically. Humans become infected by ingesting sporocysts in contaminated water (25) or food.

**CLINICAL SIGNIFICANCE**

**Cystoisospora belli**

C. belli can cause serious and sometimes fatal disease in immunocompetent individuals. Symptoms of C. belli infection include diarrhea, steatorrhea, headache, fever, malaise, abdominal pain, vomiting, dehydration, and weight loss (6, 12, 28, 29). Blood is not usually present in the feces. Eosinophilia is observed in many patients (30, 31). The disease is often chronic, with parasites present in the feces or biopsy specimens for several months to years. Recurrences are common and can occur as long as 10 years after successful treatment (32). Disease is more severe in infants and young children.

Clinical disease from C. belli infection is usually more severe in immunocompromised patients than in immunocompetent patients. C. belli infection produces diarrhea in AIDS patients that is often very fluid and secretory-like and leads to dehydration requiring hospitalization (30). Fever and weight loss are also common findings. Other opportunistic pathogens are also common copathogens in these patients. C. belli superinfection of the small bowel was seen in a patient who was immunosuppressed with systemic corticosteroids to aid in treatment of eosinophilic gastroenteritis (31). C. belli has been observed in both renal transplant (33) and liver transplant (34) patients. C. belli-induced intestinal lesions and responses to chemotherapy are usually similar to those observed in immunocompetent patients. C. belli has been observed in patients with concurrent Hodgkin’s disease (6), non-Hodgkin’s lymphoproliferative disease (35), human T-cell leukemia virus type 1-associated adult T-cell leukemia (36), and acute lymphoblastic leukemia and human T-cell leukemia virus type 1-associated T-cell lymphoma (37). These patients respond to specific anti-C. belli treatment. Extraintestinal cyst-like stages have been documented for AIDS patients and may play a role in relapse of infection (7). These usually contain a single merozoite-like stage (Fig. 4) and are called monoocyte tissue cysts. Many thousands of these stages can be present (7).

Infections with C. belli in the gallbladder epithelium (38–40) and endometrial epithelium (41) have been reported, and oocysts have been observed in bile samples (42). Clinical signs in patients with parasites in these locations are not specific for coccidiosis, and parasites are located after tissue biopsy as part of a diagnostic workup. Infection of the biliary tract with C. belli was the first HIV-related opportunistic infection in one patient, and it may have represented an AIDS-defining infection in that case (40). The parasites probably reach these extraintestinal sites as merozoites from the gut or zoites from extraintestinal locations, and the epithelial cells of these tissues are permissive to parasite entrance and multiplication.

**Cyclospora cayetanensis**

Nonbloody watery diarrhea is the main clinical symptom of C. cayetanensis infection. Symptoms of nausea, fatigue, abdominal cramps, and fever were reported in >50% of clinical cases in one foodborne outbreak, with headache
and vomiting occurring in 45 to 30% of these patients (13). Some individuals can be infected and show no clinical signs. In most immunocompromised patients, typical symptoms of cyclosporiasis include cycles of diarrhea with anorexia, malaise, nausea, and cramping and periods of apparent remission. C. cayetanensis infection can be associated with biliary disease in both immunosuppressed patients and immunologically normal patients (43). Developmental stages of C. cayetanensis have been seen in the gallbladder epithelium of AIDS patients with acalculous cholecystitis (44). Oocysts can be observed in the bile of patients with active biliary disease.

**Intestinal Sarcocystis Infections**

Clinical Sarcocystis infections in humans can manifest primarily as intestinal disease if infected meat is ingested or as muscular disease if sporocytes are ingested (45). Intestinal disease occurs soon after consumption of infected meat (3 to 6 h) and is characterized by nausea, abdominal pain, and diarrhea. Intestinal disease can be more severe in individuals who have additional enteropathogens present in the gut. Intestinal Sarcocystis infection combined with invasion by Gram-positive bacteria has been associated with several cases of segmental enterocolitis in Thailand (46). Experimental studies with human volunteers have produced more-severe disease in those who have ingested pork containing S. suihominis than in those who have ingested beef containing S. hominis (45). Some individuals can be infected and show no clinical signs.

**Muscular Sarcocystis Infections**

Muscular Sarcocystis infections (Fig. 5) in humans are usually subclinical or associated with only mild clinical signs and are usually considered incidental findings (17, 47, 48). Clinical case reports are from Southeast Asia. Three outbreaks of acute muscular sarcocystosis have been reported from Malaysia (25, 26, 49). In the first reported outbreak, clinical signs associated with muscular Sarcocystis infection occurred in 7 of 15 members of a U.S. combat unit (25). The signs developed about 3 weeks after the troops returned from the jungle and were fever, myalgia, bronchospasm, fleeting pruritic rashes, transient lymphadenopathy, and subcutaneous nodules. Eosinophilia, elevated erythrocyte sedimentation rate, and elevated levels of muscle creatine kinase were present in these troops (25). The second (26) and third (49) outbreaks occurred in travelers returning from Tioman Island off the east coast of Malaysia. The second outbreak, during the summer of 2011, was in 32 patients, most of whom were from Germany (~50%), other European countries, North America, and Asia. Within days or weeks of returning home, most patients experienced fever and muscle pain (26). All had peripheral eosinophilia, and most had elevated serum creatinine phosphokinase levels (26). The third outbreak was reported in 65 patients returning from Tioman Island (26) and occurred during July and August of 2011 and 2012. The 65 patients originated from Germany (n = 25), France (n = 20), the Netherlands (n = 12), Switzerland (n = 3), Belgium (n = 2), Spain (n = 2), and Singapore (n = 1) (49). Most patients experienced fever and myalgia, while fewer had arthralgia, asthenia, headache, cough, and diarrhea (49).

Decreased immunity or cancer may make individuals more susceptible to muscular Sarcocystis infection. Sarcocystis have been reported in the heart of a patient with Hodgkin’s disease (50) and the larynx of a patient with squamous cell carcinoma (51).

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

The results obtained in the diagnostic laboratory are only as good as the material presented for testing. Choosing the appropriate sample and sample fixative is extremely important (52). Universal precautions should be followed when fresh stool samples are handled. If samples are to be sent to another laboratory for diagnosis, they should be fixed in an appropriate fixative. A 5% or 10% formalin solution is an appropriate fixative for stools suspected of containing intestinal coccidia. Formalin fixation does not interfere with some of the immunodetection methods currently employed to detect Cryptosporidium and Giardia duodenalis, which is a drawback of polyvinyl alcohol fixative. Oocyst structure lasts for several months when stools are stored at 4°C in formalin fixatives.

**DIRECT EXAMINATION**

**Microscopy**

Oocysts of C. belli and C. cayetanensis and sporocytes of Sarcocystis species are readily identified in fresh unstained wet mounts, based on their characteristic sizes and morphologies (Table 1; Fig. 1). This is especially true if oocysts and sporocytes are present in large numbers. Autofluorescence of oocysts of C. belli and C. cayetanensis and oocysts and sporocytes of Sarcocystis (Fig. 3) is an especially useful tool (53, 54) and has replaced many of the staining techniques previously used for these parasites in laboratories equipped with appropriate fluorescent microscopes.

Concentration techniques, such as formalin-ethyl acetate (rarely formalin-ether) sedimentation or sucrose centrifugal flotation, are helpful when few oocysts are present. Sucrose centrifugal flotation has been found to be superior to formalin-ether sedimentation for demonstrating oocysts of C. cayetanensis (55). The same should be true for oocysts of C. belli and sporocytes of Sarcocystis spp. Few laboratories employ sucrose concentration, and fortunately, direct wet smears can be very useful: their utility approaches that of sucrose centrifugal flotation when coupled with autofluorescence examination (55). Staining procedures may adversely affect the autofluorescence of oocysts and sporocytes.

Stained fecal smears have been widely used to demonstrate C. cayetanensis oocysts and, to a lesser extent, C. belli oocysts (53, 56). C. belli and C. cayetanensis oocysts stain red with the modified Kinyoun’s acid-fast stain, and this method is widely used (Fig. 2). The main drawbacks are that staining can be variable and some oocysts do not stain (57). Oocysts usually do not stain with trichrome, chromotrope, or Gram-chromotrope stain (57). Some C. cayetanensis oocysts stain light blue with Giemsa stain (57). Variations on the safranin staining technique stain C. cayetanensis oocysts orange or pinkish orange, and heating and other treatments have been used to increase the staining frequency of oocysts. Flow cytometry has been used to detect C. cayetanensis oocysts in human stool samples (58). The results of flow cytometry examination were similar to those of microscopy, and preparation times for the two methods were similar (58).

A single negative stool specimen is not conclusive in the examination of stools for coccidial parasites; a total of three or more stool specimens collected on subsequent days need to be examined before coccidial infection can be ruled out. Liquid stool samples can be concentrated by centrifugation, and the pellet may be used for examination by use of wet mounts, concentration techniques, or stained smears.
Large numbers of oocysts may make diagnosis less challenging but do not always translate directly to the severity of clinical signs. Some individuals may excrete oocysts and be asymptomatic.

Cases of muscular Sarcocystis infection are diagnosed based on the detection of sarcocysts in muscle samples taken from biopsy specimens or postmortem samples.

**Culture**

*In vitro* culture of intestinal coccidial parasites is most often used as a tool to study developmental biology or to identify active chemotherapeutic agents. It presently has limited use in diagnosis of active human infection.

Only minimal development of *C. belli* occurs in human (ileocecal adenocarcinoma [HCT-8 cells] or epithelial carcinoma of the lung [A549]) or primate (African green monkey kidney [Vero] or Madin-Darby bovine kidney) cell cultures (59). No reports on development of *C. cayetanensis* in cell culture have been published. Bradyzoites of *S. hominis* undergo sexual development and produce oocysts in cell culture (60). Vascular schizonts stages of human Sarcocystis species have not been reported for in vitro systems, but continuous cultures of several mammalian and avian species have been reported.

**Antigen Detection**

The inability to produce stages in cell cultures and provide a source of diagnostic antigens has limited the usefulness of antigen detection for these coccidial parasites of humans.

**Nucleic Acid Detection**

There are no U.S. Food and Drug Administration-approved nucleic acid tests for the detection of infections with *C. belli*, *C. cayetanensis*, or Sarcocystis species. Several research laboratories have developed nucleic acid-based detection tests to demonstrate infection with these parasites in stool and tissue samples.

Detection of *C. belli* by PCR with primers based on internal transcribed spacer (ITS) region and small-subunit RNA sequences has been reported (2, 61, 62). Three different genotypes of *C. belli* can be identified with PCR and restriction fragment length polymorphism using MboII digestion (62). Coinfection of a single patient with two different genotypes has been observed (62). Molecular diagnosis of *cytisporiosis* employing extended-range PCR screening has been proven to detect *C. belli* in biopsy material from a patient who was febrile examination and histological examination negative on initial testing (63). Developmental stages were eventually observed in biopsy material and confirmed the findings (63). A real-time PCR using the internal transcribed spacer region 2 small-subunit RNA sequences has been developed to detect *C. belli* in stool samples (61).

Much attention has been placed on molecular methods to detect *C. cayetanensis* oocysts in stools, in water samples, and on produce because of the numerous outbreaks of *C. cayetanensis* infections (64). The 18S rRNA gene is presently the most frequently used target. Because *C. cayetanensis* is closely related to *Eimeria* species (65) from vertebrates, it is important that tests designed to detect *C. cayetanensis* in the water or on produce be examined for cross-reactivity to *Eimeria* spp. (66). *Cyclospora* species infecting mammals other than humans may also be present in water samples or on produce, and proofs of specificity are needed for these tests designed to look at environmental sources of *C. cayetanensis* and to detect *C. cayetanensis* oocysts on produce.

Quantitative PCR assays have been developed for *C. cayetanensis* oocysts in stool samples (67). This method detected DNA of the 18S ribosomal gene sequence from as little as 1 oocyst of *C. cayetanensis* per 5 ml of reaction volume. A multiplex PCR to detect *Cyclospora*, *Cystoisospora*, and microsporidia in stool samples has been developed (68).

S. *hominis* sporocysts in human stool can be detected using PCR-restriction fragment length polymorphism and sequencing of a partial 18S rRNA gene product. Several PCR methods have been developed to detect sarcocysts in the muscles of animals, and the U.S. Centers for Disease Control and Prevention (CDC) is presently attempting to develop a Sarcocystis-specific PCR to detect muscular Sarcocystis infection (26).

**SEROLOGIC TESTS**

The inability to obtain usable quantities of antigens from *C. belli*, *C. cayetanensis*, and *Sarcocystis* spp. has greatly limited the use of serologic diagnostic tests for these parasites in human stool samples. It is very difficult to obtain enough oocysts or sporocysts from feces to conduct serologic tests. The development of an enzyme-linked immunosorbent assay that measures IgG and IgM antibodies, using *C. cayetanensis* oocysts as antigen, has been reported (69). This study is questionable because the authors stated that they obtained their oocysts from experimentally infected guinea pigs, yet well-controlled studies indicate that humans are the only suitable host for *C. cayetanensis* (70). Attempts were made to develop an indirect fluorescent-antibody assay to detect IgG, IgA, and IgM specific for *C. cayetanensis*, using sectioned oocysts (71). None of the sera from four patients with positive stools reacted in the indirect fluorescent-antibody assay.

The CDC is presently attempting to develop a Sarcocystis-specific Western blot to detect muscular Sarcocystis infection (49; D. H. Esposito and S. Handali, personal communication, April 2013). As of this writing, no test is available.

**TREATMENT**

**Cystoisospora belli**

The drug of choice for the treatment of *C. belli* is trimethoprim-sulfamethoxazole. A dose of trimethoprim (160 mg)-sulfamethoxazole (800 mg) two to four times a day for 10 to 14 days results in clearance of parasites, a decrease in diarrhea, and a decrease in abdominal pain within a mean of 2.5 days after treatment (72). Before the advent of combination antiretroviral therapy (cART), it was recommended that patients with HIV-1 infection and CD4+ cell counts of <200 should receive secondary prophylaxis with trimethoprim (320 mg)-sulfamethoxazole (1,600 mg) once daily or three times a week to prevent relapse. In most cases, secondary prophylaxis is not needed once the CD4+ count exceeds 200. However, a recent study described eight cases of chronic *C. belli* infection that persisted despite standard trimethoprim-sulfamethoxazole therapy, secondary prophylaxis, and good immunological and virological response to cART (73). Four patients died, two remained clinically ill, and two recovered (73).

For patients unable to tolerate sulfonamides due to allergy or intolerance, there is no standard treatment. Pyrimethamine at a dose of 50 to 75 mg/day is an effective alternative treatment for patients with sulfonamide allergies (74). Secondary prophylaxis using pyrimethamine at 25 mg/day can be used for patients not on cART (74). Pyrimethamine should be given with folic acid (5 to 10 mg/day) to minimize bone marrow suppression. Another alternative agent?
is ciprofloxacin, a fluoroquinolone that inhibits topoisomerase. In a randomized study of 22 patients with cystoisosporiasis and HIV infection, all of the 10 patients who received trimethoprim-sulfamethoxazole had a cessation of diarrhea within 2 days, and 10 of 12 patients who received ciprofloxacin (500 mg twice daily) had a cessation of diarrhea within 4.5 days (75). All three patients (two with diarrhea and one without) who had persistent C. belli oocysts in their stools responded to trimethoprim-sulfamethoxazole treatment (75). In patients who responded to ciprofloxacin, continued prophylaxis with ciprofloxacin prevented recurrence of disease (75). Nitazoxanide has been used to treat C. belli infections (76, 77). Two patients who were given 500 mg of nitazoxanide twice daily for 3 days were oocyst negative after treatment (77). A patient treated with 500 mg of nitazoxanide twice daily for 7 days became oocyst negative by day 14 after treatment (76). Treatment failure was likely due to the negative by day 14 after treatment (76). Treatment failure was observed in a patient with biliary cystoisosporiasis and malabsorption when 2 g of nitazoxanide was given orally twice daily (78). Treatment failure was likely due to the lack of absorption of nitazoxanide and poor levels of the drug in the serum (78). Elevations in liver function tests and nausea are potential side effects of orally administered nitazoxanide.

In a study of eight AIDS patients with C. belli enteritis treated with diclazuril 200 mg/day for 7 days, treatment resulted in resolution of diarrhea in four of eight patients (79). Diclazuril 300 mg twice a day was reported to successfully treat C. belli in an AIDS patient who was hypersensitive to trimethoprim-sulfamethoxazole and pyrimethamine, and in this case, when the dose was decreased to 300 mg/day, the diarrhea recurred (80). Treatment with other antiprotozoal agents, such as metronidazole, tinidazole, quinacrine, and furozolidone, appears to be of little value for this infection.

**Cyclospora cayetanensis**

The drug of choice for the treatment of C. cayetanensis infection is trimethoprim (160 mg)-sulfamethoxazole (800 mg) given twice daily for 7 days (81, 82). Clearance of parasites, a decrease in diarrhea, and a decrease in abdominal pain occurred within a mean of 2.5 days after treatment. Patients on cART likely do not need secondary prophylaxis.

For patients unable to tolerate sulfonamides due to allergy or intolerance, there is no standard treatment. Nitazoxanide has been evaluated for activity against C. cayetanensis, and in these studies, its efficacy for the treatment of cyclosporiasis has been ~70% (83, 84). It should be appreciated, however, that only a few patients with cyclosporiasis were treated in any of these studies (83, 84). Another alternative agent is ciprofloxacin, a fluoroquinolone that inhibits topoisomerase. In a randomized study of 20 patients with cyclosporiasis, all of the 9 patients who received trimethoprim-sulfamethoxazole had a cessation of diarrhea within 3 days, and 10 of 11 who received ciprofloxacin (500 mg twice daily) had a cessation of diarrhea within 4 days; however, only 7 of 11 patients treated with ciprofloxacin cleared the organism from the stool (75). Anecdotal data suggest that the following drugs are ineffective: albendazole, azithromycin, pyrimethamine, nalidixic acid, norfloxacin, tinidazole, metronidazole, quinacrine, tetracycline, doxycycline, and diloxamine furoate (L. M. Weiss et al., unpublished data).

**Sarcocystis hominis** and **Sarcocystis suihominis**

There is no known treatment or prophylaxis for intestinal infection, myositis, vasculitis, or related lesions due to sarcocystosis in humans. It is clear that individuals who travel to Malaysia (25, 26, 49) should take precautions and not drink water or consume food potentially contaminated with sporocysts. Supportive therapy for patients with severe diarrhea is indicated. For six patients in Thailand with segmental necrotizing enteritis, treatment consisted of surgical resection of the affected areas of the intestine and antibiotics for the associated bacterial infection (46).

There is a case report of albendazole having efficacy in an outbreak of eosinophilic myositis due to Sarcocystis spp. (25). It is likely that steroids have a role in decreasing the inflammatory response in cases of myositis and vasculitis due to Sarcocystis spp. infection, but this has never been evaluated in a controlled trial.

**Treatment Failure**

There are no documented reports of drug-resistant strains of C. belli, C. cayetanensis, or Sarcocystis species. Development of resistance to trimethoprim-sulfamethoxazole has been suggested in one study of eight AIDS patients with C. belli, but other factors such as antigen-specific immune deficiency or generalized reduction in gut immunity could not be excluded (75). It appears that treatment failures are most likely to be related to poor drug absorption or distribution than to true drug resistance.

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

Both C. belli and C. cayetanensis are usually identified by stool examination and are rarely misidentified in human feces. Quantification of the number of organisms found per high-power field is not required. Stool examinations that are reported as negative should indicate that at least three stool examinations are needed to detect organisms in 95% of infected individuals and that a single specimen may miss as many as 30% of infected patients. If acid-fast or similar stains are done on the stool examination and are positive, then this should be indicated in the report. Computer report notes can indicate that trimethoprim-sulfamethoxazole is the drug of choice for treatment of these parasites. PCR can be used for the identification of these organisms but is not commercially available and should be indicated as an experimental test. Serology is not currently used for diagnosis of these diseases in humans. Of the coccidia discussed here, only C. cayetanensis is reportable to state health departments and the CDC, as it has been associated with outbreaks and the contamination of human food sources.

*S. hominis* and *S. suihominis* can be identified by their characteristic morphology in stool specimens or in tissue biopsy specimens. They cannot be identified to the species level based on sporocyst structure and can only be identified as Sarcocystis spp. Due to the rarity of these infections, confirmation of the observed organisms should be obtained from experts in parasitology. Laboratory reports should indicate whether expert confirmation of the identity of these organisms has been obtained.

**REFERENCES**

Cryptosporidium spp. inhabit the brush borders of the gastrointestinal and respiratory epithelium of various vertebrates, causing enterocolitis, diarrhea, and cholangiopathy in humans (1). Immunocompetent children and adults with cryptosporidiosis usually have a short-term illness accompanied by watery diarrhea, nausea, vomiting, and weight loss. In immunocompromised persons, however, the infection can be protracted and life-threatening (2). In developing countries, cryptosporidiosis is one of the most important causes of moderate to severe diarrhea and diarrhea-associated death (3). Cryptosporidium spp. are well-recognized water- and foodborne pathogens in industrialized nations, having caused many outbreaks of human illness (4, 5).

DESCRIPTION OF THE AGENT

Cryptosporidium spp. are intracellular parasites that primarily infect epithelial cells of the intestine and biliary ducts. In severely immunosuppressed persons, the respiratory tract is sometimes involved. The involvement of the respiratory system in immunocompetent persons may be more common than previously believed, although its role in cryptosporidiosis transmission is not yet clear (14). The infection site varies according to species, but almost the entire development of Cryptosporidium spp. occurs between the two lipoprotein layers of the membrane of the epithelial cells.

Cryptosporidium infections in humans or other susceptible hosts start with the ingestion of viable oocysts (Fig. 1). Upon contact with gastric and duodenal fluid, four sporozoites are liberated from each excysted oocyst; invade the epithelial cells; develop to trophozoites surrounded by a parasitophorous vacuole; and undergo two or three generations of asexual multiplication and one generation of sexual reproduction, leading to the formation of new oocysts. The latter are sporulated in situ, excreted into the environment with feces, and can initiate infection in a new host upon ingestion without further development (Fig. 1). The time from ingestion of infective oocysts to the completion of endogenous development and excretion of new oocysts varies with species, hosts, and infection doses; it is usually between 4 and 10 days (15, 16). In addition to the classic coccidian developmental stages, a gregarine-like extracellular stage was described in C. parvum, which supposedly can go through multiplication via syzygy, a sexual reproduction process involving the end-to-end fusion of two or more parasites (7).

Currently, nearly 20 Cryptosporidium species and genotypes have been reported in humans, including C. hominis, C. parvum, C. meleagris, C. felis, C. canis, C. cuniculus, C. ubiquitum, C. viatorum, C. maris, C. suis, C. fayeri, C. andersoni, C. bovis, C. scrofa ruminants; C. varanii in reptiles; C. mohrii and C. scophthalmi in fish. There are also >40 host-adapted Cryptosporidium genotypes that do not yet have species names, such as Cryptosporidium horse, skunk, and hedgehog genotypes (8–12). These species and genotypes biologically, morphologically, and phylogenetically belong to three groups: intestinal, gastric, and piscine species and genotypes (13). Most of these Cryptosporidium species and genotypes have not been found in humans.

TAXONOMY

Cryptosporidium spp. belong to the family Cryptosporidiidae, which is a member of the phylum Sporozoa (syn. Apicomplexa). The exact placement of Cryptosporidiidae in Sporozoa is uncertain. It was long considered a member of the class Coccidea, in the order of Eimeriida. Recent phylogenetic studies, however, indicate that Cryptosporidiidae sp. are more related to gregarines than to coccidia (6). Putative extracellular gregarine-like reproductive stages were described (7).

Recently, the taxonomy of Cryptosporidium has gone through revisions as the result of extensive molecular genetic studies and biologic characterizations of parasites from various animals (8, 9). There are >20 established Cryptosporidium species, including C. hominis in humans; C. parvum in humans and preweaned ruminants; C. viatorum in humans; C. andersoni, C. bovis, and C. raeae in weaned calves and adult cattle; C. xiaoj and C. ubiquitum in sheep and goats; C. suis and C. scrofa ruminants; C. canis in dogs; C. felis in cats; C. cuniculus in rabbits; C. fae in guinea pigs; C. murs and C. tyzzeri in rodents; C. fayeri and C. macrosporum in marsupials; C. meleagris, C. baileyi, and C. galli in birds; C. varanii and C. serpentis in reptiles; C. fragile in amphibians; and C. mohrii and C. scophthalmi in fish. There are also >40 host-adapted Cryptosporidium genotypes that do not yet have species names, such as Cryptosporidium horse, skunk, and hedgehog genotypes (8–12). These species and genotypes biologically, morphologically, and phylogenetically belong to three groups: intestinal, gastric, and piscine species and genotypes (13). Most of these Cryptosporidium species and genotypes have not been found in humans.
FIGURE 1  Life cycle of Cryptosporidium spp. Sporulated oocysts, containing four sporozoites, are excreted by the infected host through feces and possibly other routes such as respiratory secretions (1). Transmission of Cryptosporidium spp. in humans occurs mainly through contact with infected persons (for C. hominis and C. parvum) or animals (for C. parvum mostly) and consumption of contaminated water and food (2). Following ingestion (and possibly inhalation) by a suitable host (3), excystation (a) occurs. The sporozoites are released and parasitize epithelial cells (b, c) of the gastrointestinal tract or other tissues such as the respiratory tract. In these cells, the parasites undergo asexual multiplication (schizogony or merogony) (d to f) and then sexual multiplication (gametogony), producing microgamonts (male) (g) and macrogamonts (female) (h). Upon fertilization of the macrogamonts by the microgametes (i), oocysts (j, k) develop that sporulate in the infected host. Two different types of oocysts are produced, the thick-walled oocyst (j), which is commonly excreted from the host; and the thin-walled oocyst (k), which is primarily involved in autoinfection. Oocysts are infective upon excretion, thus permitting direct and immediate fecal-oral transmission. Courtesy of DPDx (http://www.cdc.gov/dpdx/). doi:10.1128/9781555817381.ch142.f1

promised persons. The distribution of these species in humans varies among different geographic areas and socioeconomic conditions, with C. canis and C. felis mostly seen in humans in developing countries, C. ubiquitum mostly in industrialized nations, and C. cuniculus mostly in the United Kingdom. This is probably the result of differences in infection sources and transmission routes (17).

EPIDEMIOLOGY, TRANSMISSION, AND PREVENTION
Cryptosporidium spp. have a worldwide distribution, and their oocysts are ubiquitous in the environment. In the United States, the number of annual reported cases of cryptosporidiosis has increased more than 2-fold since 2004; there were 2,769 to 3,787 annual reported cases between
of cryptosporidiosis increases as the CD4 count falls, especially below 200 cells/μl (32).

Anthroponic versus Zoonotic Transmission

Studies in the United States and Europe have shown that cryptosporidiosis is more common among homosexual men than among persons in other HIV transmission categories (42), indicating that direct person-to-person or anthroponic transmission of cryptosporidiosis is common. Contact with persons with diarrhea has been identified as a major risk factor for sporadic cryptosporidiosis in industrialized countries (28, 43–46). This is exemplified by the high prevalence of cryptosporidiosis in day care facilities and nursing homes and among mothers with young children in these countries.

Only a few case-control studies have assessed the role of zoonotic transmission in the acquisition of cryptosporidiosis in humans. In industrialized countries, contact with farm animals (especially cattle) is a major risk factor in sporadic cases of human cryptosporidiosis (28, 30, 43, 44, 47, 48). Contact with pigs, dogs, or cats was a risk factor for cryptosporidiosis in children in Guinea-Bissau and Indonesia in one study (49, 50). A weak association was observed between the occurrence of cryptosporidiosis in HIV-positive persons and contact with dogs in another study (51). In other studies, no increased risk in the acquisition of cryptosporidiosis was associated with contact with companion animals (52).

The distribution of C. parvum and C. hominis in humans is a reflection of the role of different transmission routes. Thus far, studies conducted in developing countries have shown a predominance of C. hominis in children or HIV-positive adults. This is also true for most areas in the United States, Canada, Australia, and Japan. In Europe and New Zealand, however, several studies have shown almost equal prevalence of C. parvum and C. hominis in both immunocompetent and immunocompromised persons (17). In contrast, children in the Middle East are mostly infected with C. parvum (53). The differences in the distribution of Cryptosporidium genotypes in humans are considered to be an indication of differences in infection sources (17, 48, 54, 55); the occurrence of C. hominis in humans is most likely due to anthroponic transmission, whereas C. parvum in a population can be the result of both anthroponic and zoonotic transmission. Thus, in most developing countries, it is possible that anthroponic transmission of Cryptosporidium plays a major role in human cryptosporidiosis, whereas in Europe, New Zealand, and rural areas of the United States, both anthroponic and zoonotic transmissions are important.

Recent subtyping studies based on sequence analyses of the 60-kDa glycoprotein (gp60) gene have shown that many C. parvum infections in humans are not results of zoonotic transmission (17). Among several C. parvum subtype families identified, IIa and IIc are the two most common families. The former has been identified in both humans and ruminants and thus can be a zoonotic pathogen, whereas the latter has been seen only in humans (13, 17, 56) and thus is an anthroponic pathogen. In developing countries, most C. parvum infections in children and HIV-positive persons are caused by the subtype family IIc, with IIa largely absent, indicating that anthroponic transmission of C. parvum is common in these areas (13, 17). In contrast, both IIa and IIc subtype families are seen in humans in developed countries. Even in the United Kingdom, where zoonotic transmission is known to play a significant role in the transmission of human cryptosporidiosis, anthroponic transmission of C. parvum also occurs (57). Another C. parvum subtype family commonly found in sheep and goats, IIId, is the dominant C. parvum subtype family in humans in Middle Eastern countries (53). Results of multilocus subtyping support the conclusions of gp60 subtyping studies (58–61).

Waterborne Transmission

Epidemiologic studies have frequently identified water as a major route of Cryptosporidium transmission in areas where the disease is endemic (62). In most tropical countries, Cryptosporidium infections in children usually peak during the rainy season; thus, waterborne transmission probably plays a role in the transmission of cryptosporidiosis in these areas (63–65). Seasonal variations in the incidence of human Cryptosporidium infection in industrialized nations have also been partially attributed to waterborne transmission (27, 28, 30, 66). In the United States, there is a late summer peak in sporadic cases of cryptosporidiosis (22, 28, 30), which is largely due to increased participation in recreational activities such as swimming and water sports (67). In a Canadian study, swimming in a lake or river was identified as a risk factor (45). The role of drinking water in sporadic Cryptosporidium infection is not clear. In Mexican children living near the U.S. border, cryptosporidiosis is associated with consumption of municipal water instead of bottled water (68). In England, there is an association between the number of glasses of tap water drunk at home each day and the occurrence of sporadic cryptosporidiosis (43). In the United States, drinking untreated surface water was identified as a
risk factor for the acquisition of Cryptosporidium in case-control studies (46, 69), and residents living in cities with surface-derived drinking water generally have higher antibody levels against Cryptosporidium in their blood than those living in cities with groundwater as drinking water, indicating that drinking water plays a role in the transmission of human cryptosporidiosis (70). Nevertheless, case-control studies conducted with both immunocompetent persons and AIDS patients in the United States and Canada have failed to show a direct linkage of Cryptosporidium infection to drinking water (71–73).

Numerous waterborne outbreaks of cryptosporidiosis have occurred in the United States, Canada, the United Kingdom, France, Australia, Japan, and other industrialized nations (4, 74). These include outbreaks associated with both drinking water and recreational water (swimming pools and water parks). After the massive cryptosporidiosis outbreak in Milwaukee, WI, in 1993, the water industry has adopted more-stringent treatments of source water. Currently, the number of drinking-water-associated outbreaks is in decline in the United States and the United Kingdom, and most outbreaks in the United States are associated with recreational water (30, 67). Even though five Cryptosporidium species are commonly found in humans, C. parvum and C. hominis are responsible for most cryptosporidiosis outbreaks, with C. hominis responsible for more outbreaks than C. parvum (17). This is even the case for the United Kingdom, where C. parvum and C. hominis are both common in the general population. Recently, there was one drinking-water-associated cryptosporidiosis outbreak caused by C. cuniculus (75). An outbreak of C. meleagridis also occurred in a high school dormitory in Japan, although the role of waterborne transmission in the occurrence of the outbreak was not clear (76).

**Foodborne Transmission**

Foodborne transmission is also important in cryptosporidiosis epidemiology. Cryptosporidium oocysts have been isolated often from fruits, vegetables, and shellfish (77–80). Direct contamination of food by fecal materials from animals or food handlers has been implicated in several foodborne outbreaks of cryptosporidiosis in industrialized nations (78). In most instances, human infections were usually due to consumption of contaminated fresh produce and unpasteurized apple cider or milk (81–87).

Very few case-control studies have examined the role of contaminated food as a risk factor in the acquisition of Cryptosporidium infection in areas where the disease is endemic. A pediatric study in Brazil failed to show any association between Cryptosporidium infection and diet or type of food hygiene (52). Case-control studies conducted in the United States, the United Kingdom, and Australia have actually shown a lower prevalence of Cryptosporidium infection in immunocompetent persons with frequent consumption of raw vegetables (28, 43, 46, 88), probably because of continuous exposure to Cryptosporidium-contaminated fresh produce. It is estimated that ~8% of Cryptosporidium infections in the United States are foodborne (5).

**Prevention**

As for any pathogens that are transmitted by the fecal-oral route, good hygiene is the key in preventing the acquisition of Cryptosporidium infection (89). Immunocompromised persons especially should take necessary precautions in preventing the occurrence of cryptosporidiosis (90). This includes washing hands before preparing food and after using the bathroom, changing diapers, and contacting pets or soil (including gardening); avoiding drinking water from lakes and rivers, swallowing water in recreational activities, and drinking unpasteurized milk, milk products, and juices; and following safe-sex practices (avoiding oral-anal contact).

During cryptosporidiosis outbreaks or when a community advisory to boil water is issued, individuals should boil water for 1 min to kill the parasite or use a tap water filter capable of removing particles <1 μm in diameter. Immunocompromised persons also should avoid eating raw shellfish and should not eat uncooked vegetable salads and unpeeled fruits when traveling to developing countries (90).

**CLINICAL SIGNIFICANCE**

In developing countries, frequent symptoms of cryptosporidiosis in children include diarrhea, abdominal cramps, nausea, vomiting, headache, fatigue, and low-grade fever (2). The diarrhea can be voluminous and watery but usually resolves within 1 to 2 weeks without treatment. Not all infected children have diarrhea or other gastrointestinal symptoms, and the occurrence of diarrhea in children with Cryptosporidium ileocolitis (92). Cryptosporidiosis has been associated with increased mortality in developing countries (3, 63, 93).

Unlike in developing countries, immunocompetent persons with sporadic cryptosporidiosis in industrialized nations usually have diarrhea (1, 29, 88). The median number of stools per day during the worst period of the infection is 7 to 9.5 (88). Other common symptoms include abdominal pain, nausea, vomiting, and low-grade fever (29, 88). The duration of illness has a mean or median of 9 to 21 days, with a median loss of 5 work or study days and hospitalization of 7 to 22% of patients (27, 29, 88). Patients infected with C. hominis are more likely to have joint pain, eye pain, recurrent headache, dizziness, and fatigue than those infected with C. parvum (94). There are significant differences among different Cryptosporidium species and C. hominis subtype families in clinical manifestations of pediatric cryptosporidiosis (92).

Cryptosporidiosis in immunocompromised persons, including AIDS patients, is frequently associated with chronic, life-threatening diarrhea (32). Sclerosing cholangitis and other biliary involvements are also common in AIDS patients with cryptosporidiosis (95). In severely immunocompromised persons, respiratory system involvement is common (96). Cryptosporidiosis in AIDS patients is associated with increased mortality and shortened survival (97, 98). Variations in the infection site (gastric infection, proximal small intestine infection, or ileocolonic infection versus panenteric infection) have been seen in AIDS patients with cryptosporidiosis. They may contribute to differences in clinical presentation and survival (99, 100). Likewise, different Cryptosporidium species and C. hominis subtype families are associated with different clinical manifestations in HIV-positive persons in developing countries (101).

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

Currently, most active Cryptosporidium infections are diagnosed by analysis of stool specimens. Stool specimens are
usually collected fresh or in fixative solutions such as 10% buffered formalin and polyvinyl alcohol (PVA) (102). However, stool specimens fixed in formalin and mercury-based preservatives (such as LV-PVA) cannot be used for molecular diagnosis. For outbreak investigations, Cryptosporidium spp. present are frequently genotyped and subtyped by PCR methods, which require the use of fresh or frozen stool specimens or stools stored in Cary-Blair transport media or preserved in TotalFix (Medical Chemical Corporation, Torrance, CA), zinc PVA, or 2.5% potassium dichromate. It is recommended that whenever possible multiple specimens (three specimens passed at intervals of 2 to 3 days) from each patient should be examined if Cryptosporidium infection is suspected and the examination of the initial stool specimen is negative. This is because carriers with low oocyst shedding are common, and examination of individual specimens can lead to the detection of only 53% of infections (103).

Examination of intestinal or biliary biopsy is sometimes used in the diagnosis of cryptosporidiosis in AIDS patients (99). However, the sensitivity of the diagnosis depends on the location of tissues examined; the duodenum is usually infected with Cryptosporidium only in severe infection, and the terminal ileum and colon have significantly higher detection rates than the duodenum (103). Thus, upper endoscopic biopsies are much less sensitive than colonoscopic biopsies in diagnosing cryptosporidiosis.

**DIRECT EXAMINATION**

In clinical laboratories, Cryptosporidium spp. in stool specimens are commonly detected by microscopic examination of oocysts or immunologic detection of antigens (104).

**Microscopy**

Stool specimens can be examined directly for Cryptosporidium oocysts by microscopy of direct wet-mount or stained fecal materials if the number of oocysts in specimens is high. Cryptosporidium oocysts in humans generally measure 4 to 6 μm. Occasionally, C. muris oocysts are also found, which are more elongated and measure 6 to 9 μm. Oocysts present are often concentrated using either traditional ethyl acetate or Weber-modified ethyl acetate concentration methods (104). Concentrated stool specimens can be examined by microscopy in several ways. Cryptosporidium oocysts can be detected by bright-field microscopy in direct wet mounts. This allows the observation of oocyst morphology and more accurate measurement of oocysts, which is frequently needed in biologic studies. Differential interference contrast can be used in microscopy, which produces better images and visualization of internal structures of oocysts. Most Cryptosporidium species look similar under microscopes and have similar morphometric measurements (8).

More often, Cryptosporidium oocysts in concentrated stool specimens are detected by microscopy after staining of the fecal smears. Many special stains have been used in the detection of Cryptosporidium oocysts, but modified acid-fast stains are the most commonly used (104), especially in developing countries, because of their low cost, ease of use, lack of need for special microscopes, and simultaneous detection of several other pathogens such as Cystoisospora (formerly Isospora) and Cyclospora (Fig. 2). Two stains widely used are the modified Ziehl-Neelsen acid-fast stain and modified Kinyoun’s acid-fast stain (104). Oocysts are stained bright red to purple against a blue or green background (Fig. 2).

Direct immunofluorescence assays (DFAs) have been used increasingly in Cryptosporidium oocyst detection by microscopy, especially in industrialized nations. Compared to acid-fast staining, DFA has higher sensitivity and specificity (105). Many commercial DFA kits are marketed for the diagnosis of Cryptosporidium, most of which include reagents allowing simultaneous detection of Giardia cysts (Table 1). Oocysts appear apple green against a dark background in immunofluorescence microscopy (Fig. 3). Because of the high sensitivity and specificity, DFA has been used by some as the gold standard or reference test (105, 106). It has been shown that most antibodies in commercial DFA kits react with oocysts of almost all Cryptosporidium species, making identification to the species level impossible (107, 108).

Compared with DFA, the sensitivity of most microscopic methods is probably low. The detection limit for the combination of ethyl acetate concentration and DFA was shown to be 10,000 oocysts per gram of liquid stool and 50,000 oocysts per gram of formed stool (109, 110). A similar sensitivity was achieved with fecal specimens from dogs (111). The sensitivity of modified acid-fast staining was 10-fold lower than that of DFA (110), probably because acid-fast stains do not consistently stain all oocysts (112). The sensitivity of the DFA can be significantly improved by the incorporation of an oocyst isolation step using an immunomagnetic separation technique (113).

**Antigen Detection**

Cryptosporidium infection can also be diagnosed by the detection of Cryptosporidium antigens in stool specimens by immunoassays (104). Antigen capture-based enzyme immunoassays (EIAs) have been used in the diagnosis of cryptosporidiosis since 1990. In recent years, EIAs have gained popularity because they do not require experienced microscopists and can be used to screen a large number of samples (114). In clinical laboratories, several commercial EIA kits are commonly used (Table 1). High specificity (99 to 100%) has been generally reported for these EIA kits (105, 106, 115). Sensitivities, however, have been reported to range between 70% (105) and 94 to 100% (106, 116–118). Occasional false positivity of EIA kits is known to occur in the detection of Cryptosporidium (119, 120), and manufacturers’ recalls of EIA kits have occurred because of high nonspecificity (121). If a patient is in the carrier state or undergoing self-cure, the number of oocysts may drop below the sensitivity levels of these kits (105). Most EIA kits have been evaluated only with human stool specimens presumably from patients infected with C. hominis or C. parvum (118). Their usefulness in the detection of Cryptosporidium spp. in animals may be compromised by the specificity of the antibodies.

In recent years, several lateral flow immunochromatographic assays have been marketed for rapid detection of Cryptosporidium in stool specimens (Table 1). In evaluation studies, these assays have been shown to have high specificities (>90%) and sensitivities (98 to 100%) (105, 122–127). However, sensitivities of 68 to 75% were shown in some studies for some assays (105, 128–130). High false-positive rates (positive predictive value, 56%) for several rapid assays have been reported recently in clinical diagnosis of cryptosporidiosis in the United States (131). This has prompted the Council of State and Territorial Epidemiologists to change the case definition of rapid assay-positive cases from confirmed cases to probable cases. It has also been shown recently that some rapid assay kits have low sensitivity (<35%) in detecting some Cryptosporidium species other than C. hominis and C. parvum (130).

TYPING SYSTEMS
Molecular techniques, especially PCR and PCR-related methods, have been developed and used in the detection and differentiation of Cryptosporidium spp. for many years (132). A few of the PCR assays are commercially available (Table 1). Several genus-specific PCR-restriction fragment length polymorphism-based genotyping tools have been developed for the detection and differentiation of Cryptosporidium at the species level (133–137). Most of these techniques are based on the small-subunit rRNA gene. Other genotyping techniques are designed mostly for the differentiation of C. parvum and C. hominis and thus cannot detect and differentiate other Cryptosporidium spp. or genotypes (17). Their usefulness in the analysis of human stool specimens is compromised by their inability to detect C. canis, C. felis, C. suis, and C. muris (138).

Several subtyping tools have also been developed to characterize the diversity within C. parvum or C. hominis (17). One of the most commonly used techniques is sequence analysis of the gp60 gene (also known as gp40/15) (24, 56, 139, 140). Most of the genetic heterogeneity in this gene is present in the number of a trinucleotide repeat (TCA, TCG, or TCT), although extensive sequence differences are also present between families of subtypes. Multilocus mini- and microsatellite subtyping tools for C. parvum and C. hominis have also been developed (59, 141–144). The usefulness of subtyping tools has been demonstrated by the analysis of samples from foodborne and waterborne outbreaks of cryptosporidiosis (46, 60, 85, 87, 145–156).

ISOLATION PROCEDURES
The in vitro cultivation of Cryptosporidium spp. remains inefficient despite recent advances (157, 158). The low parasite yields and oocyst production have limited the usefulness of parasite culture in the isolation and diagnosis of Cryptosporidium. Nevertheless, in vitro cultivation of early Cryptosporidium developmental stages in several epithelial cell lines (HCT-8, Madin-Darby bovine kidney, Caco-2, etc.) has been used widely in research studies to assess potential drugs and oocyst disinfection methods and to characterize parasite development, differentiation, and biochemistry (157). The recent development of procedures for long-term maintenance of C. parvum and C. hominis in cell and cell-free culture, if verified, could promote the use of in vitro cultivation methods in routine diagnosis of Cryptosporidium infection (158, 159).

TREATMENT
Numerous pharmaceutical compounds have been screened for anti-Cryptosporidium activities in vitro or in laboratory animals (160–162). Some of those showing promise have been used in the experimental treatment of cryptosporidiosis in humans, but few have been shown to be effective in

*CE, Conformité Européenne or European Conformity (medical device that met standards set by the European Union and can be legally sold in those countries); FDA, approved by the U.S. Food and Drug Administration; ISO 34, produced in compliance with the International Standards Organization Guide 34; CLIA, laboratory protocols meet regulations of the Clinical Laboratory Improvement Amendment.
*Not available in the United States.
controlled clinical trials (32, 163). Oral or intravenous rehydration and antimotility drugs are widely used whenever severe diarrhea is associated with cryptosporidiosis. Nitzoxanide is the only U.S. Food and Drug Administration-approved drug for the treatment of cryptosporidiosis in immunocompetent persons. Clinical trials have demonstrated that nitzoxanide can shorten clinical disease and reduce parasite loads (161, 164). This drug, however, is not effective in the treatment of Cryptosporidium infections in immunodeficient patients (163, 164). For this population, paromomycin and spiramycin have been used in the treatment of some patients, but their efficacy remains unproven (161–163).

In industrialized nations, the most effective treatment and prophylaxis for cryptosporidiosis in AIDS patients is the use of highly active antiretroviral therapy (HAART) (161, 162, 165). It is probably also an effective prevention for cryptosporidiosis in HIV-positive persons in developing countries (166). It is believed that the eradication and prevention of the infection are related to the replenishment of CD4+ cells in treated persons and the antiparasitic activities of the protease inhibitors (such as indinavir, nelfinavir, and ritonavir) used in HAART (162, 165). Relapse of cryptosporidiosis is common in AIDS patients who have stopped HAART (167). In developing countries, protease inhibitors are generally not included in HAART regimens. Limited reports have shown that cryptosporidiosis is still common in HIV-positive patients receiving HAART in developing countries, although at lower frequencies than those generally reported in untreated HIV patients (166, 168, 169).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Cryptosporidiosis is a notifiable disease in most states in the United States and in some other industrialized countries, although only ~1.4% of actual cases are diagnosed in the United States (5). Thus, the detection of the pathogen in stools or tissues should be reported to the local health department in addition to the physicians. Because most routine diagnostic tests cannot differentiate Cryptosporidium species, the detection of Cryptosporidium oocysts or antigens in stools or other specimens should be reported as Cryptosporidium positive without referring to the nature of species involved. From a public health point of view, the reporting of a significant number of cases above background levels in industrialized nations indicates the likely occurrence of outbreaks of cryptosporidiosis or false positivity of diagnostic kits (120, 121, 170, 171). In situations like this, it is crucial to have the test results verified with a confirmatory test such as DFA or PCR and to report them to the state or local public health department. The inclusion of both positive and negative controls in each test run and stringent adherence to recommended procedures will reduce the occurrence of test errors. In the United States, patients positive for Cryptosporidium by immunochromatographic assay-based rapid tests are considered by the Council of State and Territorial Epidemiologists as probable cryptosporidiosis cases. The diagnostic result requires confirmation by a second assay, such as DFA, EIA, or PCR.

The findings and conclusions in this report are those of the authors and do not necessarily represent the views of the Centers for Disease Control and Prevention.

Nematodes*
HARSHA SHEOREY, BEVERLEY-ANN BIGGS, AND NORBERT RYAN

TAXONOMY OF NEMATODES

Nematodes are unsegmented cylindrical worms with a body cavity containing an alimentary canal and genital system; the sexes are separate. They lack circular muscles and move by flexing their bodies. There are four larval stages and the adult worm. In most instances, the third-stage larva is the infective stage. There are a variety of morphological features which form the basis for taxonomy of nematodes. At the anterior end, mouthparts may possess structures for attachment or penetration. These may include spines, hooks, or cutting plates. The pharyngeal cavity may be short, hollowed out, or long and capillary. Esophageal shape also varies, but the esophagus usually ends in a muscular bulb. In the male, features of the tail may include caudal papillae and copulatory spicules (sclerotized copulatory aids). In the majority of cases, males carry more taxonomically useful information than females; the latter may often be unidentifiable to the species level in the absence of males. Studies strongly suggest that nematodes are actually related to the arthropods and priapulids in a newly recognized group, the Ecdysozoa (2, 3). All these nematodes belong to kingdom Animalia, subkingdom 3 Bilateria, and phylum Nemathelminthes (Nematoda) (see chapter 132).

ASCARIS LUMBRICOIDES (ROUNDWORM)

Taxonomy
A. lumbricoides belongs to the class Secernentea, order Ascarida, superfamily Ascaridoidea, and family Ascarididae.

Of the three genera of ascaridid nematodes regularly occurring as parasites of humans, only Ascaris is a true human parasite. The others (Toxocara and Toxascaris) are common parasites of cats and dogs and occasionally infect humans. Ascarids are related to anisakids, with three distinct lips, but differ in that their life cycle is linked to terrestrial rather than aquatic conditions.

Ascaris suum was thought to be a separate species in pigs but has recently been found to be genetically similar to the human species A. lumbricoides (4).

Description
Eggs
Eggs of A. lumbricoides (Fig. 2A to C) are usually seen in two forms: unfertilized and fertilized. The egg shell of a fertilized egg (45 to 75 by 35 to 50 μm) consists of an inner lipid layer responsible for selective permeability, a chitin protein layer responsible for structural strength, and an outer vitelline layer. The inner layer contains a lipoprotein, ascaroside, which helps prevent formaldehyde, disinfectants, and other chemicals from contacting the embryo. The outer surface of the fertilized egg has an uneven deposit of mucopolysaccharide with adhesive properties. Eggs appear brown due to staining by bile. The unfertilized eggs have thinner walls and distorted mammillations. These eggs are usually more elongated in shape, measure 85 to 95 by 43 to 47 μm, and may have either a pronounced mammillated coat or little or no mammillated layer. The
FIGURE 1 Relative sizes of helminth eggs. doi:10.1128/9781555817381.ch143.f1
presence of only unfertilized eggs suggests that only female worms are present in the intestine. During the development of the eggs, the parent worm must supply the zygotes with sufficient nutrients to ensure progression to the infective second-stage larvae and subsequent survival.

Larvae

During an incubation period of 2 to 3 weeks in soil, first-stage larvae develop inside the eggs and molt to form the second-stage larvae. Following ingestion of eggs, the larvae hatch in the jejunum; second-stage larvae have a typical filariform appearance (measuring approximately 250 by 14 μm). They migrate across the intestinal wall and enter the circulation to reach the lungs, growing to approximately 560 by 28 μm. A further molt occurs in the lungs, and the larvae develop over 8 or 9 days to reach a size of 1.2 mm by 36 μm. They are carried to the throat and are swallowed. Growth is rapid after the fourth and final molt in the intestine.

Worms

Adult male and female *A. lumbricoides* worms (Fig. 2D) are colored light brown-pink when fresh, turning white with storage. Egg laying commences at 8 to 9 weeks, when females measure 15 to 20 cm, and they may reach 45 cm by 5 mm; males are generally smaller, at 15 to 31 cm by 3 mm. Males have a curved tail containing a cloaca, a pair of copulatory spicules, and caudal papillae. Adult worms live in the lumen of the small intestine and feed on digestion products.

Epidemiology and Prevention

*A. lumbricoides* infection is one of the most common human infections, with more than a billion people estimated to be infected worldwide. Although it has a worldwide distribution, it is most common in tropical and subtropical areas of the developed and underdeveloped worlds. It is particularly associated with crowding and poor sanitation. Contamination of soil by human excreta can result in a layer of eggs within silt that is easily disturbed, resulting in contamination of root and vegetable produce.

Preventive measures consist of health education about personal hygiene and sanitation, and drug therapy.

Transmission and Life Cycle

Eggs passed in feces (diagnostic stage) have an unsegmented ovum; this develops in the soil over 10 to 15 days to reach an infective stage larva (Table 1). Eggs may survive in this form for years under favorable conditions of heat and humidity. Infection follows the ingestion of embryonated eggs (infective stage) that hatch in the small intestine. Larvae penetrate the intestinal mucosa, and the venous circulation carries them to the lungs. From here they migrate to the trachea and are swallowed. They then complete their development into mature adult worms in the small intestine, with eggs produced after 60 to 70 days. A minority of individuals develop heavy infections and act as an important source of transmission.

The prepatent period (from egg ingestion to egg production) is approximately 2 months.

Clinical Significance

Initial infection is usually asymptomatic. Migration of larvae through the lungs may result in an eosinophilic pneumonitis with cough, fever, and dyspnea. This may occur up to 2 weeks after infection and lasts approximately 3 weeks. Bronchospasm may be prominent and is occasionally fatal.

The clinical features in established infections relate to the worm burden. Most infections are light and asymptomatic, but nonspecific abdominal symptoms may occur. There is risk of intestinal obstruction with increasing worm burden. Intestinal obstruction has a high mortality rate in some settings (5). Heavy infections are also associated with malnutrition and impaired growth in children.

Ectopic ascariasis occasionally occurs when adult worms attempt to escape the gut lumen. This may be a spontaneous event or occur in response to febrile illness, medication, or anesthesia. Worms may enter hepatobiliary and pancreatic ducts or the appendix and cause obstruction, resulting in biliary colic, cholecystitis, acute cholangitis, acute pancreatitis, appendicitis, or a hepatic abscess. It occurs more commonly in countries with high rates of infection where the parasite is endemic. (For more on the clinical significance of *A. lumbricoides*, see reference 6.)

Diagnosis

The primary diagnosis of infection is by demonstration of eggs in feces (7, 8). The fertilized eggs are round to oval, bile stained, mammillated, and thick walled. Both fertilized and unfertilized eggs may be found in the same specimen. Multiple specimens taken on separate days may be required. Concentration methods such as formalin-ethyl acetate sedimentation should be used for optimal yield. The flotation technique is unsuitable, as unfertilized eggs have a high density. Decorticated fertile and infertile eggs may be difficult to recognize (Fig. 2A to C). Motile larvae may sometimes be seen in expectorated sputum but rarely in feces. Occasionally, an adult worm (usually female) may be passed in feces or may spontaneously migrate out of the anus, mouth, or nares, particularly in children.

Identification is relatively straightforward because no other human parasite is as large as *A. lumbricoides*. However, it should be noted that earthworms of comparable size can occasionally be retrieved from toilets and submitted for identification. The distinguishing features of *Ascaris* adult worms are that they have tapering ends (Fig. 2D), a lateral white line along the entire length of the body, three lips at the anterior end, and a tough cuticle.

Treatment

Albendazole and mebendazole are effective (see chapter 149 and reference 9). These benzimidazoles should not be used in first trimester of pregnancy or in children <12 months of age. The WHO recommends use in second

FIGURE 2 Various eggs and adult worms of intestinal nematodes (magnification, ×850). (A) Fertile egg of *A. lumbricoides*. (B) Decorticated fertile egg of *A. lumbricoides*. (C) Infertile egg of *A. lumbricoides*. (D) *A. lumbricoides* adult worm with typical cylindrical body with tapering ends and thick cuticle. The *A. lumbricoides* adult worm is the largest of the human pathogenic nematodes, 15 to 35 cm in length. (E) Embryonated infective egg of *E. vermicularis*. (F) Adult worms in feces (arrow). (G) *E. vermicularis* adult female. Adult females are usually 8 to 13 by 0.3 to 0.5 mm. Shown is the anterior end of a female worm with the characteristic cervical alae. Typical eggs can also usually be seen in the field. (H) Egg of *T. trichiura.*

doi:10.1128/9781555817381.ch143.f2
and third trimesters of pregnancy and in children >12 months of age.

For a summary of *A. lumbricoides*, see Table 2.

**ENTEROBIAUS VERMICULARIS (PINWORM OR THREADWORM)**

**Taxonomy**

*E. vermicularis* belongs to the class Secernentea, order Oxyurida, superfamily Oxyuroidea, and family Oxyuridae.

Only the genus *Enterobius* of the Oxyuridae regularly occurs in humans and other primates.

**Description**

**Eggs**

Pinworm eggs (Fig. 2E) are ovoid, 50 to 60 by 20 to 35 μm, and asymmetrically flattened on one side and appear colorless when recovered from the perianal skin. The outer layer of the egg shell is albuminous and sticky, enabling the egg to adhere readily. The egg contains an immature first-stage larva, but this develops rapidly to become infective.

**Larvae**

The larvae hatch in the small bowel and then migrate to the large bowel to complete molting and development.

**Worms**

Adult female worms (Fig. 2F and G) measure approximately 8 to 13 by 0.3 to 0.5 mm, with cervical alae or wing-like expansions at the mouth and a long, pointed tail (hence the name pinworm). Male worms are 2.5 by 0.2 mm but are rarely seen.

*Enterobius gregorii* was thought to be a sister species of *E. vermicularis*, and it has a slightly smaller spicule (sexual organ). However, its existence is controversial, and some experts think that *E. gregorii* is a younger or immature stage of *E. vermicularis*, as no differences have been found on molecular analysis (10).

**Epidemiology and Prevention**

*E. vermicularis* infection has a worldwide distribution and is more common in children than adults.

Preventive measures consist of health education about personal hygiene and sanitation, as well as drug therapy.

**Transmission and Life Cycle**

Adult worms inhabit the cecum, appendix, and ascending colon. The female migrates down the colon when mature and deposits her eggs on perianal and perineal skin (diagnostic stage). More than 10,000 eggs may be deposited, become infective within 6 h (Table 1), and remain viable for up to 5 days.

Transmission is either autoinfection, directly from the anal and perianal regions to the mouth, usually by fingernail contamination, or from exposure to a contaminated environment. When swallowed, the embryonated eggs (infective stage) hatch in the small bowel. Larvae migrate to the large bowel, where they mature into adult worms. Retroinfection, in which larvae migrate from the anal skin back to the rectum, is thought to be possible.

The prepatent period (from egg ingestion to egg production) is 3 to 4 weeks.

**Clinical Significance**

Children are most commonly infected. Many patients are asymptomatic or present with pruritus ani and perineal pruritus. The pruritus may be severe and is worse at night. Excoriation from scratching and secondary bacterial infection is often evident. With heavy worm burdens, poor con-
centration, enuresis, and emotional distress are features. Occasionally, the presence of worms in the appendix contributes to inflammation and true appendicitis (11). Reinfec-
tion (autoinfection or retroinfection) is also possible.

General symptoms, including abdominal pain, weight
loss, and loss of appetite, may occur.

The presence of ectopic worms and eggs in several sites,
including the female genital tract, the epididymis,
and the peritoneum, has been reported. They rarely cause
serious complications. (For more on the clinical significance
of _E. vermicularis_, see reference 6.)

**Diagnosis**

The primary diagnosis of infection is by demonstration of
the presence of eggs on the skin in the perineal area by
using the “sticky tape” method (eggs adhere to cellulose
tape and can then be detected microscopically). Briefly, a
strip of cellulose tape with the adhesive side outwards on
a microscope slide is pressed firmly against the right and
left perianal folds. The tape is then spread back over the
slide with the adhesive side down and examined directly
under the microscope. Visibility of eggs can be improved
by lifting the tape from the slide, adding a drop of xylene
or xylene substitute, and pressing the tape back down on
the slide. This helps clear the preparation and the eggs can
be observed clearly (7, 8). If an opaque tape is submitted
by mistake, a drop of immersion oil on the top of the tape
will clear it enough for microscopy. Repeated preparations
on 2 or 3 consecutive days may be required. Commercial
collection kits (Evergreen Scientific, Los Angeles, CA, or
Swube [Becton Dickinson], Sparks, MD) are available in
some countries. Eggs are occasionally present in feces. Eggs
are non-bile stained, ovoid, asymmetrical with a characteris-
tic shape (concave on one side and flat on the other),
smooth, and thick walled and may contain a partially or
tic shape (concave on one side and flat on the other),
are non-bile stained, ovoid, asymmetrical with a characteris-

**HOOKWORMS**

**Taxonomy**

_Ancylostoma duodenale_ (Old World Hookworm)

_A. duodenale_ belongs to the class Secernentea, order
Strongylida, superfamily Ancylostomatoidea, and family
Ancylostomatidae.

_Necator americanus_ (New World Hookworms)

_N. americanus_ belongs to the class Secernentea, order
Strongylida, superfamily Ancylostomatoidea, and family
Ancylostomatidae.

_Ancylostoma_ and _Necator_ are the two genera of Ancyl-
lostomatidae that infect humans. Other genera may occur as
rare “accidental” parasites.

**Description**

**Eggs**

Eggs (Fig. 3A) of _A. duodenale_ and _Necator americanus_ are
indistinguishable. They are oval, with a thin shell, and measure
approximately 56 to 75 by 36 to 40 μm. They have a clear
space between the developing embryo and the shell. When
passed, eggs are only at the four-cell stage; development of
larvae occurs in moist, shady, warm soil, where larvae hatch
within 1 to 2 days.

**Larvae**

First-stage rhabditoid larvae (Fig. 3E and G) from the
hatched eggs measure about 200 μm in length. They feed
on organic debris and molt twice over a 5- to 8-day period.
The infective, nonfeeding third-stage larvae measure from
500 to 700 μm, those of _Ancylostoma_ being generally longer
than those of _Necator_. These infective filariform larvae re-
main viable in the soil for several weeks.

**Worms**

For both species, male worms (5 to 11 mm) are shorter than
females (7 to 13 by 0.4 to 0.5 mm), and _A. duodenale_ is
generally longer and more sturdily built than _N. americanus_.
Adult worms are rarely seen, since they remain firmly at-
tached to the intestinal mucosa, feeding on blood obtained
by puncturing the capillary network in the intestinal mu-
cosa. It has been estimated that a single _A. duodenale_ worm
can withdraw as much as 0.2 ml of blood per day, whereas
_N. americanus_ withdraws approximately 0.05 ml.

**Epidemiology and Prevention**

An estimated 740 million people are infected in poor
regions of the tropics and subtropics, especially in Asia
and sub-Saharan Africa (12, 13). In addition to drug
therapy, preventive measures consist of health education
about personal hygiene, the need to wear shoes, and
avoidance of soil contamination.

</table>
Transmission and Life Cycle

Entry of third-stage or filariform larvae (infective stage) by direct penetration of the skin initiates human infection, followed by migration to the lungs within 10 days. *A. duodenale* can also infect if swallowed, but *N. americanus* cannot. *N. americanus* requires lung migration, whereas the ingestion of *A. duodenale* larvae can result in direct maturation to the adult stage in the intestine. Larvae leave the lungs after 3 to 5 weeks, pass through the trachea and pharynx, enter the gastrointestinal tract, and attach to the intestinal mucosa, where they mature into adults (Table 1). Attachment and the release of anticoagulating factors result in blood loss, which is greater with *A. duodenale*. Hookworms may survive in the host for several years. Eggs are passed in the feces into the environment, where they hatch into rhabditiform larvae that mature into filariform larvae with potential to infect new hosts.

The prepatent period from larva penetration to egg production is 4 to 8 weeks.

Clinical Significance

The major clinical manifestation of hookworm infection is iron deficiency anemia due to intestinal blood loss and depletion of iron stores. The degree of iron deficiency induced by hookworms depends on the intensity and duration of infection, the species of hookworm, and the iron status of the host. Young children, adolescent girls, women of reproductive age, and pregnant women are most at risk for iron deficiency anemia because of inadequate dietary iron and increased demand for iron in childhood and as a result of fetal growth, or increased losses due to menstruation. Anemia during pregnancy is linked to maternal morbidity and mortality, impaired lactation, prematurity, and/or low-birth-weight infants.

Patients with light worm burdens are usually asymptomatic. Moderate and heavy worm burdens cause epigastric pain and tenderness, nausea, weight loss, and diarrhea. This may lead to protein-losing enteropathy and hypoalbuminemia. In those who develop iron deficiency anemia, common symptoms are lethargy and fatigue, exertional dyspnea, and palpitations. In children, chronic malnutrition and impaired growth and development may occur.

A pruritic rash is often present at the site of penetration of larvae (“ground itch”). This must be differentiated from cercarial dermatitis and creeping eruptions from other causes. In some patients, mild cough and wheezing occur in response to larval migration through the lungs (For more on the clinical significance of hookworms, see reference 6.)

Diagnosis

The primary diagnosis of infection is by detection of eggs in feces (7, 8). Multiple specimens taken on separate days may be required. For optimal yield, both direct and concentration methods such as formaldehyde-acid acetate sedimentation should be used. Eggs are non-bile stained and usually have a 4- to 8-cell-stage embryo (Fig. 3A). Occasionally, a 16- to 32-cell-stage embryo or a developing larva may be seen, especially if there is delay in processing an unfixed fecal specimen. These larvae should be differentiated from *Strongyloides stercoralis* larvae by their morphological features (Fig. 3C to G). Hookworm eggs may be confused with *Trichostrongylus* eggs, which are generally larger or more elongated and in an advanced stage of cleavage (Fig. 3B).

Larvae are uncommon in adequately fixed fecal specimens, but motile larvae may be seen occasionally in expectorated sputum. Culture for the larval stage by the Harada-Mori technique or agar plate method is useful to detect light infections (see “Strongyloides stercoralis” below for details) (Fig. 3C to G). Adult worms are very rarely passed in feces. Usually, the worm is firmly attached to the mucosa. A colonoscopic or gastrointestinal specimen may be submitted for identification.

When hematological examination shows iron deficiency anemia, the diagnosis of hookworm infection should be considered for people who have been in areas where the infection is endemic.

Treatment

The two most practical and effective drugs for treating hookworm infections are albendazole and mebendazole. These benzimidazoles should not be used in the first trimester of pregnancy or in children <12 months of age. The WHO recommends use in second and third trimesters of pregnancy and in children >12 months of age. Pyrantel is also effective and can be used in pregnancy (see chapter 149 and reference 9).

Iron supplementation may be required for those who are deficient.

For a summary of hookworms, see Table 2.

**STONGYLOIDES STERCORALIS**

Taxonomy

*S. stercoralis* belongs to the class Secernentea, order Rhabditida, superfamily Rhabditoidae, and family Strongyloididae. Members of the family Strongyloididae exhibit an irregular alternation of generations, with a parasitic parthenogenetic female alternating with a free-living sexual generation. Only one genus, *Strongyloides*, occurs in humans.

Description, Transmission, and Life Cycle

Eggs

Eggs of the parasitic female are deposited within the mucosa of the small intestine and usually hatch before reaching the lumen. As a result, they are rarely excreted in the feces. *Strongyloides fuelleborni*, seen in Zimbabwe and Zambia, and a related species found in Papua New Guinea, are the exceptions; see below). Eggs of the free-living adult female are partially embryonated and oval and measure approximately 50 to 70 μm in length.

Larvae

First-stage, rhabditiform larvae (Fig. 3C, D, and F) measure approximately 180 to 380 by 14 to 20 μm and are characterized by a muscular esophagus comprising the anterior third of the body. A short buccal cavity (Fig. 3D) and a prominent genital primordium-located midbody (Fig. 3C) help to distinguish them from other nematodes such as hookworms (Fig. 3E). In the soil, first-stage larvae follow a direct or indirect course of development. In the direct cycle, larvae develop rapidly into infective third-stage, filariform larvae; in the indirect cycle, first-stage larvae develop into a free-living generation of adult male and female worms. Third-stage larvae are 300 to 600 by 16 μm, and their tails are notched. This feature separates them from hookworm larvae, which have long pointed tails (Fig. 3F and G).

Worms

Parasitic male forms do not occur. Parasitic females are small and thin, measuring approximately 2 to 3 mm in length.
and 30 to 50 μm in width. The anterior portion is thicker than the posterior and contains the esophagus.

The free-living adult female is approximately half the size of its parasitic counterpart, although it is nearly twice as thick (approximately 80 μm). While the reproductive systems are morphologically similar, the uterus in the free-living adult female contains significantly more eggs. The free-living adult male is slightly smaller than the female, approximately 50 μm in width.

Transmission occurs when filariform (infective-stage) larvae penetrate the skin or mucous membranes, enter the venous circulation, and are carried to the lungs. Larvae penetrate alveolar walls, migrate through the tracheobronchial tree, are swallowed, and finally reside in the mucosa of the upper small intestine. Here, they reach maturity and commence egg production; the eggs hatch immediately to release rhabditiform larvae, most of which are excreted in feces (diagnostic stage). In the soil, they undergo several molts to become infective filariform larvae (Table 1).

Some rhabditiform larvae develop into infective filariform larvae in the bowel lumen, penetrate the intestinal mucosa or perianal skin, and repeat the cycle of maturation within the same host. This process of autoinfection, uncommon among intestinal nematodes, results in chronic infections that may persist for 40 years or more.

The prepatent period (from larva penetration to egg production) is 2 to 4 weeks.

Epidemiology and Prevention

Strongyloides worms live in warm, moist soil and are widely distributed in the tropics and subtropics, a distribution similar to that of hookworms. There are an estimated 30 to 100 million patients infected with S. stercoralis worldwide. At-risk groups include those living in areas where the parasite is endemic and immigrants and refugees, indigenous peoples, and war veterans previously exposed in these regions.

Preventive measures include good personal hygiene and wearing shoes in areas where transmission occurs.

Clinical Significance

S. stercoralis infections are often chronic, lasting for several decades. Most patients have low worm burdens and are asymptomatic or have intermittent cutaneous and/or gastrointestinal symptoms. Intermittent or chronic diarrhea, abdominal pain and bloating, nausea, and anorexia are the main gastrointestinal symptoms.

Recurrent pruritic, serpiginous, erythematous rashes may occur due to larval migration in the skin ("larva currens"). These are seen most commonly on the buttocks, groin, and trunk; movement under the skin may continue for 1 to 2 days. Other, less distinctive urticarial and papular rashes also occur.

Although pulmonary symptoms are uncommon in uncomplicated strongyloidiasis, passage of larvae through the lungs may be associated with a cough, wheezing and dyspnea, and patchy infiltrates upon radiography (Loeffler-like syndrome).

Severe complicated strongyloidiasis may occur in immunocompromised or debilitated individuals and is due to accelerated autoinfection in the face of waning immunity. Hyperinfection syndrome is associated with the presence of many adult worms in the intestinal mucosa and penetration of the bowel wall by large numbers of filariform larvae. Large numbers of larvae in stool and sputum produce severe gastrointestinal and/or respiratory symptoms. These symptoms may be complicated by malabsorption or paralytic ileus. Gram-negative bacterial septicemia and meningitis may develop if enteric bacteria are spread into blood or cerebrospinal fluid during mucosal penetration by larvae. Larvae can occasionally disseminate to the central nervous system, peritoneum, liver, and kidneys. Disseminated strongyloidiasis may mimic many other diseases, including bacterial sepsis and tropical pulmonary eosinophilia. It should be considered a possibility for immunosuppressed patients who have been living in areas where strongyloidiasis is endemic. Patients on long-term corticosteroid therapy are most at risk for severe disease. Those with impaired cellular immunity due to other causes (e.g., use of immunosuppressive agents, hematological malignancies, and other chronic debilitating diseases) are also at risk.

Strongyloides species from animals can occasionally infect humans and produce persistent skin lesions similar to those produced by S. stercoralis. However, the life cycle is not completed and infection is not established (14). (For more on the clinical significance of S. stercoralis, see reference 6.)

Diagnosis

The laboratory diagnosis of strongyloidiasis can be difficult (7, 8). It is based on either demonstrating the presence of the larvae in feces or demonstrating antibodies to S. stercoralis in blood. Microscopy of feces may detect the first-stage (rhabditiform) larvae; eggs or adult worms are very rarely detected. The sensitivity of microscopy is generally low, as larvae are shed sporadically and numbers depend on the stage and severity of the infection. For this reason, multiple specimens collected over several days should be examined. Coproculture is an alternative method of detection of larvae in freshly passed stool specimen. Ideally, this should be attempted for all suspected cases, especially with patients from areas where the infection is endemic. It is important that the specimen be sent directly to the laboratory, without refrigeration or addition of preservative. Care should be exercised in the handling of these cultures, as the larvae present are filariform (infectious), capable of crossing intact skin. The various methods available for culture are as follows (for details, see reference 15):

1. Agar plate culture. A small amount of feces is placed on the center of an agar plate, and the plate is sealed and incubated at room temperature. If larvae are present, they travel away from the initial inoculum carrying bacteria from the feces. Colonies of these bacteria appear on the surface as tracks (or occasionally inside the agar) with a characteristic sinusoidal pattern (Fig. 3H). The plates are examined by microscopy for confirmation of the presence of larvae. This is the easiest culture method to perform and is now the recommended procedure (16).

2. Harada-Mori technique. The fecal specimen is smeared on the top of a strip of filter paper, dipping into 3 ml of water in a 15-ml sealed centrifuge tube. The tube is held at 25°C in the dark. After 7 to 10 days, the water can be tested by microscopy for the presence of larvae.

3. Petri dish methods. Either filter paper or watch glass is used to hold the specimen. The larvae migrate to fresh water and light.

4. Baermann technique. A modified funnel device allows sampling of the water used to moisten the fecal specimen placed on a wire mesh covered with gauze. This technique relies on the principle that larvae actively migrate out of the feces.

Occasionally, hookworm larvae may hatch in feces that have been left at warm temperatures for long periods before processing. In contrast to S. stercoralis, hookworm larvae...
have a long buccal cavity and inconspicuous genital primordium (Fig. 3C to E). The presence of larvae of Strongyloides in expectorated spum or duodenal aspirate may also be demonstrated via an enteroscope (16). Filariform Strongyloides larvae may be seen in feces or sputum in cases of hyperinfection or in cases in which infection has been identified by the culture methods described above. Although eosinophilia is common during acute infection, it does not reliably correlate with infection and may be intermittent in chronic infection. The concomitant use of steroids may significantly decrease eosinophilia in infected patients.

Demonstration of anti-Strongyloides antibodies in blood should be used as a screening test or as an adjunct for diagnosis. Used in conjunction with eosinophil count, it is very useful to monitor treatment. The decline in antibody levels is variable; it may first be observed after 6 months of effective treatment (17) and may be negative by 12 to 24 months (18). The sensitivity of the commercially available enzyme immunoassay (EIA) (Strongyloides IgG enzyme-linked immunosorber assay [EIA-4208], DRG International, Inc., Springfield, NJ) using the S. stercoralis filariform antigens test is ∼90% and is much higher than for the indirect hemagglutination test and the indirect fluorescent-antibody test. Although this test is approved in some countries (e.g., Therapeutic Goods Administration, Australia), it is not for sale in the United States (not FDA approved). Higher sensitivity (∼95%) has been reported using the U.S. Centers for Disease Control and Prevention Strongyloides EIA for patients with proven infection (17). Sensitivity may be lower in the case of severely immunocompromised patients. The specificity of EIA is ∼85%, as cross-reactions for patients with filarial and other nematode infections may occur. If antibodies are positive, efforts should be made to establish a parasitological diagnosis (microscopic and culture) and to exclude infection with other parasites that could result in cross-reacting antibodies. Strongyloides serology should be done for all candidates for immunosuppressive therapy (e.g., prior to organ transplantation or treatment for malignancies, etc.). Diagnosis by molecular techniques has been developed recently (19) but is not yet routinely available. A recent review of techniques for laboratory diagnosis of Strongyloides includes reference to molecular tests (20).

Treatment

Strongyloides stercoralis infection should always be treated because of the potential for developing severe complicated disease. Ivermectin is the drug of choice, but repeated cycles of treatment may be required for immunocompromised patients. Albendazole and mebendazole are less effective than ivermectin (thiabendazole, although effective, is no longer used due to frequent severe side effects) (16) (see chapter 149 and reference 9). These benzimidazoles should not be used in first trimester of pregnancy or in children <12 months of age. The WHO recommends use in second and third trimesters of pregnancy and in children >12 months of age.

Monitoring with stool microscopy, eosinophil counts, and serology is recommended until infection is eradicated. For a summary of S. stercoralis, see Table 2.

**STRONGYLOIDES FUELLEBORNII**

Strongyloides fuelleborni is a nonhuman primate parasite found in monkeys in Central and Eastern Africa. A similar species is found in Papua New Guinea, but no animal vector has been identified. Most human infections are asymptomatic in adults but may cause a severe protein-losing enteropathy and abdominal distension (“swollen belly syndrome”) in infants. In contrast to the case with S. stercoralis, ova of S. fuelleborni are found in feces in large numbers and resemble those of hookworms. The two Strongyloides species can be differentiated on the basis of adult worm morphology (14). Treatment is similar to that for S. stercoralis. If infection is untreated, the mortality rate is very high in infants.

**TRICHIURIS TRICHIURA (WHIPWORM)**

**Taxonomy**

_T. trichiura_ belongs to the order Enoplida, superfamily Trichinelloidea (Trichuroidea), and family Trichinellidae (Trichuridae).

**Description**

**Eggs**

Eggs of _T. trichiura_ (Fig. 2H) are lemon shaped, with a mucous plug at both ends and an unsegmented nucleus. Eggs have a double shell, with the outer one bile stained; they measure 50 to 55 by 20 to 24 μm. Under favorable conditions in soil, the eggs become fully embryonated and infective in 2 to 4 weeks.

**Larvae**

Larvae emerge in the small intestine (the second-stage larvae measure about 260 by 15 μm in length). After a period of growth they pass into the cecum, where they embed in the mucosa.

**Worms**

Adult worms have a highly characteristic shape from which the name whipworm is derived. The long, thin anterior end lies in a burrow in the mucosa, and the thicker end, which contains the reproductive tract, extends into the intestinal lumen. Worms are whitish; the males (30 to 45 mm) are shorter than the females (35 to 50 mm) and have a coiled posterior end. Adult females produce up to 20,000 eggs/day and live for approximately 3 years.

**Epidemiology and Prevention**

_Trichuris_ has a worldwide distribution and is often associated with _Ascaris_ and hookworm infections in children in tropical and subtropical areas.

Preventive measures include health education about personal hygiene, avoidance of soil contamination, and drug therapy programs in areas where infection is endemic.

**Transmission and Life Cycle**

Transmission is direct via oral ingestion of embryonated eggs (infective stage) from contaminated soil. Following ingestion, larvae are released and pass into the large bowel, where they mature into adults in mucosal crypts. The eggs passed in feces contain an unsegmented ovum (diagnostic stage), and once the eggs are in warm, moist conditions in soil, they become infective 2 to 4 weeks after passage (Table 1).

The prepatent period (from egg ingestion to egg production) is 3 months.

**Clinical Significance**

The clinical features are related to the intensity of infection; light infections are asymptomatic or present with mild gastrointestinal symptoms.
Epigastric pain, vomiting, distension, anorexia, and weight loss may occur with heavier infections and Trichuris dysentery syndrome may be seen, in extreme cases complicated by rectal prolapse. Children with severe infections may develop growth retardation due to chronic malnutrition and anemia. (For more on the clinical significance of T. trichiura, see reference 6.)

Diagnosis
The primary diagnosis of infection is by detection of eggs in feces (7, 8). Multiple specimens collected on separate days may be required. Concentration methods such as formalin-ethyl acetate sedimentation should be used for optimal yield. The eggs are bile stained and double walled with mucoid plugs at both ends, giving them a characteristic tea tray appearance (Fig. 2H).

Adult worms are rarely passed in feces and are occasionally found upon colonoscopy (21). They have a coiled, long, thin anterior region and a thicker tail, giving them the appearance of a whip (hence the name whipworm). The characteristic eggs can be seen on histology section (Fig. 4B).

Treatment
Albendazole and mebendazole are the drugs of choice (see chapter 149 and reference 9). Failures are not uncommon, and multiple doses are required. Thesebenzimidazoles should not be used in the first trimester of pregnancy or in children <12 months of age. The WHO recommends use in the second and third trimesters of pregnancy and in children >12 months of age.

For a summary of T. trichiura, see Table 2.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS
Specimens should be collected before antibiotics or antiparasitic drugs are given (for details, refer to chapter 133). It is important to transport and process feces specimens for parasitic examination as soon as possible. Clinicians and collection staff should be encouraged to either send fresh specimens to the laboratory without delay or use commercially available preservative kits. If delay is inevitable, specimens should be refrigerated or transported in commercially available vials or kits with a preservative such as polyvinyl alcohol or sodium acetate-acetic acid-formalin. If these are not available at the point of collection, preservatives should be added as soon as the specimen is received in the laboratory. Excellent directions for proper collection are available with these kits. Discussion on which preservative to use depends on various considerations such as whether permanent-stained smears or immunocassays are required, etc. (For details, see reference 15.) The use of two or three specimens collected over a period of 7 to 10 days is optimal. Refrigeration and the use of preservatives should be avoided if Strongyloides larval culture is required.

Specimens that are very small in volume or obviously dry should be rejected and a fresh specimen should be collected.

Worms retrieved at colonoscopy or submitted by the patient should be transported to the laboratory without delay. Worms can be preserved in 60% alcohol; avoid the use of formalin, as it causes contraction and hardening of tissues.

For sputum specimens, proper instructions should be given to patients, emphasizing requirements, i.e., avoidance of saliva and of use of a mouthwash before deep coughing (expectorating). Sputum and aspirates should be transported to the laboratory and processed immediately.

All specimens should be handled using standard precautions; e.g., latex gloves should be worn by anyone handling the specimens.

LABORATORY METHODS: DIRECT EXAMINATION
The specimen should be handled in a work cabinet (biological safety cabinet), and gloves and a gown should be worn. Examine the specimen and note its consistency. Look for any motile worms or segments of worms. Select and sample areas that look watery, purulent, or bloody. If feces are formed, sample from several areas of the specimen for the concentration technique.

Both the direct specimen and concentrate are examined as wet preparations diluted in saline and iodine. Scan the whole coverslip area at low-power magnification (×100). Most helminth eggs and larvae can be identified at this magnification, and diagnosis can be confirmed at high power (×400) on the basis of their shape, size, and characteristic features (Fig. 1 to 3). Smears should be prepared from a centrifuged deposit (500 × g for 10 min) for permanent staining, but this technique is not the preferred method for identification of nematode eggs or larvae; it is primarily to diagnose mixed infections with protozoa.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS
Make note of the adequacy and quality of the specimen submitted. If it is inadequate, mention it on the report.

Any helminth eggs or larvae found in feces are significant and treatment is recommended, even if the patient is asymptomatic. There is no need to quantitate helminth parasites, as this does not necessarily correlate with clinical illness. However, in rare instances, this may be required for epidemiological studies or for clinical assessment of children.

The time of collection is also important, especially when Enterobius is suspected. If the specimen is inadequate, e.g., delayed, dry, or insufficient, a repeat specimen should be requested. A freshly collected specimen and/or use of preservative kits should be encouraged where possible. Examples of interpretative comments used to ensure that adequate testing is performed are as follows.

1. Larvae of S. stercoralis not detected. A single negative result does not exclude the diagnosis of Strongyloides. Please send freshly collected feces to laboratory without delay.

2. Eggs of E. vermicularis not detected on the sticky tape preparation. A single negative result does not exclude the diagnosis of pinworm infection. Please send properly collected repeat specimen, if clinically indicated. Contact the laboratory for instructions if required.

3. No parasites detected. Excretion of parasite forms may be variable or intermittent. Repeat testing is recommended if clinically indicated. Contact the laboratory for instructions if required.

In a clinically significant case, if the first specimen is negative, ask for further specimens.

REFERENCES
Filarial Nematodes*
SOUMYA CHATTERJEE AND THOMAS B. NUTMAN

Filarial worms are arthropod-transmitted nematodes or roundworms that dwell in the subcutaneous tissues and the lymphatics. Although eight filarial species commonly infect humans, four are responsible for most of the pathology associated with these infections. These are (i) *Wuchereria bancrofti*, (ii) *Brugia malayi*, (iii) *Onchocerca volvulus*, and (iv) *Loa loa*. In general, each of the parasites is transmitted by biting arthropods. The distribution and vectors of all the filarial parasites of humans are given in Table 1. Each goes through a complex life cycle that includes an infective larval stage carried by the insects and an adult worm stage that resides in humans, either in the lymph nodes or adjacent lymphatics or in the subcutaneous tissue.

All filariae share the unique characteristic of an adult female worm that produces microfilariae. These offspring either circulate in the blood or migrate through the skin. The microfilariae can then be ingested by the appropriate biting arthropod and develop into infective larvae that are capable of initiating the life cycle once more. Certain species (*W. bancrofti, Brugia spp.*, and *L. loa*) circulate in the blood with a defined circadian rhythm or “periodicity,” which can be nocturnal (typically the lymphatic filariae) or diurnal (*L. loa*). Other species lack periodicity and are found in the peripheral blood at all hours of the day and night. When absent from the peripheral blood, the microfilariae of filarial parasites are found in the deeper visceral capillaries, particularly in the pulmonary capillaries. Because the adult worms are typically sequestered in the tissues, diagnosis of infection depends on finding microfilariae in either the blood or skin, depending on the species. Adult worms are long-lived (1), whereas the life spans of microfilariae range from 3 months to 3 years.

Microfilariae are relatively simple in their organization and structure (Fig. 1). They are vermiform and in stained preparations appear to be composed of a column of nuclei interrupted along its length by spaces and special cells that are the precursors of body organs or organelles. Some species of microfilariae are enveloped in a sheath, whereas others have no sheath (Table 1; Fig. 2).

All of the filariae are transmitted by species of blood-sucking arthropods such as mosquitoes, midges, black flies, and tabanid flies, in which the microfilariae develop to the infective larval stage (Table 1). Subsequent development of the infective larva to the gravid, adult stage in the vertebrate host requires several months and in some cases a year or more. Infection is generally not established unless exposure to infective larvae is intense and prolonged. Furthermore, the clinical manifestations of these diseases develop rather slowly.

Although these parasites are nonendemic in temperate or subtropical areas, they are often seen in individuals who have immigrated to, resided in, or traveled to tropical areas where filarial infection is endemic. There are significant differences in the clinical manifestations of filarial infections, or at least in the period over which these infections are acquired, between patients native to the areas where these infections are endemic areas and individuals who are travelers to or recent arrivals in these areas. Characteristically, the infection in previously unexposed individuals is more likely to be clinically symptomatic, compared to the clinically asymptomatic condition found in natives of the region where these infections are endemic (2, 3).

LYMPHATIC FILARIAL PARASITES

**Taxonomy**

*Wuchereria bancrofti, Brugia malayi*, and *Brugia timori* each belong to the phylum Nematoda, class Secernentea, subclass Spirurida, order Spirurida, superfamily Filarioidea, and family Filariidae.

**Description of the Agents**

There are three lymphatic-dwelling filarial parasites of humans—*Wuchereria bancrofti, Brugia malayi*, and *Brugia timori*. The adult worms usually reside in either the afferent lymphatic channels or the lymph nodes. These adult parasites may remain viable in the human host for decades. The morphologic appearance and other characteristics of the parasite can be found in Table 1 and Fig. 1 and 2.

**Epidemiology and Transmission**

*Wuchereria bancrofti*

*W. bancrofti* is the most common and widespread species of filaria infecting humans. It has an extensive distribution throughout tropical and subtropical areas of the world, including Asia and the Pacific Islands, Africa, areas of South America, and the Caribbean Basin. Humans are the only definitive host for this parasite and are therefore the natural reservoir for infection. There are both periodic

---

*This chapter contains information presented in chapter 142 by Dorian L. Fink and Thomas B. Nutman in the 10th edition of this Manual.*
and subperiodic forms of the parasite. Nocturnally periodic forms have microfilariae present in the peripheral blood primarily at night (between 10 p.m. and 4 a.m.), whereas the subperiodic forms have microfilariae present in the blood at all times but with maximal levels in the afternoon. Generally, the subperiodic form is found only in the Pacific islands (including the Cook Islands, Tuvalu [formerly the Ellice Islands], Fiji, New Caledonia, the Marquesas, Samoa, and the Society Islands). Elsewhere, *W. bancrofti* is nocturnally periodic. The natural vectors are *Culex fatigans* mosquitoes in urban settings and usually anopheline or aedean mosquitoes in rural areas.

**Brugia malayi** and **Brugia timori**

The distribution of brugian filariasis is limited primarily to China, India, Indonesia, Korea, Japan, Malaysia, and the Philippines. *B. timori* has been described to occur only on two islands in Timor. Similar to the situation with *W. bancrofti*, there are both periodic and subperiodic forms of brugian filariasis. The nocturnal periodic form is more common and is transmitted in areas where there are coastal rice fields (by mansonian and anopheline mosquitoes), while the subperiodic form is found in swamp forests (mansonian vector). Although humans are the common host, *B. malayi* also naturally infects cats.

**Clinical Significance (Description of Clinical Presentation)**

Lymphatic filariasis (LF) is associated with a variety of clinical manifestations. The four most common presentations are asymptomatic (or subclinical) microfilaremia, lymphedema, hydrocele, and acute attacks. Less frequently, LF can present with chyluria or tropical eosinophilia (4–6). The range of clinical disease varies somewhat across geographic locations and according to the species of nematode causing the infection (7). Additionally, the disease in previously unexposed individuals is more acute and intense than that found in natives of the region where it is endemic (2, 3). Patients with asymptomatic (or subclinical) microfilaremia rarely come to the attention of medical personnel except through the incidental finding of microfilariae in the peripheral blood. Although they may be clinically asymptomatic, virtually all persons with *W. bancrofti* or *B. malayi* microfilaremia have some degree of subclinical disease that includes dilated and tortuous lymphatics, which can be visualized by lymphoscintigraphy (8) and—in men with *W. bancrofti*—scrotal lymphangiectasia (detectable by ultrasound) (9). Despite these findings, the majority of individuals appear to remain clinically asymptomatic for years. Relatively few progress to either the acute or chronic stage of infection (10). Development of lymphedema may not occur until long after the initial infection. Lymphatic dysfunction develops as a primary event in response to adult filarial parasites and host immune responses in virtually all infected persons. This process has been shown to be progressive during infection and permanent once established (11). Lymphedema most commonly affects the lower extremities but can also affect the arms, the breasts in females, and the scrotum in males. Secondary effects such as thickening of the subcutaneous tissues, hyperkeratosis, fissuring of the skin, and hyperplastic skin changes can occur. Recurrent infections (acute dermatolymphangioadenitis [ADLA]) on the background of chronic skin changes and lymphatic dysfunction play a major role for lymphedema disease development and progression to elephantiasis (12, 13).

FIGURE 1  Common microfilariae found in humans. Organisms are stained with hematoxylin. Magnification, ×325. (A) W. bancrofti; (B) B. malayi; (C) L. loa; (D) O. volvulus; (E) M. perstans; (F) M. ozzardi. doi:10.1128/9781555817381.ch144.f1
Acute attacks in LF cover a variety of clinical entities that present with inflammation. True filarial adenolymphangitis (ADL), considered to reflect the death of an adult worm, presents with inflammation, swelling, and retrograde lymphangitis extending peripherally from the draining nodes, where the parasites presumably reside. Regional lymph nodes are often enlarged, and the entire lymphatic channel can become indurated and inflamed. The second type of acute attack is now labeled bacterial ADL or ADLA. Skin changes cause lesions, in particular in the toe webs, that facilitate entry of bacterial skin flora (14, 15). For these reasons, limbs become susceptible to recurrent bacterial infections (16, 17). The clinical pattern of ADLA is distinctly different from that of ADL (17). The lymphangitis develops in a reticular rather than in a linear pattern, and the local and systemic symptoms, including edema, pain, fever, and chills, are frequently more severe (18). These cause considerable acute morbidity and progression of lymphedema to elephantiasis (19). ADL and ADLA occur in both the upper and the lower extremities with both bancroftian and brugian filariasis, but involvement of the genital lymphatics occurs almost exclusively with W. bancrofti infection.

Hydrocele formation occurs in bancroftian filariasis when adult worms block retroperitoneal and subdiaphragmatic lymphatics. In males, this causes accumulation of straw-colored lymph either unilaterally or bilaterally between the visceral and parietal layers of the tunica vaginalis. The condition presents as a translucent mass obscuring palpation of the testis and differs from a congenital hydrocele or hernia in that the tunica is sealed at the top and peritoneal fluid is not communicating. If there is obstruction of the retroperitoneal lymphatics, renal lymphatic pressure can increase to the point at which they rupture into the renal pelvis or tubules so that chyluria is seen. The chyluria is characteristically intermittent and is often prominent in the morning just after the patient arises.

Tropical pulmonary eosinophilia (TPE) is a distinct syndrome that develops in some individuals infected with LF-causing species. This syndrome affects males more often than females, most commonly during the third decade of life. The majority of cases have been reported from India, Pakistan, Sri Lanka, Brazil, Guyana, and Southeast Asia. The main features include a history of residence in regions where filaria is endemic, paroxysmal cough and wheezing that are usually nocturnal, weight loss, low-grade fever, adenopathy, and pronounced blood eosinophilia (>3,000 eosinophils/μl). Patients are rarely found to have microfilariae in the blood. Chest radiographs may be normal but generally show increased bronchovascular markings, and diffuse miliary lesions or motiled opacities may be present in the middle and lower lung fields. Tests of pulmonary function show restrictive abnormalities in most cases and obstructive defects in half. Total serum IgE levels (10,000 to 100,000 ng/ml) and antifilarial antibody titers are characteristically elevated. TPE is now considered to be a form of occult filariasis in which rapid clearance of the microfilariae occurs, presumably on the basis of host immunologic hyperresponsiveness to the parasite (5). Although there is no single clinical or laboratory criterion that aids in distinguishing TPE from other pulmonary diseases, residence in the tropics, the presence of high levels of antifilarial antibodies, and a rapid clinical response to diethylcarbamazine (DEC) favor the diagnosis of tropical eosinophilia (20).

**Diagnosis**

Diagnosis of bancroftian and brugian filarial infection can be made in the right setting with clinical and historical information and noninvasively, in some cases by ultrasound. This allows adult worms to be visualized in lymphatics or dilated lymphatics to be identified. Definitive identification of parasites can be achieved with appropriate samples of blood or tissue. The timing of blood collection is critical and should be based on the periodicity of the microfilariae in the region of endemicity involved (Table 1). Recent developments in immunodiagnostic and molecular biology techniques give further options for diagnosis.

**Ultrasound**

In cases of suspected LF due to W. bancrofti, high-frequency ultrasound of the scrotum or female breast coupled with Doppler imaging may result in identification of motile adult worms ("filarial dance sign") within dilated lymphatics. Adult worms may be visualized in the lymphatics of the spermatic cord in up to 80% of infected men with microfilaremia associated with W. bancrofti (10). In brugian filariasis, ultrasounds have been used successfully to localize the adult worms in the female breast, the inguinal lymph nodes, and the lymphatic vessels of the thigh and calf (21).

**Direct Examination**

Parasites can be identified by direct examination of blood or other fluids (such as chyle, urine, or hydrocele fluid). This should take advantage of the periodicity of each organism as well as its characteristic morphologic appearance (Table 1 and Fig. 2).

**Microscopy**

A small volume of fluid is spread on a clean slide. The slide is then air dried, stained with Giemsa, and examined microscopically. The microfilariae of W. bancrofti are sheathed, lie in smooth curves in stained smears, and are 298 μm long by 7.5 to 10.0 μm in diameter. The column nuclei are dispersed; there is a short headspace, and the pointed tail is devoid of nuclei (Fig. 1A). The sheath stains faintly or not at all with Giemsa stain. The microfilariae of W. bancrofti must be distinguished from other sheathed microfilariae. The morphology of the B. malayi microfilariae is similar to that of the W. bancrofti microfilariae, in that they are sheathed, but they are somewhat smaller (279 μm by 5 to 6 μm). They can be differentiated from W. bancrofti.

**FIGURE 2** Diagrammatic representation of the anterior and posterior extremities of the common microfilariae found in humans. (a) W. bancrofti; (b) B. malayi; (c) O. volvulus; (d) L. loa; (e) M. perstans; (f) M. streptocerca; (g) M. ozzardi. doi:10.1128/9781555817381.ch144.f2
microfilariae by the presence of subterminal and terminal nuclei in the tail (Fig. 1A and B). B. timori microfilariae are similar to those of B. malayi, with conspicuous terminal and subterminal nuclei; however, B. timori microfilariae are larger (more than 300 μm long) than B. malayi. Additionally, the B. malayi sheath stains bright pink with Giemsa stain, whereas the B. timori sheath tends not to stain and that of W. bancrofti never does (22).

Because microfilariae may be present in the blood in only small numbers, sensitive procedures such as Nucleopore filtration and Knott’s concentration are also used routinely to detect infections.

**Nucleopore Filtration**

A known volume of anticoagulated blood is passed through a polycarbonate (Nucleopore) filter with a 3-μm pore. A large volume (50 ml) of distilled water is passed through (the water lyses [breaks open] the red blood cells, leaving the worms intact and more easily visible). The filter is then air dried, stained with Wright’s or Giemsa stain, and examined by microscopy. For studies in the field, 1 ml of anticoagulated blood can be added to 9 ml of a solution of 2% formalin or 10% Teepol and stored for up to 9 months before performing filtration.

**Knott’s Concentration Technique**

Anticoagulated blood (1 ml) is placed in 9 ml of 2% formalin. The tube is centrifuged at 1,500 rpm for 1 min. The sediment is spread on a slide and dried thoroughly. The slide is then stained with Wright’s or Giemsa stain and examined microscopically.

**Antigen Detection**

Assays for circulating antigens of W. bancrofti permit the diagnosis of microfilaremic and cryptic (microfilaremic) infection. Two tests are commercially available (though not in the United States). One is an enzyme-linked immunosorbent assay (ELISA) available from TropBio Pty (Townsville, Queensland, Australia; tropbio@jcu.edu.au) and the other a rapid-format immunochromatographic strip card available from Alere (http://www.alere.com/ww/en/product-details/binax-now-filariasis.html). Both assays have sensitivities that range from 96 to 100% and specificities that approach 100% (72, 73). Both tests can be used on blood drawn any time of day or night, thus avoiding the need for specific bleeding times depending on the periodicity of microfilariae. Neither of the tests is FDA approved. There are currently no tests for circulating antigens in brugian filariasis.

**Nucleic Acid Detection Techniques**

In appropriate laboratories, PCR can detect parasite DNA and is now the most sensitive technique for definitive diagnosis (23–25). For each of the lymphatic-dwelling parasites, primers and probes have been identified that are 100% specific and provide sensitivities that are up to 10-fold greater than parasite detection by direct examination. Recent diagnostic advances include highly sensitive real-time PCR assays capable of detecting relatively low copy numbers of target sequence in small samples of dried human blood (26, 27) and the loop-mediated isothermal application assay (28), which might potentially be used as a simple and specific test for point-of-care settings.

**Serologic Tests**

Immunologically based diagnosis with measured IgG or IgG4 responses against crude extracts of Brugia worms suffers from poor specificity. There is extensive cross-reactivity among filarial antigens and antigens of other helminths, including the common intestinal roundworms. Furthermore, serologic tests are unable to distinguish between active and past infections. However, these tests still have a role in diagnosis, as a negative test effectively excludes past or present infection. These tests are available commercially as well as from the National Institutes of Health.

**Treatment and Prevention**

The available chemotherapy for LF is DEC, ivermectin, and albendazole. DEC remains the treatment of choice for the individual with active LF (microfilaremia, antigen positivity, or adult worms on ultrasound), although albendazole has also been shown to have some macrofilaricidal efficacy. If the adult parasites survive, microfilaremia along with clinical symptoms can recur within months after conclusion of the therapy. Chronic low-dose DEC may also result in cure (e.g., in DEC salt). Evidence shows that the use of these drugs in combination can increase their effectiveness (29–32). The current global elimination campaign uses these three drugs in various combinations for mass treatment of communities where the parasites are endemic (33).

Most pathogenic filarial nematodes apart from L. loa harbor bacterial endosymbionts. These Wolbachia bacteria are vital for parasite larval development and adult worm fertility and viability. New approaches for treatment use antibiotics (e.g., the tetracyclines) that target Wolbachia and have been shown to reduce microfilarial levels (34). Once lymphedema is established, antifilarial medication is not useful if the patient does not have active infection. Management of lymphedema should concentrate on exercise, elevation, and local skin care with appropriate treatment of entry lesions (34). There has, however, been some recent evidence that treatment with doxycycline may decrease the severity in early stages of lymphedema, independent of its antimicrobial effects (35). Antifilarial medication is also not indicated in management of bacterial ADLA, which is addressed with skin care and antibiotics if indicated (15, 18). Hydroceles can be drained repeatedly or managed surgically (36).

Avoidance of mosquito bites is usually not feasible for residents of areas where the parasites are endemic, but visitors should make use of insect repellent and mosquito nets. Impregnated bednets have been shown to have a salutary effect. DEC can kill developing forms of filarial parasites and has been shown to be useful as a prophylactic agent in humans. Community-based intervention is the current approach to elimination of LF as a public health problem (33, 37). The underlying tenet of this approach is that mass annual distribution of antimicrofilarial chemotherapy (albendazole with either DEC [for all areas except where onchocerciasis is coendemic] or ivermectin) profoundly suppresses microfilaremia. If the suppression is sustained, then transmission can be interrupted. Community education and clinical care for persons already suffering from the chronic sequelae of LF are important components of filariasis control and elimination programs (38). Vaccines are not currently available but may have a role in the future.

**ONCHOCERCA VOLVULUS**

**Taxonomy**

Onchocerca volvulus belongs to the phylum Nematoda, class Secernentea, subclass Spiruroida, superfamily Filarioidea, and family Onchocercidae.
Description of the Agent
The adult worms of Onchocerca volvulus typically reside in nodules composed primarily of host tissue. These adult parasites may remain viable in the human host for decades. The morphologic appearance and other characteristics of microfilariae and adult worms can be found in Table 1 and Fig. 1 and 2.

Epidemiology and Transmission
Onchocerciasis, sometimes called “river blindness,” is caused by infection with Onchocerca volvulus, a subcutaneous-dwelling filarial worm. Approximately 18 million people are infected, mostly in equatorial Africa, the Sahara, Yemen, and parts of Central and South America (Guatemala, Venezuela, Mexico, Ecuador, Colombia, and Brazil). The infection is transmitted to humans through the bites of black flies of the genus Simulium, which breed along fast-flowing rivers in the above-mentioned tropical areas.

Clinical Significance (Description of Clinical Presentation)
The major disease manifestations of onchocerciasis are localized to the skin, lymph nodes, and eyes. Onchocerciasis is a cumulative infection. Intense infection leads to the most severe complications and is considered to reflect repeated inoculation with infective larvae.

Skin
Pruritus is the most frequent manifestation of onchocercal dermatitis. This pruritus may be accompanied by the appearance of localized areas of edema and erythema. Typically, skin disease appears as a papular, pruritic dermatitis. If the infection is prolonged, lichenification and pigment changes (either hypo- or hyperpigmentation) can occur; these often lead to atrophy, “lizard skin,” and mottling of the skin.

Onchocercomata
Onchocercomata are subcutaneous nodules which can be palpable and/or visible and contain the adult worm. In African patients, they are common over bony prominences; in Latin American patients, nodules tend to develop preferentially in the upper part of the body, particularly on the head. Nodules vary in size and characteristically are firm and nontender. It has been estimated that for every palpable nodule there are four deeper nontapable ones (39).

Lymph Nodes
Lymphadenopathy is frequently found, particularly in the inguinal and femoral areas. The underlying pathology consists of scarring of the lymphoid areas (O. volvulus infection in Africa) or follicular hyperplasia (O. volvulus infection in Yemen). As the lymph nodes enlarge, they can come to lie within areas of loose skin (so-called “hanging groin”) that predisposes to inguinal and femoral hernias.

Ocular Disease
Onchocercal eye disease can take many forms and can lead to severe visual loss or blindness. Usually seen in persons with moderate or heavy infections, ocular disease spares no part of the eye. Manifestations include conjunctivitis, anterior uveitis, iridocyclitis leading to secondary glaucoma, sclerosing keratitis, optic atrophy, and chorioretinal lesions (40).

Systemic Manifestations
Some heavily infected individuals develop cachexia with loss of adipose tissue and muscle mass. Among adults who become blind, there is a 3- to 4-fold increase in the mortality rate.

Diagnosis
Definitive diagnosis depends on finding an adult worm in an excised nodule or, more commonly, microfilariae in a skin snip. Microfilariae can occasionally be found in the blood and in urine, typically after treatment. Microfilariae may also be seen in the cornea and in the anterior chamber of the eye when viewed with a slit lamp.

For skin snip evaluation, a small piece of skin is elevated by the tip of a needle or skin hook held parallel to the surface, and a scalpel blade is used to shave off the skin area stretched across the top surface of the needle. Alternatively, a sclerocorneal punch can be used to obtain a blood-free circular skin specimen. Skin snips are generally obtained from an area of affected skin or from the scapular, gluteal, and calf areas (in the African form) and from the scapular, deltoid, and gluteal areas (in the Central American form). Once obtained, the skin snips are incubated in a physiologic solution (such as normal saline). The emergent microfilariae can be seen under a microscope typically within hours (in heavy infection) or within 24 h in light infections.

Direct Examination

Microscopy
Microfilariae lack a sheath and are approximately 309 μm long by 5 to 9 μm in diameter. The tail is tapered, usually bent or flexed, and without nuclei (Fig. 1D and 2c).

Nucleic Acid Detection Techniques
Assays using PCR to detect onchocercal DNA in skin snips are now in use in research laboratories and are highly specific and sensitive, provided that organisms are present in the skin samples obtained (41, 42).

Serologic Tests
Because direct detection of parasites in the skin or eye is invasive and insensitive, immunodiagnostic assays may be preferable. IgG antifilarial antibody assays, while positive for individuals with onchocerciasis, suffer from the same lack of specificity and positive predictive value seen in the blood-borne filarial infections; however, the combined use of three groups of recombinant antigens in conventional ELISA provides sensitivity and specificities that approach 100% for the diagnosis of onchocerciasis (43). A newer platform incorporates four recombinant antigens into a rapid, high-throughput luciferase immunoprecipitation system assay that is 100% sensitive and 80 to 90% specific in distinguishing onchocerciasis from related filarial infections (44). Although no recombinant antigen test is available commercially, an experimental rapid card test that detects IgG4 antibodies in serum or whole blood using recombinant Ov-16 protein has been shown to have >90% sensitivity and specificity (43, 43).

Treatment
The major goals of therapy are to prevent irreversible lesions and to alleviate symptoms. Surgical excision of nodules is recommended when the nodules are located on the head because of the proximity of the microfilaria-producing adult worms to the eye, but chemotherapy is the mainstay of treatment. Ivermectin, a semisynthetic macrocyclic lactone, is now considered the first-line therapy for onchocerciasis. It is characteristically given yearly or semiannually. Most patients have limited or no reaction to treatment. Pruritus,
cutaneous edema, and/or a maculopapular rash occur in approximately 1 to 10% of treated individuals. Significant ocular complications are extremely rare, as is hypotension (1 in 10,000). In areas of Africa where *O. volvulus* and *L. loa* are coendemic, however, ivermectin is contraindicated because of severe posttreatment encephalopathy seen in patients who show heavy *L. loa* microfilaremia (46). There has been some recent evidence that doxycycline-based therapy targeting the *Wolbachia* endosymbiont, which is present in *Onchocerca* but not *L. loa*, might have improved efficacy in areas of coinfection with no increase in adverse events (47). Ivermectin is also contraindicated for use in pregnant or breastfeeding women, based on toxicity and teratogenicity data from animal studies. Although ivermectin treatment results in a marked drop in microfilarial density, its effect can be short-lived (<3 months in some cases). Thus, it is occasionally necessary to give ivermectin more frequently for persistent symptoms (48). A 6-week course of doxycycline that targets the *Wolbachia* endosymbiont has been demonstrated to be macrofilaricidal, rendering the female adult worms sterile for long periods (49).

**Prevention**

Prevention of infection is being achieved by mass treatment programs using ivermectin (50, 51). Vector control has been beneficial in areas where the infection is highly endemic in which breeding sites are vulnerable to insecticide spraying, but most areas where onchocerciasis is endemic are not suited to this type of intervention. Community-based administration of ivermectin every 6 to 12 months is now being used to interrupt transmission in areas where the infection is endemic. This measure, in conjunction with vector control, has already helped reduce the prevalence of disease in endemic foci in Africa and Latin America. No drug has proven useful for prophylaxis of *O. volvulus* infection, and no vaccine exists.

**LOA LOA**

**Taxonomy LOA**

*L. loa* belongs to the phylum Nematoda, class Chromadorea, order Spirurida, superfamily Filarioidea, and family Onchocercidae.

**Description of the Agent**

The adult parasite lives in the subcutaneous tissues in humans; microfilariae circulate in the bloodstream with a diurnal periodicity that peaks between noon and 2:00 p.m. The morphologic appearance and other characteristics of adult worms and microfilariae can be found in Table 1 and Fig. 1 and 2.

**Epidemiology and Transmission**

The distribution of *L. loa* is limited to the rain forests of West and Central Africa (52). Tabanid flies (deer flies) of the genus *Chrysops* are the vectors.

**Clinical Significance (Description of Clinical Presentation)**

*L. loa* infection may be present as asymptomatic microfilaremia, with the infection being recognized only after subconjunctival migration of an adult worm (the so-called eye worm). The classic clinical presentation is with episodic Calabar swelling (localized areas of transient angioedema) found predominantly on the extremities. If associated inflammation extends to the nearby joints or peripheral nerves, corresponding symptoms develop. Nephropathy (presumed to be immune complex mediated), encephalopathy, and cardiomyopathy due to marked eosinophilia can occur rarely.

There appear to be differences in the presentations of *loiasis* between those native to the area where *loiasis* is endemic and those who are visitors (54). The latter tend to have a greater predominance of allergic symptomatology. The episodes of Calabar swelling tend to be more frequent and debilitating, and such patients rarely have microfilaremia. In addition, those who are not native to the area of endemicity have extreme elevation of eosinophils in the blood as well as marked increases in antifilarial antibody titers.

**Diagnosis**

Definitive diagnosis is made parasitologically, either by finding microfilariae in the peripheral blood or by isolating the adult worm from the eye or subcutaneous biopsy material following treatment. The diagnosis must often be made on clinical grounds, however, particularly for travelers (usually amicrofilaraemic) to the region where the infection is endemic.

**Direct Examination**

**Microscopy**

The microfilariae are sheathed and are up to 300 μm long. Adult females are 50 to 70 mm long and 0.5 mm wide, whereas adult males are 25 to 35 mm long and 0.25 mm wide. In contrast to the LF parasite, the nuclei extend to the end of the tail; however, they are somewhat irregularly arranged along the length of the tail (Fig. 1C and 2d). The sheath does not stain with Giemsa stain.

**Nucleic Acid Detection Techniques**

PCR-based assays for the detection and quantitation of *L. loa* DNA in blood are now available in research laboratories and are highly sensitive and specific (55, 56).

**Serologic Tests**

Available methods using crude antigen extracts from *Brugia* or *Dirofilaria* species do not differentiate between *L. loa* and other filarial pathogens. The utility of such testing in endemic populations is limited by the presence of antifilarial antibodies in up to 95% of individuals in some regions. A *Loa*-specific recombinant protein, SXP-1, has been tested and has good specificity but only limited (50%) sensitivity in conventional ELISA (57). Incorporation of SXP-1 into a luciferase immunoprecipitation system assay increased sensitivity to near 100% while also allowing for rapid, high-throughput processing of samples (58). Antifilarial IgG and IgG4, while nonspecific, may be useful in confirming the diagnosis of *loiasis* in visitors to areas where the infection is endemic with suggestive clinical symptoms or unexplained eosinophilia.

**Treatment and Prevention**

DEC is effective against both the adult and the microfilarial forms of *L. loa*, but multiple courses are frequently necessary before the disease resolves completely (59). In cases of heavy microfilaremia, allergic or other inflammatory reactions can take place during treatment, including central nervous system involvement with coma and encephalitis (60). Heavy infections can be treated initially with apheresis to remove the microfilariae and with glucocorticoids followed by small
doses of DEC. If antifilarial treatment has no adverse effects, the prednisone dose can be rapidly tapered and the dose of DEC gradually increased. Albendazole or ivermectin (although not approved for this use by the FDA) has been shown to be effective in reducing microfilarial loads, but the use of ivermectin in heavily microfilaremic individuals is contraindicated (61). DEC is an effective prophylactic regimen for loiasis (62).

MANKONELLA INFECTIONS

Taxonomy
Mansonella perstans, Mansonella ozzardi, and Mansonella streptocerca each belong to the phylum Nematoda, class Secernentea, subclass Spiruria, order Spiruroidea, and family Onchocercidae.

Description of the Agents
The adult worms of Mansonella perstans reside in the body cavities (pericardial, pleural, and peritoneal) as well as in the mesentery and the perirenal and retroperitoneal tissues, whereas the location of the adult worms of Mansonella ozzardi is unknown. The microfilariae of both parasites circulate in the blood without periodicity. For Mansonella streptocerca, the adult parasites reside in the skin. M. streptocerca microfilariae are found predominantly in the skin. The morphologic appearance and other characteristics of adult worms and microfilariae can be found in Table 1 and Fig. 1 and 2.

Epidemiology and Transmission
Mansonella perstans is distributed across the center of Africa and in northeastern South America. The infection is transmitted to humans through the bites of midges (Culicoides species). Mansonella streptocerca is largely found in the tropical forest belt of Africa from Ghana to Zaire. It is transmitted to the human host by biting midges (Culicoides species). The distribution of M. ozzardi is restricted to Central and South America as well as certain Caribbean islands. The parasite is transmitted to the human host by biting midges (Culicoides furens) and black flies (Simulium amazonicum).

Clinical Significance (Description of Clinical Presentation)
Although most patients infected with M. perstans appear to be asymptomatic, clinical manifestations may include transient angioedematous swellings of the arms, face, or other body parts (similar to the Calabar swellings of L. loa infection); pruritus; fever; headache; arthralgias; neurologic or psychological symptoms; and right upper quadrant pain. Occasionally, pericarditis and hepatitis occur (63).

The major clinical manifestations of M. streptocerca infections are related to the skin: pruritus, papular rashes, and pigment changes. These are thought to be secondary to inflammatory reactions around microfilariae. Most infected individuals also show inguinal lymphadenopathy. Lymph nodes of affected individuals may show chronic lymphadenitis with scarring; however, many patients are completely asymptomatic (64).

The clinical details of M. ozzardi infection are poorly characterized. Furthermore, many consider this organism to be nonpathogenic; however, headache, articular pain, fever, pulmonary symptoms, adenopathy, hepatomegaly, and pruritus have been ascribed to infection with this organism (74). There have been reports of an association of M. ozzardi with keratitis (65).

Diagnosis
For M. perstans infections, diagnosis is made parasitologically by finding the microfilariae in the blood or in other body fluids (serosal effusions). Microfilariae are small (203 μm by 4 to 5 μm) and have a blunt tail filled with nuclei. Perstans filariasis is often associated with peripheral blood eosinophilia and antifilarial antibody elevations (63). The diagnosis of M. ozzardi infection is made by demonstrating the characteristic microfilariae in the peripheral blood. These are small (224 μm by 4 to 5 μm) and have long attenuated tails devoid of nuclei (Fig. 1F and 2g). PCR-based assays may provide increased sensitivity (66). The diagnosis of streptocerciasis can be made by finding the characteristic microfilariae on skin snip examination (see section above on onchocerciasis diagnosis). In areas where both O. volvulus and M. streptocerca are endemic, care must be taken to correctly identify the microfilariae. M. streptocerca microfilariae have no sheath, are long and slender, and measure approximately 210 μm by 5 to 6 μm. The most characteristic feature of M. streptocerca is its crooked tail (Fig. 2f), which contains nuclei.

Treatment and Prevention
Mansonella perstans
A number of treatment regimens have been tried, but none has been shown to be particularly effective in M. perstans filariasis. However, consistent with the identification of a Wolbachia species in M. perstans (67), a randomized trial in Mali has demonstrated the utility of doxycycline (200 mg daily for 6 weeks) treatment for this infection (68).

Mansonella streptocerca
DEC is particularly effective in treating infection by both the microfilarial and the adult forms of the parasite. Following treatment, as in onchocerciasis, debilitating urticaria, arthralgias, myalgias, headaches, and abdominal discomfort are often present. Nevertheless, because DEC is contraindicated in most of Africa because of concerns with posttreatment reactions in onchocerciasis, its use in this infection is limited. Consequently, ivermectin is currently the drug of choice for this infection (69).

Mansonella ozzardi
Ivermectin is the drug of choice for this infection (70, 71) but has been associated with significant posttreatment adverse events in some patients (53). There currently are no good preventative measures for any of the Mansonella infections beyond personal protective equipment, clothing, and insect repellents such as DEET (N,N-diethyl-meta-toluamide) or permethrin.

REFERENCES

Cestodes have as their key characteristic a flattened body composed of the head or scolex (bearing the fixation organs—suckers, hooks, and bothria), the neck (where the cellular reproduction occurs, to form the strobila), and the strobila, formed by numerous segments or proglottids. As new proglottids develop in the neck region, existing ones mature as they become more distal. The more-distal proglottids are gravid, almost completely occupied by a uterus full of eggs which are passed with the stools of the carrier, either inside complete proglottids or free after proglottid breakage. In some species, proglottids can actively migrate out of the anus.

Tapeworms live in the lumen of the small intestine with the head or scolex as the only fixation organ, attached to the mucosa. They absorb nutrients from the host’s intestine both at the head and through their tegument. Accordingly, they have developed cephalic fixation organs like hooks, suckers, or shallow grooves as longitudinal suction sulci (bothria) (Fig. 1), and a specialized tegument.

Four species of cestode tapeworms inhabit the human intestine: Diphyllobothrium latum, Taenia saginata, Taenia solium, and Hymenolepis nana. They differ widely in size, intermediate host, and other characteristics, from the 12-m D. latum to the 3-cm H. nana (Table 1). More rarely, Dipylidium caninum and Hymenolepis diminuta can also inhabit the human gut; these parasites are reviewed in chapter 147. In addition, a number of cestode larvae can produce human disease if infective tapeworm eggs are ingested, mainly cysticercosis (Taenia solium), cystic hydatid disease (Echinococcus granulosus), and alveolar hydatid disease (Echinococcus multilocularis). Rarer larval cestode infections affecting humans include coenurosis (Taenia multiceps), sparganosis (Spironectra mansonioides), and cysticercosis by Taenia crassiceps. Tapeworms and especially tapeworm larval infections still represent an important cause of morbidity and mortality, not only in most underdeveloped countries but also in industrialized countries, particularly in rural areas or among immigrants from areas of endemity.

**DIPHYLLOBOTHRIUM LATUM**

Known as the fish tapeworm, *D. latum* is the longest intestinal parasite of humans. Also common in fish-eating mammals such as canids or felids (reservoir hosts), it differs from other adult tapeworms infecting humans in its morphology, biology, and epidemiology.

**Taxonomy**

*D. latum* is included in the phylum Platyhelminthes, subphylum Neodermata, class Cestoidea, subclass Eucestoda, order Pseudophyllidea, family Diphyllobothriidae, and genus *Diphyllobothrium*.

**Description of the Agent**

**Adult Tapeworm**

The adult parasite can grow to 15 m in length and apparently can live for 20 years or longer in the small intestine. It is ivory in color and has a scolex which is provided with bothria on its dorsal and ventral aspects (1, 2). *Diphyllobothrium* proglottids are much wider than they are long (∼8 by 4 mm) and are easy to recognize because their genital pore is located in the center of the proglottid rather than in the lateral edges as in all other tapeworms of humans. The coiled uterus in the center of the gravid proglottids looks yellow-brown in freshly passed specimens. The uterine pore is located in the center of the proglottid near the genital pore.

**Eggs**

Unembryonated, operculate eggs are passed in the feces. *D. latum* eggs are oval and resemble those of trematodes but are smaller (58 to 75 μm long by 44 to 50 μm wide) and have a better-defined wall. The abopercular end usually has a small knoblike protrusion. Eggs are usually numerous, and expulsion of proglottid chains is usual.

**Larvae**

After the eggs embryonate in a water environment for several weeks, ciliated six-hooked embryos (coracidia) hatch. Coracidia must be ingested by appropriate species of freshwater copepods (genus, *Cyclops*) for further development. In the copepod a solid-bodied larva, the procercoid, develops as a second larval stage and becomes infective for the second intermediate host (fish). In fish, the procercoid migrates to the flesh and develops in the third larval stage, the plerocercoid or sparganum, which is the infective stage for human or animal (canids or felids) hosts.

**Epidemiology, Transmission, and Prevention**

The geographic distribution of *D. latum* includes lake areas in Scandinavia, other areas of northern Europe, the former...
Soviet Union, Finland, northern Japan, and North America, principally the upper Midwest, Alaska, and Canada, and the southwestern coast of South America. Several other *Diphyllobothrium* species (*D. pacificum*, *D. cordatum*, *D. ursi*, *D. dendriticum*, *D. lanceolatum*, *D. daliiae*, and *D. yonagoensis*) have also been reported to infect humans but less frequently (2, 3). *Diphyllobothrium pacificum*, identified by Nybelin in 1931, is a parasite of seawater found along the western coast of South America, specifically in Peru and Chile. *D. pacificum* is much smaller than *D. latum* and usually measures 50 to 200 cm long, although it can occasionally reach 3 to 4 m.

The most common sources of human *Diphyllobothrium* infection are the pike, burbot, perch, ruff, and turbot (2).

Infected fish (undercooked, raw, or insufficiently treated flesh) transmit plerocercoids to humans or other fish-eating mammals. Infection with *Diphyllobothrium* is preventable by eating well-cooked fish or fish that has been deep-frozen (at least −10°C for 24 h).

**Clinical Significance (Description of Clinical Presentation)**

Infected individuals notice passing segment chains with their stools. The parasite may produce no clinical symptoms in some people, but when it reaches a large size it may cause mechanical bowel obstruction, diarrhea, abdominal pain, and, particularly in northern European countries, pernicious

Note the coiled, central uterus in *D. pacificum*, the absence of hooks in the scolex of *T. saginata*, and the similar appearances of the eggs of *T. saginata* and *T. solium*. Morphological characteristics shown for *D. pacificum* are similar to those of *D. latum*. doi:10.1128/9781555817381.ch145.f1
anemia resulting from vitamin B₁₂ deficiency because the tapeworm competes with the intestinal epithelium for the uptake of the vitamin. This condition is rare outside Scandinavian countries, and some authors postulate a genetic predisposition.

**Collection, Transport, and Storage of Specimens**

For identification purposes, eggs are well preserved in 5 to 10% formalin solutions. For DNA recovery, 95% ethanol would be a better option. Electron microscopy may require cacodylate buffer or other glutaraldehyde media. Adult tapeworm material is better defined if it is washed in saline, relaxed for better visualization of its internal structures by warming the saline at 55°C for a short period (5 min), and then placed between two glass slides and stored in a fixative solution. Fixatives could be 10% formalin, acetic acid-formaldehyde-alcohol, or sodium acetate-acetic acid-formaldehyde. Fixed pieces can be stained by injecting Semichon’s carmine or India ink. The proglottids can also be sectioned and stained using hematoxylin and eosin; however, morphological characteristics can be more easily seen in whole mounts.

**Direct Examination**

**Microscopy**

Eggs can be easily seen by microscopic examination of stools. Either flotation or sedimentation techniques may be used. However, since the eggs are operculated, they generally do not float using the flotation concentration method; both the surface film and sediment need to be examined if this concentration method is used. For that reason, most laboratories routinely use the sedimentation concentration method. Low-magnification microscopy should easily permit identification of the characteristic scolex or proglottids when available (Fig. 1). Neither culture nor antigen detection is relevant for the detection and identification of *D. latum*.

**Nucleic Acid Detection Techniques**

Although several groups have described genus variation in *Diphyllobothrium* by using nucleic acid detection methods, the information has no clinical relevance in terms of routine tapeworm recovery and identification (4).

**Serologic Tests**

Serologic tests are not available.

**Treatment**

Both praziquantel and niclosamide are effective drugs. At recommended doses both are associated with only mild side effects, mostly gastrointestinal.

**Evaluation, Interpretation, and Reporting of Results**

Both stool microscopy and parasite identification are unambiguous. Eggs or tapeworm pieces should be reported as *D. latum* eggs (except in South America, where *D. pacificum* is more frequently found). Other human-infecting species are rarely found.

**TAENIA SAGINATA**

Known as the beef tapeworm, *Taenia saginata* is still endemic to most of the world. Humans are its only definitive host. While *T. saginata* infections do not carry major risks for the host, differential diagnosis with *Taenia solium* is important because the latter can cause neurocysticercosis.

**Taxonomy**

*T. saginata* is included in the phylum Platyhelminthes, subphylum Neodermata, class Cestoidea, subclass Eucestoda, order Cyclophyllidea, family Taeniidae, and genus *Taenia*.

**Description of the Agent**

**Adult Tapeworm**

The adult *T. saginata* tapeworm attains lengths of 4 to 8 m and has a scolex provided with four suckers and an unarmed (no hooks) rostellum. Gravid proglottids are longer than they are wide (18 to 20 mm by 5 to 7 mm). Each proglottid has a genital pore at the midlateral margin. In mature proglottids, the ovary has only two lobes and presents a vaginal siphincter. Gravid proglottids, which are highly muscular and active, break off from the strobila and actively migrate out of the anus (a pathognomonic characteristic of this species).

**Eggs**

Eggs from *T. saginata* and *T. solium* are indistinguishable by morphological characteristics. They are spherical, measure 30 to 40 μm in diameter, and have a quite characteristic thick, yellow-brown, radiate shell (embryophore) composed of collagen subunits, which gets thicker as the eggs mature. Eggs are frequently surrounded by a thin layer of vitellum (Fig. 1). Within the egg is a six-hooked embryo, the oncosphere.

**Larvae**

The unarmed scolex is invaginated into a fluid-filled bladder, the cysticercus. Larval cysts are 4 to 6 mm long by 7 to 10 mm wide and have a pearl-like appearance in tissues.

**Epidemiology, Transmission, and Prevention**

*T. saginata* is distributed worldwide, although it is especially prevalent in some parts of Africa, Central and South America, eastern and western Asia, and some countries in Europe. Cattle serve as the intermediate host, and ingestion of eggs from contaminated pasturelands by grazing cattle results in development in cattle tissues of the infective cysticercus stage. After ingestion of the cysticercus in raw or inadequately cooked beef, it takes approximately 2 to 3 months for the infection to become patent in the human host.

In Southeast Asia there is a human tapeworm morphologically very similar to *Taenia solitaria* (*Taenia solitaria asiatica*, *Taenia asiatica*, or *Taiwan taenia*). In this tapeworm, the cysticercus stage occurs in the livers of pigs and, less frequently, in cattle. The adult tapeworm infects the human host, and its appearance is very similar to that of *T. saginata* (5, 6).

**Clinical Significance (Description of Clinical Presentation)**

Although patients may exhibit no symptoms with this infection, they usually notice passing proglottids or find them in their underwear. The mature worm can also cause abdominal discomfort, diarrhea, and occasionally intestinal obstruction as a result of its large size.

**Collection, Transport, and Storage of Specimens**

See instructions in “Collection, Transport, and Storage of Specimens” for *Diphyllobothrium*.
Direct Examination

Microscopy
Typical Taenia eggs can be found in feces. Sedimentation or the less used Kato-Katz method is apparently more sensitive for the detection of Taenia eggs in stools than other concentration techniques. Finding of Taenia eggs does not allow a species-specific diagnosis of infection; it is usually made by identification of gravid proglottids that have been passed in feces or have actively migrated out of the anus. Identification of the proglottids is based on shape and size and mainly on the morphology of the uterus, which can be demonstrated after injection with India ink or staining with carmine or hematoxylin stains. In T. saginata there are 15 to 20 primary lateral branches on each side of the central uterine stem (Fig. 1).

Antigens in stools (coproantigen) have been detected by enzyme-linked immunosorbent assay (ELISA) since 1990, but this assay is used mainly in research settings because of scarce availability.

Nucleic Acid Detection Techniques
Species-specific PCR techniques have been described to detect parasite DNA and differentiate T. saginata from T. solium. Most of these assays require actual parasite material, although some are apparently able to establish the difference with DNA from eggs in feces (7–10).

Serologic Tests
Serum antigen detection ELISAs for T. saginata cysticercosis in cattle have been developed using monoclonal antibodies to T. saginata. Although these assays can detect parasite burdens of <50 cysts per animal, they have not yet been routinely applied except in research settings (11–13).

Treatment
Both praziquantel and niclosamide are effective drugs. At recommended doses both are associated with only mild side effects, mostly gastrointestinal. In regions where T. solium is endemic, there is a possibility that latent neurocysticercosis may respond to praziquantel and cause severe headaches or seizures. Niclosamide is not absorbed from the gastrointestinal tract and thus does not carry this risk (14).

Evaluation, Interpretation, and Reporting of Results
Eggs should be reported as “Taenia sp.” because direct observation does not confirm the species. The finding of Taenia sp. eggs should be notified to the attending physician to ensure prompt treatment. The presence of the scolex in the parasite material expelled (spontaneously or posttreatment) should be reported both because it allows species diagnosis and because if it is not found, the chances of treatment failure increase.

TAENIA SOLIUM

Known as the pork tapeworm, T. solium has an extensive geographic distribution. This infection has a huge impact on human health because of its association with seizure disorders caused by infection of the human brain with its larval stage (neurocysticercosis) (15).

Taxonomy
T. solium is included in the phylum Platyhelminthes, subphylum Neodermata, class Cestoidea, subclass Eucestoda, order Cyclophyllidea, family Taeniidae, and genus Taenia.

Description of the Agent
Adult Tapeworm
The adult T. solium tapeworm measures 2 to 4 m and has a scolex provided with four suckers and a rostellum armed with two crowns of hooks. Gravid proglottids have similar length and width (approximately 1 cm). Each proglottid has a genital pore at the midlateral margin. In mature proglottids, the ovary has two main lobes and one accessory lobe (lacking in T. saginata), and a vaginal sphincter muscle is lacking (present in T. saginata). Gravid proglottids have few (<12) lateral branches on the central uterine stem (Fig. 1). Since the eggs of T. solium are infective to humans and can cause cysticercosis, extreme caution in the handling of these proglottids or infective stools is recommended.

Eggs
Eggs from T. saginata and T. solium are indistinguishable by morphological characteristics. They are spherical, measure 30 to 40 μm in diameter, and have a quite characteristic thick, yellow-brown, radiate shell (embryophore) composed of collagen subunits, which gets thicker as the eggs mature. Eggs are frequently surrounded by a thin layer of vitellum (Fig. 1). Within the egg is a six-hooked embryo, the oncosphere.

Larvae
The fluid-filled bladder (cysticercus) larvae are bigger than those of T. saginata, measuring approximately 8 to 10 mm in diameter. They lodge in the pig’s tissues, mostly in muscle and brain.

Epidemiology, Transmission, and Prevention
T. solium taeniasis and cysticercosis are highly endemic to all parts of the developing world where pigs are raised as a food source, including Latin America, most of Asia, sub-Saharan Africa, and parts of Oceania. The infection is now also increasingly diagnosed in industrialized countries due to immigration of tapeworm carriers from zones of endemicity (6, 15).

As for T. saginata, humans are the only definitive host. Ingestion of contaminated pork containing T. solium cysticerci causes human taeniasis. Conversely, T. solium eggs cause cysticercosis in pigs (the usual intermediate host) and humans. Pigs acquire cysticercosis by eating stools contaminated with infective eggs in places where deficient sanitation exists. Humans are infected by fecal-oral contamination from a tapeworm carrier, commonly in the household or another close environment.

Clinical Significance (Description of Clinical Presentation)
Human T. solium taeniasis is acquired by ingestion of infective cysticerci in inadequately cooked pork or pork products. Taeniasis seems mostly asymptomatic, and most patients do not even notice passing proglottids in stools. The clinical significance of T. solium infections relates to the risk of neurocysticercosis (see below), which is high for tapeworm carriers and their close contacts (15).

Collection, Transport, and Storage of Specimens
See instructions in “Collection, Transport, and Storage of Specimens” for Diphyllobothrium. Handling of T. solium proglottids or contaminated stools should be done with appropriate biosafety conditions to avoid cysticercosis.
Direct Examination

Microscopy
Typical *Taenia* eggs can be found in feces. Sedimentation or the less used Kato-Katz method is apparently more sensitive for the detection of *Taenia* eggs in stools than other concentration techniques. Finding of *Taenia* eggs does not allow a diagnosis of infection by the species, which is usually made by identification of gravid proglottids or, more rarely, the scolex passed in feces. Identification of the proglottids is based on shape and size and mainly on the morphology of the uterus, which can be demonstrated after injection with India ink or staining with carmine or hematoxylin stains. In *T. solium* there are few primary branches on each side of the central uterine stem (Fig. 1).

Antigens in stools (coproantigen) have been detected by ELISA since 1990. Coproantigen detection ELISA is much more sensitive than microscopy and thus highly recommended for the diagnosis of human taeniasis (specifically in the case of *T. solium* because of the risks of cysticercosis transmission), as well as to monitor the effectiveness of treatment, but its availability is still limited (16).

Nucleic Acid Detection Techniques
Species-specific PCR techniques that differentiate *T. saginata* from *T. solium* have been described. Most of these assays require actual parasite material, although some are apparently able to establish the difference with DNA from eggs in feces (7–10).

Serologic Tests
Recently, stage-specific serologic assays directed to the adult tapeworm have been developed, with high sensitivity and specificity. Mostly, serology is directed to the detection of *T. solium* antigens in relation to the diagnosis of neurocysticercosis. Antibody detection by enzyme-linked immunoelectrotransfer blot assay is the method of choice, with a sensitivity of 98% in cases with more than one viable larval cyst and a specificity of 100% (17). *T. solium* antigen detection in serum or cerebrospinal fluid has been performed in cases of human cysticercosis, based on a known genus-specific cross-reaction in ELISAs for *T. saginata*. Although these assays can detect parasite burdens of <50 cysts in infected animals, they have not yet been routinely applied except in research settings. *T. solium* antigen detection is likely to be a helpful tool to monitor the evolution of patients with severe, subarachnoid neurocysticercosis, in which high antigen levels occur (18).

Treatment
Both praziquantel and niclosamide are effective drugs. At recommended doses both are associated with only mild side effects, mostly gastrointestinal. In regions where *T. solium* is endemic, there is a possibility that latent neurocysticercosis may respond to praziquantel and cause severe headaches or seizures. Niclosamide is not absorbed from the gastrointestinal tract and thus does not carry this risk (14).

Evaluation, Interpretation, and Reporting of Results
Eggs should be reported as “*Taenia* sp.” because direct observation does not confirm the species. The finding of *Taenia* sp. eggs should be notified to the attending physician to ensure prompt treatment and minimize the chances of cysticercosis in the patient or his/her contacts. The presence of the scolex in the parasite material expelled (spontaneously or posttreatment) should be reported both because it allows species diagnosis and because if it is not found, the chances of treatment failure increase.

**HYMENOLEPIS NANA**

*H. nana* is the smallest of the intestinal tapeworms of humans and also the most common tapeworm infection throughout the world. It can be transmitted from person to person (an intermediate host is not necessarily required) (3).

Taxonomy

*H. nana* is included in the phylum Platyhelminthes, subclass Platyhelminthes, class Cestoidea, subclass Eucestoda, order Cyclophyllidea, family Hymenolepididae, and genus *Hymenolepis*.

Description of the Agent

Adult Tapeworm
The adult parasite measures 2 to 4 cm and seems to live for approximately 1 year. The scolex has four suckers and one crown of hooks.

Eggs
The eggs are 30 to 50 μm in diameter and thin shelled, and they contain a six-hooked oncosphere that lies in the center of the egg and is separated from the outer shell by considerable space. The oncosphere is surrounded by a membrane that has two polar thickenings from which arise four to eight filaments extending into the space between it and the outer shell (Fig. 1). These filaments are not seen in *H. diminuta*. Eggs may hatch inside the host’s intestine, and the embryos (oncospheres) invade the mucosa to develop into larval stages.

Larvae
The cysticercoid larvae have an invaginated scolex but no fluid-filled bladder. They lodge in the intestinal mucosa and emerge to the intestinal lumen as young tapeworms after a few days.

Epidemiology, Transmission, and Prevention

*H. nana* is normally a parasite of mice, and its life cycle characteristically involves a beetle as an intermediate host. In humans, transmission is usually accomplished by direct ingestion of infective eggs containing oncospheres. When eggs are ingested, a solid-bodied larva, a cysticercoid, first develops in the wall of the small intestine. Subsequently, the larva migrates back into the intestinal lumen, where it reaches maturity as an adult tapeworm in 2 to 3 weeks. In beetles that ingest eggs of *H. nana*, the cysticercoids develop in the body cavity and have thick protective walls around them. Although humans may acquire the infection by accidental ingestion of infected beetles (often occurring in dry cereals), direct infection is far more common and is the primary reason why *H. nana* usually occurs in institutional and familial settings in which hygiene is substandard. A feature of human *H. nana* infection is the opportunity for internal autoinfection with the parasite, which may result in large worm burdens. Autoinfection occurs when eggs discharged by adult tapeworms in the lumen of the small intestine hatch rapidly and invade the wall of the intestine; here, cysticercoids are formed, and they subsequently reenter the intestine to mature as adult worms.

### Description of the Agent

#### Adult Tapeworm

The adult parasite measures 2 to 4 cm and seems to live for approximately 1 year. The scolex has four suckers and one crown of hooks.

#### Eggs

The eggs are 30 to 50 μm in diameter and thin shelled, and they contain a six-hooked oncosphere that lies in the center of the egg and is separated from the outer shell by considerable space. The oncosphere is surrounded by a membrane that has two polar thickenings from which arise four to eight filaments extending into the space between it and the outer shell (Fig. 1). These filaments are not seen in *H. diminuta*. Eggs may hatch inside the host’s intestine, and the embryos (oncospheres) invade the mucosa to develop into larval stages.

#### Larvae

The cysticercoid larvae have an invaginated scolex but no fluid-filled bladder. They lodge in the intestinal mucosa and emerge to the intestinal lumen as young tapeworms after a few days.

#### Epidemiology, Transmission, and Prevention

*H. nana* is normally a parasite of mice, and its life cycle characteristically involves a beetle as an intermediate host. In humans, transmission is usually accomplished by direct ingestion of infective eggs containing oncospheres. When eggs are ingested, a solid-bodied larva, a cysticercoid, first develops in the wall of the small intestine. Subsequently, the larva migrates back into the intestinal lumen, where it reaches maturity as an adult tapeworm in 2 to 3 weeks. In beetles that ingest eggs of *H. nana*, the cysticercoids develop in the body cavity and have thick protective walls around them. Although humans may acquire the infection by accidental ingestion of infected beetles (often occurring in dry cereals), direct infection is far more common and is the primary reason why *H. nana* usually occurs in institutional and familial settings in which hygiene is substandard. A feature of human *H. nana* infection is the opportunity for internal autoinfection with the parasite, which may result in large worm burdens. Autoinfection occurs when eggs discharged by adult tapeworms in the lumen of the small intestine hatch rapidly and invade the wall of the intestine; here, cysticercoids are formed, and they subsequently reenter the intestine to mature as adult worms.
Clinical Significance (Description of Clinical Presentation)
Most infections cause no symptoms. However, hymenolepiasis can be associated with abdominal pain, diarrhea, headaches, or irritability, probably in infections with heavier worm burdens (19, 20).

Collection, Transport, and Storage of Specimens
See instructions in “Collection, Transport, and Storage of Specimens” for Diphyllobothrium.

Direct Examination
Microscopy
Diagnosis of the infection rests on finding the spherical eggs in feces by microscopy. Either flotation or sedimentation techniques are of help. Proglottids (Fig. 1) are rarely seen, since they disintegrate after breaking off from the main strobila. Neither culture, antigen detection, nor nucleic acid detection techniques are relevant for the detection and identification of H. nana.

Serologic Tests
Antibody detection ELISAs have been used in research settings but are of no clinical use (21).

Treatment
Both praziquantel and niclosamide are effective drugs. At recommended doses both are associated with only mild side effects, mostly gastrointestinal. A second dose of praziquantel after 10 to 15 days may decrease the likelihood of relapses. Niclosamide needs to be administered for 7 days because it is not absorbed and thus does not affect the cysticercoid larvae in the intestinal mucosa. Nitazoxanide has been reported to be useful as a therapeutic alternative (22).

Evaluation, Interpretation, and Reporting of Results
Eggs are characteristic and should be reported as H. nana eggs. The closest differential diagnosis is with H. diminuta, which rarely infects humans. The eggs of H. diminuta are bigger, lack polar filaments, and have a wider interior space and thus can be differentiated by microscopy.

LARVAL CESTODES INFECTING THE HUMAN HOST
The larval stages of Taenia solium, Echinococcus granulosus, Echinococcus multilocularis, and, less frequently, Spirometra, Taenia multiceps, and Taenia crassiceps can invade the human tissues. These are briefly described below.

Cysticercosis (Taenia solium)
In the normal life cycle of T. solium, humans are the definitive host and pigs act as the intermediate host, hosting the larval stage, or cysticercus. Porcine cysticercosis is a serious economic problem for pig farmers. However, the most serious consequences are associated with human cysticercosis (15). Larval vesicles located in the human central nervous system (Fig. 2) cause seizures or other neurological symptoms. Indeed, neurocysticercosis is associated with a significant proportion of seizure cases in areas of endemicity (23, 24). Clinical manifestations of neurocysticercosis are related to individual differences in the number, size, and topography of lesions and in the severity of the host’s immune response to the parasites. Symptoms and signs are varied and nonspecific. Parasites in the brain parenchyma usually cause seizures and headache, whereas those located in the cerebral ventricles or in the subarachnoid space (“racemose” cysticercosis) cause intracranial hypertension and hydrocephalus. Diagnosis is made using brain imaging, either computed tomography (CT) scan or magnetic resonance imaging (MRI), and confirmed by serology. CT has a lower cost (quite important for poor areas where the disease is endemic), is more available, and has better sensitivity for the detection of calcified parasites. Conversely, MRI has better sensitivity for small lesions, those located close to the skull, and intraventricular parasites. The serologic assay of choice is an immunoblot using seven purified glycoprotein larval antigens, which has 98% sensitivity and 100% specificity except in cases with a single lesion, for which sensitivity drops to approximately 70% (17, 18). Antigen detection assays have been described, but no controlled data on sensitivity and specificity are yet available. Treatment of neurocysticercosis uses antiparasitic agents (albendazole or praziquantel) for viable parasites, usually given with steroids to ameliorate the inflammation produced by the death of the cyst. Surgery is limited to excision of single, big lesions or implantation of ventricle-peritoneal shunts. Antigen detection assays permit patient monitoring and follow-up of antiparasitic treatment (18, 25).

Cystic Hydatid Disease (Echinococcus granulosus)
In the normal life cycle of Echinococcus granulosus, the dog is the definitive host and herbivores (mainly sheep) act as the intermediate host. These become infected with the larval stage (cystic hydatid) by ingesting infective eggs dispersed from the feces of a tapeworm-infected dog. Human cystic hydatid disease is an important cause of human morbidity, requiring costly surgical and medical treatment. This cestodiasis is still endemic to most of the Old World, particularly Greece, Cyprus, Bulgaria, Lebanon, Turkey, some other European countries, South America, and Africa. Sporadic autochthonous transmission is currently recognized in Alaska and other states in the United States (26). The affected organs are most commonly the liver and lungs and, more rarely, the heart, brain, bones, or other locations. Diagnosis is made using ultrasound or CT scan for liver infection or chest X-rays or CT for lung infections (Fig. 2). Antibody detection by serology is helpful, although sensitivity is lower than for other infections, reaching 80 to 85%. It is more sensitive for hepatic than for pulmonary cases. Treatment uses antiparasitic agents (albendazole or albendazole plus praziquantel) for small cysts or presurgery; PAIR (puncture, aspiration, injection, and reinjection), which is a technique of ultrasound- or CT-guided aspiration and sterilization of the cyst’s contents; or either laparoscopic or open surgery (27, 28). Spillage of cyst contents could lead to acute anaphylactic reactions or dissemination of infection in the surrounding tissues. Cystic lesions may resolve without therapy in a proportion of patients (29).

Alveolar Hydatid Disease (Echinococcus multilocularis)
The adult stage of E. multilocularis lives in the small intestine of the definitive host, commonly wild predators in the northern hemisphere, occurring in parts of Europe, Asia, Japan, and North America, including Alaska (30, 31). The larval stages infect microtine rodents that usually serve as the common intermediate host. Human infections (causing alveolar hydatid disease) occur by accidental ingestion of
FIGURE 2 Larval cestodes infecting the human host. (Top left) *Taenia solium* cysticerci in the human brain (neurocysticercosis), shown in a noncontrasted CT scan of the brain; (top right) *Echinococcus granulosus* hydatid in the human liver (hydatid disease) as seen on liver ultrasound (kind contribution of Enrico Brunetti, Universitá di Pavia, Pavia, Italy); (bottom left) *Echinococcus multilocularis* alveolar hydatid disease in human liver (kind courtesy of K. Buttenschoen and P. Kern, University Hospital Ulm, Ulm, Germany); (bottom right) *Taenia multiceps* coenurus showing multiple scolices in the cystic wall. doi:10.1128/9781555817381.ch145.f2

the oncosphere by contamination with the feces of the definitive host. The manifestation of alveolar hydatid disease resembles a slowly developing “malignant tumor” of the liver, with subsequent invasion of the blood vessels and bile ducts and metastatic dissemination. The lesions vary in size and can produce minor foci up to large infiltrating structures in the host’s tissue. Thus, alveolar hydatid disease differs greatly in the pathology and clinical course from cystic hydatid disease. This disease often affects persons aged over 50 years and is characterized by a chronic course lasting for months or years. Clinical manifestations relate to the extent of tumor-like lesions of the cyst. Besides physical examination, diagnosis usually is based on imaging techniques, including ultrasound, CT, and MRI, supported by serology. Treatment is mainly surgical. Chemotherapy with benzimidazole agents is restricted to residual, postsurgical, or inoperable lesions (32).

**Sparganosis (Spirometra mansonioides)**

Mainly found in Southeast Asian countries, the metacestode larvae of *Spirometra* species can invade the human tissues either by ingestion of contaminated crustaceans in drinking water or of infected meat (frog or snake) or by direct contact via a poultice. The most commonly affected sites are subcutaneous tissues and the eye. The diagnosis rests on the pathological demonstration of the larvae after excision by biopsy (33).

**Coenurosis (Taenia multiceps or Taenia serialis)**

*Taenia multiceps* and *Taenia serialis* have canids as definitive hosts and sheep as their normal intermediate host, harboring the larva, or coenurus. The coenurus is a vesicle containing a transparent fluid, with a fine membrane in which multiple (500 to 700) scolices can be seen. Infected sheep lose their balance and rotate in circles continuously, become dizzy, and fall (screw disease). It infrequently causes coenurosis in humans. Human infections have largely been confined to the African continent, but a few cases have been described from France, England, and North and South America. The space-occupying coenurus usually invades the brain, producing lethal lesions. Diagnosis is based on pathological demonstration of the typical larval membrane and multiple scolices (34, 35).

**Cysticercosis (Taenia crassiceps)**

*T. crassiceps* is a common tapeworm of the red fox. Larval forms are generally found in subcutaneous tissues and body cavities of rodents. Human cases are quite rare, mostly in immunocompromised patients (subcutaneous, muscular, or ocular infections) (36, 37).

Trematodes
MALCOLM K. JONES, JENNIFER KEISER, AND DONALD P. McMANUS

At least 70 species of digenean trematodes have been recorded as adult parasites from humans. All of these species are endoparasitic, occupying a variety of tissue sites (see Tables 1 to 3). Adult trematodes have distinctive morphology, often with a leaflike body plan. The most prominent morphological features in most species, however, are two rounded suckers. One of these, the oral sucker, surrounds the mouth, while the other, the ventral sucker, lies approximately one-third of the way along the body and serves as a primary attachment organ (1). Adult digeneans are rarely observed in clinical settings because they are endoparasitic, but they may be observed after anthelminthic purging or at autopsy. Hence, diagnosis of trematode diseases relies to a large extent on direct observations of excreted eggs. With few exceptions (2, 3), the eggs have distinct morphology and their presence is pathognomonic of specific infection. Despite the diverse range of body sites infected by adult trematodes, the eggs of most digenean flukes are voided with feces. Exceptions to this include Schistosoma haematobium and rarely other schistosomes, for which eggs are excreted with urine, and Paragonimus species, for which eggs are also observed in sputum. Detailed descriptions of the digenean life cycles are shown in Fig. 1 and 2. There are many subtle variations in life cycle patterns, but two predominant strategies exist for these trematodes (Fig. 1 and 2). The first strategy, exemplified by the schistosomes, is one in which humans are infected by direct invasion of the skin by cercariae. The second strategy is seen among the foodborne digeneans (4), a diverse assemblage of species, which enter humans with ingested food (Fig. 2).

Two features of the digenean life cycle are noteworthy. First, digeneans often display high specificity in their choice of first intermediate host. So intimate are these host-parasite associations that the geographical distribution of a digenean is determined largely by that of its snail host. For this reason also, many digeneans show a focal distribution in countries where they are endemic. Secondly, most human parasites are zoonotic, requiring the cooccurrence of other mammalian or avian hosts in an area of endemicity to maintain human infection.

DIGENEANS OF THE CIRCULATORY SYSTEM
Schistosomes responsible for human disease are shown in Table 1, along with their distribution, snail hosts, and treatment. Currently, an estimated 779 million people are at risk and 207 million people in 76 countries and territories have schistosomiasis, with 85% of cases occurring in sub-Saharan Africa (3). Of these, some 120 million people are symptomatic and 20 million have severe illness.

Taxonomy
Schistosomes (family Schistosomatidae) are characterized by dioecious adults, cercariae with a forked tail, and a two-host life cycle (Fig. 1). Adults occupy an intravascular site in the human host, either in the mesenteric vessels or the vesical plexus. Five species commonly infect humans, of which three (S. mansoni, S. japonicum, and S. haematobium) are the most important (Table 1). Cross-hybridization between predominantly human- and animal-parasitic species is recognized as an increasing problem in Africa (6). Morphological descriptions of adult worms, which are not encountered in diagnostic samples, are summarized elsewhere (1).

Hepatosplenic Schistosomiasis
The most extensively studied schistosome, S. mansoni, occurs throughout sub-Saharan Africa, Egypt, the Middle East, Madagascar, eastern countries of South America and some islands of the Caribbean (Table 1). It is believed that the species was carried to South America with the slave trade. The distribution of S. mansoni overlaps that of S. haematobium in many parts of Africa.

Schistosoma japonicum is responsible for significant disease in foci in Asia (7) (Table 1) but has been eradicated from Japan. Sustained control efforts in China funded in part by the World Bank reduced the number of infected people from approximately 12 million to 1 to 2 million by the late 1980s and to less than 1 million in 1999 (8). These efforts, while successful in reducing morbidity to a low level, have reached a balance point and are not likely to reduce the geographic range of the parasite or eradicate the disease (8). Unlike most other human schistosomes, S. japonicum is a zoonosis, and in China and the Philippines, ruminants, particularly water buffalo and goats, are of primary concern in perpetuating the life cycle (9, 10).

Schistosoma mekongi has a highly focal distribution in the Mekong River Basin, with foci of endemicity in Laos and Cambodia (11). Although originally regarded as a subspecies of S. japonicum, the species was recognized as distinct based on morphological characteristics, pathologic effects, and life cycle patterns. Sustained large-scale chemotherapy in provinces of endemicity in Cambodia and Laos has led to

*Modified from reference 61 with permission. Abbreviations: NR, not recorded; P, praziquantel.
FIGURE 1 Five species of Schistosoma are known to infect humans. Infection with Schistosoma mansoni, S. japonicum, S. mekongi, or S. intercalatum adults occur in mesenteric veins; S. haematobium adults occur in the vesicle plexus. Humans are infected after cercarial penetration of the skin. After penetration, the cercariae shed their bifurcated tails, and the resulting schistosomula enter capillaries and lymphatic vessels en route to the lungs. After several days, the worms migrate to the portal venous system, where they mature and unite. Pairs of worms then migrate to the site of patent infection. Egg production commences 4 to 6 weeks after infection. Eggs pass from the lumen of blood vessels into adjacent tissues, and many then pass through the intestinal or bladder mucosa and are shed in the feces or urine (see the text). In freshwater, the eggs hatch, releasing miracidia that, in turn, infect specific freshwater snails (Table 1). Reprinted from the New England Journal of Medicine (33) with permission. doi:10.1128/9781555817381.ch146.f1
control of the disease, although the disease still remains at high prevalence in some pockets and new infections are occurring (12).

Schistosoma intercalatum is responsible for rectal schistosomiasis in regions of Africa. The species occurs as two geographically isolated strains (now considered distinct species [13]), the Cameroon and the Democratic Republic of the Congo strains, which display highly focal distributions (7). This parasite belongs to the S. haematobium group of species, characterized by, among other features, eggs with a terminal spine (Fig. 3).

Genitourinary Schistosomiasis
Schistosoma haematobium, the sole agent of urinary schistosomiasis, occurs in much of the African continent as well as Madagascar and the Middle East (1, 7) (Table 1). Adult worms live in the vesical plexus. Eggs escape the host across the bladder wall to be excreted with urine.

Epidemiology and Transmission
All schistosomes of humans use freshwater aquatic snails as the intermediate host. Humans are infected through exposure to freshwater contaminated with infective larvae, the cercariae (Fig. 1). Cercariae enter the human body by percutaneous penetration.

Within regions of endemicity, factors contributing to schistosome transmission include the distribution biology and population dynamics of the snail hosts, the extent of contamination of freshwater with feces or urine, and the degree of exposure of humans to contaminated water. The recent development of large-scale dams in some areas of endemicity has led to changes in transmission dynamics (5). The impact of the Three Gorges Dam in China on the transmission of S. japonicum remains uncertain (14).

Clinical Significance
Cercarial dermatitis occurs in schistosomiasis but is more commonly reported after infection with avian schistosomes (Table 1) and Schistosoma spindale. Acute toxemic schistosomiasis (Katayama fever) can occur with any schistosome species but is more apparent in nonimmune individuals and may be characterized by fever, headache, generalized myalgias, right-upper-quadrant pain, and bloody diarrhea (15, 16).

Eggs (Fig. 3) are laid by female worms in the vasculature and must traverse endothelia and gut or bladder mucosa to escape the host. In those schistosomes infecting mesenteric veins, eggs pass through the wall of the intestine or rectum,
while for *S. haematobium*, the eggs escape across the bladder wall. For all species, however, many eggs become entrapped in tissues. The chronic effects of schistosomiasis, therefore, relate to the site of adult infections and granulomatous and fibrotic responses to entrapped parasite eggs (16). Granulomas occur in many tissues in response to entrapped eggs; however, most accumulate in tissues fed by vasculature leading from the site of adult infection. Eggs retained in the gut wall induce inflammation, hyperplasia, and ulceration, and occult blood occurs in the feces. A suggested relationship between colorectal cancer and schistosomiasis remains controversial (17). Eggs entrapped in the liver lead to portal hypertension and splenic and hepatic enlargement, potentially giving rise to the formation of fragile esophageal varices. Ascites also is common.

In urinary schistosomiasis, granulomatous inflammatory response to embolized eggs gives rise to dysuria, hematuria, and proteinuria, calcifications in the bladder, obstruction of the ureter, renal colic, hydronephrosis, and renal failure. Secondary bacterial infection of the bladder and other affected tissues may occur. There is consistent association between *S. haematobium* infection and squamous-cell carcinoma of the bladder (6). *S. haematobium* infection causes genital disease in approximately one-third of infected women, leading to vulval and perineal disease and tubal infertility, and may facilitate the transmission of HIV (18).
Collection, Transport, and Storage

Adult schistosomes are rarely encountered in clinical settings. Characteristic eggs of schistosomes (Fig. 3) voided with feces or urine are pathognomonic of infection. Detailed instructions on collection, transport, and storage of schistosome eggs in human fecal material are provided in chapter 133. The eggs of schistosomes contain fully differentiated larvae in feces or urine and hatch spontaneously upon exposure to fresh water. Although observations of viable schistosome miracidia may be advantageous for species identification, spontaneous hatching may hinder direct observations of eggs.

Detection

The presence of schistosome eggs (Fig. 3) (19) in feces or urine is diagnostic of schistosomiasis. Eggs of hepatosplenic schistosomes may be observed by light microscopy in stool specimens with or without suspension in saline. Formalin-based techniques for sedimentation and concentration are particularly useful, especially for patients releasing few eggs. Hatching tests, in which fecal matter is suspended in non-chlorinated water in darkened vessels with directed surface light, have been used to detect motile miracidia. In patients with chronic disease and with typical clinical presentation but negative urine and stool specimens, a biopsy of bladder or rectal mucosa may be helpful in diagnosis.

The Kato-Katz method of fecal smear is used in field studies for diagnosis and quantification of fecal egg burdens. Kato-Katz tests give a theoretical sensitivity cutoff of 20 eggs per g of feces (20), but the large daily variation in egg shedding and the uneven distribution of eggs in feces may lead to inconsistent counts. It has been recommended for S. mansoni infection that either five replicate slides, or sets of triplicate slides made from stools collected on two successive days, be used for assessment of infection status (21). A novel method, incorporating fixation in formalin-ethyl acetate coupled with sedimentation and digestion with potassium hydroxide, shows promise for quantitative assessment of eggs in bovine feces for epidemiological surveillance of S. japonicum (22).

Sedimentation or concentration methods are most useful for diagnosis of S. haematobium from urine samples. In addition, the use of tests for blood, protein, and eosinophils in urine, while not specific, may be indicative of infection (23). Portable ultrasound is useful for assessment of pathologic damage to tissues. The use of questionnaires in populations in which the infection is endemic is helpful in revealing infections for S. japonicum and S. haematobium but for S. mansoni may lead to underestimation of prevalence (24). An innovative test using paramagnetic beads to bind schistosome ova has been explored (25).

PCR tests for schistosomes in stools use high-repeat nuclear genomic (26) and mitochondrial sequences (27). Both tests report high sensitivity, at times exceeding that of direct coprological examination. The mitochondrial sequence probes, which amplify sequences spanning the cox2/nad6 genes for S. japonicum and S. mansoni, nad1 and nad2 for S. japonicum, and nad5 for S. mansoni, show high specificity and sensitivity (27). An interesting development is that of the use of real-time PCR to detect cell-free schistosome DNA in host plasma (28). This method utilizes a 121-bp tandem repeat sequence that represents approximately 12% of the S. mansoni genome as a target sequence for amplification.

An attractive method for diagnosis is a direct detection method for the schistosome antigen circulating cathodic antigen (CCA). An immunochromatographic dipstick (Rapid Medical Diagnostics, South Africa) that detects CCA in schistosomiasis mansoni is becoming increasingly valued as a diagnostic, especially in low-transmission settings, where fecal egg analyses show poor sensitivity (29). Commercial urine dipstick tests for microhematuria can serve as a rapid diagnostic proxy for S. haematobium infection (30).

Serology

A range of direct and indirect tests have been explored experimentally, including enzyme-linked immunosorbent assays (ELISAs) and immunoblot tests using soluble egg antigen, recombinant antigens, and detection of parasite antigen in excreta (31, 32). Host antibodies against schistosomes can persist for prolonged periods after parasitologic cure, and this, together with potential antigen cross-reactivity, can limit the value of serologic tests (31). Serology can be most valuable for diagnosis of schistosomiasis in travelers from regions of nonendemicity who visit areas that are endemic for the disease. Other indirect tests include assays for peripheral-blood eosinophilia, anemia, hypoalbuminemia, elevated urea and creatinine levels, and hypergammaglobulinemia (23, 33).

Typing

Although laboratory strains and regional variations exist among schistosomes, typing of species is of limited significance. S. japonicum occurs as a range of strains throughout different regions in Asia.

Anthelmintic Susceptibility and Treatment

Praziquantel is the drug of choice for treatment of schistosomiasis. The drug has been used in mass treatment campaigns in many countries, a development facilitated in part by reductions in costs associated with manufacture of the drug. Despite this, the anthelmintic has some limitations, as it is effective against only adult forms (34) and does not protect from subsequent infection.

Treatment failures for S. mansoni and S. haematobium infections with praziquantel have been observed, and the presence of resistant strains has been demonstrated experimentally (see chapter 133). Widespread resistance to praziquantel has not been observed clinically, but the application of the drug in mass treatment campaigns may result in new resistant forms emerging.

Derivatives of artemisinin, an antimalarial, have been subjected to trials against schistosomes in experimental models and clinical field settings (35). In contrast to praziquantel, artemether acts against juvenile schistosomes in the host and may be used as a chemoprophylactic agent (36). Combinations of drugs have been subjected to trials on a number of occasions. The combination artemisinin-mefloquine was effective against S. haematobium and S. mansoni infections (37).

A number of vaccines have entered clinical trials. These include BbLVX, a vaccine targeting the glutathione S-transferase of S. haematobium and a tetraspanin (Sm-TSP-2) and a fatty acid binding protein (Sm14) of S. mansoni. There is no clear target available yet for any form of African schistosomiasis.

Schistosome Dermatitis (Swimmer’s Itch)

This ailment arises from infection with a number of avian and mammalian schistosomes (Table 1). The avian schistosome cercariae cannot migrate from the dermal layers of human skin and induce local dermatitis accompanied by pruritus and papule formation.
FOODBORNE DIGENEANS

All other digeneans considered here represent a diverse assemblage of taxa, which infect humans through ingestion of uncooked or undercooked food (Fig. 2; see Tables 2 and 3). The vast majority of these species are zoonotic. The primary epidemiological features governing human infection include the distribution of suitable snail intermediate hosts, human food consumption behaviors, the presence of suitable zoonotic hosts, and the potential for water contamination with human or animal excreta (38).

Trematodes of the Respiratory System: Paragonimus

Taxonomy

The genus Paragonimus, family Troglocomatidae, contains approximately 50 species of leaf-shaped digeneans occurring in a range of mammals throughout the world. Species are distinguished on the basis of the surface spination and shape of the ovary. Human paragonimiasis is caused predominantly by 10 species distributed throughout Asia, Africa, and the Americas (Table 2) and include Paragonimus africanus (West Africa), P. caliensis (Central and South America), P. heterotremus (Southeast Asia, China), P. heueingensis (China), P. kellicotti (North America), P. mexicanus (Central and South America), P. miyazakii (Japan), P. skrjabini (Southeast Asia, China), P. uropbribrators (West Africa), and P. westerni (Asia) (39). The most common species infecting humans is Paragonimus westerni. Adult Paragonimus species inhabit the lungs, where they induce the formation of encapsulating cysts. The flukes are large and fleshy, measuring 8 to 16 by 4 to 8 mm. Paragonimus species have large, thick-shelled, and operculate eggs that are often not fully embryonated when observed in sputum or feces.

Epidemiology and Transmission

Some 23.2 million people have been estimated to have paragonimiasis (40). The global burden due to paragonimiasis is 197,000 disability-adjusted life years (DALYs) (40). The life cycle of Paragonimus is described in Fig. 2 and Table 2. Of the approximately 50 species, 9 have been recorded as human parasites. Eggs are passed in the lungs and are transferred up the bronchial tree with sputum. Eggs may be spat with sputum or swallowed and passed with feces. The first intermediate hosts are freshwater snails. Human infection arises after ingestion of uncooked or marinated freshwater crabs or crayfish (41), but unwashed hands of food preparers and contaminated utensils also may be a source of human infection. Wild boars can act as paratenic hosts (42). After ingestion, the immature flukes penetrate the intestinal wall and migrate to the lungs through the body cavity. All species are zoonotic, infecting carnivores, pigs, and rodents.

In the United States, autochthonous infection with P. kellicotti is becoming increasingly more common and native paragonimiasis is considered an emerging threat (39). Transmission is centered around the Mississippi Basin, where people are infected after eating undercooked crustaceans, especially crayfish.

Clinical Significance

Signs of infection include fever with dry cough, sometimes blood-stained sputum containing eggs, chest pain, dyspnea, and bronchitis, and symptoms sometimes resemble those of pulmonary tuberculosis. Peripheral blood eosinophilia is common. The flukes induce the formation of an epithelial cyst, measuring approximately 1 cm in diameter and which may calcify over time. Parasites may also occur in extrapulmonary locations, and serious complications occur when parasites are found in the brain. The necrosis of brain tissues and extensive granulomatous inflammatory response may induce symptoms similar to cerebral cysticercosis, caused by the cestode Taenia solium (23).

Collection, Transport, and Storage

Paragonimus eggs may be observed in sputum, feces, bronchoalveolar lavage (BAL) fluid, lung or pleural biopsy specimens, or surgical pleurectomy or lobectomy specimens (39) (see chapter 133). Serology is useful, as direct observations of eggs may lack sensitivity.

Detection

Diagnosis of paragonimiasis is largely dependent on observation of the eggs (19, 41) (Fig. 4) in sputum, feces, or pleural effusions. A cough with brown sputum is indicative of lung infection, and the sputum should be examined for eggs. The cysts formed around adult worms appear in X rays as characteristic rings or nodules, but direct observation of eggs is required to differentiate the disease from pulmonary tuberculosis. PCR-based methods have been developed in recent years, and though these are valuable research tools, their utility as routine diagnostic tests remains to be demonstrated (41).

Typing

Paragonimus species exist as a range of species complexes in regions of endemcity (42). While the species distinctions within a species complex has epidemiological significance, typing of species in a complex is of limited value for purposes of diagnosis or treatment and case histories are possibly most informative.

Serology

Serological tests include ELISAs using either 32- and 35-kDa antigens or parasite yolk ferritin as an antigen (23). Pleurisy with eosinophilia and dominant IgM antibody titer may be indicative of paragonimiasis (43). As P. kellicotti is an emerging zoonosis in North America, there is interest in improved serology testing for that species. Recently a Western blot serology test has been developed, based on whole adult worm extract of P. kellicotti as the antigen (44). Serology tests for paragonimiasis exist in the United States commercially and through the CDC.

Anthelminthic Susceptibility and Treatment

The current WHO recommendation for treatment is administration of praziquantel, administered at 25 mg/kg of body weight for 2 to 3 consecutive days. This treatment regime remains very effective, with the majority of patients in clinical trials being cleared of infection. Praziquantel confronts no protection against subsequent infection. Triclabendazole at 10 mg/kg or 20 mg/kg in two divided doses holds promise as a therapeutic alternative (4). The only means for prevention of infection is to cook crustacean food to at least 145°F (~63°C).

Trematodes of the Liver

At least 13 species of flukes, belonging to the families Fasciolidae, Opisthorchidae, and Dicrocoeliidae (45) (Table 2), have been recorded as adult worms from the liver and bile ducts of humans. Brief information on human dicrocoeliasis is provided in Table 2, but the reader is referred to other reviews (1, 46) for more information on the lancet flukes.
Taxonomy

**Family Opisthorchidae**

Of the opisthorchid parasites infecting humans (Table 2), only three species are of major significance, namely, *Opisthorchis viverrini*, *Opisthorchis felineus*, and *Clonorchis sinensis*. Adult opisthorchids of humans are macroscopic, flattened lanceolate flukes, approximately 5 to 10 mm in length.

**Family Fasciolidae**

Fascioliasis, caused by flukes of the genus *Fasciola*, is primarily a disease of herbivorous mammals. Two species are responsible for hepatic disease in humans, *Fasciola hepatica* and *F. gigantica*. Both species are macroscopic flukes over 2 cm in length, with *F. gigantica* being sometimes as long as 7 cm. The diseases caused by the two flukes are similar. The species differ in geographic distribution, with *F. gigantica* occurring in Africa and Asia and *F. hepatica* occurring in these continents as well as Europe, the Americas, and Oceania.

**Epidemiology and Transmission**

The life cycle information for opisthorchids and fasciolids is presented in Fig 2 and Table 2. In opisthorchids, the metacercariae are found encysted in the muscles of cyprinid fish (45), and fish of other taxa are not susceptible to infection. Thus, effective transmission to humans requires the colocation of

---

**FIGURE 4** Eggs of trematode parasites. (A) *Fasciolopsis buski* (magnification, ×500); (B) *Heterophyes heterophyes* (magnification, ×1,500); (C) *Clonorchis sinensis* (magnification, ×1,500); (D) *Opisthorchis viverrini* (magnification, ×1,500); (E) *Paragonimus westermani* (magnification, ×600); (F) *Nanophyetus salmincola* (magnification, ×750). (Panels B through D are from reference 19; used with permission.) doi:10.1128/9781555817381.ch146.f4
suitable snail and fish hosts. Individuals are infected by eating raw, seasoned, or undercooked fish (3).

Until recently, fascioliasis was considered a sporadic infection of humans, but it is now estimated that some 24 million people in 70 countries are infected, with 180 million at risk throughout the world (47). It has been calculated that fascioliasis causes 35,206 DALYs (40). The two causative species, *F. hepatica* and *F. gigantica*, have a worldwide distribution in domesticated animals; human disease is focal, and regions endemic for human fascioliasis are recognized (1, 23, 47).

Fasciolal metacercariae encyst on semiaquatic or moistened vegetation, predominantly watercress, grass, water mint, or salad vegetables (Fig. 2; Table 2). The frequency of the parasites in domesticated animals does not necessarily correlate with human disease. Areas of low endemicity in humans include regions of France (<3.1 cases per 100,000 people in Basse-Normandie) and Chile; regions of high endemicity are in Peru (15.64 to 34.2% in regions of endemicity and Bolivia (66.7% in the Bolivian altiplano) (47). Most of the areas with a high endemicity are regions where *F. hepatica* is present. While common zoonotic hosts are cattle and sheep, other hosts, such as pigs, equines, and rats, may serve as reservoir hosts for human infection. Children and young adults are more commonly infected than adults, suggestive of the presence of age-dependent immunity (48).

Clinical Significance
Disease severity varies among the different species (3) and with intensity of infection. *Clonorchis sinensis* infects approximately 35 million people in China, Hong Kong, India, North Korea, Siberia, Taiwan, and Vietnam (38). *Opisthorchis viverrini* infects about 10 million people in Thailand, Laos, and Cambodia, and *O. felineus* is widespread throughout Northern Europe and Asia, infecting about 1.5 million people (38). An estimated 349,737 DALYs have been attributed to liver fluke infections (40). All three species live in the bile duct and are thought to feed on biliary epithelia. Light infections are usually asymptomatic, but heavy infections can induce disease. Symptoms most commonly are associated with an acute phase of infection and may include fever, abdominal pain, hepatitis-like symptoms, and eosinophilia. A number of asymptomatic hepatobiliary abnormalities are associated with infection (49). Severe infestations with these liver flukes, which are rare, might cause obstructive jaundice, cirrhosis, cholangitis, cholecystitis, bile peritonitis, biliary obstruction, intrahepatic stone formation, cholelithiasis, biliary and liver abscesses, pancreatitis, and hepatitis. The most serious complication of infections with *C. sinensis* and *O. viverrini* is cholangiocarcinoma, the malignant bile duct cancer. *C. sinensis* and *O. viverrini* have been classified by the International Agency for Research on Cancer (IARC) as definitely carcinogenic (class 1) (50).

Many infections with fasciolid remain asymptomatic. Acute disease arises because of extensive tissue damage as parasites migrate through the hepatic parenchyma to gain access to the bile ducts. Parasite activity in the bile ducts leads to proliferation of ductal epithelium, inflammation, and fibrosis. Heavy infections can lead to cholestasis and result in hepatic atrophy and periportal cirrhosis (23). Common symptoms in chronic infection include biliary colic and cholangitis. Eosinophilia is common in all stages of disease.

Collection, Transport, and Storage
Diagnosis is made by detection of characteristic embryonated eggs in feces. Eggs of opisthorchids are minute and can be confused with those of intestinal digeneans. Serology can be useful, especially in cases where chronic infection, with low egg excretion, is suspected.

Detection
Eggs of opisthorchids (Fig. 4) are embryonated when laid and are oval, yellowish brown, and operculate, with a shoulder or thickened region of eggshell surrounding the operculum. The shell surface may appear rough and may have a small knob at the abopercular pole (45). The eggs are smaller than those of many other digeneans of humans, ranging from 20 to 35 μm in length. Opisthorchid eggs may be confused with those of other taxa, especially the heterophyids (see below). Differential diagnosis may be achieved by patient history, by examination via the formalin-ether concentration technique, and by examination of purged worms in feces after anthelmintic treatment. Recently, different PCR tests that detect and discriminate between fish-borne zoonoses caused by opisthorchids and members of the Heterophyidae were developed, based on mitochondrial (31) and ribosomal sequences (32).

The eggs of fasciolid are large compared with those of other digeneans (Table 2). *Fasciola* eggs cannot be distinguished from those of the related intestinal parasite *Fasciolopsis buski* (Fig. 4) and also resemble those of *Gastrodiscoides* (Table 3). Fasciolid eggs of individual species can also vary in morphology and size in different host species, complicating species identification in regions where more than one fasciolid is endemic (53). Detection of parasite antigen in stools is useful to distinguish between present and past infections (54). Molecular diagnosis methods, notably, tests based on loop-mediated isothermal amplification (LAMP), for detection of parasite nucleic acid in feces are promising alternatives.

Typing
A number of strains of fasciolid have been isolated. These isolates generally display reduced sensitivity to the anthelmintic triclabendazole, which remains a problem in livestock industries but not yet in human treatments (55).

Serology
Many antigen tests have been subjected to trials for *O. viverrini*, but most are plagued by cross-reactivity and persistence of antibodies after parasitologic cure (56). A coproantigen ELISA using monoclonal antibodies raised against adult *O. viverrini* excretory/secretory antigen has been developed and has displayed high specificity and sensitivity, whereas ELISAs for circulating antibodies show high sensitivity but low specificity (23).

Liver fasciolids have a long (2-month) prepatent period, and because of this, fascioliasis is one disease where serological diagnosis is valuable. Immunological tests, particularly ELISAs, based on parasite excretory/secretory antigens, cysteine protease or saposin-like antigens, display high sensitivity and specificity (57, 58). Commercial and government laboratories in many countries have serological tests for human fascioliasis, including a reference laboratory at the University of Puerto Rico.

Anthelmintic Susceptibility and Treatment
Treatment for clonorchiasis or opisthorchiasis relies on oral administration of praziquantel (25 mg/kg three times per day for up to two consecutive days is a dosage commonly used in hospitals, while a single oral dose of 40 mg/kg is
used for mass treatment programs). Recent proof-of-concept studies have shown that the Chinese anthelmintic tribendimidine possesses high activities against O. viverrini and C. smegsi, and hence further studies (including dose-finding and pharmacokinetic trials) have been launched (59).

Fasciola species are insensitive to praziquantel, and triclabendazole is the drug of choice (Table 2). There have been reports of triclabendazole-insensitive isolates in livestock (55). Artemether and artesunate have undergone trials for use in humans, but they have demonstrated only limited effect against Fasciola spp. (60).

Trematodes of the Intestine

Humans can serve as host to a wide variety of intestinal flukes. Summary information on some families of intestinal digeneans is presented in Table 3. Families Brachylaimidae, Diplostomidae, Gymnophallidae, Lecithodendridae, Microphallidae, Paramphistomatidae, Plagiorchiidae, and Strigeidae are rarely encountered in humans and are not considered further in this chapter. For further information on intestinal trematodes not provided here, the reader is referred to chapter 148 and to Fried et al. (61). Members of the families Echinostomatidae, Heterophyidae, Fasciolidae, and Troglotrematidae are commonly encountered in some countries and are discussed below.

Family Echinostomatidae

Echinostomatid flukes are small, typically 3 to 10 mm in length and 1 to 3 mm in width, with a large ventral sucker and distinctive collared spines. At least 24 species are known to parasitize humans, mostly in Asia (Table 3), for example, Echinocotrus japonicus, a common parasite of humans in Laos (62). All human infections by echinostomatids are zoonotic and focal in distribution, and foci are often in the vicinity of freshwater or brackish water habitats. Humans are infected by eating a range of raw or undercooked vertebrate and invertebrate foods, including snails (Table 3). In most cases, infection is asymptomatic. Heavy infections can lead to a range of symptoms including flatulence, colic, and diarrhea. Some heavy infections in children have been fatal. The eggs of echinostomatids are similar in shape to those of fasciolids but are smaller (Table 3). Interspecific variation in egg size occurs among the echinostomes, and species identification is not possible unless adult worms are obtained by purgation with anthelmintics. A single dose of praziquantel is recommended for treatment (63).

Family Fasciolidae

Fasciolopsis buski is the largest fluke parasitizing humans, measuring 8 to 10 cm in length and 1 to 3 cm in width (64). Adult worms inhabit the duodenum and jejunum of humans and a small range of other hosts that include pigs, horses, cattle, goats, and sheep. The species is distributed focally in many countries (Table 3). The snail intermediate hosts of F. buski are shown in Table 3. Humans are infected by eating aquatic plants on which metacercariae are encysted or by drinking metacercariae that have encysted on the water surface (61). Adults attach and feed on the intestinal wall. Human disease relates to the severity of infection, and symptoms vary from intestinal disturbance and pain, associated with eosinophilia, to severe diarrhea, gastric pain, bowel obstructions, and nausea. Feces are often profuse and yellow-green and may contain undigested food particles.

The eggs of F. buski are large, operculate, nonembryonated, ellipsoidal, and yellow (Table 3; Fig. 4). The eggs are very similar to those of other fasciolids from which species may be distinguished by observation of purged adults. The current drug of choice is praziquantel, but albendazole and mebendazole have also undergone trials (61, 63).

Family Heterophyidae

Many species of heterophyid trematodes are known to infect humans (61, 65). Heterophyids are mostly small parasites, less than 0.5 mm in length. Some species infect marine snails as intermediate hosts. Commonly encountered heterophyids of humans are Heterophyes heterophyes, Metagonimus yokogawai, and Haplorchis species. H. heterophyes infection in humans has been reported from many countries in Asia, North Africa, and the Middle East (61). Other species are often encountered in rural Asia (62).

The adult flukes are intestinal inhabitants of a wide range of piscivorous birds and mammals. Eggs (Fig. 4) are embryonated when passed from the host but do not hatch until ingested by a snail intermediate host (1). Cercariae encyst in a range of fish including mugilids, cyprinids, and gobids. Humans are infected by consumption of raw, freshly salted, or undercooked fish (Table 3). Disease symptoms in humans relate to infection intensity and arise because of parasite irritation of the intestinal mucosa. Eggs may on occasion pass into the bloodstream and lodge in tissues. These eggs have been known to cause fatal myocarditis in the Philippines (23). Diagnosis of heterophyids is facilitated by observation of eggs in feces (Table 3). Heterophyid eggs are similar in size to those of opisthorchiid liver flukes, and care must be taken to differentiate the infections. Often, this can be achieved only by examination of purged adult worms. The recommended treatment for heterophyid infection is a single dose of praziquantel (Table 3).

Family Troglotrematidae

This family of small oval flukes parasitize mammals, including humans. One species, Nanophyetus salmincola, found along the coastal U.S. Pacific Northwest, is found as metacercariae of salmonid fish. The species may be the most commonly encountered human trematode endemic to North America. Praziquantel is efficacious for nanophyetiasis.

REFERENCES

This chapter covers the less common causes of helminthic parasitic infections, particularly those caused by the less common nematodes and cestodes. The trematodes are discussed thoroughly in chapter 146. This chapter is not inclusive, given the wide variety of helminthic parasites that have been reported to cause human disease, but includes some of the most interesting and challenging of parasitic diseases. The reader who desires further information about these and other helminths of medical importance is directed to Pathology of Infectious Diseases, volume 1, Helminthiasis, by the Armed Forces Institute of Pathology (AFIP) (1) and the Centers for Disease Control and Prevention’s (CDC) parasitology website (http://www.cdc.gov/dpdx).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

The collection, transport, and storage of specimens are similar regardless of the type of helminth present, so these guidelines are consolidated here to reduce duplication. Worms present in the lumen of the gastrointestinal tract, such as Anisakis, can be retrieved by endoscopy. Surgical resection specimens may contain a worm or larvae. The intact worm and surgical specimens may be preserved and transported in 10% neutral buffered formalin. Stool is an important diagnostic specimen for parasites that reproduce within the intestinal tract, e.g., Capillaria philippinensis, and should be collected and fixed in a standard manner similar to that used for the detection of eggs and parasites (i.e., formalin and polyvinyl alcohol), if available. Alternative, mercury-free fixatives are also acceptable (2). Blood for serology should be handled in a standard manner. Additional information about serologic tests for the diagnosis of parasites covered in this chapter is also available through the CDC at http://www.cdc.gov/dpdx/HTML/Diagnostic Procedures.htm.

LESS COMMON NEMATODES

Anisakis and Related Species

Description of the Agents

Anisakis species (for which Anisakis simplex is the type species), Pseudoterranova decipiens, and Contracaecum species are nematodes of the family Anisakidae, superfamily Ascaridoidea, and class Secernentea.

Epidemiology, Transmission, and Prevention

The larvae of anisakids are present in many varieties of fish for which marine mammals are the definitive host; human infections occur if raw or poorly cooked infected fish is consumed (3). Fish that have been salted or pickled may still contain viable anisakid larvae. Similarly, the smoking of fish or marinating fish in lime juice (e.g., ceviche) does not reliably kill these parasites. Disease may be prevented by consuming only thoroughly cooked fish.

Clinical Significance

The clinical features vary depending on the stage of disease. Early, within 12 h of eating infected fish, patients experience nonspecific acute abdominal pain (4). At this phase, the larvae are associated with the superficial aspects of the mucosa. Superficial larvae may migrate up the esophagus and cause coughing, potentially with excretion of the worm. Additionally, intraluminal transit of the worm may result in mid- to lower abdominal pain, as the small intestine and colon are involved. More-severe symptoms occur if the worm penetrates through the mucosa into the submucosal and deeper tissues (Fig. 1). This evokes hypersensitivity, leukocytosis, and eosinophilia (5). Sudden, intense abdominal pain may be thought to represent appendicitis, acute gastritis, a gastric ulcer, or chronic colitis (e.g., Crohn’s disease) (6). Diarrhea and constipation may occur, and the stool contains occult blood. Immunoglobulin E (IgE)-mediated hypersensitivity reactions to anisakids have been described and include acute urticaria and anaphylaxis (7).

Direct Examination by Microscopy

The intact worms are white to cream, nonsegmented larvae that measure 10 to 50 mm by 0.3 to 1.2 mm. One dorsal and two subventral reduced lips and a triangular boring tooth are useful for identification. The mucron or tail spine is another useful feature for the identification of Anisakis larvae. Histopathologic analysis of infected tissues often demonstrates cross sections of the worm and the host inflammatory response, which contains numerous eosinophils. Cross-sectional studies are useful for identifying the type of anisakid present. Species-specific PCR assays or broad-range PCR assays with DNA sequencing will afford differentiation by molecular methods once the genetic variability that exists among these parasites is determined (9).

Serologic Tests

Serologic tests to detect the immunologic response to Anisakis and related species are available at commercial refer-
FIGURE 1 (top row, left) This *Anisakis* species (arrows) has penetrated into the deep tissues of the abdomen. Multiple cross sections of the worm, which is 300 μm in diameter, are seen in the omentum. Movat’s stain; original magnification, ×2.5. doi:10.1128/9781555817381.ch147.f1

Also note the presence of the two prominent bands of somatic muscle (long arrow). The worm diameter is 1.1 mm. Movat’s stain; original magnification, ×25. doi:10.1128/9781555817381.ch147.f5

FIGURE 6 (bottom row, right) The bipolar plugs (arrows), pitted eggshell, and rectangular shape are characteristic of *Capillaria* species. This photomicrograph is from a human small intestine and demonstrates an egg that is 40 μm long. Hematoxylin and eosin stain; original magnification, ×490. doi:10.1128/9781555817381.ch147.f6
ence laboratories in the United States. Although these tests are not currently performed at the CDC, that institution may be contacted for assistance in locating a commercial laboratory that may perform this test, if necessary. A variety of serologic assays have been developed, but they vary in sensitivity and specificity. These assays identify 85 to 90% of infected individuals, with a demonstrable serologic response occurring from 10 to 35 days postinfection. The specificity of these assays suffers from cross-reactivity with other ascarids. However, this cross-reactivity may be desirable to detect related species, e.g., *Pseudoterranova*, but may limit the utility of this assay in certain populations, such as those who are likely to have or have been infected with intestinal ascarids. Conversely, more-specific assays have been devised to detect *Anisakis*, but these, unfortunately, do not detect the related species that may cause "anisakiasis" in the broadest sense (i.e., anisakidosis).

**Treatment**
Removal of the larva via endoscopy while it is associated only with the superficial mucosa is the most efficacious treatment. Surgical resection, however, may be needed for more deeply insinuated larvae (9). Anthelmintic drugs do not appear to be useful, but corticosteroids may be used to decrease the associated inflammation.

**Trichinella Species**

**Description of the Agents**
*Trichinella spiralis* is the most important cause of human disease in this genus, but other species, such as *Trichinella pseudospiralis* and *Trichinella britovi*, also cause trichinosis (10). *Trichinella* species are nematodes of the family Trichinellidae and class Adenophorea.

**Epidemiology, Transmission, and Prevention**
Trichinosis occurs worldwide (11). The life cycle of *T. spiralis* is different from that of other nematodes in that the infected mammal that first serves as the definitive host for the parasite also harbors infective larvae encysted within muscle (i.e., the intermediate host) (Fig. 2) (10). The domestic pig is the most important host for the transmission of this roundworm to humans, but the meat of bears, walruses, and other wild game may also contain infective larvae. The ingestion of wild game poses the greatest risk for infection in countries with strict animal husbandry regulations. The parasitic cycle is propagated in the barnyard between pigs and rodents. Disease may be prevented by eating only thoroughly cooked meat products of potential hosts and by attempting to control trichinosis in these hosts through good animal husbandry practices.

**Clinical Significance**
Infections vary from mild, subclinical disease to severe illness, depending upon the parasite load. The clinical manifestations vary with the stage of infection. Gastrointestinal symptoms, associated with adult worms, last only about a week and include nausea, vomiting, abdominal pain, and diarrhea. Fever, facial edema that is particularly predominant around the eyes, myalgia, and marked peripheral eosinophilia are the four cardinal features of trichinosis. The major clinical findings extracted from 5,377 well-documented cases were myalgia, diarrhea, fever, facial edema, and headaches (11). If larval migration involves the brain and meninges, then neurologic symptoms predominate, whereas involvement of the myocardium causes myocarditis and possibly arrhythmias or sudden cardiac death. Unlike skeletal muscle, the larvae do not encyst in these other tissues.

**Direct Examination by Microscopy**
The direct microscopic examination of a muscle biopsy sample, performed by simply compressing the fresh muscle fibers between glass slides and observing the specimen microscopically, may disclose larvae. More commonly, larvae are detected by histopathologic analysis of formalin-fixed, paraffin-embedded tissue sections (Fig. 2).

**Nucleic Acid Detection Techniques**
Although nucleic acid amplification assays have been developed for *Trichinella spiralis*, the clinical utility of these assays has yet to be determined. They are, however, tools for assessing the prevalence of infections in domestic pigs, as well as in wildlife (12, 13).

**Serology**
The antibody response begins 3 to 5 weeks after infection in 80 to 100% of patients and follows the acute phase of disease. Therefore, the conversion from a negative serologic test during acute illness is evidence of disease. The tests are highly sensitive, and although they are less than 100% specific, cross-reactivity usually results in test values in the equivocal range. These tests are available at the CDC and from several commercial laboratories.

**Treatment**
Therapy varies according to the stage of disease. Thiabendazole or albendazole is active against the intestinal worm but not against the encysted larvae. There is no proven method to kill the encysted larvae. Well-controlled therapeutic studies are lacking. Corticosteroids, salicylates, and antihistamines may lessen symptoms caused by the associated inflammation.

**Toxocara Species**

**Description of the Agents**
*Toxocara canis* is the intestinal ascariid of dogs and other canids, whereas *Toxocara cati* is the intestinal ascariid of cats. Although larvae of both species can cause toxocariasis in humans, most infections are caused by *T. canis* (14). *Toxocara* species are in the family Ascarididae and the class Secernentea, within the phylum Nemathelminthes.

**Epidemiology, Transmission, and Prevention**
Toxocariasis has a worldwide distribution, but the prevalence of zoonotic disease varies widely by geographic area. The seroprevalence of human disease reflects helminthic control in dogs and cats. The highest infection rates occur among the poor, and there is an association with dog ownership (15). The natural cycle of *Toxocara* begins with the hatching of unembryonated eggs in the feces of the definitive host. The adult female worm passes a large number of eggs per day; therefore, one instance of stool contamination of the environment, such as in a sandbox, can cause significant contamination. The L2 (i.e., second-stage) larvae develop in the eggs after 10 to 20 days of incubation in the soil; the eggs at this stage are infective. If the eggs are ingested by a suitable definitive host, then the larvae penetrate the intestinal tract and migrate through the liver, bloodstream, and lungs. The larvae then migrate up the respiratory tract, are swallowed, and mature into adult worms in the intestinal tract. Paratenic hosts (e.g., rabbits) may also participate in the life cycle by harboring infective larvae after egg inges-
Eggs are not produced in humans in toxocariasis, so a stool examination is not helpful for diagnosis. However, occasionally the eggs of another geohelminth, such as Ascaris, hookworm, or Trichuris, may be present because of common risk factors. The detection of the migrating larvae in surgically excised tissues by histopathologic evaluation provides the definitive morphological diagnosis, but larvae are not always present in biopsy specimens. When present, the single minute lateral ala and the cross-sectional diameter are useful criteria for identifying these parasites in histologic sections (Fig. 3) (19).

Serologic Tests

Serologic studies are important for the establishment of the diagnosis of toxocariasis; results of these should be used in conjunction with clinical findings as well as other laboratory findings, such as increased IgE and eosinophilia (20). Positive results in the absence of other corroborative findings could represent a previous, asymptomatic infection. The sensitivity and specificity of these assays are high but less than 100%. It is difficult to determine the precise parameters of serologic assays, since there is not a better parasitological test (i.e., a gold standard) to confirm the presence of a true infection. These tests have also been used successfully in seroepidemiologic studies. Tests are available at the CDC and from commercial reference laboratories.

Treatment

There is no proven therapy. Anthelmintic therapy with albendazole or a similar therapeutic is often used. Corticosteroids may be necessary to control the inflammatory response in patients with a large parasite burden. Eye infections require a combined medical and surgical approach (21).

**Dracunculus medinensis**

*Description of the Agent*

*D. medinensis*, also known as the Guinea worm, is not a filarial worm but rather a member of the family Dracunculidae, which is in the class Secernentea of the phylum Nematodirina (23). Other *Dracunculus* species that infect a variety of other animals exist but do not cause human disease.

**Epidemiology, Transmission, and Prevention**

Dracunculiasis is found only in the rural parts of Africa. Disease occurs more commonly in the dry season and affects men more commonly than women. It is most common in individuals from 10 to 60 years old, which taxes the productivity of affected communities. An intensive effort by the World Health Organization, local governments, and numerous other humanitarian organizations has significantly decreased the annual incidence of disease (23). Updates and additional information are available from the WHO and CDC at their respective websites (http://www.who.int/topics/dracunculiasis/en/ and http://www.cdc.gov/parasites/guineaworm/). Significantly, there were no cases reported in January 2013, which was the first zero-case month in the history of the eradication program. At the beginning of this program (1986), an estimated 3.5 million people in 20 countries were affected. The annual incidence of worldwide disease was diminished by an astounding 98% by December 2001, and seven countries completely eradicated the disease. Substantial progress continues to be made to eradicate this disease. These substantial efforts have led to only 542 reported cases in 2012. The eradication of a devastating disease may be near at hand, but continued vigilance is necessary.

Infection follows drinking contaminated freshwater that contains copepods, which harbor the infective larvae. After ingestion, the larvae migrate to the retroperitoneum, where they mature and mate. The female worm eventually migrates to a subcutaneous location, where a blister forms, which bursts upon contact with water and releases numerous larvae. The larvae are ingested by a copepod, wherein they become infective. Preventive measures are centered on education and providing clean drinking water (26, 27). There are current challenges to provide clean drinking water in parts of South Sudan and Mali due to lack of security (23). Clinical Significance

Patients are asymptomatic during larval penetration of the gastrointestinal tract and retroperitoneal maturation and mating of the worms. Symptoms are secondary to inflammation and tissue damage caused by worm migration. Although lesions are most common in the lower extremities, they may occur anywhere in the body. A serpiginous tract is produced, which is caused by the migrating worm under the skin (Fig. 4). The large blister that is formed may become secondarily infected. Dead worms may be absorbed, calcify, or produce symptoms secondary to location (e.g., arthritis due to location within a joint).

**Direct Examination and Microscopy**

The presence of the end of a worm protruding from a burst blister or ulcer in the appropriate setting is diagnostic. The microscopic analysis of these worms in cross section demonstrates a 30- to 50-μm-thick cuticle, indistinct lateral cords, prominent dorsal and ventral bands of smooth muscle, and a large uterus filled with rhabditoid larvae that fills the body cavity (Fig. 5).

**Serologic Tests**

Serologic tests are usually not necessary for the diagnosis, given the obvious findings in people at risk for disease. They are, however, useful for seroprevalence studies and to identify infected individuals prior to the partial emergence of the adult worm.

**Treatment**

The oldest and traditional treatment, as depicted in an ancient Egyptian medical text, the *Papyrus Ebers*, consists
of removing the gravid worm by wrapping the exposed end of the worm around a stick and applying gentle pressure for days. Treatment with thiabendazole and mebendazole, although not lethal for the worm, facilitates removal by this process (26). Although it is often effective, risks include rupture or breaking of the worm prior to full removal. Currently, surgical excision is preferred (27). Anti-inflammatory agents and antihistamines are important for symptomatic relief. Antibiotics may be necessary to curtail secondary bacterial infections, and tetanus vaccination is important.

**Capillaria philippinensis**

**Description of the Agent**

*Capillaria philippinensis* is a trichurid nematode responsible for intestinal capillariasis (22, 28). *Capillaria* species are in the family Trichuridae of the class Adenophorea.

**Epidemiology, Transmission, and Prevention**

The natural parasitic cycle of *C. philippinensis* likely involves marine, fish-eating birds as the definitive hosts and fish as the intermediate hosts. Humans become infected by ingesting raw or undercooked fish that harbor the infective larvae. Larvae at various stages of maturation may be found in the lumen of the intestine of the definitive host or the patient. Therefore, the population of parasites within the lumen of the bowel may increase (hyperinfection) without the consumption of additional contaminated fish. Thorough cooking of fish is protective.

**Clinical Significance**

Infections with *C. philippinensis* are relatively rare; 82 patients with intestinal capillariasis were reported in Thailand from 1994 to 2006 (29). Rarely, because intraintestinal hyperinfection is possible, infections may be fatal. Nonspecific gastrointestinal complaints predominate early in the course of disease; these include watery diarrhea, weight loss, abdominal pain, edema, and weakness (29). As the disease progresses and the number of worms increases, there is continued diarrhea with malabsorption leading to cachexia (24). Endoscopy may be useful for establishing the diagnosis, but stool examination remains the diagnostic test of choice (25). Death occurs secondarily to malnutrition or because of secondary bacterial infections (e.g., septicemia).

**Direct Examination by Microscopy**

Microscopic examination of the stool may demonstrate a mixture of eggs and larvae. The eggs of *C. philippinensis* (Fig. 6), which have bipolar plugs, are superficially reminiscent of the more commonly recognized trichurid worm, *Trichuris trichiura*. The plugs of *C. philippinensis*, however, are nonprotruding, the egg is more rectangular, and there is a distinctive pitting of the eggshell (30). The adults superficially resemble *Strongyloides stercoralis* but may be differentiated by the presence of stichocytes and three bacillary bands, with the latter being recognized most easily in cross section.

**Serologic Tests**

Serologic tests are not available from the CDC or from commercial reference laboratories in the United States. An enzyme-linked immunosorbent assay for the screening of sera for antibodies directed against *C. philippinensis* has been developed and holds promise (31). This assay is particularly useful in infected patients who are negative by conventional stool examination. The sensitivity of the assay is excellent (100%), with a moderate specificity that is limited by cross-reactivity in patients with trichinellosis, strongyloidiasis, trichuriasis, and infections by other helminths.

**Treatment**

Albendazole, mebendazole, or thiabendazole may be used for therapy. Relapsing disease requires prolonged anthelmintic therapy. Aggressive electrolyte replacement and monitoring are critical, as are control of diarrhea and administration of nutrients.

**Gnathostoma Species**

**Description of the Agents**

*Gnathostoma* species are gastric spirurid nematode parasites for which the definitive hosts are a variety of mammals (32). Infective L3 (i.e., third-stage) larvae are known to cause disease in humans, but it is also thought that L2 (i.e., second-stage) larvae encountered in infected copepods in unclean drinking may also cause disease. Gnathostomiasis may be considered a subtype of visceral larva migrans. *Gnathostoma spinigerum* is the most common cause of human disease, but *Gnathostoma hispidum*, *Gnathostoma nipponicum*, and *Gnathostoma doloresi* may also cause human disease. *Gnathostoma* species belong in their own family, Gnathostomatidae, of the class Secernentea.

**Epidemiology, Transmission, and Prevention**

*Gnathostoma spinigerum* has essentially a worldwide distribution. Dogs and cats are the primary definitive hosts for this gnathostome, whereas *G. hispidum* and *G. doloresi* infect wild and domestic pigs and *G. nipponicum* is a parasite of weasels. The adult male and female gnathostomes live in a tumor produced in the wall of the stomach of the definitive host, where they mate and produce eggs. The eggs are passed in the stool, and once in water, they hatch and release first-stage larvae. The larvae then infect and mature into second-stage larvae within the copepod Cyclops. When a variety of intermediate hosts, such as fish, snakes, eels, or frogs, eat the copepod, the larvae penetrate the gastric wall of the new host, wherein they develop into third-stage (L3) larvae, migrate to the musculature, and encyst. If an appropriate definitive host eats the intermediate host, the advanced L3 larvae excyst and penetrate the gastric wall. The L3 larvae then migrate through the liver, muscles, and connective tissues, only to return to the stomach and mature into adults. Alternatively, paratenic hosts, such as birds, may eat the second intermediate host; the L3 larvae ingested remain viable within the paratenic host, which may pass them on either to the definitive host or to humans.

Humans are accidental hosts in which the nematode larvae cannot mature to adulthood and continue to migrate aimlessly and aggressively (32). The parasite is transmitted to humans through the ingestion of raw or undercooked meat from a secondary intermediate host or a paratenic host. Disease can be prevented by thoroughly cooking potentially infected foods.

**Clinical Significance**

The clinical presentations of gnathostomiasis are protean, –36). Although the infection is not commonly fatal, significant morbidity may be associated with infection. The clinical manifestations depend on the tissues in which the larva is migrating. Panniculitis, creeping eruptions, and pseudofurunculosis are dermatologic manifes-
tations of gnathostomiasis (34). Any visceral organ may be
affected, and although Gnathostoma is not neurotropic, the
eyes and central nervous system (CNS) may be involved
(35, 36).

Direct Examination and Microscopy
Mature (adult) gnathostomes are not present in humans,
but the L3 larvae are. This form is morphologically similar
to the adult form but is smaller, measuring 3 to 4 mm in
length by 630 μm in diameter (G. spinigerum). The head
bulb contains four rows of cephalic hooklets, with approxi-
mately 45 hooklets per row. The body of the larva, like that
of the adult, is covered with transverse rows of sharply
pointed spines that diminish toward the posterior end of
the worm. An entire worm may be expelled spontaneously
or may require surgical excision.

Serologic Tests
Serologic assays have been developed predominantly in
areas of endemicity. These are not available in the United
States, but the CDC can assist in identifying a source for
testing, if necessary. The possibility of cross-reactivity should
be considered with these tests, as well as other serologic
assays for helminthic parasites. Like any test, they should
be used only in the appropriate clinical context.

Treatment
Surgical removal of the parasite is the most effective treat-
ment but is difficult to achieve due to parasite migration;
this may be aided by advanced imaging tools (37). Treat-
ment usually involves some type of anthelmintic medicati-
on, such as albendazole or ivermectin. There remains con-
troversy regarding the treatment of CNS gnathostomiasis,
wherein there is a concern that anthelmintic therapy will
kill the invading worms and increase the inflammatory reac-
tion; treatment is supportive and may include corticosteroid
use to control the inflammatory response (38).

Parastrongylus (Angiostrongylus) Species

Description of the Agent
Parastrongylus cantonensis and P. costaricensis are filariform
worms that are the most important causes of angiostrongy-
liasis (38). This parasite is also commonly referred to by
the former genus name, Angiostrongylus. Parastrongylus
belongs to the family Angiostrongylidae and the class
Secernentea.

Epidemiology, Transmission, and Prevention
Parastrongylus spp. are widely distributed throughout the
world but represent an important public health threat in
Southeast Asia, the Asian Pacific Islands, Africa, and the
Caribbean. These parasites persist in a wide variety of
rodents, which serve as the definitive host. The adult
worms Parastrongylus cantonensis reside in the pulmonary
artery and the right side of the heart of the rodent,
whereas the adult form of P. costaricensis resides in the
ileum. Eggs released from the adult worms lodge in
capillaries, where they hatch and release larvae. The larvae
subsequently migrate up the trachea (P. cantonensis)
and are swallowed and passed in the feces. These larvae
infect mollusks, particularly snails and slugs that are the
intermediate host. Within the snail, they mature into the
infective L3 larvae. A number of animals, including
shrimp, crabs, fish, and frogs, may eat the infected mollusks
and serve as important paratenic hosts. Rodents that
ingest either the infected mollusk or tissues from the
paratenic host thereby become infected. In the definitive
host, the infective larvae penetrate the intestine, become
blood borne, and migrate to the CNS, where they molt
twice. Thereafter, the worms reenter the systemic circu-
lation and finally reside in either the right ventricle and
pulmonary artery (P. cantonensis) or the ileum (P. costari-
censis) to mature and complete the cycle. Humans become
infected through the ingestion of tissue from either an
infected mollusk or an infected paratenic host or through
excretions from snails or slugs (i.e., slime) that contaminate
other foodstuff (e.g., vegetables). Prevention of disease can
be achieved through control of the local rat population, the
thorough cooking of mollusks and meat from paratenic
hosts, and the washing of vegetables that may be contami-
nated with snail or slug slime.

Clinical Significance
The clinical manifestations reflect the worm burden and
the site of worm residence, the CNS for P. cantonensis and
the ileocecal region for P. costaricensis. The worms of P.
cantonensis remain juvenile, tend to remain associated with
the brain and meninges in human infections (Fig. 7), and
usually die in this location. Conversely, P. costaricensis often
reaches sexual maturity and releases eggs in the intestine.
Patients with CNS disease demonstrate signs and symptoms
typical of meningitis or meningocerebritis, with headache,
fever, possibly eosinophilia (10 to 60%), and any of a number of neurologic disturbances, depending on the
location of the worms. The cerebrospinal fluid (CSF) dem-
onstrates pleocytosis, eosinophilia (26 to 75%), and elevated
protein and occasionally contains immature worms. Alter-
natively, patients may have infections of the eye, with reti-
nal detachment and blindness. Less commonly, human in-
fections may result in pulmonary disease. Infections with
P. costaricensis result in eosinophilic enteritis with diarrhea
and abdominal pain.

Direct Examination and Microscopy
Demonstration of the worms in histologic sections or intact
in clinical specimens from the CSF, eye, or other infected
tissue definitively establishes the diagnosis. Eosinophilia in
the CSF may be the first indicator of a possible parasitic
infection of the CNS. The differential diagnosis of the causes
of CSF eosinophilia, however, is broad and includes other
parasitic infections, e.g., with Gnathostoma or Toxocara spp.,
alergic reactions, and coccidioidomycosis. The gross ap-
ppearance of an adult female worm is distinctive, with the
spiral winding of the uteri and ovarian branches imparting
a “barber pole” appearance. Cross section of the female
demonstrates a large intestine and two uteri, whereas cross
section of the male reveals a large intestine and a single
reproductive tube. Eggs are not produced in human tissues
by P. cantonensis, whereas they may be produced by P.
costaricensis. The eggs of P. costaricensis remain embedded
in tissue in the human host and do not appear in stool.
The eggs are oval, thin shelled, somewhat resembling a
hookworm egg, and usually measure 60 to 65 by 40 to
45 μm.

Serologic Tests
Serologic assays are powerful tools for the diagnosis of angio-
strongyliasis, particularly since P. cantonensis is usually lo-
cated in a difficult-to-access location, the CNS. The sero-
logic assays that have been developed vary with respect to sensitivity and specificity, so it is important that the user understand the performance characteristics and the limitations of the assay under consideration (39). Although intrathecal antibody is not always produced during infection, when detected, the presence of intrathecal antibody synthesis provides strong evidence of infection. This assay is available from some commercial laboratories in the United States.

Treatment
The optimal treatment has not been established. Fortunately, the disease is often self-limited. Removal of CSF and the administration of corticosteroids and nonsteroidal anti-inflammatory agents have been used to control pain and inflammation. A variety of anthelmintic medications have been used, with mebendazole being the current drug of choice. Careful monitoring of the patient is important, since anthelmintic therapy may sometimes exacerbate the symptoms (40). Corticosteroids may be used alone or in combination with anthelmintic therapy (40).

**Dirofilaria immitis and Other Dirofilaria Species**

**Description of the Agents**
*Dicrofilaria immitis*, the filarial dog heartworm with worldwide distribution, causes human pulmonary dirofilariasis (40). There are a variety of other *Dicrofilaria* species that may accidentally infest humans. For example, *Dicrofilaria tenuis*, a raccoon parasite common in the southeast United States, *D. ursi* infects bears in the northern United States and Canada, and *Dicrofilaria repens* is a dog parasite restricted to the Old World (41, 42). *Dicrofilaria* species belong to the family Onchocercidae in the class Secernentea.

**Epidemiology, Transmission, and Prevention**
Although dogs are the most important host for *D. immitis*, other mammals, such as fox and bear, are also suitable hosts. The blood of infected dogs or other suitable hosts contains microfilariae that are released from the adult worm, which resides in the right ventricle of the heart. These are taken into the mosquito during a blood meal, wherein they mature into infective L3 larvae and are capable of being transferred to another mammal during a blood meal. The larvae migrate through subcutaneous tissues and eventually enter the bloodstream and the right side of the heart, wherein they mature into adults in a permissive host. Humans, however, are unsuitable or nonpermissive hosts. In humans, the worm dies before it reaches maturity and is swept into the pulmonary arterial circulation. It subsequently becomes lodged in the subsegmental pulmonary arteries and arterioles and causes thrombosis, infarction, inflammation, and eventually a granulomatous reaction surrounded by a wall of fibrous tissue (Fig. 8).

The geographic distribution of disease reflects the prevalence of canine dirofilariasis. The areas of highest prevalence in the United States are in the South, particularly along the Gulf and Atlantic coasts and along the Mississippi River (43). Interestingly, dog ownership is not a risk factor for disease. Prevention is centered on the control of zoonotic disease. The use of mosquito repellents, particularly in areas of high endemicity, is also recommended to interrupt transmission.

**Clinical Significance**
Slightly more than one-half of the patients with dirofilariasis are asymptomatic. The remainder have nonspecific symptoms, such as cough, chest pain, hemoptysis, low-grade fever, chills, and malaise (44). Only 5 to 10% of infected patients have peripheral blood eosinophilia. In addition to pulmonary manifestations, *D. immitis* has also rarely been identified in subcutaneous abscesses, the abdominal cavity, the eyes, and the testes. *Dicrofilaria* species other than *D. immitis* are more likely to be found in a subcutaneous location (Table 1). Pampligione et al. undertook a critical review of human pulmonary dirofilariasis in the Old World and suggested, based on traditional morphologic findings, that the cause of pulmonary dirofilariasis in these geographic regions may more likely be due to a *Dicrofilaria* species other than *D. immitis*, namely *D. repens* (45). The nodules caused by *D. immitis* are often discovered by a routine chest radiograph and must be excised in most instances to exclude malignancy (43). These nodules are usually single, but occasionally two or three nodules may be present.

**Direct Examination and Microscopy**
The pulmonary nodules produced by *D. immitis* are characteristically small (0.8 to 4.5 cm; mean, 1.9 cm), subpleural, spherical, and well circumscribed. *Dicrofilaria immitis* has a smooth, thick cuticle (5 to 25 μm) with the three distinct layers characteristic of the genus *Dicrofilaria*; other *Dicrofilaria* species that infect humans have a similar cuticle, but with external longitudinal ridges (Fig. 9 and 10). The thick, multilayered cuticle projects inwardly at the lateral chords, forming two prominent, opposing internal longitudinal ridges. The somatic musculature is typically prominent, but the lateral chords are usually poorly preserved. Transverse sections may reveal two large uteri and a much smaller intestine in female worms (Fig. 9); a single reproductive tube and an intestine are present in males. The definitive identification of the worm based on internal structures may be difficult or impossible, given the advanced stage of parasite degeneration in many of these specimens. The presence of a parasitic worm in a pulmonary artery and in association with a pulmonary infarct, however, is usually sufficient for a diagnosis.

**Serologic Tests**
Serologic tests to detect antibody to *Dicrofilaria* are commercially available from several reference laboratories. Although advances have been made to increase specificity without sacrificing sensitivity, cross-reactivity may occur in patients infected with other nematodes, particularly other filarial worms. As with many serologic assays, a positive test is useful, whereas a negative test does not exclude the possibility of infection.

**Treatment**
Excision of the nodule is curative. Additional antiparasitic therapy is not necessary.

**Other Less Common Nematodes**
There are a number of less common nematodes other than those described here. Some of these and their important associated features are included in Table 1.

**LESS COMMON CESTODES**
Descriptions of some less common cestodes are given below and in Table 2.
Dipylidium caninum

Description of the Agent
Dipylidium caninum, a common tapeworm of dogs and cats, also commonly infects children (46, 47). Dipylidium belongs to the family Dipylidiidae, the order Cyclophyllidea, and the class Cestoidea (Cestoda).

Epidemiology, Transmission, and Prevention
Dipylidiasis occurs throughout the world. This disease, like hymenolepiasis, is transmitted primarily through the ingestion of an infected flea. In the natural cycle, the dog or cat contains the intestinal adult parasite, which releases gravid proglottids filled with eggs. The eggs are ingested by fleas or lice, which are the intermediate hosts. The eggs hatch within the intermediate host, releasing larvae that penetrate the body cavity, where they mature into infective cysticercoid larvae. When an infected intermediate host is ingested or lice, which are the intermediate hosts. The eggs hatch within the intermediate host, releasing larvae that penetrate the body cavity, where they mature into infective cysticercoid larvae. When an infected intermediate host is ingested, the cysticercoid metacestode larva attaches to the small body cavity, where they mature into infective cysticerci.

Clinical Significance
Dipylidiasis is usually an innocuous infection. Larger worm burdens may cause weight loss, abdominal pain, failure to thrive, or the appearance of colic, but such severe disease is uncommon. Disease usually comes to the attention of parents and pediatricians when motile, gravid proglottids are seen in the stool.

Direct Examination by Microscopy
The proglottids of D. caninum resemble a rice grain on gross examination. These differ from those of most other cestodes in that they have two genital pores (dipylos means two gates), which can be appreciated with the use of a dissecting microscope and by compressing the proglottid between two glass slides. The identification may also be achieved by the cycle. This maturation to the adult tapeworm occurs in the more common animal hosts, such as dogs and cats, but also occurs in humans. Prevention is achieved by deworming animals and controlling fleas and lice.

4Praziquantel is the treatment of choice for infections with adult tapeworms; it is also effective for treatment of coenurosis. Effective preventive measures center around controlling disease in the zoonotic host (e.g., cats or dogs) or controlling the zoonotic hosts themselves (e.g., rats). Controlling intermediate hosts is also effective but may prove more difficult.

*This parasite is covered in detail in chapter 145 in this Manual.

demonstrating the characteristic egg packets (Fig. 11) and/or characteristic eggs that have distinct morphological features (i.e., four envelopes). A fecal examination is likely to be negative for eggs or egg packets, since intact proglottids are usually passed in the stool. Microdissection or histologic examination of the proglottids reveals the eggs and egg packets. In addition to the egg packets, the histologic examination of the proglottid reveals other features common to cestodes, such as a tegument, smooth muscle, and calcareous corpuscles.

Serologic Tests
Serologic tests are not usually performed, since the disease is usually subclinical and unsuspected and the diagnosis is achieved when the proglottids are discovered and examined.

Treatment
Both praziquantel and niclosamide are effective against D. caninum. Upon discovery, examination and treatment of household pets should proceed, as should aggressive flea control.

Sparganosis  Description of the Agents
Sparganosis is the infection of humans by L3 plerocercoid larvae of a pseudophyllidean tapeworm (48). The plerocercoid larva in a human host does not reach maturity and is known as a sparganum. The tapeworms that cause sparganosis are Spirometra mansoni, Spirometra mansonioides, Spirometra ranarum, and Spirometra erinacei. The precise taxonomic relationship of a cestode known as Sparganum prolierum is unclear, but this organism may simply represent a variant of S. mansonioides or S. erinacei. Spirometra species belong to the family Diphyllobothriidae, the order Pseudophyllidea, and the class Cestoidea (Cestoda).

Epidemiology, Transmission, and Prevention
Adult Spirometra species are widely distributed tapeworms of animals, particularly dogs and cats. The parasitic cycle for these worms begins with the passage of eggs from an infected suitable host. The coracidium that emerges from the egg infects the first intermediate host, a copepod. The...
second intermediate host, which includes snakes, frogs, and fish, becomes infected by ingesting the infected copepod. The cycle is completed when a permissive (i.e., definitive) host ingests the second intermediate host. Humans are non-permissive hosts and may become infected by ingesting raw or undercooked meat from a second intermediate host or by drinking contaminated water that contains the infected copepod Cyclops. Humans have also become infected by using infected animal flesh (e.g., frog flesh) as a poultice.

Clinical Significance
The results of ingesting a plerocercoid larva depend on both the species of the host and the species of the larva. For example, the ingestion of a plerocercoid larva of Diphyllobothrium latum by a human results in the development of an adult tapeworm, whereas the ingestion of a plerocercoid larva of a Spirometra species results only in the continued existence of the larva (i.e., the sparganum) in the new host (49). This is a situation wherein the human is behaving biologically like a second intermediate or paratenic host. The clinical features of disease are influenced by worm burden (most patients harbor only a single worm), worm location, and worm viability. Sparganate migrate, but this migration usually does not cause symptoms. Migration to a subcutaneous location, however, may result in a nodule. This nodule may be excised to exclude the possibility of malignancy. Ocular sparganosis, particularly involving the conjunctiva, may result following the application of a folk medicine poultice that contains raw snake or frog tissues. Inflammation and sometimes calcification ensue following death of the sparganum, and when these occur in the brain, they may cause obstructive hydrocephalus (36).

Direct Examination and Microscopy
The spargana of Spirometra species are flat, ribbon-like worms that superficially resemble adult tapeworms (Fig. 13). Closer inspection demonstrates an immature anterior end without hooklets; a cleft or ventral groove, termed a bothrium, is present (Fig. 13) (50). Mature proglottids are not produced. Histopathologic examination of the sparganum demonstrates calcareous corpuscles characteristic of a cestode. Developed internal organs are not seen, but rather, irregularly scattered smooth muscle fibers and excretory ducts are seen in a loose stroma.

Serologic Tests
If the diagnosis is not suspected, it is usually made when a viable sparganum is unexpectedly discovered during surgery. The gross findings are largely diagnostic, but histopathologic examination can be used for confirmation. In such instances, serology is not useful. However, if this disease is clinically suspected, the diagnosis may be achieved through the combination of radiology and serology (51). Serologic tests for Spirometra are not commercially available, so one may have to send sera to specialized centers.

Treatment
Medical therapy is currently deemed unsuitable for the treatment of sparganosis; the plerocercoid larva is resistant to praziquantel. Complete surgical excision is recommended. An incomplete excision, particularly if the anterior end of the larva remains in the tissue, may result in continued growth of the organism (1).

SUMMARY
There are a wide variety of less commonly encountered helminthic parasites, which may be nematodes, cestodes, or trematodes. The diseases caused by these parasites are interesting and demonstrate their highly evolved life cycles and the complex interactions with their hosts. These diseases range from subclinical, e.g., dipyldiasis, to possibly life threatening, e.g., baylisascariasis. In many instances, the disease occurs only in a particular geographic area, which is largely determined by the biological ranges of the definitive and intermediate hosts. Dietary customs are also important in the prevalence of human disease, as many of these are associated with the ingestion of raw animal products. The treatment of these parasites varies depending on the infectious agent, but common preventive measures may significantly diminish the transmission of many of these parasitic diseases. These measures include the zoonotic control of parasitic disease in animal hosts and the vectors of transmission, washing of fruits and vegetables, access to clean drinking water, and thorough cooking of meats before consumption.

REFERENCES

Arthropods comprise a diverse group of invertebrate animals (Fig. 1), united in a common body theme (bauplan) of a jointed, chitinous exoskeleton. Four major groupings have classically been recognized: insects, arachnids, crustacea, and millipedes/centipedes; a fifth group contains only a living fossil, the horseshoe crabs, which have existed unchanged for hundreds of millions of years. All arthropod classes were extant hundreds of millions of years ago, thereby providing ample opportunity for life history traits such as parasitism to independently evolve, and evolve multiple times, in each class.

Medically important arthropods have long been considered to comprise mainly ectoparasites, parasites that limit their activities to the skin. Parasitism, however, is only one of several associations that constitute the interaction of arthropods of medical importance with humans. Arthropods may actively defend themselves against predation (crushing or swatting) by biting, stinging, piercing, or secreting noxious chemicals. Such defenses would operate regardless of the attacker, be it human or other arthropod. Passive modes of defense may inadvertently affect humans, such as irritation after brushing the urticarial hairs of certain caterpillars. Arthropods may also be medically important due to indirect effects: fear of insects, delusional parasitosis, or allergy due to dust mites. The various modes by which arthropods may affect human health thus reflect the diversity of these animals, but there are very few instances in which it may be argued that natural selection favored the reproduction of those that focused on causing misery. Accordingly, arthropods should be viewed as a normal part of the environment, which under individual circumstances may cause pathology. In addition, because of their ubiquity, spurious associations with pathology are common.

**ARTHROPODS AS VECTORS**

Arthropods are thought of by many in clinical settings with respect to their role as vectors, i.e., transmitters of infectious agents including viruses, bacteria, protozoa, and helminths. Infectious agents may have an obligate relationship with an arthropod (biological transmission) or may simply contaminate an arthropod (mechanical transmission). Malaria parasites undergo a complex developmental cycle within certain mosquitoes and could not perpetuate without them. In contrast, the agent of trachoma (Chlamydia trachomatis) is found on the external surfaces of eye gnats and flies (1) and may be transferred between hosts by the act of landing and crawling; but C. trachomatis more commonly perpetuates by direct contact with hosts. Mechanical transmission of an infectious agent is dependent on its stability and quantum of infection. HIV, for example, does not survive long outside the body, and the femtoliter or so of material that may contaminate the mouthparts of a mosquito would not contain enough viable lymphocytes with HIV to initiate infection; thus, mosquitoes have never been epidemiologically linked with HIV transmission, even though mosquitoes and other hematophagous arthropods obviously feed on viremic individuals.

There are five major groups of vectors: the diptera (flies and mosquitoes), the hemiptera (kissing bugs), the siphonaptera (fleas), the anoplura (lice), and the acarines (ticks and mites). The general life history strategies for each group provides the basis for understanding vectorial capacity, which is the sum of physiological and ecological attributes that allow transmission. Specific vector-pathogen relationships are discussed in detail in chapters focusing on the respective agents but are succinctly summarized here in Table 1.

**Diptera**

The dipteran vectors are winged insects that include mosquitoes, sandflies, blackflies, gnats, horse/deerflies, and tsetse flies. These range in size from minute (ceratopogonid midges less than 2 mm in length) to large (horseflies more than 2 cm in length). Unlike other winged insects, dipterans have only one pair of wings. Those that take blood meals as adult females may serve as vectors. Blood meals are used as nutrient to produce eggs (anautogeny); once those eggs are laid, another blood meal may be taken and more eggs produced. Thus, unless a mosquito (as an example of a dipteran) inherits infection (transovarial or vertical transmission), the first blood meal infects it and the second allows the agent to be transmitted; under favorable environmental circumstances, a mosquito may survive for several weeks and take more than two blood meals. Both male and female flies and mosquitoes also require sugar meals (usually from plant nectar), but sugar meals can result in reproduction only in certain species (autogeny).

Eggs are laid in water or within detritus. Vermiform larvae emerge from the eggs and develop through several stages (instars) in water or detritus, feeding on organic material or bacteria, culminating in pupae from which emerge new adults, thereby undergoing complete metamorphosis (holometabolous development). Depending on species and
ambient temperature, the duration of the dipteran life cycle may be as short as a week or so. Tsetse flies are an unusual exception to this pattern and produce only one advanced larva for each blood meal, with the larva nourished internally from milk gland analogs during a gestation of several weeks (2). This large maternal investment in offspring makes adulticiding (trapping, spraying) very effective in reducing tsetse populations and thereby reducing the transmission of the agents of sleeping sickness.

The diptera are only transiently associated with a blood meal source. Host-seeking cues include body heat, carbon dioxide (exhaled by the host), mechanical vibrations, and lactic acid or other skin-associated compounds. The flies visually seek hosts with their compound eyes, mainly larger dark-colored objects with movement, but proximal odorant cues associated with a host seem required to initiate feeding (3). The widely used repellent diethyltoluamide (DEET) works by modulating the odor-gated ion channel formed by the dipteran odorant receptor complex on the antennae (4). Once a host has been identified, feeding is initiated and completed within minutes. Sandflies, blackflies, and mosquitoes have a diverse salivary armamentarium of pharmacologically active substances that promote finding and removing blood. During probing, antihemostatic and anti-inflammatory chemicals are secreted into the feeding channel created in the epidermis. Probing lacerates capillaries, and the ADP that is released from damaged endothelial cells would serve to promote platelet activation, but by secreting an apyrase that cleaves ADP into a monophosphate, platelet aggregation is greatly reduced during blood feeding. In addition, local inflammatory processes are temporarily diminished due to secretion of chemicals such as prostaglandin E2 (5). Thus, the first few bites from a given species remain unnoticed by the host, although factors in the saliva of blackflies may leave an egg-sized lump that is hot to the touch at the site of their bites. Such lumps may persist for several days and may be accompanied by low-grade fever. Such “blackfly fever” should not be misinterpreted as infection; it resolves on its own without treatment. The variety of proteins that are deposited within skin during vector feeding are the basis for hypersensitivity reactions, mainly itch, in hosts that are exposed to bites more than once over the course of weeks. Repeated exposure over months may lead to tolerance and a return to failing to react to bites. Although much work remains to be done, there appears to be some cross-reactivity between salivary products from different groups of vector so that some individuals may equally react to the bites of mosquitoes, bugs, or ticks.

The blood-feeding flies have cruder salivary tools, reflecting their less elegant way of feeding, which usually involves scraping the skin with a roughened maxilla and feeding

</table>
from the pooled blood or lymph. Accordingly, fly bites are more painful regardless of prior exposure, and few successfully engorge to repletion on humans.

Freshly blood-fed dipterans seek a resting place for diuresis and digestion, usually the nearest vertical surface. This behavior renders those species that bite within houses susceptible to control by indoor residual insecticide spraying.

The transient nature of infestation by blood-feeding dipterans means that few specimens are submitted to clinical laboratories. Other than analyses related to confirming the diagnosis of a vector-borne infection, dipterans would come to the attention of laboratorians for issues related to hypersensitivity or for myiasis (see below).

**Hemiptera**

The only hemiptera that serve as vectors are the kissing or reduvid bugs, belonging to a diverse and speciose order of minute-to-large insects with compound eyes, antennae, sucking mouthparts, two pairs of wings (one delicate pair hidden under an outer pair of more robust ones), and a segmented abdomen. All are easily seen without magnification, adult bedbugs being roughly 1 cm in length, and adult triatomines ranging in size from 1 cm to more than 5 cm. Small numbers of eggs are produced by females, from which emerge miniature versions of the adults. These nymphs undergo an incomplete metamorphosis (hemimetabolous development), with development through five nymphal stages, each one requiring a blood meal to proceed. The full duration of the life cycle can be as little as 3 months or as great as 2 years. Reduvid bugs are cryptic, living within cracks of mud walls or other narrow, confined spaces. They serve as vectors of trypanosomes (Trypanosoma cruzi, the agent of Chagas disease; and Trypanosoma rangeli, an apparently nonpathogenic trypanosome that is often cotransmitted with T. cruzi) in the Nearctic. Triatoma rubrofasciata transmits a trypanosome that infects monkeys in Southeast Asia (6), but to date there is no known bug-transmitted trypanosomiasis of humans in the Palearctic. Interestingly, there are good natural cycles of T. cruzi transmission within the United States from California through virtually all of the southern-central states, north to Maryland, but there are only rare human cases of autochthonous Chagas disease reported. Two factors account for this paradox: people live in quality houses that are less likely to have infestations of bugs, and more importantly, the main southern U.S. vector, Triatoma sanguisuga, does not defecate on the host while feeding (7). Transmission of T. cruzi to humans requires contamination of the site of the bite or mucosa by trypanosomes that are excreted in the bug feces, although recent outbreaks that resulted from drinking sugar cane juice contaminated with reduvid excreta have been reported in Brazil (54).

As with mosquitoes, salivary products from reduvids contain a variety of pharmacologically active compounds. Unlike those of mosquitoes, repeated reduvid feedings may cause a dangerous anaphylactoid reaction in residents of houses in which the bugs are common. Scientists working with reduvid bugs often need to carry an epinephrine injector with them due to their propensity to feeding their colonies upon themselves, thereby receiving large doses of salivary antigens.

Although it is possible that a true reduvid bug may be presented by a patient for identification in clinical settings outside Latin America, it is more likely that such specimens are related heteropterans such as assassin bugs, which are insect predators, or the plant-feeding stink bugs, chinch bugs, harlequin bugs, or squash bugs. Assassin bugs may inflict extremely painful wounds by their piercing mouthparts, but these would require only typical first aid measures and perhaps a booster of tetanus toxoid given the depth of the puncture wound (proboscis range in length from 3 to 8 mm). The plant feeders may issue noxious secretions, which may taste bad if accidentally ingested (from a bug that infested a fruit or vegetable that was eaten directly from the vine) but would otherwise not be a cause for concern.

Bedbugs (Cimex lectularius, Cimex hemipterus) are hemipterans but are not known to serve as vectors for any pathogen. These bugs with short broad heads, oval bodies, and four-jointed antennae undergo incomplete metamorphosis, with four nymphal stages, each taking a blood meal to proceed. The duration of the life cycle is roughly 6 to 8 weeks but may be as long as 11 months, depending on temperature and humidity; they may survive for months without feeding. They are small, 5 mm or less in length as adults (Fig. 2). They are cryptic and require hiding places such as cracks in walls, mattress foundations, or rattan furniture. At night, bedbugs emerge and infest sleeping people, taking 10 to 20 minutes for engorgement. Feeding is often interrupted by the movements of people during their sleep, and so multiple bites may result from a single bedbug (Fig. 2). Blood meals may be taken every week or so, depending...
on the stage, with batches of 10 to 50 eggs laid; one female may lay 200 to 500 eggs in her life. Repeated exposure to bedbug bites may lead to anaphylactic reactions. Various laboratory studies have reported the survival of diverse agents such as HIV (8), hepatitis B virus, Francisella tularensis, or West Nile virus within artificially infected bedbugs. Epidemiologically, bedbugs have never been associated with any of these infections. Although one can never say never, the likelihood that a bedbug has served as a vector is infinitesimally small, and a physician may want to question a patient more closely on known risky practices such as intravenous drug abuse. Bedbug infestations have emerged as a major complaint of urban dwellers (http://www.cdc.gov/nceh/ehs/Publications/Bed_Bugs_CDC-EPA_Statement.htm), particularly those in multifamily homes in communities with great ethnic diversity. Bedbugs are easily transported in luggage or within discarded and repurposed furniture, particularly mattresses.

Bedbug control has become more challenging due to the development of insecticide resistance in many of their populations. A large proportion (>70%) of an infestation is associated with the bedding, mattress and box spring, and headboard and frame. The mattress and box spring should be encased in a bug-proof fabric bag. The headboard and frame need to be treated with an insecticide that penetrates all joints and cracks. All furniture within the home needs to be inspected and similarly treated, as do the baseboards of all walls and any other location where bugs and their eggs may be hiding; “bug bombs” are not appropriate for such treatments because their droplet size precludes deep penetration of such hiding places. Luggage may be treated prior to travel with the same insecticide, following the label instructions, to prevent the introduction of bedbugs into a home.

Siphonaptera

The fleas are bilaterally compressed, heavily chitinized insects with greatly modified hind legs for their characteristic jumping mode of locomotion; they lack wings. Fleas are generally small, no larger than 5 mm in length. Fleas undergo complete metamorphosis, starting from a wormlike larva feeding on organic debris and blood pellets expelled, often with remarkable force and over a long distance, from the anus of the adult flea. The larva develops through three molts (has three instars) and then secretes a cocoon, in which it pupates. The female flea requires blood for egg production; one blood meal may serve for the production of several dozen eggs, which are laid on the fur of the host. Eggs become detached from the host’s fur, coming to rest within its nest. Most fleas are known as “nest parasites.” Individual fleas usually live for a couple of months, laying eggs daily, but may rarely persist for as long as a year. As with most arthropods, the duration of the life cycle is affected by temperature and relative humidity, but on average most species take 30 to 75 days to develop from egg to adult.

Of the 2,000 or so flea species that have been described, the vast majority are from rodents and have varying degrees of host specificity. Because fleas are generally nest parasites, are relatively host specific, and cannot travel long distances (crawling or jumping on the order of a few meters, implying that humans must be directly associated with their habitat for infestation to occur), only a few species are of medical importance. These include the “human” flea (Pulex irritans), the dog and cat fleas (Ctenocephalides canis and Ctenocephalides felis), the main plague vector (Xenopsylla cheopis), and the sticktight flea (Echidnophaga gallinacea). Of these, C. felis is the most notorious pest, feeding voraciously and rapidly developing dense infestations. Chronic infestations of homes are largely due to the presence of a cat or dog (despite its name, this flea does feed on either animal), their bedding, wall-to-wall carpeting, and relatively great humidity within the home. (Cold climates rarely have self-sustaining infestations because winter heating tends to dry out the carpets and molding and other places where the larval fleas tend to be hidden.) Although bites sustained over several weeks usually induce a typical delayed-type hypersensitivity reaction, with an intensely itching red spot developing at the site of the bite (usually around the ankles), note that not all members of a household react in the same manner. Some people are more attractive to arthropods than others; others react differently to bites. It is quite possible for only one person to have itchy bites and others in the same house have none, and thus a diagnosis of flea bite should not depend on the perception that if a household is infested, everyone should demonstrate similar lesions.

The human flea actually feeds on a variety of mammals, including domestic livestock. In tropical sites where homes have dirt floors and livestock share living accommodations, extremely dense infestations may develop. Although this flea is cosmopolitan in its distribution, the cat flea appears to have supplanted it as the major flea pest for humans in many countries.

An unusual flea, the chigoe or jigger (Tunga penetrans), attaches to a host and maintains a feeding site. Originally found in Latin America, the chigoe has been carried across to sub-Saharan Africa by humans and may be found anywhere there. This flea often penetrates under toenails or burrows into skin between toes, or in the soles of feet, an infestation known as tungiasis (Fig. 3). The female T. penetrans swells to 10 times its size, and the host’s immune response causes skin to swell up and cover her, with only

FIGURE 3 Tungiasis. (A) Low-power section of dermal lesion showing flea uterus filled with developing eggs. (B and C) Demonstration of progressive edema and secondary bacterial infection of Tunga lesion. (Reprinted from reference 56.) doi:10.1128/9781555817381.ch148.f3
the end of the abdomen exposed. Through this opening, she deposits eggs and feces. When the flea dies, the lesion becomes secondarily infected, causing great irritation and pain. Tourists often become infested by walking barefoot in shady spots around beaches.

Perhaps the most famous flea is the plague vector, the oriental rat flea, Xenopsylla cheopis. Although it prefers rats (Rattus rattus, Rattus norvegicus) as hosts, in their absence (or when they die) it feeds on humans and other animals. These fleas may be found on rats in virtually every tropical or warm temperate port city around the world, having been transported there with their hosts by trade ships. Plague is usually maintained in enzootic foci by wild rodents and their more specific fleas, but in Vietnam, Madagascar, and India, rats and X. cheopis appear to be important for perpetuation. Although enzootic plague usually results in sporadic cases, the great fecundity of rats under the right circumstances means that explosive outbreaks of plague may occur in urban areas, with hundreds or thousands of cases. Human exposure in the western United States is enzootic, may be due to chance contact with ground squirrels or their fleas (often Diamanus montanus) in sheds, disused cabins, and crawl spaces or by digging around burrows. Domestic cats often serve as an intermediary, hunting moribund rodents and subsequently exposing their owners.

**Phthiraptera**

Infestation by lice is called pediculosis. The lice are wingless, flat (dorsoventrally), elongate, small (0.4- to 10-mm) insects that are generally characterized by strong host specificity. Classically, two orders were recognized, the Mallophaga (chewing lice) and the Anoplura (the sucking lice); the former now comprises three suborders, and the latter remains as a suborder, all within the order Phthiraptera, which contains about 4,000 species. Of these, the sucking lice are clinically relevant, although the chewing lice may be presented as spurious ectoparasites or associated with double-pored tapeworm (Dipylidium caninum) infection. Most chewing lice are commensals of birds, whereas the sucking lice feed mainly on mammals.

Lice undergo incomplete (hemimetabolous) development, with nymphal forms resembling adult lice, and are often found concurrently with the adults. Thus, size may appear to greatly vary within a single collection of specimens from one host. All lice are delicate and very sensitive to temperature and humidity requirements; all die within days without the host.

Chewing lice usually are found in the feathers of birds, feeding on skin fragments. Virtually all chewing lice lack piercing mouthparts and therefore do not feed on blood. The dog-biting louse (Trichodectes canis) may be presented as a specimen because it is a common commensal of dogs and may be spuriously associated with “bites.” Dogs serve as definitive hosts for D. caninum, the eggs of which are shed in feces; the feces dry on the fur, and the louse may then ingest the eggs. The tapeworm eggs hatch, and a cysticercoid becomes localized in the hemocoel of the louse. Transmission is effected when the louse is accidentally ingested, usually when the dog is grooming; humans (usually children) are incidentally infected if their hands become contaminated and then touch food or drink or are placed in their mouths.

Book lice (order Psocoptera, also known as psocids) resemble chewing lice and live on molds infesting old books. They are frequently presented as specimens in diagnostic workups for itches of unknown etiology but do not infest humans or any other animal.

The lice of greatest clinical importance (Fig. 4) are the head louse (Pediculus humanus capitis), the body louse (Pediculus humanus corporis), and the pubic louse (Phthiris pubis). All of these sucking lice have prominent claws attached to each of their legs, morphologically adapted for grasping the hairs of their host. They feed at least daily and deposit 1 to 10 eggs from each blood meal, gluing claws attached to each of their legs, morphologically adapted for grasping the hairs of their host. They feed at least daily and deposit 1 to 10 eggs from each blood meal, gluing one egg at a time onto the shafts of hairs (or in the case of the body louse, onto threads within clothing). The eggs, or nits, are almost cylindrical in shape and have an anterior operculum. Nits hatch within 4 to 15 days, and each of the three nymphal stages lasts 3 to 8 days. Lice are transferred between hosts by close physical contact or, in the case of body lice, by sharing clothing. Schools are excellent sites for the spread of a louse infestation, not only through the sharing of hats and scarves, but by children deliberately infesting others during play. It is possible that transient circumstances, such as a subway headrest recently used by an infested head, could serve as the means for transfer. The oft-tendered excuse “I got it from a toilet seat” with reference to pubic lice should not be dismissed out of hand, but the probability

**FIGURE 4** Lice. (A) Head louse nits; (B) body louse; (C) pubic louse; (D) vagabond's disease. (Source: Department of Tropical Public Health, Harvard School of Public Health).
doi:10.1128/9781555817381.ch148.f4
of acquiring a louse in this manner is far less than by skin-to-skin contact. On the other hand, the presence of pubic lice on the eyebrows usually denotes a sexually transmitted infection, and pubic louse infestation of a child is cause for an inquiry into the possibility of child abuse.

Body or pubic louse infestation may result in intense irritation for several days, with each bite generating a red papule. Chronically infested individuals may become desensitized or may develop a non-specific febrile illness with lymphadenopathy, edema, and arthropathy (although such signs and symptoms should prompt a search for the agent of trench fever). A very few chronically infested individuals may develop "morbous error" or vagabond's disease (Fig. 4), with a thickening and dark pigmentation of the skin (9).

Although body louse or pubic louse infestation may be considered evidence of poor hygiene or poor judgment, infestation by head lice should not be a stigma, as it occurs in the best of families. Nor should head louse infestation be considered to be a public health menace or even a clinical problem. Very few infestations are dense enough to cause signs or symptoms, and head lice are not vectors. Nonetheless, draconian measures are taken by many school districts, banning an infested child until treatment is thorough enough to remove all nits. Many such schools fail to discriminate between live and dead nits, insisting that all traces of them be absent. Complete removal of all nit remnants can be very difficult, relying mainly on the use of fine-toothed combs, a tool that has been found in the tombs of the Egyptian pharaohs (10).

The sucking lice are both important vectors and pests. Among the most notorious vectors in history are the body lice, which may serve as vectors for the agents of epidemic typhus, trench fever, and louse-borne relapsing fever. Napoleon’s invasion of Russia in 1812 was probably thwarted by epidemic typhus decimating his troops. At the end of World War I, it is said that a typhus epidemic in Russia and Romania killed 800,000 people (11). Body lice are the product of poor hygiene, with clothes never or rarely being changed, such as in cold weather, by the homeless, or in refugee camps. Trench fever may be common in the homeless, and the most recent large outbreak of typhus was in Burundi, in Rwandan refugees. Oddly, even though the head louse is aconspicuous and appears vector competent in laboratory experiments, it has not been epidemiologically associated with any of these infections, nor has the pubic louse.

Body louse infestations are easily controlled by changing clothes and bathing regularly. Clothes that have been removed from infested individuals should be destroyed or, at the very least, securely bagged in plastic and left for at least 30 minutes. Pubic lice may be treated by shaving the pubic hair and changing underwear regularly or by a topical pediculicide as for head lice. Head lice may be removed mechanically using specifically designed louse combs, but treatment using a pediculicide is more efficient. Although insecticide resistance is widespread, the common pediculicides containing permethrin or malathion should still be used as the first-line therapy, along with environmental hygiene (laundrying bedding and clothing, particularly hats; vacuuming cushions and mattresses) and screening of family members and close friends for infestation. Retreatment a week later is required because these topical pediculicides do not act efficiently on the developing lice within nits. If infestations persist after a retreatment complemented by environmental hygiene, the new generation of prescription pediculicides such as ivermectin or spinosad should be used (12).

Acarina

The acarines are a subclass within the class Arachnida, which also contains the spiders. Acarina comprise the mites and ticks, tiny to small arthropods with eight legs as nymphs and adults (as opposed to six for insects) and with fused main body segments as opposed to three discrete ones for insects. Acarine baupläne are characterized by two functional body parts, the gnathosoma (or capitulum), which comprises the "head," and the idiosoma, which performs all the remaining functions (reproduction, motility, digestion). They undergo incomplete metamorphosis, passing through a larval and one to several nymphal stages before attaining sexual maturity. The mites are one of the most speciose groups of animals, with 45,000 recognized species. They are among the oldest terrestrial animals, dating in the fossil record to the Devonian (nearly 400 million years ago), and are found in every habitat on earth. There are two major orders of the acarines, the Acariformes and the Parasitiformes. In the former, there are two main groups, the Sarcoptiformes (astigmat) and the Trombidiiformes (prostigma), both of which contain species of clinical significance. The latter comprises three orders, the Holothyrida, the Ixodida, and the Mesostigmata. Of these, only the last two are clinically significant; the holothyrids consist of about 20 species that are found only in Australasia and some neotropical forests and are unlikely to be encountered (although they are known to secrete a toxin that may incapacitate a human that has ingested such a mite). The mesostigmata (also known as gamasida or demarayanoida) include some that infest birds or rodents, which under certain circumstances infest humans and cause itch. The ixodida consist of the ticks, which are essentially very large mites. Other than the ticks and some mesostigmatids, mites are generally not considered vectors of agents that infect humans. They are, however, important for their pest potential, causing itch, dermatitis, and allergy.

The house mouse mite (Liponyssoides sanguineus) is the vector for rickettsialpox due to infection by Rickettsia akari. The relatively mild disease, characterized by fever and exanthema, was first described after a garbage strike in Kew Gardens in the Bronx, New York, NY, during the 1940s (13). Garbage piled up, and house mice populations became dense. When the strike resolved and the garbage was removed, the mice died or emigrated, leaving behind dense infestations of hungry mites. The progestigmatid trombiculid mites (chiggers) are the vectors for the agent of scrub typhus (Orientia tsutsugamushi), a rickettsiosis of Eurasia and northeastern Australia. Nearly 3 billion people live in countries where scrub typhus is endemic. Scrub typhus is acquired from infestation by tiny (0.2-mm) larval trombiculid mites such as Leptotrombidium deliensis or Leptotrombidium akamushi; an eschar forms at the site of the chigger bite, with proximal lymphadenopathy, fever, headache, exanthema, and myalgia. Case fatality rates can range from 5 to 35% (14). Interestingly, the nymphal and adult stages of this mite feed on detritus or other arthropods and do not take vertebrate blood. Therefore, O. tsutsugamushi relies mainly on transovarial or vertical transmission (passage through the egg) for perpetuation, although rodent hosts that are infected may feed noninfected larvae and generate new matrilinesages of infected mites. All other vector-borne agents have greater opportunities for horizontal transmis-
sion, that is, amplification by infecting a vertebrate host, and having multiple blood meals during development.

Mites are extremely difficult to identify, particularly given the likely confusion with dust mites or other ubiquitous free-living forms. All require clearing and mounting on a slide and examination under a compound microscope.

Ticks are prolific vectors, with more recognized transmitted agents than any arthropod other than mosquitoes. All of the nearly 900 known species of ticks require blood for their development and reproduction. Clinically relevant ticks belong to either the Ixodidae (the hard ticks) or the Argasidae (the soft ticks); a third family, the Nuttalliellidae, comprises a monotypic genus of soft ticks found in southern Africa and for which an association with a pathogenic agent has yet to be described. Hard ticks are so named because of the hardened sclerotized idiosomal shield or scutum. In female hard ticks, the scutum is on the anterior third of the idiosoma, with the remainder of the idiosoma consisting of pleated, leathery cuticle that allows for tremendous expansion during blood feeding. In male hard ticks, which may or may not feed at all, the scutum extends the length of the idiosoma. In contrast, soft ticks have no scutum; their entire idiosoma is leathery.

The “head,” or capitulum, consists of the holdfast (hypostome), the chelicerae (which are homologs of insect mandibles), and the palps, which cover the mouthparts (hypostome and chelicerae) and serve a sensory function. Chelicerae act as cutting organs, the two sides sliding past each other, with the cutting teeth at the end gaining a purchase into a host’s skin. The hypostome is thereby inserted and allows anchoring of the entire tick due to recurved, backward-facing teeth or denticles (Fig. 5). Many hard ticks also secrete a cement around the hypostome. Often, when removing an attached dog tick (Dermacentor variabilis) from a host, a large piece of skin comes with the hypostome, mostly cement and surrounding epidermis. Thus, by virtue of the cement and denticles, tick hypostomes rarely emerge intact when a tick is removed. “Leaving the head in” is not critical, and most times the remnant is walled off as a foreign body or works itself out, perhaps by the act of scratching. Treatment, therefore, should simply be disinfection of the site of the bite and certainly not excavation of the epidermis looking for the head. Soft ticks are transient feeders and are only rarely found attached.

Hard ticks require several days to complete their blood meal; the number of days depends on the species and stage of the tick. North American deer ticks (Ixodes dammini) feed 3 days as a larva, 4 days as a nymph, and 7 days as the female. The closely related European sheep or castor bean tick, Ixodes ricinus, feeds 2 days as a larva, 3 days as a nymph, and 7 days as the female. The duration of feeding depends also on host immune status (previous exposure may induce immediate-type hypersensitivity, which slows down the feeding process) and temperature (I. dammini or I. ricinus feeds twice as long on cold reptiles as on those that are held at 37°C). The extended duration of feeding is required for the cuticle to soften so that the idiosoma may accommodate 10 to 100 times its weight in blood; and the site of the bite is prepared so that a pool of lymph and blood is available for removal. During the first 70% of the feeding process, very little blood or lymph appears to be present within ticks, which remain dorsoventrally flat. Hemoglobin is excreted from the anus, lipids are retained, and water from the blood is recycled back into the host as saliva (17). In the last day, usually in the last 3 or 4 hours of the blood meal, the tick takes what has been termed “the big sip,” removing a large volume of whole blood and then detaching and dropping from the host.

Because they must remain attached for days, hard ticks have evolved means of temporarily disabling a host’s local inflammatory response, which might inhibit its feeding. Hard tick saliva is an extremely complex mixture of anticoagulant, anti-inflammatory, and antimicrobial agents (18) that act mainly at the site of the feeding lesion. Tick saliva also neutralizes Th2 responses systemically (19). Hosts that have never been exposed to ticks do not realize that a tick is attached. Indeed, most patients with Lyme disease or spotted fever never knew that they had been “bitten” (20, 21). The most dangerous tick is not necessarily the one that a patient finds and removes, thus aborting the transmission process, but the one that he or she never knew was there and which was able to complete its feeding.

In contrast, soft ticks are more like mosquitoes in their feeding, spending tens of minutes to no more than a few hours feeding, usually as their host is sleeping. Soft tick saliva does not “need” to be as biochemically complex, and in fact some species have painful bites. The pajarillo (pajarillo), Ornithodoros coriaceus, of California and Mexico is renowned for its “toxic bite,” causing local pain and burning (9).

Tick life cycles have an extended duration, usually months or years. Deer ticks, for example, take 2 years to go from egg to egg. For this reason, there is generally no risk associated with hard ticks engorging and dropping off a companion animal within a patient’s home. The engorged tick will not feed again and will take weeks to molt or lay eggs, and in the interim, usually the relative humidity within the house is too low for extended survival of the tick. On the other hand, cats as opposed to dogs appear to be a risk factor for acquiring Lyme disease, perhaps because deer ticks feed well on dogs but poorly on cats; ticks, particularly nymphs, may detach in mid-feed and readily reattach to the cat’s owner (22). The exception to the lack of risk associated with ticks engorging and detaching in the house.
hold is with the brown dog tick (Rhipicephalus sanguineus), which is the vector of Marseille fever (Mediterranean spotted fever, boutonneuse fever) and of *Ehrlichia canis* and has also recently been documented as a vector of Rocky Mountain spotted fever. These ticks hide behind wall molding to molt and indeed are known for dense infestations covering the interior walls of dog kennels.

Ticks can be difficult to identify, depending on their state of engorgement and whether mouthparts are intact. Although tick systematists have recently altered some of the generic epithets, in general the classic Centers for Disease Control and Prevention (CDC) diagrams of the mouthparts and idiosoma (Fig. 6) can be used to classify a tick to at least the genus level. Often, simply knowing the country in which a tick may have been acquired can significantly narrow down the list of possibilities (Table 2).

**ARTHROPODS AS “SCALARS”**

Vectors impart directionality to a pathogen. In contrast, there are arthropod-pathogen relationships that are not characterized by directionality, and in a manner analogous to mathematical terminology, arthropods that inadvertently serve as a source of infection are called scalars (23). Helminths may use an arthropod as an intermediate host, but that arthropod does not deliver the infectious stage of the helminth during an obligate behavior such as blood feeding. Drinking water with copepods (crustacea) containing third-stage larvae of the filarial nematode *Dracunculus medinensis* initiates infection when the copepods are digested by stomach acids, thereby liberating the nematode larvae; but the stage larvae of the filarial nematode *Dracunculus medinensis* serve as a source of infection are called scalars (23). Helminths may use an arthropod as an intermediate host, but that arthropod does not deliver the infectious stage of the helminth during an obligate behavior such as blood feeding. Drinking water with copepods (crustacea) containing third-stage larvae of the filarial nematode *Dracunculus medinensis* initiates infection when the copepods are digested by stomach acids, thereby liberating the nematode larvae; but the copepods did not swim towards a vessel scooping water out for drinking. Accordingly, the patient’s history needs to specifically address the following: the possibility of exposure via drinking from natural bodies of water (copepods and *Dracunculus*); the presence of flour beetles, fleas, or roaches (hymenolepidid cestodes, Dipylidium caninum; Gongylonema spp.); eating crabs or crayfish (Paragonimus spp.); or being in an environment with dense infestations of houseflies (trachoma). With the exception of houseflies and trachoma (which perpetuates in the absence of flies, spreading by direct contact with ocular exudates), all these are obligate relationships.

**Muscod Flies**

The muscoid diptera include the muscids (houseflies, stable flies), the Calliphoridae (blowflies), and the Sarcophagidae (the flesh flies). Egg deposition and larval development occur in characteristic materials, viz., fecal material for houseflies, decaying plant material for stable flies, live flesh for blowflies, and carrion for the flesh flies. These flies can be remarkably prolific within short periods of time: a female housefly, for example, deposits 100 to 150 eggs in moist, decaying organic material, usually excrement, at one time but may do so 20 or more times (24). Larvae emerge from the eggs within 12 hours. Three larval stages develop during a week, and a puparium is formed. The adult fly emerges from the pupa within 4 days, and copulation may occur within 1 day. Thus, a full life cycle may take as few as 12 days.

Houseflies have received much attention for their potential as scalars because of their association with poor hygiene. Flies are strong fliers and move readily from outdoors to indoors. A large fleshy structure at the apex of the proboscis provides a surface for contamination, as do the hairy body and legs of the fly. In addition, flies may regurgitate while feeding, and the vomitus may contain organisms that were acquired in a previous landing. Houseflies commonly feed on human excrement, and virtually every possible enteric pathogen (those causing amebiasis, cholera, typhoid, hepatitis A, poliomyelitis; even roundworms and *Helicobacter pylori*) has been detected within or upon them. With few exceptions, such findings are epidemiologically irrelevant inasmuch as all of the agents perpetuate in their absence. Poliovirus, for example, was recovered in flies captured from sites where polio was actively being transmitted (25), but use of dichlorophenyltrichloroethane (DDT) failed to curtail the epidemic. In contrast, residual DDT treatment of army camps reduced the incidence of shigellosis (26). It is likely that individual cases of enteric disease may derive from fly contamination of food, but whether the risk of such an event merits worry by patients or their health care providers remains unclear. Dense infestations of flies should be reduced (by source reduction, i.e., by preventing flies from getting access to garbage and excrement); a few flies in the house do not warrant setting off a bug bomb.

**Cockroaches**

Roaches are dorsoventrally flattened, smooth-bodied, winged insects with long antennae, biting mouthparts, and abdominal projections ( cerci). The outer pair of wings is thick and leathery and the inner pair membranous. Roaches may fly but usually scuttle about on long spiny legs. They undergo incomplete metamorphosis, with the immature forms looking like miniature adults, although without wings. Eggs are laid within a hard capsule, the ootheca, which is deposited in a dark crevice. Development is slow, taking about 4 weeks between molts; many roaches have only one generation each year. Roaches can live for months without food, but water seems critical. They are omnivorous, feeding on the finest of foods to the vilest of waste, usually at night. Secretions deposited by scent glands (including trail and aggregation pheromones) give rise to a characteristic disagreeable odor that confirms an infestation even when live roaches cannot be found. Common roaches range in size from the small German cockroach (Blattella germanica), about half an inch in length, to the American cockroach, nearly two inches. Much work has been done attempting to incriminate roaches as scalars (27). A roundworm (*Gongylonema* spp.) normally infecting ingulates may encyst within roaches and be transmitted to humans when ingested, usually as a contaminant of food. As with flies, the presence of roaches suggests poor environmental hygiene, but only rare instances of enteric disease might be associated with them.

The main role of cockroaches in public health appears to be as a major cause of asthma, perhaps as commonly a cause as is the dust mite, as well as a cause of wheezing, rhinitis, or atopic dermatitis. Their feces (frass) contains the allergens Bla g 1 and Bla g 2, which cross-react with known allergens such as fungi, as well as tropomyosin, a panallergen found on dust mites, crustaceans, and mollusks (28). Patients sensitized to cockroach allergens frequently (>70% of the time) have specific IgE reactivity to the 20- to 90-kDa Bla g 1 protein. Although sensitization is a main cause of frass-associated rhinitis, prior exposure is not required to trigger airway inflammation.

Dense infestations of cockroaches may develop quickly and promote respiratory illness. Hence, any detection of an

aHGE, human granulocytic ehrlichiosis (*Ehrlichia chaffeensis* or *Ehrlichia canis*); RMSF, Rocky Mountain spotted fever; STARI, southern tick-associated rash illness (etiologic unknown, possibly *Borrelia*); CTE, Colorado tick fever; TIBOLA, tick-borne lymphadenopathy; KFD, Kyasanur forest disease; ATBF, African tick bite fever (*Rickettsia africae*).

active infestation should prompt control efforts. Control of roach infestations can be difficult. Boric acid, deposited along walls, behind moldings, and around other sites where they may hide, is effective in killing adults and nymphs by abrading cuticle between abdominal segments, rendering the roach prone to desiccation. Removing standing water (wiping up and getting rid of clutter around sinks) can also reduce infestations by preventing access to water. Roach infestations are most common in apartment buildings serving transient student or immigrant populations, who bring the insects in with their household goods.

**DIRECT INJURY DUE TO ARTHROPODS**

**Arthropods Typically Thought of as Vectors**

Vectors such as lice, ticks, bugs, fleas, mosquitoes, and blackflies may directly cause injury by their bites, either by hypersensitivity reactions or toxic effects of their salivary products. Hypersensitivity reactions manifest mainly as itch, with the comonitant potential for secondary infection due to scratching. Bedbug and flea bites may cause immediate-type hypersensitivity reactions with itchy erythema greater than 3 cm in diameter (Fig. 2). Ticks may induce a chronic local granulomatous lesion, persisting for months, perhaps due to remnants of the mouthparts (denticles) left within the epidermis. This phenomenon is particularly pronounced with “seed tick” infestation (stepping into a newly emerged batch of larval *Amblyomma* ticks, often thousands), where dozens or hundreds of ticks may attach at the belt line. Itch may be immediately relieved by calamine (or pramoxine [Caladryl] with diphenhydramine [Benadryl]) lotion or even holding the affected part under very hot running water, which will induce mast cells to degranulate. Over-the-counter hydrocortisone creams may help mild cases of itch, but severe cases may require prescription strength steroid cream (e.g., 0.05% betamethasone). Daily application of hydrocortisone should promote a resolution of itch within a week. Tick granulomas may be treated with tretinoin (Retin A) gel (0.05%), which may promote the turnover of epidermis and ejection of remaining antigenic material (personal observation).

As mentioned in the introduction to diptera, blackfly bites may produce “blackfly fever,” usually as a dose-dependent reaction. Usually, the sites of the bites become edematous, with a golf ball-sized lump and an oozing punctate lesion. Fever and myalgia manifest that night and disappear within 24 hours. Such symptoms should not be construed as infection; few pathogens, if any, have such a short prepatent period. Treatment is symptomatic. Similarly, soft tick bites due to pajaorrello or the African tampan (*Ornithodoros moubata*) may immediately cause pain, swelling, and irritation at the site of the bite, with raised hard wheals (29). The effects are said to last several days, with “irritability” of the affected part. Anecdotally, hunters in northern New England and the upper Great Lakes may complain of bites of *Dermacentor albipictus* larvae (a species that usually feeds
only on ungulates such as deer or moose) during the early winter; apocrypha indicate that Native Americans called these larvae “bite all same as a piece of fire” (30). The condition has not been studied.

An unusual toxicosis due to tick bite is tick paralysis. The presence of certain feeding ticks induces an acute ascending paralysis. First described for sheep and cattle in Australia in 1843, a similar disease was reported for a child in Oregon in 1912. The Australian *Ixodes holocyclus* attacks cattle, sheep, and dogs but rarely humans, and thus tick paralysis is not a common clinical condition there. However, in the western United States, bites of *Dermacentor andersoni* commonly produce cases of “staghers” in cattle or sheep, which may terminate fatally. Children are the usual victims of tick paralysis, with ticks attached at the nape of the neck. The illness is characterized by fatigue, irritability, distal paresthesias, leg weakness with reduced tendon reflexes, ataxia, and lethargy. Unless the tick is removed, quadriplegia and respiratory failure may result; the case fatality rate without treatment can be 10%. Removal of the tick induces a miraculous recovery within 48 hours. (Tick biologists usually attribute “it” to suggest such an etiology for the tale of Snow White, who awakens after the Prince bends over her and kisses her, probably removing a tick from behind her ear.) A 40- to 60-kDa toxin has been isolated from *I. holocyclus* and has been named holocloctoxin (31); an antitoxin has been produced for veterinary use; others with a much smaller molecular weight have also been isolated. The toxin has not been isolated from the American tick paralysis ticks. Other ticks (*Amblyomma americanum, Ixodes* spp.) have also been reported to induce tick paralysis.

An enigmatic red meat allergy has been associated with the bites of Lone Star ticks in the eastern United States. A severe hypersensitivity reaction to treatment with cetuximab was found to be geographically limited and due to IgE reactivity with galactose-alpha-1,3-galactose (alpha-Gal). Such IgE reactivity was also associated with a newly recognized red meat allergy, which manifested as urticaria or anaphylaxis 3 to 6 hours after ingesting beef, pork, or lamb. Patients recalled recent multiple tick bites, and subsequently detailed studies of individual cases, epidemiological association between anti-alpha-Gal IgE and Lone Star tick bites, and correlation of IgE to tick proteins and alpha-Gal together have provided evidence for causality (32). Similar associations have also been reported for Europe and Australia, with sheep ticks (*Ixodes ricinus*) and paralysis tick (*I. holocyclus*), respectively, suspected as the culprits. Alpha-Gal is a major component of internal tick tissues, and hence Gal is a major component of internal tick tissues, and hence many of tick larvae that live as adults in the lungs and air passages of hosts including fish, amphibians, reptiles, and some mammals. The body, like that of arachnids, consists of a cephalothorax and indistinct abdomen, with no legs; often, the cuticle appears ringed or annulated. Chitinous hooks protrude from the head. Their size ranges from 1 to 10 cm. Although long thought to be in its own phylum, recent cladistic analyses based on morphologic and molecular characters place the tongue worm within the Crustacea and find it to be most closely related to the branchiurid fish lice (33). Pentastomes undergo a complex life cycle with incomplete development, requiring intermediate hosts in which the nympha stages may encyst.

Human infestation by *Linguatula serrata* may be due to ingestion of eggs (from contamination by nasal discharges from the dog intermediate host) or ingestion of encysted nympha within the raw or poorly cooked liver, lungs, or mesentery of an intermediate host such as rabbits, cattle, or sheep (34). A nasopharyngeal syndrome results, known as halzoun in the Middle East and marrara in Sudan. Facial edema, nasal discharge, coughing, and sneezing are due to the migration of nympha forms into the nasopharynx. Removal of the offending nymphs (by visual inspection and forceps) and symptomatic treatment with antihistamines to reduce edema may be helpful. *Armillifer armillatus* and *Porocephalus crotaali* of snakes also cause infections in humans, probably as a result of contaminating drinking water with eggs from their feces and not because of ingestion of poorly cooked snake meat. Usually, human infection is noted only at autopsy or by the presence of a calcified abdominal or lung object in radiographs. Treatment is symptomatic.

The most common of the ectoparasite-caused direct injury is scabies, caused by infestation with the human scabies mite (*Sarcoptes scabiei*). A number of different populations of *S. scabiei* have been treated as full species based on their tropism for other animals (including dogs, pigs, sheep, cattle, and goats), but all are morphologically identical. Infestation may occur anywhere in the world. Canine sarcotic mange is commonly associated with scabies infestations in the owners of the dogs. In either animal or human scabies, transmission is by direct personal contact, and infestations often cluster among groups of people, particularly families. There is little evidence that environments become contaminated; fomites have not been identified.

The female scabies mite burrows beneath the stratum corneum (Fig. 7), leaving behind eggs and feces within a tracklike trail. A few dozen eggs are deposited, and these hatch within a week. Larvae form new burrows but may also emerge from the skin and move freely about. Nymphs develop from fed larvae, and they in turn develop into the adult male and female. Normal infestations consist of a dozen or two female mites. Nocturnal itching begins within a month of the first infestation but may begin within a day in previously exposed individuals. Thus, newly exposed individuals, prior to their recognizing an infestation by the presence of itching, may serve to contaminate other individuals. Erythematous papules and vesicles first appear on the webs of fingers, and spread to the arms, trunk, and buttocks. The burrows contain a granular, highly antigenic feces, which cause both delayed and immediate-type hypersensitivity reactions. Interestingly, in individuals who are immunocompromised, hundreds of female mites may be found, itching is minimal, but a hyperkeratosis is prominent. Such “crusted” or Norwegian scabies are highly infectious to other people.

Scabies infestations can be easily diagnosed by scraping a newly developed papule (not one that has been scratched) with a scalpel coated with mineral oil. The scrapings in oil may be transferred to a slide and examined at a magnification of ×100 or ×400 bright-field for 300- to 400-μm mites or the smaller black fecal granules. Scabies may be treated by topical 5% permethrin cream or 1% permethrin rinse (Nix, which is the same as used for head lice). Generally, 12.5% benzyl benzoate is the treatment of choice due to
Dermatophagoides farinae, the mites, which are human commensals that feed on flakes of skin shed from a person. The mites themselves do not infest a person but remain in the environment (usually within bedding or carpets) to feed and develop. About one-half of the mites float and move and can be seen at a magnification of ×20. Humidity less than 60% greatly reduces dust mite infestations, as do periodic vacuuming and washing of bedding and carpets. Pityriasis folliculorum, with small pustules appearing on the forehead, has been attributed to them.

Dust mite allergies (one of many causes of asthma, rhinitis, and atopic dermatitis) are due to inhalation of feces excreted by Dermatophagoides farinae or related pyroglyphid mites, which are human commensals that feed on flakes of skin shed from a person. The mites themselves do not infest a person but remain in the environment (usually within bedding or carpets) to feed and develop. About one-half of the mites may be shed from a person each day; one female mite lays one egg a day, for about 2 months; thus, large accumulations of mites may readily develop. The 300- to 400-μm-long mites may be presented by patients as suspects for other nonspecific lesions or sets of signs and symptoms because they may be found in virtually all houses and can be detected if dust is allowed to settle on standing water; the mites float and move and can be seen at a magnification of ×20. Humidity less than 60% greatly reduces dust mite infestations, as do periodic vacuuming and washing of bedding and carpets.

Myiasis is the infestation of human or animal tissue by fly larvae, deposited as eggs or first-stage larvae; the larvae develop by feeding on the surrounding tissue, emerge as third-stage larvae, and pulate in the environment. There are three kinds of myiasis with respect to life cycle patterns: obligate, facultative, and accidental. Obligate myiasis reflects the need for larvae to feed well during development because adult flies do not feed or feed poorly. Botflies comprise the main examples of obligate myiasis. Most botflies normally infest animals, and thus human botfly infestation by these species is considered zoonotic. Two flies, Dermatobia hominis (human botfly) and tumbu fly (Cordylobia anthropophaga), are more adapted to humans, as illustrated by their life cycles. The former fly lays its eggs on a transport (phoretic) host such as a mosquito, and when the mosquito feeds on a human, the eggs hatch during the course of the blood meal, and the larvae penetrate the skin at the site of the mosquito bite or burrow in on their own. The latter fly is attracted to sweat, urine, or feces and oviposits on clothing that has been spread out to dry on the ground or hung up to dry, on areas of cloth that are redolent with such odors, which may remain when primitive clothes-washing practices are used. The eggs hatch when placed close to the body, and the larvae burrow into the skin. Thus, any clothing washed in tropical countries without the aid of modern soap powders and dryers should be ironed before wearing.

Facultative myiasis is usually due to infestation by blowflies (Phormia regina), green bottle flies (Lucilia sericata), and related calliphorids; by flesh flies (Wohlfahrtia spp.); or by common houseflies (Musca domestica). These flies normally deposit eggs into fecal or other rotting organic material but directly lay eggs into wounds or necrotic tissue; however, the larvae may not conform themselves to such resources and may move into healthy tissue.

Accidental myiasis includes the incidental findings of fly larvae, often houseflies, under wound dressings or within unusual sites such as the gastrointestinal (GI) tract. The rat-tailed maggot (Eristalis tenax) is actually a hoverfly (syrphid) that breeds in sewage or dirty water. Eggs might be deposited around the anus during defecation, and the larvae may find their way into the lower GI tract or urethra. Drinking unfiltered dirty water might cause temporary infestation of the gut, with larvae surviving into the lower intes-
tine. More often, larvae are found in containers of stool samples that are intended for the clinical laboratory and are most likely due to oviposition after the sample is taken. A variety of clinical presentations are evident depending on the site where the larvae are present. Bottles cause furuncular lesions or migratory integumomyiasis (a serpiginous track may be produced in the skin). Wound myiasis comprises shallow or pocketlike initial lesions that become more deeply invasive. Maggots may invade the nose and accompanying structures, causing nasal or oral myiasis. Maggots may get into the ears, producing aural myiasis. Ophthalmomyiasis is due to external or internal infestation. Enteric, vaginal, or vesicomyiasis is due to invasion of the gut or genitalia. In all presentations, pathology may be due to tissue trauma or local destruction but is more often associated with secondary bacterial infection. On the other hand, many maggots do not promote bacterial infection but rather secrete bacteriolytic compounds and have been used as a surgical intervention to debride wounds (36). Indeed, sterile L. sericata maggots are available by prescription in the United States (www.monarchlabs.com) to help with wound debridement. Thus, the development of secondary bacterial infection. On the other hand, many maggots do not promote bacterial infection but rather secrete bacteriolytic compounds and have been used as a surgical intervention to debride wounds (36). Most stings by hymenoptera cause localized reactions, sometimes with extreme pain, and resulting in a transient induration with hyperemia. By virtue of their living in large colonies, bees and ants may swarm an intruder, and dozens if not hundreds of stings may be sustained. Airway obstruction may result should multiple stings be received on the face or neck. Although the honeybee’s agricultural value in pollinating plants greatly exceeds any slight risk due to their stings, African honeybees (Apis mellifera adansonii), a subspecies of the regular honeybee; also known as “killer bees”), which were imported into Brazil in the hopes that they would be better pollinators, can be dangerous because they are more aggressive than the typical honeybee. Bees differ from wasps and ants in that their stinging apparatus is forcibly torn out during the act of stinging, thereby ensuring the death of individual bees as a result. Wasps and ants may sting multiple times; some fire ants may hang on by their mandibles and repeatedly insert their posteriorly located stinger.

Bumblebees, paper wasps, yellow jackets, and hornets may all sting, usually as a result of intruding too near a nest. The most important clinical manifestation of bee or wasp stings is anaphylaxis. Chest tightness, nausea, vertigo, cyanosis, and urticaria may be seen even in individuals who apparently had never previously been exposed. Dozens of people die each year in the United States due to bee sting anaphylaxis.

Ants, on the other hand, rarely pose a risk for anaphylaxis but may produce a reaction that may persist for a longer duration. An induration or wheal may be observed immediately after the sting, and a papule that itches or remains irritated for several days may develop. Secondary bacterial infection may ensue. Fire ants (Solenopsis invicta) may bite or sting, both modes accompanied by the injection of a venom, an ethyl ketone for the former and various 2,6-dialkypiperidines for the latter. Other ants (the formicinae) have a venom that is mainly formic acid.

**Urticating Caterpillars**

Lepidoptera (moths and butterflies) undergo complete development, with the well-known caterpillar and cocoon stages. More than 100,000 species of these familiar insects have been described. Although certain adult moths (in four superfamilies) may imbibe blood or tears, no signs or symptoms are associated with what is evidently an independent evolution of hematophagy. At least eight families of Lepidoptera, however, have caterpillars with urticating hairs, and some of the neotropical species can produce surprisingly severe reactions, including a hemorrhagic syndrome (Lonsonia achelous, a saturniid moth of the Amazon) due to a fibrinolytic toxin exuding from poison spines (37). More typical are rashes caused by contact with hairs (erucism, or eruc rash). A common shade tree pest, the browntail moth (*Nygma phaeorhoea*), in Europe and northeastern North America, liberates tiny barbed hairs when the caterpillar molts. These hairs are blown about by the
wind, and when skin is exposed, a severe dermatitis results; ingestion or inhalation can also cause significant irritation of the mucosa or bronchospasm. Contact with the eye may induce conjunctivitis. Dermatitis produced by urticating hairs typically comprises itchy, erythematos patches associated with small vesicles and edema. These lesions are only where the hairs have free access to the skin or where contact is made. Use of a masking tape-type lint roller can be very effective in removing urticating hairs, which may or may not be visible.

Scorpions
Scorpions are arachnids with a characteristic crablike appearance. The body consists of the cephalothorax and a segmented abdomen with a segmented tail, which terminates in a prominent stinging apparatus (aculeus). The four pairs of legs include well-defined pincers on the first pair of legs. Scorpions may range in size from 2 to 10 cm. Scorpions undergo incomplete development (immature stages look like miniature adults). Of the 1,000 or so species that are known, fewer than 50 have been reported to cause illness with their sting. Scorpions are problems mainly in the warmer climates. The bulbous end of the tail contains muscles that force venom through the stinger. All scorpions are predatory on other arthropods, immobilizing their prey with their venom. Humans are stung by walking barefoot at night, by not shaking their shoes out in the morning in an area of endemicity, by lifting rocks or logs, or in bedding that is on the floor. The stings cause local pain (probably due to the great biogenic amine content of the venom), edema,
discoloration, and hysteresis. Systemic signs can include shock, salivation, confusion or anxiety, nausea, tachycardia, and tetany. Venom characteristics differ depending on the genus of scorpion; some stimulate parasympathetic nerves and can lead to secondary stimulation of catecholamines resulting in sympathetic stimulation, which in turn may contribute to respiratory failure (38). Others affect the central nervous system, are hemolytic, or cause local necrosis. Hypersensitivity and anaphylaxis may occur in individuals who are repeatedly exposed.

Treatment is usually symptomatic, although in areas with known dangerous species, i.e., the Middle East (Leiurus spp., Buthacus spp., Buthus spp.), southern Africa (Parabuthus spp., Buthus spp., Uroplectes spp., South and Central America (Tityus spp.), and the southern United States (Centruroides spp.), quickly applying a pressure bandage over the sting and immobilizing the limb (if that is where the sting was) would help to prevent venom from traveling via the lymphatics. Lidocaine may be injected directly into the sting to reduce pain. Medical attention should be sought as soon as possible because antivenin, when administered promptly, reduces morbidity. However, antivenin is usually species specific, and without bringing the culprit in for identification, antivenin use would be on a presumptive basis.

Centipedes and Millipedes
The centipedes (class Chilopoda, 2,800 species) and millipedes (class Diplopoda, 8,000 species) are elongate, vermiform arthropods with dozens of segments, each of which bears a pair of legs. Both undergo an incomplete development, with larvae looking like miniature adults. The word “centipedes” would suggest having 100 segments (and pairs of legs) or fewer and the word “millipedes,” more than 100 and up to 1,000. This simplification is not quite correct, but in general, possession of many legs indicates a millipede and fewer legs (but more than insects or ticks) indicates a centipede. Other differences are apparent: millipedes are rounded in cross section, but centipedes are dorsoventrally flattened; millipedes have mouthparts that are ventral and nonpiercing, whereas centipedes have mouthparts that protrude anteriorly and are clearly capable of piercing. Millipedes move slowly, reflecting their mode of life as feeders on detritus. Centipedes are very rapid predators on other arthropods.

The diversity of both millipedes and centipedes is greatest in the tropics, and virtually all those of medical importance are found in warm climates. Millipedes may squirt a noxious, corrosive fluid from pores on their segments. Such fluid may contain benzoquinone, aldehydes, and hydrocyanic acid and cause an immediate burning sensation followed by erythema and edema, even progressing to blistering (39). Most millipedes also have a repugnant smell; both the corrosive fluid and the smell tend to protect them from predation. People become exposed when they step on or sleep on millipedes or provoke them (children playing with them are often victims). Treatment consists of washing the affected site as soon as possible to dilute and remove the corrosive fluids and is symptomatic for the skin lesions and pain. Centipedes have powerful biting mandibles and small fanglike structures (forcipe) situated between them and derived from the first pair of legs that may inject a venom. This venom is used to immobilize prey but is also used in defense. Centipede bites occur when people step on or sleep on them or play with them. Envenomation is manifested by local pain and swelling, with proximal lymphadenopathy. Headache, nausea, and anxiety are common. Skin lesions may ulcerate and become necrotic. Death due to centipede bite has been confirmed for only one case, a Filipino child who was bitten on the head by a large Scutigera coleoptrata of the eastern United States, is commonly found in bathtubs. This hairy-looking, small (5- to 8-cm-long) centipede is actually beneficial, preying on roaches and other potential pests within houses. Its strong mandibles can, however, inflict a painful pinch, and it does have a mild venom that produces a bite similar in quality to a bee sting.

Spiders
The order Araneae comprises nearly 30,000 species, but only a fraction of them have any medical importance. Most are very small (<0.5 cm or smaller in length), but a few may be as large as a man’s hand. Two major suborders are recognized: the Mygalomorphae, in which the fang-tipped chelicerae operate in parallel using an up-and-down stroke, and the Araneomorphae, in which the chelicerae operate like insect mandibles, with a side-to-side motion. Spiders have an unsegmented cephalothorax, an abdomen, four pairs of legs, the prominent chelicerae, and spinnerets, specialized organs that secrete the silk for making webs. All spiders are predatory on other arthropods and use their venom to immobilize prey, which are stored live. Spiders rend their prey with their chelicerae and bathe them with a digestion fluid for hours prior to ingestion. Thus, although all spiders have stout chelicerae and can bite and all spiders have a venom with which to immobilize their prey, most are too small to be noticed by humans even if they were to be bitten. The spiders of main medical interest belong to four groups (40, 41): the funnel web or trapdoor spiders of Australia (Atrax spp., Hydrocynge spp.), New World and southern African recluse spiders (Loxosceles spp.), South American armed spiders (Phoneutria spp.), and the cosmopolitan wolf spiders (Latroductus spp.). The recluse and widows have been widely transported by humans.

The clinical manifestations and complications of envenomation may differ between the four main spiders, and the syndromes caused by each have been given names that reflect the identity of the spider. With spider bites in general, there are local pain and erythema at the site of the bite, and this may be accompanied by fever, chills, nausea, and joint pains. In loxoscelism, the site of the bite ulcerates and becomes necrotic. Skin may slough, and there may be destruction of the adjacent tissues. Hemolysis, thrombocytopenia, and renal failure may ensue. With latrodectism, phoneutriism, and funnel web neurotoxicity, the venoms have a strong neurotoxic action. Muscle rigidity and cramping (similar to acute abdomen) are seen with latrodectism; complications include electrocardiogram (EKG) abnormalities and hypotension. With phoneutriism, visual disturbances, vertigo, and prostration may occur; complications include hypotension and respiratory paralysis (40). Funnel web spiders induce autonomic nervous system excitation, with muscular twitching, salivation and lachrymation, nausea and vomiting, and diarrhoea; fatal respiratory arrest may result from aspnea or laryngospasm (42).

Funnel web spider bites require prompt first aid, and the same recommendations could be used for latrodectism or phoneutriism. A compression bandage should be applied over the site of the bite, and the affected limb should be immobilized by splinting with a compression bandage if bitten on an extremity (standard procedures for snakebite). This may help prevent the venom from moving from the local lymphatics. The patient should seek medical attention as soon as possible for antivenin treatment. Otherwise, treatment is symptomatic with analgesics and antipyretics.
Tarantulas are popular pets and appear fearsome. Fortunately, they are docile, and most injuries associated with them are due to their urticating hairs, particularly with respect to conjunctivitis. They do, however, have robust mandibles and venom and should not be provoked; bites are similar in quality to a bee sting.

Necrotic dermal lesions are often classified as loxoscelism even if the appropriate spiders are not known to be present in the area: only 35 of 216 diagnoses of “brown recluse spider bites” proved to be supported by the minimum evidence for assigning such a specific etiology, viz., the known presence of *Loxosceles reclusa* within the geographic area of exposure (43). In the eastern United States, some necrotic dermal lesions may actually be due to the bite of the yellow sac spider, *Cheiracanthium mildei* (44), or the related *Cheiracanthium inclusum*, causing a painful eschar that may last for weeks (but see reference 45). Severe reactions to tick bite or even the erythema migrans of Lyme disease may be confused with reclus or other spider bites (46).

**Miscellaneous Injury Due to Arthropods**

Beetles (coleoptera) comprise 40% of all insect species, but even with this great diversity, very few may be harmful. Most injury is related to vesication by secretions containing cantharidin. The hemolymph (blood) of some of these beetles, generally called the blister beetles, also contains this irritant, and thus exposure may be by direct contact with live or dead (crushed) beetles. Cantharidin is the active ingredient of the Spanish fly, the alleged aphrodisiac made from pulverized *Lyttia vesicatoria*. Ingestion of Spanish fly would irritate the ureter and urethra and cause painful priapism. Overdose or chronic use causes renal tubular necrosis. It is likely that Spanish fly is no longer in demand given the availability of nitric oxide inhibitors.

An unusual group of carabids, the bombardier beetles, spray a boiling-hot (100°C) jet of benzoquinone as a defense (47), causing burns and blistering. Blistering is also produced by crushing the staphylinid beetle *Paeides fusca* of Southeast Asia, which contains a toxic alkaloid, pederin.

More commonly, carpet beetles (dermestids), which feed on wool rugs and other animal fur products, are associated with a papulovesicular eruption. In particular, larval dermestids and their hairs or shed skins (exuviae) cause a contact dermatitis.

Water beetles (actually members of the Hemiptera), also known as water skimmers, can inflict strong pinches on unsuspecting toes wading through water.

**OTHER INJURY**

**Delusory or Illusion of Parasitosis**

Illusory parasitosis is a condition in which a patient who has a real itch has the mistaken belief that the current itch is due to active infestation by irrelevant arthropods. Often, the itch is due to a drug reaction, sunburn, detersgents, irritating dusts, poison ivy, or even *bona fide* arthropod bites (among many other potential sources of itch) that were sustained months in the past. Once a patient has been helped to identify the actual cause of the itch, he or she will not persist in blaming an arthropod. In contrast, in delusory parasitosis (also known as Ekbom syndrome), the patient cannot be dissuaded that the source of discomfort is probably not an arthropod. In some patients, there are no objective lesions but simply an insistence that they are infested. Many such cases are highly educated people and can describe their infestation with great detail. However, they rarely produce a specimen, and when they do, it is usually not an arthropod or part thereof. Delusory parasitosis can be a serious illness, which can be treated by experienced mental health professionals.

**IDENTIFYING SUBMITTED SPECIMENS**

For most purposes, identification to the species level (“this is *Eutrombicula alfredugesi*”) may not provide any more clinically relevant information than identification to a higher taxonomic level (“this is a chigger”). In some cases, simply being able to say “this is definitely an arthropod part, perhaps beetle” may be all the information that is required (in this example, a beetle part may suggest dwarf tapeworm infection or be consistent with urticaria due to the hairs of dermastid beetle larvae or with vesication due to the hot spray of the bombardier beetle). A whole arthropod may be compared with the bauplan diagram to place it within a general group. A classic pictorial key published by the CDC (available from http://www.dpd.cdc.gov/dpdx/HTML/CDFProducts.htm) or a simple dichotomous key (Table 3) may be used to narrow the identification down to a known genus of medically important arthropod. Anything more specific usually requires consulting a taxonomic reference or finding an entomologist who can help. Agricultural extension services, university entomology departments, local mosquito or pest control organizations, parasitologists, or local bug-collecting enthusiast clubs may all be of help in identifying a specimen and usually do not charge out of professional courtesy. (Note that few such entities may be Clinical Laboratory Improvement Amendments [CLIA] certified, and thus fee for service is problematic.)

In some cases, a patient may insist that an arthropod specimen be tested for the presence of an infectious agent. This is particularly common in areas where Lyme disease is endemic. The value of such a practice is dubious, other than for psychologically satisfying the patient’s demand. Some commercial laboratories test for the presence of Lyme disease spirochetes using a PCR assay, but given that the prevalence of infection in the vector may range from 15 to 70%, a positive test is likely. Furthermore, at least with deer ticks, other agents, such as those causing human granulocytic ehrlichiosis (HGE) and babesiosis, may be present but not revealed by tick testing for Lyme disease spirochetes. Other tick species also are likely to have guilds of microbes as opposed to a sole agent (48). In any event, by the time a PCR result is rendered, the patient may already be experiencing signs and symptoms. For Lyme disease, and likely for ehrlichiosis, postexposure prophylaxis may be provided in the form of two doses of 100 mg doxycycline, if the patient remains unconvinced.

The most important variable in determining the riskiness of a tick bite is how long the tick has fed (Fig. 9). If a deer tick is attached for no more than 24 hours, regardless of whether it is demonstrated to be infected with Lyme disease spirochetes, *Babesia microti*, or the agent of granulocytic ehrlichiosis, the likelihood of an infectious dose of organisms being transmitted is very small. The biological basis for this “grace period” is a phenomenon known as reactivation, wherein pathogens within ticks require a period of replication after emerging from a period of dormancy that they enter during the long interstadiatal period between blood meals (49). Reactivation was first described for the agent of Rocky Mountain spotted fever, which attains infectivity...
TABLE 3 Key to the common arthropod classes, subclasses, and orders of medical importance, adult stages only

1. Three or four pairs of legs [2]  
   Five or more pairs of legs [22]

2. Three pairs of legs with antennae (insects: class Insecta) [3]  
   Four pairs of legs without antennae (spiders, ticks, mites, scorpions: class Arachnida) [20]

3. Wings present, well developed [4]  
   Wings absent or rudimentary [12]

4. One pair of wings (flies, mosquitoes, midges: order Diptera) [5]  
   Two pairs of wings [6]

5. Wings with scales (mosquitoes: order Diptera)  
   Wings without scales (other flies: order Diptera)

6. Mouthparts adapted for sucking, with an elongate proboscis [7]  
   Mouthparts adapted for chewing, without an elongate proboscis [8]

7. Wings densely covered with scales, proboscis coiled (butterflies and moths: order Lepidoptera)  
   Wings not covered with scales, proboscis not coiled but directed backward (bedbugs and kissing bugs: order Hemiptera)

8. Both pairs of wings membranous, similar in structure, although size may vary [9]  
   Front pair of wings leathery or shell-like, serving as covers for the second pair [10]

9. Both pairs of wings similar in size (termites: order Isoptera)  
   Hind wings much smaller than front wings (wasps, hornets, and bees: order Hymenoptera)

10. Front wings horny or leathery, without distinct veins, meeting in a straight line down the middle [11]  
    Front wings leathery or paperlike, with distinct veins, usually overlapping in the middle (cockroaches: order Dictyoptera)

11. Abdomen with prominent cerci or forceps; wings shorter than abdomen (earwigs: order Dermaptera)  
    Abdomen without prominent cerci or forceps; wings covering abdomen (beetles: order Coleoptera)

12. Abdomen with three long terminal tails (silverfish and firebrats: order Thysanura)  
    Abdomen without three long terminal tails [13]

13. Abdomen with narrow waist (ants: order Hymenoptera)  
    Abdomen without narrow waist [14]

14. Abdomen with prominent pair of cerci or forceps (earwigs: order Dermaptera)  
    Abdomen without cerci or forceps [15]

15. Body flattened laterally, antennae small, fitting into grooves in side of head (fleas: order Siphonaptera)  
    Body flattened dorsoventrally, antennae projecting from side of head, not fitting into grooves [16]

16. Antennae with nine or more segments [17]  
    Antennae with three to five segments [18]

17. Pronotum covering head (cockroaches: order Dictyoptera)  
    Pronotum not covering head (termites: order Isoptera)

18. Mouthparts consisting of tubular joined beak; three- to five-segmented tarsi (bedbugs: order Hemiptera)  
    Mouthparts retracted into head or of the chewing type; one- or two-segmented tarsi [19]

19. Mouthparts retracted into the head; adapted for sucking blood (sucking lice: order Anoplopleura)  
    Mouthparts of the chewing type (chewing lice: order Mallophaga)

20. Body oval, consisting of a single saclike region (ticks and mites: subclass Acari)  
    Body divided into two distinct regions, a cephalothorax and an abdomen [21]

21. Abdomen joined to the cephalothorax by a slender waist; abdomen with segmentation indistinct or absent; stinger absent (spiders: subclass Aranae)  
    Abdomen broadly joined to the cephalothorax; abdomen distinctly segmented, ending with a stinger (scorpions: subclass Scorpiones)

22. Five to nine pairs of legs or swimmerets; one or two pairs of antennae; principally aquatic organisms (copepods, crabs, and crayfish: class Crustacea)  
    Ten or more pairs of legs or swimmerets absent; one pair of antennae present; terrestrial organisms [23]

23. Body segments each with only one pair of legs (centipedes: class Chilopoda)  
    Body segments each with two pairs of legs (millipedes: class Diplopoda)

*Data from references 9 and 58.*
within tick salivary glands only after 12 to 18 hours of exposure to a host. Reactivation is probably a general phenomenon with most ixodid (hard) tick-transmitted agents, the only known exceptions being the viruses causing tick-borne encephalitis and the related Powassan fever, in which transmission is thought to be instantaneous with attachment.

Estimating the degree of engorgement may provide more of an index of individual risk than the actual presence or absence of infection. A simple measurement may be made with deer ticks and might be tried for other species of ticks. The scutal index is the ratio of the length of the tick from the tip of the mouthparts to the caudal edge of the tick to the width of the scutum, the dark shield on the dorsum of the tick. A scutal index of >2.5 suggests that a deer tick has been attached for more than 24 hours, and therefore transmission is likely (50). Such a finding might prompt a physician to provide prophylactic antibiotics, which would effectively abort Lyme disease or HGE. Although such prophylaxis would not prevent babesiosis, note that of the agents transmitted by deer ticks, B. microti requires the greatest duration of attachment for infectivity, probably relating to the requirement for sporogony during attachment.

Much progress has been made in a universal barcoding system for identifying animals by means of DNA sequences (51). In particular, the 5’ end of the mitochondrial cytochrome C oxidase subunit I (COI), usually a 648-base pair portion, is used as a PCR target, and the nucleotide sequence that is obtained from the amplification product can be compared to a large online database (http://www.boldsystems.org/views/login.php). Most species of animals contain unique sequences in their COI gene and thus can be discriminated from other related species. Nearly 750,000 sequences have been accessioned in the BOLD database. For the phylum Arthropoda, barcode sequences exist for all 16 classes; for Insecta, all 30 orders are represented. Accordingly, virtually any putative arthropod sample may be identified to the order level and possibly to family or genus level by extracting its DNA, amplifying the COI gene, sequencing, and then submitting the data in FASTA format to the BOLD server. Assuming that the equipment is available (thermal cycler, gel electrophoresis, pipettors, and other materials common to molecular biology laboratories), such an identification might cost on the order of $150 to $200 (5 hours of technician time, PCR reagents, commercial rate for sequencing 300 base pairs) with a few days’ turnaround (usually, a minimum of 24 to 48 hours from submission of the DNA to receipt of the sequencing chromatogram is required for DNA sequencing). A simple DNA extraction technique (“HotSHOT,” which uses hot sodium hydroxide and Tris neutralization) may be used on most samples to prepare them for PCR analysis (52). The assay conditions and PCR primers for amplifying an informative portion of the COI gene may be adopted from published analyses of preserved museum specimens, which often contain degraded DNA similar to that of many forensic or clinical samples (53). The advantage to the barcoding approach is that the method is not subjective and does not require the extensive training and expertise for morphological identification; anyone with general expertise in molecular biology may be engaged. Classically based methods, however, require little more than a microscope, can be virtually instantaneous, and may be rendered as a professional courtesy without fee. Some commercial websites (e.g., www.identifyus.com) offer virtual morphologic identification in real time, with clients uploading a photograph of the offending arthropod to be identified quickly by an expert. Alternatively, amateur entomologist websites (e.g., www.bugguide.net) can be extremely helpful in identifying samples.

A number of effective antiprotozoal and anthelmintic drugs are currently available. Antiparasitic agents are important both for therapy of infected individual patients and for control of parasitic infections at the community level. Large-scale chemotherapy is reducing transmission, morbidity, and mortality of infections including lymphatic filariasis, onchocerciasis, schistosomiasis, and infection with intestinal nematodes. However, the lack of financial incentives to develop new agents is a major limitation to the future of antiparasitic chemotherapy. Emerging resistance among parasites, a lack of effective antiparasitic vaccines, and the enormous burden of disease worldwide also pose challenges to the effective management of parasitic infections.

This chapter focuses on the mechanisms of action, pharmacology, clinical utility, and adverse effects of common first-line antiparasitic therapies and newer drug alternatives. Most helminth infections in humans can be treated with one of five drugs, namely, albendazole, mebendazole, praziquantel, ivermectin, and diethylcarbamazine (DEC), so these five drugs are reviewed in detail. Another agent, nitazoxanide, has both anthelmintic and antiprotozoal activity and is also discussed. Other major antiprotozoal drugs, including those used for malaria, gastrointestinal protozoal infection, leishmaniasis, and trypanosomiasis, are also reviewed, but an exhaustive list of all antiparasitic drugs is not included. Specifically, we have excluded discussion of agents without a first-line indication or that are recommended only in special situations, such as furazolidone in children. Tribendimidine is a promising new agent for treatment of liver flukes (clonorchiasis and opisthorchiasis), but trials are still under way and it has not yet been approved for use so is not discussed. Additionally, antibacterial and antifungal agents that can also be used for treatment of protozoal infections, such as the 5-nitroimidazoles, trimethoprim-sulfamethoxazole, azithromycin, and amphotericin, are not discussed in detail here, but their general indications for parasitic infections are shown in Tables 1 and 2. Resistance to antiparasitic agents and drug susceptibility testing are dealt with in separate chapters.

**ANTHELMINTIC AGENTS**

**Benzimidazoles**

The benzimidazoles are antiparasitic agents with a broad spectrum of activity against many helminthic and certain protozoal infections. All members of the benzimidazole class have in common a bicyclic ring system in which benzene has been inserted. Mebendazole and albendazole, both of which are synthetic agents, are the most widely used drugs of this class. Mebendazole is 5-benzoyl-2-benzimidazole carboxylic acid, and albendazole is methyl 5-(propylthio)-2-benzimidazole carbamate. The low cost, high efficacy, and ease of administration of these two agents have led to their widespread use for many human parasitic infections. Major indications for their use are shown in Tables 3 and 4. Whereas mebendazole has been approved for treatment of multiple nematode infections by the U.S. Food and Drug Administration (FDA), albendazole is used preferentially as first-line treatment for many parasite infections but is nevertheless considered investigational and given as a “non-approved indication” in all cases except when used as treatment for hydatid infections and neurocysticercosis (1).

Other members of this drug class include flubendazole, thia-bendazole, and triclabendazole. Flubendazole, a parafuranso analogue of mebendazole, has the same mechanism of action as mebendazole and albendazole. It is licensed in Europe for the treatment of intestinal nematodes but is not licensed in the United States. It has shown good activity against adult filarial parasites in animal models if given parenterally (2). It also exhibits activity against protozoa of Echinococcus granulosus, but currently there are no data on its efficacy for treatment of hydatid disease in humans (3). Thiabendazole, 2-(4-thiazolyl)-1H-benzimidazole, has similar mechanisms of action to those of the other benzimidazoles, but it is frequently associated with side effects. It has now been replaced by other anthelmintic agents (4) but is sometimes still used topically for treatment of cutaneous larva migrans. Triclabendazole is a newer imidazole derivative that has been used as a veterinary agent for many years. It is thought to act on microtubules, causing decreased parasite motility. It is the drug of choice for fascioliasis (5, 6), although resistance is emerging in animals and this may pose a threat to treatment of human patients in the future (7-9). It is the preferred therapy for paragonimiasis (10). Triclabendazole is well tolerated, and few significant adverse effects have been described, but it is not recommended for use during pregnancy because of insufficient safety data. It is considered investigational by the U.S. FDA and may be obtained from the Centers for Disease Control and Prevention (CDC) in the United States for paragonimiasis, but it is not widely available. These three agents are not discussed further.
Mechanism of action. The antiparasitic activity of albendazole and mebendazole results mainly from their ability to bind to a cytoskeletal protein of parasites called β-tubulin, thereby inhibiting the polymerization of tubulin into microtubules (11). The disruption of microtubule synthesis within parasitic intestinal cells results in decreased absorptive function. In addition, mebendazole and albendazole directly inhibit glucose absorption by parasites, leading to a depletion of parasite glycogen stores, insufficient energy sources for formation of ATP, and inability to reproduce or survive (12, 13). Although tubulin is also present in mammalian tissue-dwelling parasites, it contributes to their minimal mammalian toxicity (4).

Pharmacokinetics. Benzimidazoles are poorly soluble in water and therefore are not well absorbed following oral administration. Although this limits their activity against tissue-dwelling parasites, it contributes to their minimal toxicity and to their efficacy in the treatment of many intestinal helminthic infections (14). Less than 20% of mebendazole is absorbed after oral administration, with peak plasma concentrations seen at 2 to 4 h. It is metabolized in the liver to inactive compounds, eliminated in the bile, and excreted predominantly in the feces. It is 95% protein bound in plasma, and its serum half-life is 2.5 to 5.5 h. Levels in serum are markedly variable between individuals, but concentrations in tissue and in echinococcal cysts tend to be low (15).

The oral bioavailability of albendazole is also poor, with <10% absorption following an oral dose (16). Administration of albendazole with a fatty meal markedly improves bioavailability, by up to 5-fold. It is rapidly metabolized in the liver, and concentrations of the parent drug in plasma are negligible. However, its primary metabolite, albendazole sulfoxide, also has anthelmintic activity (17). This results in a higher efficacy of albendazole than that of mebendazole for most indications. Albendazole sulfoxide is 70% protein bound and is widely distributed throughout the body. Peak concentrations of albendazole sulfoxide in plasma are seen after 2 to 5 h but show great intersubject variability, ranging from 0.45 to 2.96 mg/liter following a single dose of 15 mg/kg of body weight (18). Albendazole induces enzymes of the cytochrome P450 system responsible for its metabolism. Cimetidine and dexamethasone both raise drug levels (19), and coadministration with praziquantel also increases the levels of both active drugs (20, 21). Albendazole sulfoxide has been detected in urine, bile, liver, cyst fluid, and cerebrospinal fluid (CSF). Levels in plasma are 3- to 10-fold and 2- to 4-fold higher than those in cyst fluid and CSF, respectively (22, 23). Albendazole sulfoxide has a half-life of ∼9 h. It is oxidized further to inactive compounds such as albendazole sulfone and is mainly excreted in the urine.

Neither mebendazole nor albendazole is dialyzable. No dosage adjustment is required for individuals with renal impairment, but a reduction in dose should be considered if there is significant hepatic insufficiency. Benzimidazoles are not available as intravenous formulations.

Spectrum of activity. The benzimidazoles are effective against adult worms and developing helminth embryos. Albendazole and mebendazole have similar and broad ranges of activity (Tables 3 and 4). Both drugs have good efficacy against many common intestinal nematode infections, including ascariasis, trichuriasis, enterobiasis, and hookworm infections. Three-day regimens of mebendazole and 1 to 3 days of albendazole are generally recommended for therapy.

\(^b\)This is not an exhaustive list of all possible parasitic infections, but commonly encountered parasites are included.

of individual patients (with the longer duration being particularly preferable for trichuriasis and hookworm infection therapy) (24). A single dose of either drug is often used for mass or targeted community treatment of intestinal nematodes in areas of endemicity. Albendazole is preferred in most instances, but the efficacy of albendazole against very heavy infections with *Trichuris trichiura* remains questionable, and mebendazole may be preferable in this circumstance. The reported curative efficacies of both drugs for different parasitic infections vary according to the baseline intensity of infection in the patient, geographic location, diagnostic tests employed, and duration of follow-up post-treatment.

Mebendazole and albendazole also have activity against other nematode infections, including angiostrongyliasis, trichostrongyliaisis, capillariasis, trichinellosis, gnathostomiasis, toxocarasis, and cutaneous larva migrans. Additionally, albendazole is increasingly being used in combination with either DEC or ivermectin for treatment of Bancroftian or Brugian filariasis and loiasis; it is particularly useful for these infections as part of a single-dose regimen for mass chemotherapy programs. Although albendazole displays some efficacy against *Strongyloides stercoralis*, ivermectin consistently yields higher cure rates and is the recommended treatment of choice.

Both mebendazole and albendazole also show activity against certain cestode infections. Albendazole is again preferred because of its more favorable pharmacokinetics, and it is now considered the drug of choice for medical management or adjunctive treatment of hydatid disease due to *E. granulosis*. Prolonged albendazole therapy (minimum of 10 years) can also be used for inoperable alveolar echinococcosis or as adjuvant therapy for patients with *Echinococcus multilocularis* infection. Additionally, albendazole is used for treatment of parenchymal neurocysticercosis. Although considered primarily an anthelmintic agent, albendazole is also an alternative agent for giardiasis.

**Adverse effects.** Adverse effects following short courses of the benzimidazoles mebendazole and albendazole are infrequent and generally mild. Transient abdominal pain, nausea, and diarrhea may develop. Headache, dizziness, insomnia, and allergic phenomena are also reported. With prolonged high-dose therapy, such as for echinococcosis,

Praziquantel

Praziquantel is a synthetic heterocyclic isoquinolone-pyrazine derivative. Major indications for its use are shown in Table 5. It has the unique characteristic of being active against almost all trematodes and cestodes, but it is not useful for treatment of nematode infections (4). It has been approved for use by the U.S. FDA (1).

Mechanism of action. Praziquantel induces ultrastructural changes in the teguments of parasites, resulting in increased permeability to calcium ions. Calcium ions accumulate in the parasite cytosol, leading to muscular contractions and ultimately to paralysis of adult worms. By damaging the tegument membrane, praziquantel also exposes parasite antigens to host immune responses (30, 31). These effects lead to dislodgment of worms from their intestinal sites and subsequent expulsion by peristalsis.

Pharmacokinetics. Praziquantel is available for oral administration, and >80% of the drug is absorbed. Coadministration with a high-carbohydrate meal increases drug concentrations in serum (32). The drug is biotransformed in the liver, and metabolites are excreted mainly in the urine. The cytochrome P450 hepatic metabolism of praziquantel is induced by corticosteroids, phenytoin, and phenobarbital.

*Adapted from reference 1.*

Praziquantel levels in serum are therefore lowered when any of these drugs are coadministered. Cimetidine, which inhibits P450-mediated metabolism, can be given concurrently to increase levels of praziquantel in plasma. Levels in plasma peak after 1.5 to 2 h, and after a single 40-mg/kg dose, peak levels have been reported as 1.007 to 1.625 mg/liter (33). Praziquantel does not cross the blood-brain barrier well, so levels in CSF are only approximately 20 to 25% of those in plasma (14, 32). It is 80% protein bound, and its half-life in serum is 1 to 3 h. It is not dialyzable, and no adjustment in dose is recommended in either renal or hepatic insufficiency.

**Spectrum of activity.** Praziquantel is active against the larval and adult stages of many trematodes. It is the drug of choice for schistosomiasis and is effective for all Schistosoma species that infect humans. It is used both for treatment of individuals and in mass community chemotherapy programs and leads to decreased transmission and prevalence of infection. Praziquantel is also used for treatment of opisthorchiasis, clonorchiasis, paragonimiasis, and intestinal fluke infections, including fasciolopsiasis, heterophyiasis, and metagonimiasis. In contrast to other human trematode infections, praziquantel has not proven to be effective in the treatment of Fasciola hepatica infection.

Many cestode infections can also be treated with praziquantel. Most tapeworm infections respond, including those caused by Taenia, Diphyllobothrium, and Hymenolepis species. Because praziquantel does not kill eggs, precautions should be taken to prevent autoinfestation and laboratory-acquired infection, particularly for Taenia solium. Praziquantel is also used in the treatment of neurocysticercosis as an alternative or adjunct to albendazole, although its overall benefit remains unclear.

Praziquantel has also been used in combination with albendazole for treatment of echinococcal infections. Praziquantel has high protoscolicidal activity in vitro, and some reports have suggested superior efficacy of the combination to that of either drug alone (34–36).

**Adverse effects.** Adverse effects of praziquantel are generally mild, but many studies report that some side effects occur in >30% of patients. Common reactions include dizziness, lethargy, headache, nausea, and abdominal pain. Hypersensitivity reactions occur rarely (37, 38). Severe adverse reactions are uncommon, although administration to individuals with neurocysticercosis can result in seizures and neurological sequelae related to precipitation of an inflammatory response (39).

Animal studies do not suggest a teratogenic effect of praziquantel (pregnancy category B), but an increased abortion rate has been seen in rats. There are minimal data on its safety in humans, but there is a very low potential for adverse effects on either the mother or her unborn child (40), and when praziquantel has been used during pregnancy, no increase in abortion rates, preterm deliveries, or congenital abnormalities has been noted (41). Consequently, praziquantel can be given after the first trimester. No adverse effects of praziquantel administration during lactation have been reported, but it is excreted in human breast milk and discontinuation of breast feeding on the day of therapy and for the following 72 h is sometimes suggested. However, owing to available data regarding its safety profile, in 2002 the World Health Organization recommended that it can be considered for use in pregnant and lactating women (42). It is FDA approved for children aged 4 years and over.

**Ivermectin**

Ivermectin is a semisynthetic macrocyclic lactone derivative of avermectins, which are natural substances derived from the actinomycete Streptomyces avermitilis. Major indications for its use are shown in Table 6. It was initially developed as an agent for veterinary use but is now used widely in humans. Ivermectin is a potent oral agent with relatively broad-spectrum anthelmintic activity. It has been approved by the U.S. FDA as an oral therapy for onchocerciasis and uncomplicated strongyloidiasis (1) and as a topical treatment for head lice.

**Mechanism of action.** Ivermectin causes an influx of chloride ions across glutamate-gated chloride channels in nerve and muscle cell membranes, resulting in hyperpolarization of the affected cells and consequent paralysis and death of parasites (4, 43–46). It has also been postulated that ivermectin may act as an antagonist of the neurotransmitter γ-aminobutyric acid (47). Although specific ivermectin binding sites have been identified in mammalian brain tissue, the affinity of ivermectin for sites within parasites is ∼100 times greater than that for mammalian tissue.

**Pharmacokinetics.** Ivermectin is available as an oral preparation. There is no parenteral preparation of ivermectin approved by the FDA, but it has been given via the rectal and subcutaneous routes to critically ill patients with disseminated strongyloidiasis who are unable to tolerate oral therapy (48, 49). It is rapidly absorbed following oral administration. Bioavailability is thought to increase ~2.5-fold if it is taken with a high-fat meal; recommendations are to administer the drug on an empty stomach with water. Ivermectin is metabolized in the liver and excreted almost
entirely in the feces. Peak levels in serum occur at 4 to 5 h, and levels of ~46 μg/liter have been reported after a single 12-mg dose (15). It is highly protein bound in plasma, and it has a half-life of 10 to 18 h. The drug accumulates in fat tissue and does not readily cross the blood-brain barrier (50).

**Spectrum of activity.** Ivermectin is the drug of choice for onchocerciasis and strongyloidiasis. In onchocercal infections, ivermectin does not significantly affect the viability of adult worms, but it impairs release of microfilariae, and is a potent microfilaricidal agent, leading to a sustained reduction in microfilaraemia for many months (44). It can be used both for the treatment of individual patients and in mass chemotherapy programs in areas where onchocerciasis is endemic. The role of combination therapy with ivermectin is being explored. In uncomplicated strongyloidiasis, ivermectin has excellent efficacy in immunocompetent patients (47). In disseminated strongyloidiasis, ivermectin is administered daily until stool and sputum exams are negative for larvae.

Ivermectin also has activity against microfilariae of *Wuchereria bancrofti*, *Brugia malayi*, and *Loa loa*. It does not have a significant effect on adult worm viability in these infections, so reduced microfilaraemia is sustained only with repeated doses, and it has not replaced DEC as first-line therapy for these infections. Ivermectin also has activity against *Mansonella ozzardi* and *Mansonella streptocerca* microfilariae.

**Adverse effects.** Ivermectin is generally well tolerated. Most of the adverse effects that occur following its administration are a result of the host’s immune response to destruction of parasites rather than to toxic effects of the drug per se. Adverse effects include fever, rash, dizziness, pruritus, myalgia, arthralgia, and tender lymphadenopathy; the severity of these symptoms relates to the pretreatment intensity of infection rather than to ivermectin concentrations in serum (56). Transaminitis is occasionally reported. Severe reactions occasionally occur, including a hypersensitivity response to dying microfilarial parasites known as the Mazotti reaction. This anaphylactoid response is characterized by allergic manifestations including pruritis, edema, fever, and systemic hypotension. However, these reactions are primarily restricted to individuals with high parasite loads. In patients infected with *L. loa* who have elevated levels of microfilaraemia, ivermectin has been associated with the development of fatal encephalopathy (57) and so should be avoided.

Ivermectin (pregnancy category C) has been shown to be teratogenic in mice, rats, and rabbits when given in repeated doses of 0.2, 8.1, and 4.5 times the maximum recommended human dose, respectively. Teratogenicity was characterized in the three species by cleft palate; clubbed forepaws were additionally observed in rabbits. These developmental effects were found only at or near doses that were maternotoxic to the pregnant female (14, 44). There are insufficient data to recommend its use in pregnant women, although the risk of fetal damage in 203 pregnant women inadvertently treated with ivermectin was no greater than that in controls, and it has been suggested that ivermectin can be given safely after the first trimester (58–60). It is excreted in breast milk in low concentrations, so it should be avoided in lactating women when possible. It is not recommended in children weighing <15 kg.

**Diethylcarbamazine**

DEC is a piperazine derivative. Its main use is in filarial infections. Major indications for its use are shown in Table 7. DEC is not licensed for use in the United States, but it can be obtained from the CDC under an Investigational New Drug (IND) protocol.

**Mechanism of action.** The mode of action of DEC is uncertain. It is predominantly a microfilaricidal agent, and it is thought that its main effect is to inhibit arachidonic acid metabolism and alter the surface membranes of microfilariae, thereby enhancing destruction via host immune responses (12, 13). It also has some macrofilaricidal activity under certain conditions, likely via hyperpolarization and immobilization of adult worms (61).

**Pharmacokinetics.** DEC is available only in tablet form. It is freely soluble in water and is almost completely absorbed after oral administration. The drug is metabolized in the liver, although >50% is excreted unchanged in the urine. There is negligible protein binding, and it is widely distrib-

Pyrantel Pamoate

Pyrantel, a tetrahydropyrimidine, is a relatively broad-spectrum agent against nematodes. It is associated with more side effects and lower efficacy than the benzimidazoles, so it has now largely been replaced. It is approved by the U.S. FDA but is considered investigational for most indications except enterobiasis.

Mechanism of action. Pyrantel is a depolarizing neuromuscular blocking agent. It exerts its anthelmintic effect via release of acetylcholine and inhibition of helminthic acetylcholinesterase. This results in stimulation of ganglionic receptors and spastic paralysis of adult worms. The worms become dislodged from the intestinal wall and are expelled in the feces by normal peristalsis.

Pharmacokinetics. Pyrantel is administered orally but is almost insoluble in water and is therefore poorly absorbed from the gastrointestinal tract. Peak levels in serum occur after 1 to 3 h. More than 50% is excreted unchanged in the feces. The absorbed drug is partially metabolized in the liver. There is no significant interaction with food.

Spectrum of activity. Pyrantel has excellent efficacy in the treatment of ascariasis and hookworm and pinworm infections. It also has some activity against Trichostrongylus. It is not active against *T. trichiura*.

Adverse effects. Although pyrantel is generally well tolerated, it can lead to adverse reactions, including anorexia, nausea, vomiting, abdominal cramps, and diarrhea. It has also been associated with neurotoxic effects, including headache, dizziness, drowsiness, and insomnia. Transient increases in hepatic enzymes have also been reported, and one study reported nephrotic syndrome temporally related to its use (67). Animal studies have not shown adverse effects in the fetus, and it has been used during pregnancy in humans without harmful fetal effects (pregnancy category C) (68). It is not recommended for children <2 years of age.

AN AGENT WITH ANTHELMINTIC AND ANTIPROTOZOAL ACTIVITIES: NITAZOXANIDE

Nitazoxanide is a 5-nitrothiazole derivative with broad-spectrum activity against numerous intestinal protozoa, helminths, and anaerobic bacteria. Major indications for its use are shown in Table 8. It was initially developed as a veterinary anthelmintic with activity against intestinal nematodes, cestodes, and liver trematodes (69). The U.S. FDA has approved it for use for the treatment of diarrhea caused by *Cryptosporidium* species and *Giardia duodenalis* in pediatric and adult patients (69, 70).

Mechanism of action. Nitazoxanide inhibits pyruvate ferredoxin oxidoreductase, an enzyme essential to anaerobic energy metabolism. This is its mechanism of action against anaerobic protozoa and bacteria (e.g., *Trichomonas vaginalis*, *Entamoeba histolytica*, and *Clostridium perfringens*), although for protozoa additional mechanisms may also be involved (71). The exact mechanism of nitazoxanide’s activity against helminths has not yet been determined.

Pharmacokinetics. Nitazoxanide is given by the oral route and is available as a suspension or in tablet formulation. Bioavailability is nearly doubled by administration with food (72). It is absorbed from the gastrointestinal tract, with approximately one-third of the oral dose excreted in
The quinoline derivatives can be divided into four groups: the 4-aminoquinolines; the cinchona alkaloids; synthetic compounds, such as mefloquine and halofantrine; and the 8-aminoquinolines. A related drug, piperaquine, which is a bisquinoline, is now often used in combination with artemisinin derivatives for treatment of malaria. Although it is used in Europe, it is not approved by the U.S. FDA.

### 4-Aminoquinolines

The 4-aminoquinolines include chloroquine, hydroxychloroquine, and amodiaquine. Chloroquine is the most widely used of these agents. It is an inexpensive, safe drug that has been used extensively for treatment and prophylaxis of all Plasmodium species that infect humans, although resistance to chloroquine in Plasmodium falciparum is prevalent globally in most malarial regions. Hydroxychloroquine is a related synthetic compound with an identical clinical spectrum, similar pharmacokinetics, and similar adverse effects. Amodiaquine is another related agent with the same mechanism of action and spectrum of activity. It is reported to be more effective than chloroquine for parasite clearance, but its use has been restricted due to uncommon serious side effects, as noted below. It has not been approved by the U.S. FDA (1).

**Mechanism of action.** The main mechanism of action of the 4-aminoquinolines is thought to be via nonenzymatic inhibition of heme polymerization. Asexual intraerythrocytic malaria parasites actively concentrate quinoline ring compounds within hemoglobin-containing vesicles. In the absence of drug, plasmodia degrade host erythrocyte hemoglobin to provide amino acid nutrients essential for parasite growth. The degradation of hemoglobin produces free heme, which is stored as ferriprotoporphyrin IX within the red blood cell. Ferriprotoporphyrin IX is toxic to the parasite and is usually polymerized into nontoxic malaria pigment (hemozoin). In the presence of drug, there is inhibition of the conversion of heme into hemozoin, leading to the accumulation of products toxic to the parasite and resulting in parasite death (79). These agents also inhibit protein synthesis by inhibiting incorporation of phosphate into DNA and RNA and by inhibiting DNA and RNA polymerases (13). Chloroquine also raises the pH of the vesicle (80).

### ANTIMALARIALS

A number of agents are approved for use for treatment of malaria. The most commonly recommended agents are shown in Table 9.

### Quinoline Derivatives

The quinoline derivatives can be divided into four groups: the 4-aminoquinolines; the cinchona alkaloids; synthetic compounds, such as mefloquine and halofantrine; and the 8-aminoquinolines. A related drug, piperaquine, which is a bisquinoline, is now often used in combination with artemisinin derivatives for treatment of malaria. Although it is used in Europe, it is not approved by the U.S. FDA (1).

**Mechanism of action.** The main mechanism of action of the 4-aminoquinolines is thought to be via nonenzymatic inhibition of heme polymerization. Asexual intraerythrocytic malaria parasites actively concentrate quinoline ring compounds within hemoglobin-containing vesicles. In the absence of drug, plasmodia degrade host erythrocyte hemoglobin to provide amino acid nutrients essential for parasite growth. The degradation of hemoglobin produces free heme, which is stored as ferriprotoporphyrin IX within the red blood cell. Ferriprotoporphyrin IX is toxic to the parasite and is usually polymerized into nontoxic malaria pigment (hemozoin). In the presence of drug, there is inhibition of the conversion of heme into hemozoin, leading to the accumulation of products toxic to the parasite and resulting in parasite death (79). These agents also inhibit protein synthesis by inhibiting incorporation of phosphate into DNA and RNA and by inhibiting DNA and RNA polymerases (13). Chloroquine also raises the pH of the vesicle (80).

### ANTIMALARIALS

A number of agents are approved for use for treatment of malaria. The most commonly recommended agents are shown in Table 9.

### Quinoline Derivatives

The quinoline derivatives can be divided into four groups: the 4-aminoquinolines; the cinchona alkaloids; synthetic compounds, such as mefloquine and halofantrine; and the 8-aminoquinolines. A related drug, piperaquine, which is a bisquinoline, is now often used in combination with artemisinin derivatives for treatment of malaria. Although it is used in Europe, it is not approved by the U.S. FDA (1).

**Mechanism of action.** The main mechanism of action of the 4-aminoquinolines is thought to be via nonenzymatic inhibition of heme polymerization. Asexual intraerythrocytic malaria parasites actively concentrate quinoline ring compounds within hemoglobin-containing vesicles. In the absence of drug, plasmodia degrade host erythrocyte hemoglobin to provide amino acid nutrients essential for parasite growth. The degradation of hemoglobin produces free heme, which is stored as ferriprotoporphyrin IX within the red blood cell. Ferriprotoporphyrin IX is toxic to the parasite and is usually polymerized into nontoxic malaria pigment (hemozoin). In the presence of drug, there is inhibition of the conversion of heme into hemozoin, leading to the accumulation of products toxic to the parasite and resulting in parasite death (79). These agents also inhibit protein synthesis by inhibiting incorporation of phosphate into DNA and RNA and by inhibiting DNA and RNA polymerases (13). Chloroquine also raises the pH of the vesicle (80).

### ANTIMALARIALS

A number of agents are approved for use for treatment of malaria. The most commonly recommended agents are shown in Table 9.

### Quinoline Derivatives

The quinoline derivatives can be divided into four groups: the 4-aminoquinolines; the cinchona alkaloids; synthetic compounds, such as mefloquine and halofantrine; and the 8-aminoquinolines. A related drug, piperaquine, which is a bisquinoline, is now often used in combination with artemisinin derivatives for treatment of malaria. Although it is used in Europe, it is not approved by the U.S. FDA (1).

**Mechanism of action.** The main mechanism of action of the 4-aminoquinolines is thought to be via nonenzymatic inhibition of heme polymerization. Asexual intraerythrocytic malaria parasites actively concentrate quinoline ring compounds within hemoglobin-containing vesicles. In the absence of drug, plasmodia degrade host erythrocyte hemoglobin to provide amino acid nutrients essential for parasite growth. The degradation of hemoglobin produces free heme, which is stored as ferriprotoporphyrin IX within the red blood cell. Ferriprotoporphyrin IX is toxic to the parasite and is usually polymerized into nontoxic malaria pigment (hemozoin). In the presence of drug, there is inhibition of the conversion of heme into hemozoin, leading to the accumulation of products toxic to the parasite and resulting in parasite death (79). These agents also inhibit protein synthesis by inhibiting incorporation of phosphate into DNA and RNA and by inhibiting DNA and RNA polymerases (13). Chloroquine also raises the pH of the vesicle (80).
Pharmacokinetics. The 4-aminoquinolines are extensively distributed in tissues and are characterized by a long elimination half-life. Despite similarities in their chemical structures, these drugs show differences in their biotransformation and routes of elimination (81).

Chloroquine is available in oral and parenteral forms. Many different formulations are manufactured worldwide. Chloroquine is rapidly absorbed from the gastrointestinal tract after oral administration and has oral bioavailability exceeding 75%. Food has variable effects on absorption. The drug is distributed extensively in body tissues and reaches high levels within the brain (82). Chloroquine binds to melanin-containing cells in the skin and eye, so it can also reach high levels at these sites. There is marked variability in peak concentrations in plasma between individuals, but within 3 h of initiating standard oral treatment doses (10 mg chloroquine base/kg, followed by three doses of 5 mg/kg at 6, 24, and 48 h), concentrations in blood remain above 1 nmol/liter for at least 4 days (83). It is ~60% protein bound and has a half-life of 3 to 6 days. Approximately 30 to 50% of the drug is metabolized to inactive compounds in the liver, and the remainder is excreted in the urine. Treatment reduction (usually 50% of the normal dose) is required in patients with severe renal or hepatic failure. It is not dialyzable.

In contrast, amodiaquine is a produg and is almost entirely metabolized to a biologically active metabolite, desethylamodiaquine, following oral administration. Otherwise, it has pharmacokinetic properties similar to those of chloroquine but has a smaller volume of distribution.

Spectrum of activity. The 4-aminoquinolines are efficient and rapidly acting blood schizonticides. They can be used in both the treatment and prophylaxis of infection with susceptible strains of all Plasmodium species. They have no effect on tissue schizonts or exoerythrocytic stages. They are gametocytocidal for Plasmodium vivax and Plasmodium malariae but have minimal effect on P. falciparum gametocytes. Following infections with P. vivax or Plasmodium ovale, primaquine is also needed to eradicate liver hypnozoites and prevent relapses of infection.

Chloroquine currently is still a first-line option for therapy for some P. vivax, P. malariae, and P. ovale infections, but increasing resistance among P. vivax isolates globally, and especially among P. vivax infections acquired in Indonesia, East Timor, Papua New Guinea, and the Solomon Islands, is emerging. It also remains the treatment of choice for susceptible P. falciparum strains, although P. falciparum strains from almost all areas of the world have developed resistance to it and so it is now rarely used for P. falciparum. It is also effective against Plasmodium knowlesi infections (84). Because of its potential toxicity, amodiaquine is not recommended for prophylaxis of malaria and is generally not used as first-line treatment. However, it results in faster parasite clearance and more rapid resolution of symptoms than those with chloroquine, and it may be effective in some cases of chloroquine-resistant malaria, so it is used as an alternative treatment regimen in some areas.

Chloroquine is also active against E. histolytica trophozoites but is rarely used for this indication, as the nitroimidazoles are the drugs of choice.

Adverse effects. Chloroquine has a bitter taste. It is generally well tolerated at the doses required for malaria prevention or treatment, even when taken for prolonged periods. However, it can lead to nausea, abdominal discomfort, dizziness, retinal pigmentation, blurred vision, electrocardiographic changes, muscular weakness, and, rarely, transient psychiatric symptoms. It can also cause severe pruritus, particularly in African blacks. Irreversible neuroretinopathy can result if it is taken at high doses for prolonged periods. If taken as an overdose, it can cause shock, arrhythmia, and death.

At the doses used for malaria treatment or prophylaxis, chloroquine has rarely been reported to cause adverse congenital effects (pregnancy category C) (85). However, affinity for melanin-containing tissues, such as the retina, iris, and choroid of the eye, has been reported, and definitive delineation of fetal risk remains undefined. It is used commonly for treatment and prophylaxis of malaria in pregnant women, without evidence of teratogenicity, and it is generally agreed that the benefits of preventing and treating malaria in pregnant women outweigh the potential fetal risks. Chloroquine is excreted in small amounts in breast milk.

Amodiaquine is more palatable than chloroquine and seems to cause less itching. However, serious adverse events, including agranulocytosis, aplastic anemia, and drug-induced hepatitis, have been reported. These have occurred predominantly following long-term amodiaquine use (mean, 7 to 8 weeks) for malaria prophylaxis. While short-term treatment regimens are thought to be safe (86), this drug is now used uncommonly.

Chinone Alkaloids
The chinone alkaloids, quinine and quinidine, contain a quinoline ring. Quinidine is the diastereoisomer of quinine. Quinine was originally extracted from the bark of the South American chinone tree, but a synthetic form is now available, usually as a quinine sulfate salt. Quinidine is more active than quinine, but it is also more cardiotoxic.

Mechanism of action. The exact target of chinone alkaloids is unknown. They are thought to act by forming complexes with ferritoporphyrin IX, thereby interfering with hemoglobin digestion and resulting in cell lysis and death of schizonts (87). They also interfere with the function of plasmodial DNA and inhibit the synthesis of parasite nucleic acids and proteins. Quinidine also interacts with certain fatty acids present in parasitized erythrocytes, preventing red blood cell lysis and interrupting schizont maturation (13). Additionally, it increases intracellular pH, resulting in lethal effects on the parasite.

Pharmacokinetics. Quinine is available for oral administration as a sulfate salt and for parenteral administration as quinine dihydrochloride. It is >80% absorbed from the gastrointestinal tract following oral doses. It is widely distributed in body tissues, but concentrations in CSF are <10% of concurrent levels in plasma. It is >90% protein bound. Quinine is metabolized in the liver, and the native drug and its metabolites are excreted in the urine (82). It has a short half-life of 8 to 12 h, necessitating multiple daily doses. After a single dose of 650 mg of quinine sulfate, peak concentrations in serum are ~3.2 mg/liter in healthy individuals but are higher (8.4 mg/liter) in patients with malaria. Intravenous quinine is used in many countries where oral therapy cannot be tolerated, but quinidine gluconate is considered the parenteral drug of choice in the United States (1). Both agents have similar pharmacokinetic properties.

The pharmacokinetic properties of the chinone alkaloids are considerably altered in patients with malaria, with a reduction in clearance that is proportional to the severity
of disease. Consequently, doses should be decreased by 30 to 50% after the third day of treatment to avoid accumulation of drug in seriously ill patients (88). Drug levels may also be increased by administration with foods that alkalinize the urine, because increased tubular reabsorption results. Caution is recommended for patients with significant liver impairment, and dose reduction is required if there is renal impairment. Both agents are partially dialyzable.

**Spectrum of activity.** The cinchona alkaloids can be used in the treatment of all *Plasmodium* species that infect humans. Their main indication is for chloroquine-resistant *P. falciparum*. Oral therapy is indicated for uncomplicated malaria, but intravenous formulations of quinine dihydrochloride or quinidine gluconate are used in severe infections.

Quinine and quinidine are blood schizonticides but have little effect on sporozoites or preerythrocytic forms of the parasite. Consequently, they do not eradicat *P. vivax* or *P. ovale* hypnozoites in the liver. They also are not gametocyctic against *P. falciparum*. Although resistance to these agents has emerged in Southeast Asia and Africa, they remain useful drugs for the treatment of malaria worldwide; however, over recent years they have been replaced by artemisinin derivatives for first-line malaria treatment.

Quinine is also used for the treatment of babesiosis. It is ineffective when used as a single agent but can be given together with clindamycin or azithromycin (1).

**Adverse effects.** Quinine has an extremely bitter taste and can be associated with nausea, vomiting, and epigastric pain. It also often leads to the symptom complex of cinchonism (nausea, tinnitus, dysphoria, and reversible high-tone deafness). Quinine can also cause hyperinsulinemic hypoglycemia, especially in children and pregnant women with severe malaria, as it increases release of insulin from the pancreas. It has also been associated with massive hemolysis in patients with heavy *P. falciparum* infections. Agranulocytosis, thrombocytopenia, retinopathy, and tongue discoloration are additional adverse effects that have been described. Overdose of quinine can lead to ataxia, convulsions, and coma.

When used as treatment for severe malaria, intravenous quinidine is associated with cardiac arrhythmias. It prolongs the QT interval, widens the QRS complex, and prolongs the PR interval. It can therefore lead to hypotension and ventricular arrhythmias, including torsades de pointes. Consequently, it should be administered only in an intensive care setting with cardiac monitoring. As with quinine, administration can also result in blood dyscrasias and cinchonism.

Despite reports of congenital defects following administration of quinine during pregnancy, it can be administered during pregnancy when the benefits of maternal treatment outweigh the potential fetal risks (pregnancy category C) (89, 90). Quinidine has not been reported to be teratogenic. Quinine can have an abortifacent effect and can lead to induction of labor. It is excreted in small amounts in breast milk but can be administered during breast feeding when necessary.

**Synthetic Quinoline Compounds**

**Mefloquine**

Mefloquine is a synthetic 4-quinoline methanol compound structurally related to quinine.

**Mechanism of action.** Mefloquine interacts both with host cell phospholipids and with ferritoproporphyrin IX of the parasitized erythrocyte (13). Its action is thought to rely on interference with the digestion of hemoglobin during the blood stages of the malaria life cycle, likely via a mechanism similar to that of quinine (87). It does not inhibit protein synthesis.

**Pharmacokinetics.** Mefloquine is available for oral administration only. Food enhances bioavailability, and it should not be taken on an empty stomach. It is >85% absorbed following oral administration and is concentrated within red blood cells (91). It is >95% protein bound and has a half-life of 2 to 4 weeks. Because of its long half-life, mefloquine is frequently used for prophylaxis of malaria, as a once-weekly dose. However, when mefloquine is administered weekly, it requires about 8 weeks before steady-state drug levels are reached, so a loading dose is often recommended. Peak concentrations in plasma occur at 6 to 24 h, and following a single dose of 500 mg or 1,000 mg orally, they are 430 and 800 μg/liter, respectively. In healthy volunteers, a dose of 250 mg once weekly produces maximum steady-state plasma concentrations of 1,000 to 2,000 μg/liter, which are reached after 7 to 10 weeks. It is highly lipophilic, is widely distributed throughout the body, and can cross the blood-brain barrier. Mefloquine is metabolized in the liver and excreted through the bile and feces. There are no specific recommendations regarding the need for dosage adjustment in patients with renal or hepatic failure. It is not dialyzable.

**Spectrum of activity.** Mefloquine is active against the erythrocytic schizonts of all *Plasmodium* species causing human malaria, and it has been used for both chemoprophylaxis and therapy. Since weekly administration is sufficient for chemoprophylaxis, it is convenient for use in travelers to areas where malaria is endemic. Its main utility in malaria treatment results from its activity against most chloroquine-resistant *P. falciparum* strains, although resistance has been recognized, particularly in some areas of Southeast Asia. When used for therapy, it should be combined with another agent, usually an artemisinin derivative. Mefloquine does not kill tissue schizonts, so patients infected with *P. vivax* should subsequently be treated with an 8-aminoquinoline. It also has no effect on gametocytes.

**Adverse effects.** Adverse reactions to mefloquine include nausea and vomiting, agranulocytosis, and aplastic anemia, as well as central nervous system (CNS) effects such as dysphoria, dizziness, disturbed sleep, nightmares, and ataxia. Severe neuropsychiatric reactions, including delirium and seizures, have been reported occasionally and are thought to occur in approximately 1:200 to 1:1,300 patients treated for acute falciparum malaria (92, 93). Mefloquine can also potentiate dysrhythmias in individuals on β-blockers. Mefloquine is teratogenic in high doses in animals, but reports on humans do not support teratogenic effects (pregnancy category B) (94). A possible higher rate of spontaneous abortion has been suggested, so it is generally avoided in the first trimester of pregnancy if possible. However, limited data suggest that it is probably safe to use even during the first trimester, and it can be used in later stages of pregnancy if the benefits outweigh the potential risks (95). It is excreted in low concentrations in breast milk but can be used in lactating women when necessary.

**Halofantrine**

Halofantrine is a synthetic phenanthrene-methanol compound. It has not been approved by the U.S. FDA (1),
and because of its potential cardiac side effects, it has limited indications for use.

Mechanism of action. Halofantrine has activity against the asexual erythrocytic stages of malaria parasites, although the exact mechanism of action is unclear.

Pharmacokinetics. Halofantrine is available only for oral administration but has variable bioavailability. Absorption is enhanced by administration with fatty food, but because high levels in blood enhance toxicity, it is recommended for administration on an empty stomach. After three doses of 500 mg of halofantrine hydrochloride (at 0, 6, and 12 h), a maximum concentration in plasma of 896 μg/liter was reported (96). Halofantrine is metabolized in the liver to an active metabolite, N-desbutylhalofantrine. The half-lives of halofantrine and its metabolite are 6 to 10 days and 3 to 4 days, respectively. It is excreted mainly in the feces.

Spectrum of activity. Halofantrine is efficacious in the treatment of P. vivax and P. falciparum malaria, but data concerning P. ovale and P. malariae are limited (97). It is not recommended for prophylaxis of malaria because of toxicity. It is active against blood-stage schizonts only and appears to have no effect against sporozoites, gametocytes, or tissue-stage parasites. Halofantrine is more active than mefloquine, but cross-resistance between these drugs occurs. Its expense and potential toxicity also limit its use.

Adverse effects. Halofantrine leads to gastrointestinal adverse effects, including nausea, vomiting, diarrhea, and abdominal pain. It also has potential cardiovascular toxicity and causes concentration-dependent prolongation of the QT interval. It is therefore contraindicated in patients with long QT syndrome, as it can lead to cardiac arrest (98). It can also lead to pruritis and hepatic enzyme elevations. Halofantrine is contraindicated in pregnancy. The degree of excretion in breast milk is unknown, and it is not advised for use in lactating women.

Lumefantrine
Lumefantrine is a drug with a similar structure to that of halofantrine. It is widely used as a long-acting partner drug to artemether in a fixed-dose combination for malaria.

Mechanism of action. The exact mechanism by which lumefantrine exerts its antimalarial effect is unknown. However, it seems to inhibit the formation of β-hemin by forming a complex with hemin and inhibits nucleic acid and protein synthesis.

Pharmacokinetics. The oral bioavailability of lumefantrine is highly variable and increases up to 3- to 4-fold when it is taken with a high-fat meal. Peak levels in plasma are seen after 6 to 8 h. Lumefantrine is 99.7% protein bound, and its half-life is 3 to 6 days. It is highly lipophilic and has an apparent large volume of distribution. Peak levels in plasma vary considerably, but after administration of six tablets containing 2,780 mg of lumefantrine, median levels in plasma of 8 to 9 μg/ml were reported (99). Lumefantrine is extensively metabolized in the liver, and the major metabolite found in plasma is desbutyl-lumefantrine. It should be used with caution in patients with severe renal or hepatic failure.

Spectrum of activity. In its fixed-dose combination with artemether, lumefantrine has efficacy against all Plasmodium species.

Adverse effects. Lumefantrine is well tolerated, with rare mild adverse reactions such as diarrhea, nausea, abdominal pain, and vomiting. There is no evidence of significant cardiotoxicity associated with lumefantrine use, but it is recommended that it be avoided in patients at risk for QT prolongation. Artemether-lumefantrine has been assigned to pregnancy category C by the FDA. There are no human data on the excretion of lumefantrine into breast milk, but animal data suggest some excretion. The effects in the nursing infant are unknown, and it should be used with caution in lactating women.

8-Aminoquinolines
The 8-aminoquinolines are primaquine and tafenoquine (WR 238,605). Tafenoquine is not yet commercially available and has not been approved by the U.S. FDA (1).

Mechanism of action. The 8-aminoquinolines interfere with parasite mitochondrial enzymes involved in energy production. They also have an inhibitory action against DNA, although the exact mechanism by which this occurs is unclear (13). An active metabolite of the drug is thought to interrupt the mitochondrial transport system and pyrimidine synthesis in hypnozoites (100).

Pharmacokinetics. The 8-aminoquinolines are well absorbed after oral administration, with >90% bioavailability. Primaquine is rapidly metabolized in the liver, and its half-life is 4 to 9 h, so it needs to be administered daily. Following a single 45-mg oral dose, a mean peak level in serum of 153.3 μg/liter was observed after 2 to 3 h (101). It is found at relatively low concentrations in most body sites. Tafenoquine has a longer half-life of 2 to 4 weeks. Weekly or possibly monthly doses seem to be sufficient for prophylaxis, thus making it better tolerated than primaquine (102). A single dose of tafenoquine may be sufficient for prevention of relapse following P. vivax infections (103). Optimal dose-finding studies are being performed.

Spectrum of activity. Primaquine is less active against blood-stage malarial forms than most other antimalarial agents are, but it is very active against preerythrocytic sporozoites and exoerythrocytic tissue schizonts of all malarial species. Its main use is to prevent relapse of P. vivax and P. ovale infections from latent hypnozoites following treatment with chloroquine. Additionally, it is gametocytocidal against Plasmodium, especially P. falciparum, and can interrupt transmission of malaria. It is also an effective causal prophylactic agent but traditionally has been used infrequently in this way for travelers. Tafenoquine is reported to be more active than primaquine and has higher schizonticidal activity (104).

Adverse effects. Mild gastrointestinal side effects, including nausea and abdominal pain, are common following 8-aminoquinoline administration. They should not be used in people with glucose-6-phosphate dehydrogenase deficiency, as they can induce hemolysis. Patients with NADH methemoglobin reductase deficiency are at risk of developing methemoglobinemia. Primaquine also occasionally causes arhythmic. Interference with visual accommodation has also been reported. These agents should also not be used during pregnancy or lactation because of the potential risk of hemolytic effects in the fetus.

Artemisinin (Qinghasou) Derivatives
Artemisinin is an extract from the Chinese herbal plant Artemisia annua, also known as qinghasou. It is a sesquiterpene
lactone peroxide. Synthetic derivatives include artemether, dihydroartemisinin, arteether, and artesunate. Although not officially approved for use by the U.S. FDA, the intravenous formulation of artesunate is available via the CDC under an IND for patients with severe malaria.

Mechanism of action. Artemisinin and its derivatives act mainly against the asexual erythrocytic stages of malaria parasites. They have an antiparasitic effect, particularly on young, ring-form parasites, leading to their clearance and preventing development of more mature pathogenic forms. They bind to the parasite membrane and to ferricprotein IX, so they are highly concentrated within parasites and reach 100 to 300 times higher concentrations in *P. falciparum*-infected red cells than in uninfected cells (105). By binding iron in the malarial pigment, they lead to the production of toxic oxidative free radicals that damage parasite organelles and alkylate parasitic proteins, leading to inhibition of protein synthesis and ultimately to parasite death.

Pharmacokinetics. The derivatives of artemisinin have greater solubility than artemisinin and consequently have been developed for easier administration by a variety of routes. Artesunate is water-soluble and can be given intravenously, intramuscularly, orally, or by suppository. Arteether and arteether are oil-soluble and are available in tablet, capsule, and intramuscular injection forms. Although artesunate is the most potent in vitro, there is no apparent clinical difference in efficacy between the formulations. The artemisinin derivatives have a short half-life of <1 to 2 h. They are usually administered once daily for a minimum of 3 days. All are metabolized to the active compound, dihydroartemisinin. After single oral doses of 2 and 4 mg of dihydroartemisinin/kg of body weight in healthy volunteers, median peak values in plasma of 181 and 360 μg/liter, respectively, were observed (106). Inhibitors of cytochrome P450, such as grapefruit juice, increase the levels of arteether in plasma. Artemisinin is eliminated by glucuronidation to inactive metabolites (4, 107). The pharmacokinetics of artesunate may be altered by pregnancy and by acute malaria infection. Artemisinin derivatives should be used with caution in individuals with hepatic or renal impairment.

Spectrum of activity. The artemisinin derivatives are effective against *P. falciparum* and *P. vivax* and are the most potent and rapidly acting parasiticidal drugs. They act specifically against the erythrocytic stages of *Plasmodium*. They are effective against multidrug-resistant *P. falciparum* and are the drugs of choice against mefloquine- and/or quinine-resistant *P. falciparum* isolates and against chloroquine-resistant *P. vivax*. The artemisinin derivatives are also active against gametocytes, reducing gametocyte carriage by ~90% and therefore decreasing malaria transmission in areas where they are widely used (108, 109). They are not effective against the intrahepatic hypnozoite stage of *P. vivax* or *P. ovale* infections. Late recrudescence is common unless these agents are combined with another drug, so they should be administered with a second agent such as mefloquine or doxycycline or in fixed combinations such as artemether-lumefantrine, artesunate-amodiaquine, or dihydroartemisinin-piperaquine. The artemisinin derivatives are usually associated with quick clearance of parasitemia, and recent randomized trials comparing them with quinine have shown a benefit in terms of mortality in adults treated for severe *P. falciparum* malaria (110–112). However, artemisinin-resistant *P. falciparum* malaria is now also emerging, particu-

larly along the Thai-Cambodian border, characterized clinically by a substantial delay in parasite clearance (113). Despite limited data, the oral artemisinin derivative combinations seem effective against *P. knowlesi*, *P. ovale*, and *P. malariae* infections. Intravenous artesunate is used for those affected by severe malaria due to *P. knowlesi* (114). The artemisinin derivatives also have antitrematode activity and have been studied in schistosomiasis. They are less effective than praziquantel but may have a role as part of combination therapy in the future (115–117).

Adverse effects. The artemisinin derivatives are very well tolerated, with no serious toxicity or subjective adverse effects, although hematopoietic suppression has been described. They have been associated with adverse neurological effects in animal models, but there is no evidence that this occurs in humans. Fetal deaths and congenital malformations seen in rodent studies have not been observed in clinical trials involving 1,837 pregnant women, including 176 patients in the first trimester, exposed to an artemisinin agent or artemisinin-based combination therapy (118, 119). Although it is generally recommended that they be avoided in pregnancy because of insufficient safety data, they can be used, particularly after the first trimester, if the benefits outweigh the risks. The amount excreted in breast milk is unknown.

Antifolates

Pyrimethamine-sulfadoxine, also known as Fansidar, is still used for treatment of malaria in some countries despite widespread resistance. Pyrimethamine is a synthetic amino-pyrimidine antimalarial agent, and sulfadoxine is a long-acting sulfonamide agent.

Mechanism of action. Pyrimethamine acts against the asexual erythrocytic stage of *Plasmodium* by inhibiting the plasmodial enzyme dihydrofolate reductase. Although it is active against *P. falciparum*, rapid development of resistance occurs and is a major factor limiting its use. Combining pyrimethamine with a sulfonamide or sulfone provides sequential, synergistic inhibition of the folate biosynthesis pathway. Malaria parasites are unable to utilize host-derived folic acid, so inhibition of folic acid biosynthesis prevents malarial DNA replication, ultimately leading to cell death.

Pharmacokinetics. Fansidar tablets comprise 25 mg of pyrimethamine and 500 mg of sulfadoxine. Both drugs are well absorbed orally. After oral administration of a single tablet, peak concentrations of pyrimethamine and sulfadoxine in plasma are 0.13 to 0.4 μg/liter and 51 to 76 μg/liter, respectively. The half-life of pyrimethamine is 80 to 95 h, and the half-life of sulfadoxine is 130 to 200 h (88). Both components are ~90% protein bound. Sulfadoxine is metabolized in the liver, and both agents are excreted mainly in the urine.

Spectrum of activity. Pyrimethamine-sulfadoxine is effective for both treatment and chemoprophylaxis of *P. falciparum* malaria. It is no longer recommended for routine prophylaxis because of the potential for severe adverse effects. It acts mainly against blood schizonts and does not have significant gametocytoidal activity. Pyrimethamine-sulfadoxine also has some efficacy in the treatment of *P. vivax* infection, but it has longer parasite and fever clearance times and higher failure rates (30 to 40%) than chloroquine and thus is not recommended. The efficacy of
pyrimethamine-sulfadoxine against *P. ovale* and *P. malariae* has not been adequately evaluated.

Pyrimethamine is also used in combination with sulfadiazine for the treatment of toxoplasmosis.

**Adverse effects.** Pyrimethamine-sulfadoxine can result in adverse effects, including rash, nausea, vomiting, headache, and peripheral neuritis. It can also be associated with more serious and occasionally fatal reactions, including Stevens-Johnson syndrome and blood dyscrasias (particularly agranulocytosis and megaloblastic anemia). Other reported adverse effects include hepatitis, toxic nephrosis, exfoliative dermatitis, and erythema multiforme. The long half-life of the sulfamethoxazole component means that sensitivity reactions can be sustained for prolonged periods even after the drug is discontinued.

Pyrimethamine has been associated with teratogenic effects in animals. There are no controlled human studies, but it has been used frequently during pregnancy, particularly in African countries, and has been associated with good fetal outcomes. It is officially recommended for use during pregnancy only when potential benefits outweigh the possible risks to the fetus. Pyrimethamine-sulfadoxine can cause kernicterus in infants, so it should be used with caution in pregnant women late in the third trimester. Both pyrimethamine and sulfadoxine are excreted into breast milk and are preferably avoided during lactation.

**Atovaquone-Proguanil (Malarone)**

Malarone is a tablet combination of 250 mg of atovaquone and 100 mg of proguanil. Atovaquone is a hydroxynaphthoquinone, and proguanil is an antifolate. Malarone has been approved for use by the U.S. FDA for prophylaxis and treatment of malaria.

**Mechanism of action.** *Plasmodium* species are dependent on *de novo* pyrimidine biosynthesis, which is selectively coupled with electron transport. Atovaquone inhibits the electron transport system in the mitochondria of parasites, thereby blocking nucleic acid synthesis and inhibiting replication (120). When used as monotherapy, atovaquone is associated with high recrudescence rates. Proguanil also acts against the asexual erythrocytic stage of the parasite by selectively inhibiting plasmodial dihydrofolate reductase. However, in combination with atovaquone, it acts via a different mechanism and directly lowers the effective concentration at which atovaquone causes collapse of the mitochondrial membrane potential (121).

**Pharmacokinetics.** Atovaquone is a highly lipophilic compound with low aqueous solubility and poor and variable oral availability. Its absorption is increased if administered with fatty foods or a milky drink. It is not metabolized and is excreted almost exclusively in the feces. It is 99% plasma protein bound, and its half-life is 2 to 4 days. Atovaquone levels vary widely between individuals (122). Proguanil is rapidly and extensively absorbed after oral administration. It is metabolized by cytochrome P450 in the liver to the active cyclic triazine metabolite, cycloguanil. It is 75% protein bound and is excreted mainly in the urine. Its half-life is 12 to 21 h. After two Malarone tablets twice daily for 3 days, mean levels of proguanil in plasma of 170 μg/liter have been reported. The pharmacokinetics of Malarone are altered during pregnancy. No dosing adjustments are required in the setting of mild to moderate hepatic or renal insufficiency. However, with severe renal impairment (creatinine clearance of <30 ml/min), use of Malarone is contraindicated for prophylaxis, but it can be used for treatment if the benefits outweigh the risks.

**Spectrum of activity.** Atovaquone-proguanil is effective against asexual and sexual forms of the *P. falciparum* parasite and is recommended for treatment and prophylaxis of *falciparum* malaria. It is used frequently for chemoprophylaxis in travelers to areas where malaria is endemic. Atovaquone-proguanil is also effective for treating *P. vivax* and *P. ovale* infections, but neither drug is effective against hypnozoites, so primaquine is additionally required to prevent relapses after drug discontinuation. Atovaquone-proguanil also showed good efficacy against *P. malariae* and *P. knowlesi* in limited studies (114, 123). Reports of clinical failures and resistance of *P. falciparum* isolates to atovaquone-proguanil via single mutations to the cytochrome *b* gene are emerging.

**Adverse effects.** Atovaquone-proguanil is generally very well tolerated. Side effects are mild and include anorexia, nausea, vomiting, abdominal pain, diarrhea, pruritis, and headache. Between 5 and 10% of recipients develop transient asymptomatic elevations in transaminases and amylase. Because of inadequate safety data, it is not recommended for prophylaxis during pregnancy (pregnancy category C) or lactation. It is also not recommended for treatment during pregnancy but can be considered if warranted. There are insufficient safety data to recommend its use in children weighing <5 kg.

**OTHER ANTIPROTOZOAAL AGENTS**

**Diloxanide Furoate**

Diloxanide furoate, also known as Furamide, is a substituted acetanilide. Its main use is as a luminal amebicidal agent. It is not widely available in the United States and can be obtained only from specific pharmacies (1).

**Mechanism of action.** The mechanism of action of diloxanide furoate is unknown.

**Pharmacokinetics.** Diloxanide furoate is available in tablet form. The parent drug is poorly absorbed following oral administration, but it is hydrolyzed in the bowel lumen to an active compound, diloxanide. This is >90% absorbed and is glucuronidated in the liver, reaching peak levels in serum within 1 to 2 h. Metabolites are excreted primarily in the urine.

**Spectrum of activity.** Diloxanide furoate acts primarily as a luminal agent and helps to clear the bowel of *E. histolytica* cysts, thereby preventing relapse in cyst carriers (124). It is not effective for amebae in the bowel wall or in other tissues such as the liver, so it is generally given with a 5-nitroimidazole.

**Adverse effects.** Side effects are generally not severe but include rash, nausea, abdominal pain, diarrhea, and flatulence. It is not recommended in pregnancy or during lactation.

**Iodoquinol**

Iodoquinol is a halogenated 8-hydroxyquinoline derivative, diiodohydroxyquin.

**Mechanism of action.** Iodoquinol is thought to act by inactivating essential parasitic enzymes and inhibiting parasite multiplication (13).
Pharmacokinetics. Iodoquinol is available for oral administration but is very slowly absorbed, with <8% reaching the systemic circulation, so it is excreted primarily in the feces. Small amounts of absorbed drug are glucuronidated in the liver, and small quantities of glucuronic acid metabolites are excreted in the urine. It should not be used in individuals with renal or hepatic insufficiency and should be used with caution in patients with thyroid or neurologic disease.

Spectrum of activity. Iodoquinol is a potent amebicidal drug. It is effective against trophozoites and cysts of *E. histolytica* located within the lumen of the intestine and is used to eradicate amebic cysts to help prevent relapse of infection (124). Because it is poorly absorbed systemically, it is not effective for invasive intestinal or extraintestinal *E. histolytica* infections and is therefore frequently combined with a 5-nitroimidazole.

Iodoquinol also has activity against *Balantidium coli*, *Dientamoeba fragilis*, and *G. duodenalis*. It has also been used for *Blastocystis hominis*, although the significance of this agent as a true pathogen remains controversial (125).

Adverse effects. The main side effects of iodoquinol include nausea, abdominal cramps, diarrhea, headache, pruritis, and rash. Skin and hair may temporarily be stained yellow-brown following exposure. At high doses or with prolonged use, it can cause optic neuritis, optic atrophy, peripheral neuropathy, ataxia, and seizures. It is also associated with nephrotoxicity. It should be avoided in individuals who are sensitive to iodine. The degree of safety associated with its use in pregnancy or lactation is uncertain, so it is recommended that it be avoided.

Pentavalent Antimonial Compounds

The pentavalent antimony derivatives are used for treatment of leishmaniasis. They include sodium antimonylgluconate (or stibogluconate), also known as Pentostam, and N-methylglucamine antimoniate (or meglumine antimoniate), also known as Glucantime. Selection of one drug over the other is based primarily on cost and availability. Neither drug is licensed for use in the United States, but sodium stibogluconate is available from the CDC for individual patient use (1).

Mechanism of action. The precise mechanism of action of the pentavalent antimony derivatives remains unclear. They are thought to inhibit enzymes of glycolysis within parasites. Because glycolysis is the major source of parasitic ATP, the blockade of this source of energy is fatal to parasites (13).

Pharmacokinetics. The pentavalent antimonials are administered parenterally (intramuscularly or intravenously) or via intralesional injection. New formulations and drug delivery approaches are being investigated. The drugs remain in plasma and are excreted predominantly by the kidneys. Small amounts are metabolized in the liver to trivalent antimony, which contributes to the toxicity associated with their use. Following intramuscular administration of an initial dose of 10 mg of antimony per kg of body weight, mean peak antimony concentrations in blood of 9 to 12 mg/liter at 2 h have been reported (126). There are no specific guidelines regarding dose adjustment for renal impairment.

Spectrum of activity. Antimony preparations are efficient in killing many protozoan and helminthic parasites but are no longer recommended for most parasitic infections because of their toxicity. They are still used for the treatment of visceral, mucocutaneous, and cutaneous leishmaniasis, as few effective alternatives exist, although increasing drug resistance is emerging. Various treatment regimens are used, often involving 28 days of therapy, but the exact duration and efficacy vary depending on the type of leishmaniasis, the severity of the lesion, and the area of endemicity.

Adverse effects. Minor adverse effects from the pentavalent antimonials are common and include nausea, vomiting, headache, and malaise (127). More severe reactions, such as leukopenia, agranulocytosis, and electrocardiographic changes (prolongation of the QT interval and ventricular arrhythmias), can also occur. Renal insufficiency, proteinuria, and elevation of hepatic and pancreatic enzymes have also been described.

Miletefosine

Miletefosine is a phosphocholine analogue that was originally developed as an anticancer compound. It is the first effective oral agent for visceral leishmaniasis and is becoming increasingly important because of growing resistance of *Leishmania* strains to pentavalent antimonials. Miletefosine was registered in 2002 for the oral treatment of visceral leishmaniasis in India and has been approved for use in Germany. It is not approved by the U.S. FDA (128) and requires an emergency IND request to the FDA (1). Miletefosine has shown ameba-killing activity in vitro against the free-living ameba *Naegleria fowleri* and has been used successfully to treat patients infected with *Balamuthia* and disseminated *Acanthamoeba* infections.

Mechanism of action. The mechanism of action of miltefosine is not well understood. The drug interferes with cell signaling pathways and appears to act on key enzymes involved in the metabolism of ether lipids present on the surfaces of parasites (129, 130). Miletefosine does not appear to have a direct immunostimulatory effect, but it does induce apoptotic cell death (131, 132). It has been shown to be active against both the extracellular promastigote form and the intracellular amastigote form of *Leishmania* parasites both in vitro and in vivo (133).

Pharmacokinetics. Miltefosine is well absorbed after oral administration and is widely distributed. Minimal pharmacokinetic data are available for humans, but in rats the drug is rapidly taken up and accumulates in the kidney, liver, lung, spleen, and adrenal glands (130). Upon oral administration of miltefosine at 30 mg/kg of body weight twice per day, concentrations of 155 to 189 nmol/g of tissue are achieved (129). Miltefosine has a long half-life of about 8 days and is slowly metabolized by phospholipase.

Spectrum of activity. Miltefosine has activity against *Leishmania* spp. and *Trypanosoma cruzi* both in vitro and in vivo, but clinical studies to date have been limited to leishmaniasis. In vitro activity of miltefosine against *Trypanosoma brucei* spp., *E. histolytica*, and *Acanthamoeba* spp. has also been demonstrated (134). The majority of studies using miltefosine have examined its role against visceral leishmaniasis in India. In clinical trials, miltefosine has been found to have a cure rate of >90% at 6 months in both adults and children (135, 136), although emerging resistance is reducing its efficacy. Different combination therapy strategies involving miltefosine are being used in various geographic regions. Recent studies have also examined its effi-
cacy in New World cutaneous leishmaniasis and have generally found 70 to 90% efficacy for most species (137). It is also used for post-kala-azar dermal leishmaniasis. There are also recent case reports of clinical success using miltefosine in combination with other agents for granulomatous amebic encephalitis (138, 139).

**Adverse effects.** In various clinical trials, toxic effects associated with miltefosine have usually been found to be tolerable and reversible, although the therapeutic window appears to be narrow (131). Mild to moderate gastrointestinal side effects, including nausea, vomiting, and diarrhea, occur in up to 60% of patients. Dose-related motion sickness is also reported in up to 40% of patients (140). A mild increase in aspartate aminotransferase and creatinine and/or blood urea nitrogen levels has been reported, with reversible hepatotoxicity and renal damage in a few cases (130, 135). Miltefosine is abortifacient and teratogenic in animals and should not be used in pregnancy or breast feeding. Contra
cption must be used in women of childbearing age during and for 3 months after treatment.

**Pentamidine**

Pentamidine is an aromatic diamidine compound that is used as an antiprotozoal agent in the treatment of leishmaniasis and African trypanosomiasis. Its use has been approved by the U.S. FDA (1).

**Mechanism of action.** Pentamidine is chemically related to guanidine. Its mechanism of action has not been defined clearly and may not be uniform against different organisms. It is possible it inhibits dihydrofolate reductase and interferes with aerobic glycolysis in protozoa. It may also interfere with amino acid transport; precipitate nucleotides and nucleotide-containing coenzymes; and inhibit DNA, RNA, and protein synthesis (141).

**Pharmacokinetics.** Pentamidine is currently available as an isothionate salt. It is poorly absorbed from the gastrointestinal tract. When used for protozoal infections, it must therefore be administered intramuscularly or intravenously, but it can be given via inhalation for prevention of *Pneumocystis jirovecii* pneumonia. Following intravenous administration of a 4-mg/kg dose, concentrations in plasma of 0.3 to 1.4 mg/liter have been reported (142). The highest concentrations of the drug are found in the kidney, liver, and spleen, and pentamidine penetrates poorly into the CNS. It has a short half-life in serum of 6.5 to 9 h because it is rapidly and extensively taken up by tissues. Its extensive tissue binding results in prolonged excretion over a period of 6 to 8 weeks, and it is eliminated unchanged via the kidneys. Pentamidine should be used cautiously in the presence of renal or hepatic failure, but no dosage adjustment is recommended.

**Spectrum of activity.** The antiparasitic indications for pentamidine include leishmaniasis and African trypanosomiasis, but its main use is as an antifungal agent for treatment and prophylaxis of *P. jirovecii* pneumonia. Despite activity against *Leishmania* spp., pentamidine's toxicity means that it is used predominantly in individuals intolerant of antimonial compounds, in disease that is refractory to other treatment, or in combination therapy. Pentamidine is also active against African trypanosomes, and it is first-line treatment in early disease, but its utility is restricted to trypanosomiasis without CNS involvement. Since CNS involvement occurs early with *T. brucei rhodesiense*, it is used more frequently for *T. brucei gambiense* infections. Pentamidine is also sometimes used in combination therapy for granulomatous amebic encephalitis caused by *Acanthamoeba* and *Balamuthia* species.

**Adverse effects.** More than half of parenteral pentamidine recipients experience some adverse effect from therapy. Administration is associated with a variety of reactions that appear to be unrelated to drug concentrations in plasma (141). Immediate reactions include nausea, anorexia, dizziness, pruritus, and hypotension. Pentamidine can also produce local effects, including pain and necrosis at the site of injection. In addition, pentamidine administration is associated with hematologic effects, particularly leukopenia (up to 10% of recipients) and thrombocytopenia (~5% of recipients), as well as with electrolyte abnormalities, including hyperkalemia, hypomagnesemia, and hypocalcemia. Other severe adverse effects include ventricular arrhythmias, pancreatitis, hypo- or hyperglycemia, hepatotoxicity, and acute renal failure. Pentamidine has also been associated with Stevens-Johnson syndrome. Finally, occasional seizures and hallucinations have been reported. There are minimal available safety data regarding the use of pentamidine in pregnancy (category C) or lactation, and its use is therefore not recommended.

**Paromomycin**

Paromomycin, which was initially named aminosidine, is an oral, poorly absorbed, broad-spectrum aminoglycoside. It is active against Gram-negative and many Gram-positive bacteria as well as some protozoa and cestodes. It is approved by the U.S. FDA for use in noninvasive intestinal amebiasis and is sometimes used off-label for cryptosporidiosis, *D. fragilis* infection, and giardiasis. Paromomycin is used in parenteral intramuscular (visceral and cutaneous leishmaniasis), topical (Old World and New World cutaneous leishmaniasis), and oral (protozoal infections) formulations.

**Mechanism of action.** Paromomycin is a protein synthesis inhibitor that exerts its function by binding to 16S rRNA, thus inhibiting protein synthesis. However, when used for treatment of leishmaniasis, it has additional mechanisms of action that are incompletely understood but seem to involve inhibition of parasite metabolism and mitochondrial respiration (143).

**Pharmacokinetics.** Paromomycin is not systemically absorbed after oral administration and is passed in feces without being metabolized. Following an intramuscular injection, peak concentrations in plasma are achieved within 0.5 to 1.5 h and the half-life is 2 to 3 h. Plasma protein binding is negligible. Mean concentrations in plasma 1 h after a dose of 12 to 15 mg/kg are 18.3 to 20.5 μg/ml. Paromomycin is widely distributed in the body after parenteral administration, with measurable concentrations achieved in bone, synovial fluid, and peritoneal fluid but with negligible CNS penetration. It should be used with caution in patients with renal impairment.

**Spectrum of activity.** Oral paromomycin has activity against the intestinal protozoa *G. duodenalis, Cryptosporidium parvum*, and *D. fragilis*. It is the drug of choice for giardiasis in pregnancy because of its safety and is also used in cases that have not responded to other agents (144). In addition, it has activity as a luminal agent to clear intestinal infections with *E. histolytica*, but it is not effective in extraintestinal amebiasis. It has also been used for treatment of B.
hominis infections, and it has activity against T. vaginalis. Paromomycin also is used parenterally or topically in visceral and cutaneous leishmaniasis, sometimes in combination with other agents. Although it has activity against most tapeworm infections, it is not used for this indication due to the availability of alternate agents (145, 146).

Adverse effects. The most common side effects of paromomycin are nausea, increased gastrointestinal motility, abdominal pain, and diarrhea. As with other aminoglycosides, systemic absorption of paromomycin following intramuscular injection may cause reversible ototoxicity and nephrotoxicity. It can also cause an increase in hepatic transaminases. With parenteral administration, ∼50% of patients experience mild pain at the injection site.

Because oral paromomycin is not systemically absorbed, it does not adversely affect the fetus or infant so can be used during pregnancy and lactation. However, parenteral aminoglycosides cross the placenta and may accumulate in fetal plasma and amniotic fluid. No reproductive toxicity has been observed in animals, but insufficient data are available regarding the use of paromomycin in pregnant women to recommend it for its use. All results to date indicate that parental paromomycin is safe during lactation provided that the mother and infant have normal renal function (143).

Suramin
Suramin is a polysulfonated naphthylamine derivative of urea. Its main indication is in the treatment of African trypanosomiasis. It is not licensed for use in the United States but is available from the CDC via a compassionate drug protocol (1).

Mechanism of action. The mechanism of action of suramin is not fully understood but is thought to be via inhibition of enzymes associated with DNA metabolism and protein synthesis of the trypanosomal parasites (147).

Pharmacokinetics. Suramin is dispensed as a sodium salt and is soluble in water. It is not absorbed when given orally and is usually administered as a 10% solution by slow intravenous infusion. Following intravenous injection, it is rapidly distributed, and >99% becomes bound to plasma proteins. It does not cross the blood-brain barrier. It undergoes little or no metabolism and has a half-life of 41 to 78 days. It is excreted in the urine. It should not be used in the presence of renal failure or significant hepatic dysfunction.

Spectrum of activity. Suramin is an effective drug for early hemolymphatic stages of T. b. gambiense infection. It also has some effect in early T. b. rhodesiense infection, provided that there is no CNS involvement (148). Suramin was used to treat onchocerciasis prior to the development of ivermectin. An advantage of suramin is that it has macrofilaricidal activity, damaging the intestinal epithelium of adult O. volvulus worms and resulting in their death, but it is associated with frequent toxic effects at required doses (149). Suramin also has activity against adult W. bancrofti worms but is not recommended for this indication (13).

Adverse effects. Potential side effects include an immediate reaction, with nausea, vomiting, shock, and loss of consciousness, following suramin injection. Other adverse effects include renal impairment, exfoliative dermatitis, and neurological toxicity. It has also been associated with pancytopenia. Suramin has been reported to be teratogenic in rodents (150). No case of infant malformation has been described in humans, but it is not recommended for use during pregnancy except in circumstances where there is no suitable alternative.

Melarsoprol
Melarsoprol is a trivalent arsenical compound. Its main use is in the treatment of African trypanosomiasis. It is not licensed for use in the United States but is available from the CDC via a compassionate drug protocol (1).

Mechanism of action. Melarsoprol appears to act by binding to essential thiol groups of trypanosomes and has a particularly high affinity for the active site for pyruvate kinase. This results in interference with energy generation within parasites, thereby preventing trophozoite multiplication.

Pharmacokinetics. Melarsoprol is absorbed if given orally but is generally administered by the intravenous route. It is prepared as a solution in propylene glycol and is given by slow intravenous infusion. It is estimated that <1% penetrates the CNS, and concentrations in CSF are up to 30-fold lower than concentrations in serum (12, 151). However, it is an efficacious agent that can be used for late stages of trypanosomal disease, although resistance has been reported. Melarsoprol has a half-life of ∼35 h. Its metabolism has not been well studied, but it is excreted predominantly in the urine.

Spectrum of activity. Melarsoprol is active in the treatment of all stages of African trypanosomiasis due to T. b. gambiense and T. b. rhodesiense and is the only available treatment for late-stage T. b. rhodesiense infection. Treatment courses have been reduced from 1 month to 10 days (152). However, because of its toxicity, it is generally reserved for use in late stages of disease involving the CNS.

Adverse effects. Melarsoprol is commonly associated with significant toxicity, including vomiting, abdominal pain, hepatotoxicity, peripheral neuropathy, hypersensitivity reactions, myocarditis, cardiac arrhythmias, and albuminuria. Administration can also lead to a reactive encephalopathy in up to 10% of patients, and this is associated with significant mortality. Hypersensitivity reactions are also relatively frequent. The injection is very irritating, and extravasation during intravenous administration should be avoided. There are minimal data available regarding potential teratogenic effects.

Eflornithine
The main indication for use of eflornithine (also known as difluoromethylornithine) is for treatment of African trypanosomiasis. Drug availability is limited, and it is not available in the United States for systemic use.

Mechanism of action. Eflornithine selectively and irreversibly inhibits ornithine decarboxylase, an enzyme required for the formation of polyamines needed for cellular proliferation and differentiation in parasites. It therefore leads to inhibition of parasite growth (153).

Pharmacokinetics. Eflornithine can be administered by mouth and has >50% oral bioavailability, but significant diarrhea frequently results, so it is usually given intravenously. No protein binding of the drug occurs following intravenous administration. It crosses the blood-brain barrier and produces CSF-to-blood ratios between 0.13 and 0.5 (154, 155). The half-life is 3 to 3.5 h, and ~80% of the
dose is excreted unchanged by the kidneys. Dose reduction is required in patients with significant renal impairment.

**Spectrum of activity.** Eflornithine is used for treatment of *T. b. gambiense* when there is CNS involvement. Nifurtimox-eflornithine combination therapy is now standard first-line treatment for CNS-stage *T. b. gambiense* infection (152, 156). Eflornithine is ineffective as monotherapy in *T. b. rhodesiensе* infection (157). It displays some activity against other parasites, including *Plasmodium* species, *C. parvum*, and *T. vaginalis*, but is not used for these indications because of toxicity.

**Adverse effects.** Side effects of eflornithine occur in up to 40% of patients. Common adverse reactions include vomiting, abdominal pain, diarrhea, dizziness, arthralgias, hearing loss, and rash. Bone marrow toxicity resulting in anemia, thrombocytopenia, and leukopenia has also been described. Eflornithine has been shown to arrest embryonic development in animals (158). There are no good studies of its safety in pregnancy or lactation (pregnancy category C), so it should only be used when the potential maternal benefits outweigh the possible risks to the fetus.

**Nifurtimox and Benznidazole.** The two agents used for treatment of American trypanosomiasis are nifurtimox and benznidazole. Nifurtimox is a synthetic nitrofuran, and benznidazole is a 2-nitroimidazole derivative. Neither is approved for use by the U.S. FDA, but nifurtimox is available from the CDC for compassionate use (1).

**Mechanism of action.** Benznidazole has an inhibitory effect on protein and RNA synthesis in *T. cruzi* cells (159). It is thought to cause increased phagocytosis, cytokine release, and production of reactive nitrogen intermediates that result in destruction of intracellular parasites (160).

The mechanism of action of nifurtimox seems to be related to its metabolism to chemically reactive radicals that cause production of toxic reduced products of oxygen, such as superoxide, hydrogen peroxide, and hydroxyl radicals (12, 161). These compounds accumulate within trypanosomes, leading to toxic effects, including membrane damage and enzyme inactivation. It may also cause direct inhibition of protein synthesis via damage to parasite DNA (162).

**Pharmacokinetics.** Benznidazole is available for oral administration and has a bioavailability of >90%. It is ~40% protein bound. It has a half-life of ~12 h and has good tissue penetration (163). Nifurtimox is administered orally but has poor oral bioavailability. It is metabolized in the liver and has a half-life of ~3 h. Dose reduction is advised for patients with significant hepatic or renal impairment, but no specific guidelines exist.

**Spectrum of activity.** Both benznidazole and nifurtimox are used for the treatment of acute *T. cruzi* infection (Chagas’ disease). Neither agent has demonstrated efficacy in late stages of disease, and indications for treatment of chronic infection remain controversial but are expanding (164–166). No randomized trial has evaluated the comparative safety and efficacy of nifurtimox and benznidazole in adults (167). Nifurtimox is now also increasingly being used in combination with eflornithine for first-line treatment of *T. b. gambiense* infection. It also has been shown to have some activity in leishmaniasis but is not routinely used for this indication.

**Adverse effects.** Side effects are common with benznidazole and are seen in up to 40% of treated individuals, commonly including vomiting, abdominal pain, peripheral neuropathy, rash, and pruritus. Bone marrow suppression and neuropsychiatric reactions have also been reported. Nifurtimox has significant side effects that preclude the completion of therapy in many patients. Adverse effects include anorexia, nausea, rash, headache, sleep disturbance, peripheral neuropathy, and myalgias. Less-frequent but more severe toxicities include psychosis and convulsions. Benznidazole crosses the placenta, but there are minimal data regarding teratogenic effects for either agent in either animals or humans (168). Nifurtimox is detected in breast milk, so caution is recommended during breast feeding (169). Similarly, safety data for benznidazole and lactation are lacking, so withholding treatment during breast feeding is again recommended.

Mechanisms of Resistance to Antiparasitic Agents

W. EVAN SECOR, JACQUES LE BRAS, AND JÉRÔME CLAIN

Parasitic diseases rank among the most prevalent and severe diseases worldwide and yet their control relies heavily on a single tool: the drugs used for chemotherapy or prophylaxis. This situation exists because no effective antiparasitic vaccines are available and implementation of other control measures often proves to be difficult in countries where parasitic diseases are endemic. This dependence on drugs is compounded by the relative paucity of the current armamentarium of antiparasitic products, a situation attributable largely to a lack of economic incentives for research and development. Furthermore, those drugs that are available are too often used incorrectly in communities and in control programs, a practice that encourages the selection of drug-resistant parasites.

The complex biologic interactions between parasites and their hosts (and at times vectors) significantly influence the emergence and expression of drug resistance. In many cases the observed resistance is true resistance, attributable to biologic characteristics of the parasites that enable them to survive drug concentrations that are lethal to susceptible members of the species. Mechanisms for such true resistance are varied and include a decrease in drug accumulation within the parasite or modifications in parasite enzyme structure or metabolic pathways. However, various host factors modulate the clinical and parasitologic responses to drug treatment, and the observed responses do not necessarily reflect true parasite resistance or susceptibility. For example, in populations with high rates of exposure to parasitic infections, the resulting high rates of immunity might suffice to eliminate an infection with drug-resistant parasites or treated with an ineffective drug. Conversely, treatment with a drug to which the parasite is biologically susceptible will not necessarily result in therapeutic success if the host takes an inadequate dose of the drug, absorbs it poorly, or lacks the immune response that might be needed for a successful antiparasitic synergism with the drug. Such host factors may be especially important in the areas where most parasitic diseases prevail, where high rates of parasite transmission result in high rates of immunity in most of the population, or where, conversely, malnutrition and human immunodeficiency virus (HIV) infection frequently decrease the patient’s immune status.

Greater understanding of the epidemiology and mechanisms of drug resistance can provide valuable guidance for a better use of existing compounds and for the development of novel products. A selective review of drug resistance in five diseases will illustrate the existing problems and their potential solutions. A summary of the proposed mechanisms of resistance is provided in Table 1.

**MALARIA**

**Overview**

Malaria remains the most visible indicator of the adequacy of health control in all regions of the world with a hot and humid season. By 1955, the World Health Organization (WHO) had established projects for malaria eradication by using indoor residual spraying of insecticides to limit contact between humans and the anopheles vector and by mass administration of pyrimethamine and chloroquine to kill erythrocytic-replicating forms of the parasites (1). As these programs faced infrastructure deficiencies and resistance to insecticides, the vector control was often neglected and the bulk of expenditure was devoted to the use of antimalarial drugs against fever, mainly chloroquine, with sulfadoxine-pyrimethamine as a secondary drug. *Plasmodium falciparum*, the most virulent species, has become the dominant species and its resistance to chloroquine and sulfadoxine-pyrimethamine, and further, to all known drugs, has developed to various degrees. Sub-Saharan Africa alone contributes about 80% of the annual 207 million patients worldwide suffering from malaria, leading to an estimated 627,000 deaths (2).

Severe malaria affects mainly those without acquired adequate clinical immunity, such as young children or particular groups, such as pregnant women. Since the beginning of the 21st century, a specific effort of integrated control has been made and a reduction in transmission is starting to be observed in parts of Africa (3). The most spectacular action (together with the widespread use of long-lasting insecticidal nets) was the global establishment of malaria treatment with artemisinin-based combination therapies (ACTs), associating a curative dose of a drug with long elimination half-life and a dose of a rapidly active drug able to destroy a large parasite load in few hours. This bitherapy is based on a derivative of artemisinin, a substance extracted from sagebrush grown mainly in China, which generates oxidative stress in the parasite. The combination of multiple drugs enhances clinical efficacy and may delay the acquisition of parasite resistance. We need to consider the history of the emergence and spread of resistance to chloroquine and sulfadoxine-pyrimethamine as premonitory of the risk of losing the effectiveness of ACTs if their use is not controlled.

150
The 4-amino quinoline drug chloroquine, a cornerstone of antimalarial chemotherapy since the 1940s due to its low cost, its safety, and its rapid action, lost most of its usefulness as the frequency of \textit{P. falciparum} chloroquine-resistant strains increased and peaked in the 1980s. From limited original foci in Southeast Asia, South America, and Papua New Guinea, resistance has spread inescapably and is now found in most areas of endemicity, including Africa, the continent with the heaviest malaria burden. Chloroquine no longer constitutes an appropriate option for prompt and effective treatment (or prophylaxis) in most countries where \textit{P. falciparum} malaria is the dominant endemic species. With increased use of sulfadoxine-pyrimethamine, the second affordable, relatively safe, and easily administered drug after chloroquine, parasite resistance to sulfadoxine-pyrimethamine has developed very quickly following the same itineraries as the spread of chloroquine resistance a few years before. Nevertheless, specific groups of people in areas of endemicity still rely on sulfadoxine-pyrimethamine for presumptive treatment of fever or for intermittent preventive treatment as the most effective way to prevent severe consequences of malaria. Losing the two low-cost antimalarials is often seen by experts as a public health disaster. Reducing transmission intensity could slow the spread of resistance but, paradoxically, below a critical level, it may accelerate the selection of multigenic resistance (3). This critical situation has prompted international initiatives to help face the high cost of ACTs, to make affordable rapid-diagnostic tests available everywhere, and to renew mosquito-control programs by an extensive distribution of insecticide-impregnated nets. Learning from the past that delay in detection and control of resistance to ACTs may ruin all programs without alternatives for decades, forced real-time drug-resistance surveillance to be set up and drug development to be reinforced.

**Mechanisms of resistance to selected antimalarials**

Chloroquine concentrates from nanomolar levels outside the parasite to millimolar levels within the digestive vacuole of the intraerythrocytic trophozoite, where it inhibits hemoglobin degradation (4). Chloroquine forms complexes with hematin, a by-product of host-cell hemoglobin digestion by the parasite, which accumulates in large quantities and eventually kills the parasite. The resistant isolates have in common a defect in chloroquine accumulation in the digestive vacuole (5). Several mechanisms have been proposed to explain the altered chloroquine accumulation, such as changes in the pH gradient or altered membrane permeability leading to a decreased drug uptake or increased drug efflux (6). Chloroquine accumulation has high structural specificity; this suggests the involvement of either a specific transporter/permease or a molecule associated with hematin in the digestive vacuole (7). Following demonstration that chloroquine resistance is reversible by verapamil, earlier studies focused on the orthologue of the mammalian multidrug resistance (mdr) gene, whose products are overex-

pressed in cancer cells where they expel cytotoxic drugs (8).

This strategy led to the identification of the \textit{pfmdr1} gene product (protein Piroplasm \textit{PFNPGH-1}), a transporter located in the membrane of the parasite digestive vacuole (9). Chloroquine susceptibility was found to be altered by PIPGH-1 mutated at specific amino acid residues and in specific parasite genetic backgrounds (10). However, current evidence indicates that \textit{pfmdr1} does play a secondary role in chloroquine resistance, except in Madagascar where it plays a major role in chloroquine-treatment failures (11).

Following years, using a genetic cross between chloroquine-sensitive and chloroquine-resistant parasites, inheritance data led to the key discovery of the \textit{P. falciparum} chloroquine resistance transporter (\textit{pfcr}) gene (12–13). The \textit{pfcr} gene encodes a transmembrane protein (PICRT), as does PfPGH-1, located in the membrane of the digestive vacuole (13). A complex set of mutations (or haplotype) of this gene is found in most natural isolates from chloroquine-treatment failures and in isolates with an \textit{in vitro} chloroquine-resistant phenotype (13–15). Finally, transfection of chloroquine-sensitive parasites with the mutant \textit{pfcr} genotypes found in resistant isolates suffices to confer chloroquine resistance (16). Mutant PICRT has acquired the property to expel chloroquine outside of the digestive vacuole (17) which is dependent on a charge loss at codon 76 (usually the K76T mutation) in the first transmembrane helix of the transporter (17–18). The role of the other \textit{pfcr} mutations which systematically accompany K76T remains elusive (6).

At least four independent mutant \textit{pfcr} haplotypes carrying the K76T mutation are seen, varying geographically: Asia-Africa, Papua, and South America 1 and 2 (15). A major event in chloroquine resistance was the emergence on the Thai-Cambodian border in the 1950s of CVIET haplotype in codons 72–76 of the \textit{pfcr} gene under drug-pressure selection; this haplotype has now spread to most of the \textit{P. falciparum} Asian and African territories (15, 19). Nonetheless, the wild \textit{pfcr} parasites have not been totally replaced, and their prevalence increases when drug pressure is removed (20). The \textit{pfcr} K76T mutation is now a valuable molecular marker used in epidemiological surveys of chloroquine resistance. Its estimated prevalence may offer a useful predictor of the clinical efficacy of chloroquine in a given area, provided that appropriate adjustments are made for host factors, particularly immunity, that may result in parasite clearance in spite of treatment with an ineffective drug (21).

Amodiaquine, piperaquine, and pyronaridine, which are in the first line of therapy as partners of artemisinins, share with chloroquine a quinoline scaffold, whereas mefloquine and lumefantrine, the other partners of ACTs, belong to amino-alcohols. Neither the mechanism of action of these drugs nor resistances to them are as clearly understood, as for chloroquine. However, the \textit{pfmdr1} gene appears to be involved in parasite response to diverse antimalarials as mutations or amplification of the gene alters parasite susceptibility to desethyl amodiaquine, the active metabolite of amodiaquine (22), quinine, mefloquine, lumefantrine, and artemisinins (10, 23–26). Similarly, wild-type and various mutant \textit{pfcr} alleles associate with altered susceptibility to various antimalarials (lumefantrine, amodiaquine, artemisinins) in addition to chloroquine (6, 16, 27). Transporters other than PICRT and PIPGH-1, such as PfMRP-1 and PNHE-1, may be involved in resistance to mefloquine, lumefantrine, pyrimethamine (28, 29), and quinine, respectively.

Resistance to artemisinins recently emerged in western Cambodia and has now spread across mainland Southeast Asia. It manifests as a delayed parasite-clearance time following treatment initiation and as higher failure rate (30–31). Extensive genetic studies have shown that artemisinin resistance is a genetically determined trait (32) and pointed out specific regions of the parasite genome that are associated with the \textit{in vitro} delayed parasite-clearance time (33–35). Comparative genomics of laboratory-selected and Cambodian field-derived artemisinin-resistant parasites led to the identification of missense mutations in the \textit{kelch13} gene as an \textit{in vitro} and \textit{in vivo} marker of artemisinin resistance (36). How this mutant protein contributes to artemisinin resistance remains to be clarified.

Regarding drugs that antagonize a single enzyme, such as antifolates or inhibitors of the mitochondrial respiratory chain, a single gene modification is often sufficient to generate high-grade resistance. Malaria parasites mostly rely on \textit{de novo} synthesis for folate supply. Cycloguanil (produced by the pro-drug proguanil), and its analogue, pyrimethamine, were the first satisfactory synthetic antifolate antimalarials to be on the market in the 1940s. Both inhibit the plasmodial dihydrofolate reductase (PfDHFR), a key enzyme in the folate synthesis pathway of the parasite. Unfortunately, resistance emerged almost instantaneously and independently from several areas where the drugs had been introduced and these antimalarials were soon supplanted by chloroquine (37). A resurgence in the use of PfDHFR inhibitors took place with the demonstration in 1967 that potentiation with other antifolates from the sulfone/sulfonamide group (such as sulfadoxine or dapsone), which inhibit the plasmodial dihydropteroate synthase (PfDHPS), by-passed resistance and sulfadoxine-pyrimethamine became the new spearhead to face chloroquine resistance in Southeast Asia (37). However, resistance to sulfadoxine-pyrimethamine emerged soon after the increased use of sulfadoxine-pyrimethamine in Thailand. Resistance to PfDHFR inhibitors is conferred by mutant PfDHFR enzymes to which antifolate drugs bind less efficiently compared to the wild-type version (38–39). Stepwise acquisitions of pyrimethamine and then sulfadoxine-pyrimethamine resistance in \textit{P. falciparum} are mirrored by the stepwise acquisitions of PfDHFR mutations: first the key mutation S108N, then the additive mutations N51I and C59R, and finally the additive mutation I164L (39, 40). Other additive mutations can be found in specific areas such as in South America (41). The quadruple-mutant N51I-C59R-S108N-I164L which associates with the highest level of sulfadoxine-pyrimethamine resistance as well as to decreased sensitivity to chlorproguanil-dapsone (an attempt to develop a new antifolate combination similar to sulfadoxine-pyrimethamine) has been reported mostly in Southeast Asia. However, the triple mutant N51I-C59R-S108N, which is widespread in Africa, also associates with treatment failure to sulfadoxine-pyrimethamine (42). This triple mutant N51I-C59R-S108N \textit{pfdhfr} gene emerged in Southeast Asia, and spread all over Asia and Africa in the following years (43, 44).

Resistance to sulfone/sulfonamide group (sulfadoxine being the major antimalarial compound) is conferred by mutant PfDHPS enzymes to which antifolate drugs bind less efficiently compared to the wild-type version (45, 46). Resistance to sulfadoxine has been traced to a set of sequential mutations in the \textit{pfdhps} gene. The likely initial event consisted of an A437G mutation, with subsequent additional mutations conferring increasing degrees of resistance (37). These resistance mutations have appeared independently multiple times and in multiple endemic sites (47). Altogether, resistance to the sulfadoxine-pyrimethamine combination appears to require three mutations in the \textit{pfdhfr}
gene, and the probability of sulfadoxine-pyrimethamine treatment failure increases with additional mutations in \( pfmdr1 \). The clinical outcome of a sulfadoxine-pyrimethamine treatment is subjected to additional host factors such as the level of folates and of acquired immunity and drug absorption and metabolism (42, 48). Cross-resistance has been demonstrated between cycloguanil and pyrimethamine (38, 39, 49). Consequently, interest in other antifolates, such as chlorproguanil plus dapsone (LapDap), to treat parasites resistant to sulfadoxine-pyrimethamine has been limited.

The combination of atovaquone and proguanil was registered in 1996 in North America and Europe where, within 10 years, it became the most used antimalarial for prophylaxis and first-line treatment of non-severe \( P. falciparum \) malaria. Atovaquone is a ubiquinone analogue and binds to cytochrome \( b \) (PcCytB), a component of the complex III in the mitochondrial-respiratory chain (50). In association with proguanil, the effective concentration at which it collapses the mitochondrial membrane potential is diminished (51). In addition, proguanil is partially metabolized to the active drug cycloguanil by human P450 cytochromes. The contribution of the resulting low cycloguanil blood concentrations to the therapeutic efficacy of atovaquone-proguanil remains yet to be substantiated. As with the antifolates, atovaquone resistance emerged almost instantaneously (52). Resistance to atovaquone is conferred by mutant PcCytB to which atovaquone binds less efficiently compared to the wild-type version (53). The substitution of \( Y \) for \( S \) or \( N \) or \( C \) in codon 268 of PcCytB is found associated with treatment failures and confers a high level of atovaquone resistance (54) that proguanil could not thwart (55). Remarkably, the resistance mutation is not detected in areas of endemcity (56), and it seems to evolve repeatedly during primary infections (57). Due to the risk of rapid extension of resistance and high cost of the drug, the deployment of atovaquone in regions where malaria is endemic has not been considered as a priority.

Chloroquine resistance in Plasmodium vivax, the second most common malaria parasite, has been very limited despite widespread chloroquine use. \( P. vivax \), which relapses from dormant parasites in the liver, developed partial resistance to primaquine, the only drug active against liver forms (58). Primaquine’s diminished efficacy is also associated with polymorphisms in the host cytochrome \( P-450 \) 2D6, resulting in altered concentrations of the active metabolites (59). While drug resistance in \( P. vivax \) remains at low magnitude, increasing attention has recently focused to tackle this threat. Investigations on mechanisms of resistance in this species currently examine the potential role of \( P. vivax \) homologues of \( pfcr \) (60), \( pfmdr1 \) (61), \( pfldhfr \) (62), and \( pfldhps \) (63).

**TRICHDOMONIASIS**

Infection with *Trichomonas vaginalis* is one of the most common causes of human vaginitis as well as the most prevalent nonviral sexually transmitted disease (64). *T. vaginalis* infections are associated with preterm delivery, low birth weight, and greater susceptibility to infection with HIV as well as increased shedding of virus in HIV-infected individuals (65–67). As a result, expedient treatment of this infection has become an important public health concern (68, 69).

*T. vaginalis* is a facultative anaerobe and trichomoniad is most commonly treated with the 5-nitroimidazole class of drugs. Two members of this group, metronidazole and tinidazole, are the only drugs licensed for treatment of trichomoniasis in the United States. Tinidazole is more active at equimolar concentrations than metronidazole and is recommended if treatment with metronidazole fails (70–72). However, strains clinically resistant to metronidazole can have cross-resistance to tinidazole. The molecular epidemiology of *T. vaginalis* suggests that clinically resistant isolates are genetically related and are concentrated within one of two major subpopulations (73–75). In a survey of women attending sexually transmitted disease clinics in six U.S. cities, 4.3% of isolates exhibited drug resistance (76), suggesting that almost 160,000 residents in the U.S. alone may be affected (171).

The 5-nitroimidazoles enter parasites in an inactive form by passive diffusion. Once inside, the drug is reduced to the active nitro-radical anion that is thought to cause parasite death by breaking or disrupting DNA. A number of electron donors have been proposed for drug activation, including ferredoxin, pyruvate-ferredoxin oxidoreductase (PFOR), and malic enzyme in the hydrogenosome, which is the source of ATP generation in these amitochondriate parasites (77–79). Drug resistance occurs when transcription of one or more of these enzymes is decreased, and laboratory-adapted resistant isolates have smaller hydrogenosomes (80). However, clinical resistance does not correlate with lower transcript levels of these enzymes or smaller hydrogenosome size (80, 81).

The nitroimidazole drugs are also reduced by the flavin enzyme thioredoxin reductase and covalently bind and inhibit proteins associated with thioredoxin-mediated redox regulation (82). An in vitro-induced nitroimidazole-resistant strain demonstrated reduced thioredoxin reductase activity, not as a result of decreased enzyme concentration but because of a deficiency in the necessary FAD cofactor. Trichomonads with minimal PFOR and malate-dehydrogenase activity remained susceptible to metronidazole (82). Furthermore, use of a flavin inhibitor rendered a normally susceptible isolate resistant to high concentrations of metronidazole. Flavin inhibition also reduced levels of PFOR and malate dehydrogenase, suggesting that the decreased hydrogenosomal redox enzymes observed in resistant isolates may be a consequence rather than a cause of metronidazole resistance (83). A third possible mechanism for nitroimidazole resistance was suggested by the observation that trichomonas isolates that harbored *Mycoplasma hominis* symbionts had a mean in vitro resistance level 10-fold higher than noninfected trichomonads (84). However, the increased mean resistance of the *M. hominis*-infected isolates was still lower than typically observed for resistant isolates. In a separate study, there was no association of mycoplasma infection with clinical resistance (85). It remains unclear which, if any, of these mechanisms is responsible for the clinical nitroimidazole resistance observed in some *T. vaginalis* infections.

Treatment of patients who have metronidazole-resistant trichomoniasis often results in an immediate resolution of symptoms and a negative wet mount. However, within 3 to 4 weeks, in the absence of further exposure, symptoms may recur as the number of organisms rises. Thus, it is important to monitor efficacy of treatment for up to a month and to encourage patients to avoid unprotected intercourse during this time. When nitroimidazole resistance is encountered, patients are often successfully treated with increased doses of drug for a longer time (71, 72); however, many patients cannot tolerate high doses of metronidazole and such practices may only exacerbate the development of drug resistance. In addition, some patients experience hypersensitivity reactions in response to metronidazole and tinidazole.
Clearly, alternatives to the nitroimidazoles for treatment of T. vaginalis infections are needed (86). A library of 1,040 FDA-approved drugs was recently tested against metronidazole-sensitive and -resistant isolates in vitro in an attempt to find alternate oral therapies for trichomoniasis. While no drugs were as effective as the 5-nitroimidazoles, some enhanced the activity of metronidazole when used in combination (87). Intravaginal treatment with drugs such as furazolidone and paromomycin sulfates that are not absorbed well from the intestine or cannot be ingested has been successful to cure some patients but, in general, has limited efficacy (86, 88). Povidone-iodine and boric acid have also shown efficacy for some patients but additional clinical testing is needed (88, 89).

LEISHMANIASIS

Leishmaniasis is transmitted to humans by phlebotomine sandfly vectors and manifests itself in a variety of syndromes. Depending in part on which of the possible 20 species of Leishmania that infects humans is present, pathology can range from a cutaneous lesion that is self-limiting to the most severe mucosal or visceral forms. The identification of leishmaniasis as an important opportunistic infection in patients with AIDS has presented new challenges for treatment of this disease, with increased treatment failures and drug toxicity in HIV-1 positive individuals (90, 91). Use of antileishmanial drugs is limited by their high cost, the difficulty of their administration (injections for several weeks), and/or their associated toxicity. These factors are even more consequential in the developing countries where leishmaniasis is endemic and can lead to premature self-termination of therapy, which in turn may promote increased levels of resistance (92). While true drug resistance has been described for isolates of some Leishmania spp., other species or isolates may just differ in their intrinsic sensitivity to certain compounds (93–96). True resistance is more likely in anthropoponotic forms of leishmaniasis, such as Leishmania donovani and Leishmania tropica, because the zoontotic species that primarily infect animals, with humans as an occasional host, rarely encounter drugs and serve as a reservoir for drug-sensitive parasites (94, 97).

The frontline drugs for treating Leishmania infections caused by all species and all clinical forms have long been the pentavalent-antimonials compounds such as sodium stibogluconate and meglumine antimoniate. These compounds are inexpensive compared to other anti-leishmanial drugs but their extensive use has led to widespread treatment failure. For example, in some areas of endemia in India, treatment failure of visceral leishmaniasis caused by L. donovani is as high as 65% (98). Evidence for true drug resistance in this setting comes from observations that isolates from clinically resistant patients require higher in vitro concentrations of drug to kill the parasites than do isolates from patients who respond to treatment (99). However, the correlation between clinical outcome of treatment for leishmaniasis and the in vitro susceptibility of the causative isolate is not always clear (93–95, 100).

Pentavalent antimonials are produgs that become reduced within the mammalian host cell or parasite to an active trivalent form that boosts the intracellular cytotoxic potential of macrophages, as well as disrupts the parasite’s redox metabolism; many of the proposed mechanisms of resistance across the various Leishmania spp. involve a lower intracellular concentration of active drug (101, 102). One mechanism by which this occurs is a decrease in aquaglyceroporins on the parasite’s surface, resulting in less uptake of drug (103, 104). Resistance has also been associated with increased production of trypanothione or glutathione that binds with the trivalent antimonials and sequestration of the resulting thiol-drug conjugates into intracellular organelles by ATP-binding cassette (ABC) transporters (101, 105, 106). Increased expression of the enzymes involved in thiol synthesis or of the ABC transporter promotes resistance to pentavalent antimonials; inhibition of these pathways in resistant strains increases susceptibility to the drug (102, 103, 105–109). Adding to the difficulty of defining resistance mechanisms, more than one of these mechanisms may arise, even within closely related parasite strains (101). Genomic, proteomic, and metabolomic approaches have further revealed the complex, multifactorial nature of antimonial resistance in Leishmania spp. as well as indicate other mechanisms that could be in play, such as protection from reactive-oxygen species and stress response (95, 96, 100, 101, 104, 110, 111).

Because of the high level of pentavalent-antimonial resistance, this treatment is no longer considered useful in parts of India and, in these places, miltefosine is now the primary treatment for visceral leishmaniasis (96, 112). Miltefosine was originally developed as an anti-cancer drug and is particularly promising because it can be taken orally and has fewer side effects than most of the parenteral treatments for leishmaniasis (113). As a result, although the drug is more expensive than other therapies, it can be administered on an outpatient basis, reducing the overall cost for treatment in comparison to less costly drugs that require hospitalization. Enthusiasm is tempered, however, both because it is teratogenic, thereby limiting its regulated use in women of child-bearing age, as well as the observation that leishmanial resistance to miltefosine develops easily in vitro (113). Relapse rates of 20% within 1 year after miltefosine treatment have already been reported (114). As with the antimonials, resistance to miltefosine has been associated with mechanisms that decrease intracellular concentrations, and inhibitors of ABC transporters can restore drug susceptibility in vitro (115–117). However, recent studies suggest that these mechanisms do not explain all of the clinical resistance to miltefosine and other mechanisms, such as infectivity of the parasite strain, may be involved (112, 114, 118).

Another drug now being used for primary treatment of visceral leishmaniasis is amphotericin B, which interacts with parasite-specific 24-alkyl sterols and induces pore formation in the parasite plasma membranes (92). The use of amphotericin B has been limited in the past due to its high cost and toxicity; however, new lipid-associated formulations of amphotericin B have greatly reduced toxicities and retain good efficacy even when administered in lower doses (119). Like the pentavalent antimonials, optimal activity of amphotericin B may require competent host immune responses (120, 121). Nevertheless, amphotericin B seems to be superior to antimonials for treatment of leishmaniasis in HIV-infected individuals (90, 91). Lipid-associated formulations of amphotericin B are phagocytized by host monocytes and accumulate in the phagocytic lysosomes where Leishmania amastigotes reside. Although parasite isolates from HIV-positive patients who relapsed with L. infantum demonstrated no decrease in their in vitro susceptibility to amphotericin B (121), clinically resistant isolates have been obtained from patients infected with L. donovani. Interestingly, although the mode of action of amphotericin B is thought to differ greatly from that of the antimonials, field isolates indicated that those with greater sodium-antimonyl-glucuronate resistance had greater in vitro resistance to amphot-
tericin B (115). As with the other anti-leishmania drugs, amphotericin B resistance is associated with greater drug efflux and altered thiol metabolism (122).

Part of the challenge for understanding drug activity and treatment failure during leishmaniasis relates to the intracellular location of the amastigotes within host macrophages. As a result, treatment efficacy involves host factors in addition to the parasites and therapeutic compounds (123). For example, intracellular killing of amastigotes is dependent on macrophage production of nitric oxide, which is inhibited by the cytokine interleukin-10 (IL-10). Interestingly, some antimony-resistant isolates of *L. donovani* express a unique glycan that upregulates the ABC transporter in the parasite as well as IL-10 production by the host (108, 124). As a result, neutralization of IL-10 has been suggested as an adjunct therapy for visceral leishmaniasis (125).

**AFRICAN TRYPANOSOMIASIS**

*Trypanosoma brucei rhodesiense* and *Trypanosoma brucei gambiense* are the etiologic agents of human African trypanosomiasis (HAT). The two subspecies are endemic in east- and west-central Africa, respectively, with *T. b. gambiense* causing the vast majority of infections (126, 127). Because these parasites possess antigenic-switching mechanisms, host immune responses are ineffective and the prospects for the development of vaccines against these organisms are meager. Control efforts have largely been focused on prevention through reduction of the tsetse fly vector, usually through traps or insecticides (126). However, recent political unrest with subsequent loss of an effective public health infrastructure in parts of Africa has caused a resurgence of this disease. As a result, drug treatment is the only medical intervention available to combat sleeping sickness for the foreseeable future.

HAT has two stages; an initial bloodstream stage followed by invasion of the central nervous system in the second stage, which causes the meningoencephalitic systems associated with “sleeping sickness,” the more familiar name for HAT (126). Pentamidine and suramin are drugs used for treatment of the first stage but not advanced disease because they are highly ionic and do not cross the blood-brain barrier. Furthermore, use of suramin is avoided for treatment of *T. b. gambiense* because of the risk of severe allergic reactions that it can cause in onchocerciasis patients (126, 127). While clinical resistance to these drugs does not seem to be a problem, failures can occur when infections are diagnosed and treated after disease has progressed past the hemolymphatic stage. Late-stage, central nervous system disease is treated with melarsoprol, eflornithine, or nifurtimox-eflornithine combination therapy (126, 127). Eflornithine is effective against late-stage *T. b. gambiense* infections that are resistant to melarsoprol, but *T. b. rhodesiense* parasites are naturally tolerant to this drug (129). The drugs for HAT are difficult to administer or are relatively toxic, which can contribute to premature cessation of treatment that can in turn contribute to the development of drug resistance.

Pentamidine and melarsoprol share an amimidin-like moiety with amino purines that is recognized and actively taken up by nucleoside transporters in the trypanosome membrane, resulting in concentration of these compounds within the parasite (127). One of these receptors, the *T. brucei* P2 adenosine transporter, or TbAT1, has been extensively studied and resistance to pentamidine and melarsoprol is associated with loss of functional *TbAT1* expression, including in field isolates (127, 130, 131). However, *TbAT1* knock-out parasites were only partially resistant, leading to the discovery of a high-affinity pentamidine transporter (HAFT) that also concentrates pentamidine within the parasites (132). Recently, HAFT has been identified as aquaglyceroporin 2, and loss of this receptor is shown to confer melarsoprol/pentamidine cross-resistance (133, 134). *T. brucei* parasites also express an ABC transporter that, similar to *Leishmania*, functions as an efflux pump and may contribute to the melarsoprol resistance of certain isolates (127, 128, 135).

While melarsoprol treatment failure may be as high as 20% in some settings (136), field resistance to eflornithine and nifurtimox has not been documented. Nevertheless, resistance in laboratory strains has been readily induced for both drugs (137, 138). Eflornithine resistance is associated with the loss of a nonessential amino acid transporter that is responsible for drug uptake, raising the concern that field resistance could easily develop (137).

**SCHISTOSOMIASIS**

Drug resistance in human helminths is rare, a fact attributed to their long reproduction cycles and to their lack of multiplication inside the human host (the exception being *Strongyloides stercoralis*). Thus, when considering treatment failures in schistosomiasis, it is important to distinguish characteristics leading to reduced drug efficacy from true drug resistance. For example, persons with very high levels of infection are less likely to be cured with single-dose therapy than individuals with lower worm burdens (139, 140). This is in part related to the fact that the standard drug used to treat schistosomiasis, praziquantel, is only effective against the adult stage of the parasite and, even under the best conditions, a single dose of praziquantel does not demonstrate complete efficacy (141, 142). Immature worms that may be present at the time of drug treatment, especially in areas of high transmission, are not susceptible to the initial treatment and subsequently develop into patent infections that give the impression of drug resistance. As a result, two treatments spaced 4 to 6 weeks apart are more effective than a single treatment and should be attempted when drug resistance is suspected (139, 143, 144). Rapid reinfection in areas of high transmission should also be considered as a possible explanation for apparent praziquantel-treatment failure (145, 146).

Suspected true praziquantel resistance has been described for *Schistosoma mansoni* infections in Egypt and Kenya (147, 148). Eggs obtained from the feces of individuals who could not be successfully treated have been used to establish infections in mice, confirming the drug-resistance phenotype (147–149). However, widespread clinical resistance has not developed, even in areas with high-intensity treatment pressure for a prolonged time (150–152). Laboratory and field studies have shown decreased diversity of schistosomes following praziquantel treatment suggestive of a genetic bottleneck, a warning sign for development of drug resistance (153, 154). However, this observation has not been consistent in all field studies (155, 156).

The exact mechanism of praziquantel, and as a result the mechanism of drug resistance, is not definitively understood. In drug-susceptible parasites, praziquantel-induced damage to the tegument of adult schistosomes renders the worms susceptible to attack and killing by the host’s immune response; the effect of drug on resistant parasites is reduced (157). The unique beta subunit of the schistosome calcium-ion channel is a molecular target for praziquantel with treatment rapidly inducing a calcium-dependent, sustained muscle contraction in the worm’s tegument (158, 159). However, no differences in this gene’s sequence or expression were observed among a limited number of praziquantel-resistant and -susceptible
parasite strains (160). Furthermore, cytochalasin D reverses the effects of praziquantel without altering the calcium influx, thus raising the possibility that this is not the effector of parasite death (161). Other proposed mechanisms of praziquantel action include inhibition of the worm’s nucleoside uptake and binding to, and altering the function of, schistosome myosin-light chain (162, 163). One potential mechanism of drug resistance includes increased expression of a P-glycoprotein ATP-dependent efflux-pump homologue in parasite strains that have reduced susceptibility to praziquantel (164, 165). Cross-breeding of adult worms with different levels of sensitivity to drug results in offspring with an intermediate phenotype, suggesting that at least artificially induced resistance displays partial dominance (166). Differential gene transcription between susceptible and resistant parasites and between adult and juvenile worms in response to praziquantel may also play a role in drug susceptibility (167, 168).

Although widespread praziquantel resistance has not been observed, as mass drug-administration programs are increasingly employed, there is a fear that resistance may emerge (169). This risk reiterates the need for ongoing monitoring of praziquantel resistance and efforts for the discovery of new drugs or repositioning of existing compounds to treat for schistosomiasis (170).

FUTURE PERSPECTIVES

Several factors contribute to the emergence of drug-resistant parasites. Those parasite species with short life cycles and high multiplication rates that occur in areas of intense transmission are most likely to develop resistant subpopulations. The selection of such populations is encouraged when the parasites are repeatedly exposed to suboptimal drug concentrations. This pattern can result from the use of drugs with long half-lives, or more typically, from the frequent, often unjustified use, of inadequate doses of drugs, a common occurrence in countries where parasite infections are endemic. Public health interventions to correct these factors have not always been successful and would benefit from a better understanding of the drug-resistance mechanisms used by parasites. These mechanisms are very diverse and have been difficult to study, but recent technological advances now provide long-awaited tools that will facilitate the task. The genome sequences for several Plasmodium species, T. vaginalis, Leishmania major, T. brucei, S. mansoni, and Schistosoma haematobium, have been compiled. When these data are used, for example, in combination with microarray technology or whole-genome sequencing, where the DNA of drug-resistant parasite strains is compared to drug-susceptible strains, identification of the genes that confer resistance should proceed even more rapidly than in the last few years. In addition, genomic, transcriptomic, and proteomic data may also be useful in the design of new chemotherapeutic agents as they help researchers identify metabolic processes of parasites that are sufficiently different from those of their human hosts to allow specific attack.

Accurate methods for ascertaining responses of parasites to antiparasitic drugs can prove useful at several levels. They can assist in the clinical management of individual patients, they can yield epidemiologic information that may guide drug use policies and public health interventions, and they offer crucial research tools for the development of new and better drugs. Drug susceptibility tests fall into four broad categories: in vivo tests, in vitro tests, tests with experimental animals, and molecular tests.

In vivo tests with patients directly assess the clinical efficacies of existing compounds. These tests are performed in actual epidemiologic investigations, and their modest technical requirements make them suitable for use under field conditions in developing countries. The interpretation of in vivo tests is limited by potential interference by factors related to the host (e.g., immunity or variations in drug intake or metabolism) or to the environment (e.g., reinfections). However, such tests have proven instrumental in guiding drug use policies, particularly for malaria.

In vitro tests circumvent these interferences by isolating the parasites from their hosts and investigating them in culture under controlled laboratory conditions. These tests have been modified several times for increased performance and assessments of other drugs (1). An increasing number of laboratories, including field facilities.

Molecular techniques are being used in an increasing number of laboratories, including field facilities. These different categories of tests provide complementary information. At one end of the spectrum, molecular tests analyze parasites at their most basic biologic level, without any outside interference. At the other end, in vivo tests in patients reflect complex interactions between host and parasite yet are most relevant for clinicians and public health practitioners. While a good correlation between results of various test methods is desirable, some degree of discrepancy should be expected to result from factors linked to the host or the culture conditions. Indeed, a judicious analysis of such discrepancies might provide valuable insights into the mechanisms of drug action and resistance.

These points are illustrated in the following discussions of five parasitic diseases, selected for their particular chemotherapeutic challenges. A summary is provided in Table 1.

**MALARIA**

Most drug resistance tests in malaria concern *Plasmodium falciparum*, the most prevalent and virulent species. Initial observations of drug-resistant malaria occur most often in a clinical context, and their confirmation is frequently sought by in vitro tests. These aim to document the parasitological and clinical response of a malaria infection in a patient treated with a standard dose of the test drug and monitored under controlled conditions. Initially standardized by the WHO for the response of *P. falciparum* to chloroquine, in vivo tests have been modified several times for increased performance and assessments of other drugs (1). An increasing number of...
With regard to the fast-acting artemisinin derivatives, to artemisinin-based combined therapy (2), since 1996, as it was necessary to assess the response of Plasmodium falciparum to antimalarial drug therapy, especially in P. falciparum; it also occurs in P. vivax. Tests are used for epidemiologic assessment as well as for laboratory investigations. Short-term culture tests are also described for the in vitro testing of Plasmodium falciparum. On an experimental basis, there are in vitro tests to determine a drug's effect on liver stages and sexual stages (gametocytes).

now considered for true resistance identification within partners of artemisinins, which are frequently poorly absorbed or slowly eliminated drugs (5, 6).

The standard in vitro antimalarial drug susceptibility assay determines the ex vivo growth of replicating intraerythrocytic parasites from the ring stage (the only asexual P. falciparum stage found in patient peripheral blood) to the schizont stage in 24 to 72 h in the presence of serial drug concentrations under conditions close to in vivo conditions. With regard to the standard assay, a well-suited 96-well microtiter plate format was designed using the Trager and Jensen cultivation parameters (hypoxia and buffered RPMI medium with human serum), which is the basis of the most-used tests (7, 8). The simplest test format has been adapted to field work and uses 100 μl of fingerpick capillary blood mixed with medium, a 24- to 30-h candle jar incubation, a microscopic count of multineucleated schizonts, and calculation of the 50% inhibitory concentration (IC_{50}) and IC_{90} of the drug from a dose-response curve (9). Beyond this simplest format, whose reagents were prepared and commercialized through the WHO in the years 1980 to 1990, other in vitro tests that offer valuable advantages have been developed. All tests are applicable both to field-collected parasites and to the parasites growing asynchronously in long-term laboratory culture and can also be used for screening potential new antimalarials and for investigations on drug modes of action or resistance. The activities of some antimalarials, such as quinine, address only a part of the asexual erythrocytic cycle. This implies that when long-term laboratory cultivation of patient isolates or reference clones is used, synchronization at ring stage can improve the reproducibility of susceptibility results. Parasite growth and inhibition can be assessed using different methods. A parasite count by microscopic examination of culture smears is cumbersome and often poorly reproducible. Measurement of uptake of [3H]hypoxanthine offers a semiautomated, quantitative, high-output approach but necessitates use of radioactive material and specialized equipment in authorized laboratories, leading to high costs because of the handling of radioactive waste (10). Measurement of highly produced Plasmodium proteins, such as parasite lactate dehydrogenase (11) or histidine-rich protein 2 (12), by double-site enzyme-linked immunosorbent assay demonstrated a higher sensitivity than use of radioisotopes, although these tests are time-consuming and commercial kits are costly (13). Other tests measure the production of DNA during the maturation of parasites using SYBR green I fluorescent dye (14–16). The successful completion and interpretation of all in vitro tests depends on several factors that in turn depend on samples, materials, culture, and statistical methods to generate inhibitory constants. Sample factors to be considered include a recent intake of antimalarial drugs by the patient, which may decrease the test success rate; high parasite inocula, which can lead to an overestimation of resistance to some drugs (17); and folate and para-aminobenzoic acid in the culture medium, which antagonize the in vitro effect of antifolate drugs (18). Another sample factor is the short life of erythrocyte P. falciparum parasites outside the host; each day that passes at 4°C halves their capacity to survive and grow in vitro (19). Processes include the necessity of preparing and distributing dilutions of drugs in wells of plates, which results in particular difficulties for drugs other than chloroquine, as most are poorly soluble or have limited shelf lives. Culture necessitates supplementation of RPMI medium with human serum or AlbuMAX, although this can affect IC_{50}s, as they interact with drugs differently (20). All these fundamental methodological issues undermine accurate comparisons of in vitro susceptibilities either between laboratories or within a single laboratory over time. Consensus exists on parameters of culture, and suggested improvements include measures of quality control of key parameters, such as preloaded plates (titrated drug solutions) and reference of endpoints of isolate susceptibilities to those of reference clones with known susceptibilities (21). Finally, standardized mathematical analysis of concentration inhibition assays is possible through free Web-based tools (22, 23). Drug concentrations associated with the IC_{50} are determined by a modified sigmoid maximum-effect (E_{max}) model-fitting algorithm and display the precision of IC_{50} estimation. The standard in vitro antimalarial drug susceptibility assay described above, however, does not permit accurate potency measurement of the fast-acting and stage-specific artemisinin derivatives for which specific protocols have been developed recently (24–26). These new assays test the capacity of early-ring-stage parasites to survive a brief pulse exposure to high artemisinin concentrations (the so-called ring-stage survival assay [RSA]), better mimicking the situation faced by parasites in vivo. In a study with Cambodian plasmodium isolates, the survival rate estimated with the RSA correlates with in vivo parasite clearance half-lives (25).

Tests exploring antimalarial efficacy at various stages of the Plasmodium life cycle have been designed but are not adapted for routine laboratory use (27). However, the micro-technique has been adapted for testing of erythrocytic stages of P. vivax (28), and cultures of the liver and sexual blood stages of P. falciparum can also be used, although they are substantially more cumbersome (29, 30).

Genetic markers that now offer tools for assessing parasite drug resistance have been identified for several major antimalarials. Chloroquine resistance has been linked to a P. falciparum chloroquine resistance transporter (PfCRT) K76T change on a transmembrane channel in the digestive vacuole of P. falciparum, following a mutation of the pfcr gene (31, 32). P. falciparum multidrug resistance gene 1 (pfmdr1) encodes a P glycoprotein homologue of a human ABC transporter that transports toxic compounds across the digestive vacuole membrane. Point mutations and gene amplification of pfmdr1 have been linked to various extents, to altered susceptibilities to various antimalarials (chloroquine and other 4-aminoquinolines, quinine and other amino-alcohols, and artemisinin derivatives) (33–35). Regarding the artemisinins, missense mutations in the kelch13 gene have been proposed as in vitro and in vivo markers of artemisinin resistance (36). Resistance to antifolates, such as sulfadoxine-pyrimethamine, has been associated with S108N, C59R, and N51I changes in P. falciparum S108N, C59R, and N51I changes in P. falciparum dihydrofolate reductase (37–39) or its homologues in Plasmodium vivax (40). High levels of resistance to antifolate drugs are associated with the P. falciparum dihydrofolate reductase 1164L change (37, 41) or changes in the P. falciparum dihydropterotate synthase target of sulfa drugs (42). Resistance to atovaquone-proguanil has been linked to substitutions in codon 268 of the P. falciparum cytochrome b (pf cyt b) gene, resulting in the amino acid change S, N, or C, leading to high-level resistance (43). Such genetic polymorphisms can be identified in individual parasite isolates by various standard techniques, which include mutation-specific nested PCR (44) or PCR followed by sequencing (45), restriction fragment length polymorphism analysis (46), and single-nucleotide primer extension with detection of fluorescent products on a capillary sequencer (47), or by using a DNA microarray-based method (48). Next-generation sequencing also allows accurate detection of drug resistance genotypes from pooled parasite isolates (49). Possibilities for analyzing haplotypes...
In mixed parasite isolates may improve our ability to find the clinical relevance of combined mutations (50).

As long as validated molecular markers are lacking for resistance to artemisinin’s partner drugs, in vitro and in vitro surveillance will remain critical surveillance tools for the emergence of resistance to artemisinin-based combined therapy (51, 52). The judicious use of in vivo, in vitro, and molecular tests can yield valuable information that will help us to adapt drug policies before extension of resistance brings about elevated morbidity consequences (53, 54).

TRICHOMONIASIS

*Trichomonas vaginalis* is the most common nonviral sexually transmitted infection in the United States and throughout the world; however, metronidazole and tinidazole are the only drugs currently approved by the U.S. Food and Drug Administration to treat trichomoniasis. With 4.3% of *T. vaginalis*-infected sexually transmitted disease clinic patients in the United States demonstrating some degree of resistance to metronidazole, standard treatment regimens may not be effective for approximately 159,000 individuals (55, 56). Fortunately, drug susceptibility testing has proven useful in identifying alternative treatment protocols that are usually successful in effecting patient cure (57).

Susceptibility testing for *T. vaginalis* is a simple assay of parasite motility in the presence of drug (58). Axenic trichomonads are cultured in Diamond’s Trypticase-yeast-maltose medium with serial dilutions (400 to 0.2 μg/ml) of metronidazole or tinidazole dissolved in dimethyl sulfoxide (DMSO) and the appropriate parallel concentrations of DMSO in U-bottom microtiter plates. Plates are incubated at 37°C for 48 h and are then examined microscopically with an inverted phase-contrast microscope. The lowest concentration of drug in which no motile organisms are observed is defined as the minimum lethal concentration. Minimal lethal concentrations greater than 100 μg of metronidazole per ml have been associated with clinical resistance (59). This assay has been adapted to determine IC50s and screen novel compounds for antitrichomonal activity by measuring incorporation of [3H]thymidine (60, 61) or acid phosphatase activity (62). These modifications have not as yet been adapted to monitor clinically resistant isolates, but theoretically, this could be accomplished rather easily.

One difficulty of the in vitro culture method for assessing the resistance of *T. vaginalis* isolates is the need to derive axenic cultures from clinical specimens. As individuals with trichomoniasis are often infected with other sexually transmitted disease organisms that also grow in Diamond’s medium, this may require an extended time. Molecular comparisons of *T. vaginalis* isolates suggest that genetic markers for metronidazole resistance could be identified (63–66). The prospect of a molecular marker for resistant *T. vaginalis* is exciting, as it may make possible a PCR-based assay for resistance. This would obviate the need for establishing axenic cultures and may allow direct testing of specimens from patients suspected of harboring a resistant isolate.

LEISHMANIASIS

Treatment failure in leishmaniasis may result from either true drug resistance or patient factors, such as poor drug absorption, treatment compliance, or immunodeficiencies, that preclude effective chemotherapeutic action. Differentiation of these two possibilities is important for both individual patient care and general public health. Traditional testing for drug resistance in *Leishmania* is performed by culturing the promastigote form of the parasite with drug in standard cell culture media (Schneider’s medium, RPMI medium, or M199 medium) supplemented with bovine sera for 42 to 72 h at 26 to 37°C and by assessing viability by direct counting (67). [3H]Thymidine incorporation (68), enzymatic hydrolysis of p-nitrophenyl phosphate (69), conversion of 3-(4,5-dimethylthiazol-2-yl)-2,5-diphenyltetrazolium bromide (MTT) (70), or reduction of resazurin (71). [3H]Thymidine incorporation is perhaps the most sensitive method, but it requires access to radioactive materials and a scintillation counter. Hydrolysis of p-nitrophenyl phosphate and conversion of MTT are colorimetric assays, but p-nitrophenyl phosphate hydrolysis has high backgrounds caused by the drug medium components and MTT may interact with certain drugs (e.g., meglumine antimoniate). An advantage of resazurin (also known as Alamar Blue) is that it is not necessary to further manipulate the parasites in order to read the assay. Thus, drug activity can be monitored at different time points after initiation of culture. Although promastigote assays are the easiest to use, they yield clinically reliable results only for drugs (such as miltefosine and amphotericin B) that do not require cellular mechanisms for activation (72, 73). In contrast, the more widely used pentavalent antimonials require reduction by host cells to the active trivalent form. As a result, promastigote assay results correlate poorly with clinical resistance, and assays that test drug susceptibility of the intracellular amastigote form of leishmania parasites are recommended (74, 75). Unfortunately, intracellular assays are very labor-intensive. Macrophages are infected with promastigotes that must then transform into amastigotes prior to exposure to drug. Each test condition necessitates preparation of slides, which are then stained for microscopic counting of the proportion of infected macrophages and the number of amastigotes per macrophage in drug-treated and control cultures. Furthermore, promastigotes from field isolates are not uniformly infective for macrophages, leading to selection bias that may reduce the correlation between drug susceptibility assays and clinical treatment outcome (76, 77).

Intracellular assays have been facilitated by stable transformation of isolates with firefly luciferase. Cells are simply lysed, the substrate luciferin is added, and activity is measured on a luminometer (78). Similarly, transfection of isolates with the gene encoding green fluorescent protein (GFP) can be used (79). Following incubation with the drug, parasites are enumerated on a flow cytometer, with no need for addition of substrates because GFP is intrinsically fluorescent. An advantage of transfection assays is the ability to compare drug activities against promastigotes, axenic amastigotes, and intracellular amastigotes. However, these assays are more useful for screening experimental compounds rather than testing field isolates because of the challenges of standardized transfection between isolates and the expensive equipment needed to measure the results.

If transfection with exogenous genes is undesirable, mammalian cells that have been infected with parasites and treated with drug can be fixed and permeabilized. Intracellular amastigotes are then detected with anti-*Leishmania* lipophosphoglycan monoclonal antibody followed by a fluorescent-marker-labeled anti-mouse immunoglobulin antibody (80). This assay can be used for assessing the drug sensitivities of a variety of *Leishmania* species, and it is adaptable to use with individual patient isolates. Alternatively, following
Incubation of infected cells with a drug, controlled lysis of macrophages can be performed to release amastigotes that are then transformed back into promastigotes and enumerated using one of the microscopic, [3H]thymidine incorporation, colorimetric, or fluorometric assays described above (81).

As molecular mechanisms of drug resistance in Leishmania spp. become better defined, it may be possible to utilize PCR and DNA sequencing of single nucleotide polymorphisms (SNPs) for epidemiologic studies of resistant isolates. Resistance-associated SNPs from both visceral and cutaneous Leishmania species have been identified in genes for drug transporters, the stress response, and thiol and redox metabolism (82, 83). These assays are of interest, as no manipulation beyond growing parasites is needed. However, it is likely that applicability will be species and drug restricted.

AFRICAN TRYPANOSOMIASIS

As in leishmaniasis drug sensitivity testing, trypanosomes can be cultured in vitro with drug and monitored for viability by enzymatic hydrolysis of p-nitrophenyl phosphate (69) or by direct counting (84). Parasites are cultured at 37°C for 24 h in 4 to 5% CO₂ in phenol red-free Iscove’s medium containing hypoxanthine, thymidine, glutamine, L-cysteine, pyruvate, β-mercaptoethanol, and heat-inactivated bovine or horse sera. An in vitro lysis assay has been developed for testing the sensitivities of Trypanosoma brucei subspecies to melarsoprol (85). It requires the ability to culture trypanosomes and a thermostatically controlled recording spectrophotometer. As susceptible organisms die, their absorbance at 500 nm is reduced over the course of 30 min. If drug-susceptible and drug-resistant strains are available to use as controls, this technique may perhaps be adapted to field use because differences in intensity at this wavelength can be distinguished by the unaided eye. Visible color change can also be observed when trypanosomes are incubated with resazurin (86). However, unlike in assays for Leishmania drug sensitivity, the dye is added after parasites are incubated with drugs for 66 to 72 h, depending on the parasite subspecies.

Because drug resistance in African trypanosomes is primarily a function of reduced drug uptake, radiolabeled drugs can be incubated with parasites to identify resistant isolates, with reduced cellular incorporation of radioactivity suggesting resistance (87). Similarly, because drug uptake is reduced in isolates with point mutations or deletions of aminopurine transporters, it may soon be possible to utilize molecular tools to identify trypanosome isolates that are drug resistant (88). One of the genetic mutations leading to an amino acid change in the transporter responsible for melarsoprol uptake abrogates a restriction endonuclease site, while a different mutation creates one (89). Thus, PCR amplification of the appropriate gene followed by enzymatic digestion and gel electrophoresis results in different DNA banding patterns that might be used to distinguish melarsoprol-susceptible and -resistant isolates. While more clinical drug-resistant isolates must be evaluated to confirm the utility of this test, a similar banding pattern between melarsoprol-resistant laboratory-derived and field isolates (89) suggests that this tool may be useful for both management of individual patients’ infections and tracking the spread of resistance in a population (90).

SCHISTOSOMIASIS

Drug resistance testing of schistosomes differs greatly from that of protozoan parasites in both purpose and methods. Adult worms do not replicate within the definitive host, thus circumventing one of the mechanisms associated with rapid development of drug resistance. As a result, widespread resistance to praziquantel, the drug of choice for schistosomiasis, has not emerged even under heavy drug pressure (91–93). Thus, the need to evaluate drug resistance for individual infections is rare. However, because reliance on a sole drug is risky and schistosomes have developed resistance to other drugs, techniques to monitor praziquantel resistance are needed. The failure of adult worms to replicate makes drug susceptibility testing methods more challenging. Investigation of drug resistance has typically been performed by (i) obtaining eggs from an unsuccessfully treated mammalian host, (ii) infecting the appropriate intermediate snail host, (iii) isolating cercariae from the infected snail, and (iv) infecting and treating experimental animals. A protocol to determine the 50% effective dose in mice has been developed and demonstrates good reproducibility among different laboratories (94). This approach has the drawbacks of being very time-consuming and technically challenging, especially in areas of endemicity that may not have well-developed experimental snail and rodent colonies. Additionally, resistance phenotypes may not persist in the absence of drug pressure, clouding our ability to interpret results (95). Fifty-percent effective doses can also be estimated in an in vitro assay by assessing contraction of worms following perfusion and incubation with praziquantel and correspond well with in vivo results (96, 97). Although this approach is less complicated than infecting, treating, and perfusing additional mice, it still requires the availability of naïve snails and some mice to obtain the adult worms, along with the time and expertise needed to perpetuate the life cycle. In addition, the parasites that successfully infect mice may not accurately represent the diversity of field isolates. Recently, an in vitro method that circumvents these problems has been adapted to field use (98, 99). Eggs from stool samples from infected individuals are isolated and hatched to release miracidia, which are then exposed to praziquantel, and effects on morphology are monitored. The miracidia from persons who then cleared their infection following treatment were more affected by the drug than the miracidia from stools whose donors did not clear their infections. Evaluating changes in the parasite’s population structure using miracidia obtained from eggs in patients’ stools is another approach to monitor development of potential drug resistance. Changes in the genetic composition of schistosomes following treatment suggest praziquantel efficacy, while maintenance of the same microsatellite distribution may indicate treatment failure (100, 101). Ongoing surveillance for drug resistance will be an important component for schistosomiasis control programs that are dependent on mass drug administration.

FUTURE PERSPECTIVES

Most susceptibility tests for antiparasitic drugs are not routinely available in clinical diagnostic laboratories, because these procedures are not in frequent demand and present special technical requirements. Such tests are performed mainly in reference or research laboratories or during epidemiologic investigations in areas of endemicity. Thanks to recent advances in laboratory technology and genetic analysis of parasites, available tests are increasingly sophisticated and informative. The development of tests that are robust and simple to use will facilitate field studies that aim at optimizing the deployment of currently available drugs.
These field tests usefully complement the more sophisticated procedures used in research laboratories whose main orientation is toward the development of novel antiparasitic compounds and deciphering drug resistance mechanisms.

antimicrobial susceptibilities, 662
clinical significance, 654
direct examination, 656
epidemiology and transmission, 653
identification, 658–659
isolation procedures, 656
taxonomy and description of, 652
Actinobacillus actinomycescomitans, 1328
Actinobacillus equuli, 652–654, 659
Actinobacillus hominis, 652–653, 659
Actinobacillus lignieresi, 652, 654, 659
Actinobacillus suis, 652–654, 659
Actinobacillus ureae, 652–654, 658–659
Actinobacteria (class), 474, 1139
Actinobacteria (phyllum)
biocidal characteristics of human Eubacterium-like organisms, 930
identification, 926
taxonomy and description of agents, 920–921
Actinobacterium, 474, 920–921, 924, 926, 928, 930
antimicrobial susceptibilities, 931
identification, 438
taxonomy, 474–475
Actinobacterium maculatum, 927–928
Actinobacterium schufeli, 920, 923–924
Actinobacterium urinale, 920–921, 923–924, 927–928
Actinomadura
chemotaxonomic and lysosome growth characteristics, 509
clinical significance, 513–514
description of genus, 506
identification, 438
microscopy, 521
morphologic characteristics, 507
taxonomy, 525
Actinomadura chibensis, 514
Actinomadura crenae, 514
Actinomadura dassomarica, 508
Actinomadura lativa, 510, 512, 514
Actinomadura madarea, 513–514, 521
Actinomadura nitritigenes, 514
Actinomadura pelletieri, 510, 513–514, 521
Actinomadura spini, 514
Actinomadura viracea, 514
Actinomadura vulgaris, 2088
Actinomadura vulgaris elegans, 2088
Actinomyces
474, 480, 920–932
antimicrobial susceptibilities, 931, 1172, 1177, 1183–1184, 1188–1190, 1194, 1148
biocidal characteristics, 928
clinical significance, 922–924
description of agents, 920–921
direct examination, 925–926
epidemiology and transmission, 922
identification, 438, 926–930
isolation procedures, 926
metronidazole resistance, 1352
specimen collection, transport, and handling, 297
taxonomy, 474–475, 920–921
Actinomyces amylophilus, 923, 928
Actinomyces besseyi, 923, 924, 928
Actinomyces bovis, 923, 924, 928
Actinomyces citrophilus, 923, 924, 928
Actinomyces denticans, 924, 927–928
Actinomyces flavus, 924, 927–928
Actinomyces georgianus, 924, 928
Actinomyces melvernensis, 924, 929–930
Actinomyces meyeri, 923–924, 928
Actinomyces naeslundii, 920, 923–924, 927–928
Actinomyces niger, 924
Actinomyces niger subsp. antratus, 928
Actinomyces niger subsp. naeslundii, 924, 926, 928
Actinomyces naeslundii, 920, 923–924, 927–928
Actinomyces niger, 924, 926–928
Actinomyces oris, 928–929
Actinomyces radiificans, 924, 926, 928
Actinomyces radingae, 924, 923, 928
Actinomyces timonensis, 924, 928
Actinomyces tauricus, 924, 923, 928
Actinomyces ungereriti, 923, 926, 928
Actinomyces tissieae, 949, 927–928
Actinomyces tuberculatus, 1159
Actinomyces vulgaris, 504–528
antimicrobial susceptibilities, 526–527
antimicrobial susceptibility testing, 1172–1173
clinical significance, 1172
quality control, 1173
reporting of results, 1173
testing method, 1172–1173
chemothaxomic and lysosome growth characteristics, 509
clinical significance, 511–520
collection, transport, and storage, 520
colonial morphology, 510
description of genera, 506–511
direct examination, 520–521
epidemiology and transmission, 511
evaluation, interpretation, and reporting of results, 523

Sattlerella wadsworthensis, 1348
specimen choice, collection, transport, and handling, 905
Anaerobic cocci
Gram-negative anaerobic cocci (GNAC), 909–916
antimicrobial susceptibilities, 916
clinical significance, 911
description of group, 909
epidemiology, 910
evaluation, interpretation and reporting of results, 916
identification, 913, 916
isoeducation procedures, 912
taxonomy, 909
Gram-positive anaerobic cocci (G PAC), 909–916
antimicrobial susceptibilities, 913, 916
clinical significance, 910–911
collection, transport, and storage of clinical specimens, 911–912
description of group, 909
direct examination, 912
epidemiology, 909–910
evaluation, interpretation and reporting of results, 916
identification, 912–915
isoeducation procedures, 912
taxonomy, 909–910
Anaerobic colistin-nalidixic acid (CNA) agar, 327–328
Anaerobic culture
specimen processing, 287, 289
suitability of specimens for, 289
Anaerobic Gram-negative rods, 967–985
anaerobic, 967–985
antimicrobial susceptibilities, 983–984
β-lactamase tests, 1302–1303
clinical significance, 969–974
collection, transport, and storage of specimens, 975
description of group, 967–969
direct examination, 975–976
epidemiology and transmission, 969
identification, 976–983
isoeducation procedures, 976
molecular detection, 975–976
reporting, interpretation, and reporting of results, 984–985
taxonomy, 967–969
unculturable, 983
Anaerobic Gram-positive rods
Clostridium, 940–959
non-spore-forming, 920–932
antimicrobial susceptibilities, 931
clinical significance, 922–925
collection, transport, and storage of specimens, 925
direct examination, 925–926
epidemiology and transmission, 922
evaluation, interpretation, and reporting of results, 931–932
identification, 926–928
isoeducation procedures, 926
serologic tests, 931
taxonomy and description of agents, 925–927
Angiostrongylus
characteristics of genus, 970–971
clinical significance, 974
identification, 977, 981–982
taxonomy, 969
Angiostrongylus cantonensis, 969, 974, 982, 994, 997
Angiostrongylus costaricensis, 969, 974, 982
Anaplasma, 909, 911
Anaplasma hydrophylaxis, 909–910, 914–915
Anaplasma marginale, 909–911, 913–915
Anaplasma phagocytophilum, 1130
antigen detection, 1142–1143
antimicrobial susceptibilities, 1144
arthropod vector, 2507
biosecurity, 1143
description of, 1135
diagnostic tests, 1084
direct examination, 1142–1143
epidemiology and clinical diseases associated with, 1083
evaluation, interpretation, and reporting of results, 1144–1145
features of, 1137
human granulocytic anaplasmosis (HGA), 1138–1139, 1142–1145
identification, 1143
IFA, 1143–1144
isoeducation procedures, 1143
laboratory confirmation, 1142–1144
microscopy, 1141–1142
nucleic acid detection, 1143
phylogenetics, 1136
serologic tests, 1084, 1143–1144
Anaplasma pluvianum, 1136–1137
Anaplasmataceae (family), 1135–1136
Anchocyllotoma, 2329, 2332, 2501
Ancyclostoma caninum, 2531
Ancyclostoma duodenale, 2323, 2454–2456
clinical significance, 2456
description, 2454
eggs, 2454
larvae, 2454
worms, 2454
diagnosis, 2456
epidemiology and prevention, 2454
taxonomy, 2454
transmission and life cycle, 2456
viral treatment, 2455–2456
Ancyclostomatoidea (family), 2299, 2454
Ancyclostomatidae (superfamily), 2289, 2454
Ancyclostomidae (family), 2087, 2102
Andes virus, 1661–1662
Andronemas system, 2042
Anelloviridae (family), 1398, 1400–1401
Anemia
chloramphenicol, 1193
Epstein-Barr virus and, 1739
hookworm, 2456
iron deficiency, 2456
Leishmania, 2359
lineol, 1191
nitrofurantoin, 1196
parovirus B19, 1819–1820
pernicius, 2472–2473
sulfonamides, 1192
Trichinella trichiura, 2459
Trypanosoma brucei, 2366
viruses, specimens and methods for detection of, 1406
Anceuthatilica, 438
Anieific culture, anemiae, 2393–2394
Angioedema
Loa loa, 2467
Mansonella, 2468
Angiostromylin, 2498–2499
Angiostromylinidae (family), 2289
polymyxin resistance, 1232
quinolone resistance, 1232–1233
quinupristin-dalfopristin resistance, 1231
rifampin resistance, 1231
tetracycline resistance, 1233–1234
tigecycline resistance, 1234
trimethoprim-sulfamethoxazole resistance, 1234–1235
genetic basis, 1214–1217
acquisition of resistance genes, 1216–1217
in Mycobacterium tuberculosis complex, 1357–1361
mutation of cellular genes, 1214–1216
Antibiograms, 1352
Antifungal resistance screens, 1263
Antibiotic-associated diarrhea
Clostridium difficile, 944
Clostridium perfringens, 943–944
Antibiotic-resistant bacteria, inactivation of, 196
Antibody detection, fungi, 1969, 1971
Antibody interference, 100
Anticoagulants, 17
Anticomplement immunofluorescence assay
cytomagalovirus (CMV), 1728
Epstein-Barr virus, 1743–1745
Anticonvulsant hypersensitivity syndrome,
human herpesvirus 6 (HHV-6) and, 1756
Antifolate(s), 2540–2541
Antifolate resistance, 2564
Antifungal agents, 2223–2230; see also specific drugs
alylamines, 2223–2224
azoles, 2224–2227
echinocandins, 2227–2228
novel agents in development, 2230
polyenes, 2228–2229
spectrum and extent of activity, 2224
Antifungal resistance, 2236–2247
alylamine resistance, 2239, 2245
azole resistance, 2237–2243
clinical, 2236
echinocandin resistance, 2237, 2239, 2244–2245
fluorotinyl resistance, 2239, 2245–2246
microbiological, 2236–2237
polyene resistance, 2237, 2239, 2243
primary, 2237
Antifungal susceptibility testing, 2255–2273
agar dilution method, molds, 2272

Antimicrobial susceptibilities, see specific antimicrobial agents; specific organisms
Antimicrobial susceptibility testing
ability to detect resistance, 1278–1280
aminoglycoside resistance in Enterococci, 1278
carbapenem resistance, 1279–1280
ESBL-producing Enterobacteriaceae, 1279
glycopeptide susceptibility reduction in staphylococci, 1279
in Gram-negative bacteria, 1280
in Gram-positive bacteria, 1279
Antimicrobial susceptibility testing
(continued)
inducible chloramphenicol resistance, 1279
lincomycin resistance in enterococci and staphylococci, 1278
oxacillin resistance in staphylococci, 1278
penicillin resistance in staphylococci, 1278
Streptococcus resistance, 1279
vancomycin resistance in enterococci, 1278
agar dilution method, 1254, 1257–1258
advantages and disadvantages, 1258
anaerobic bacteria, 1342–1344
dilution of antimicrobial agents, 1262
for aminoglycoside resistance detection in enterococci, 1287–1288
incubation, 1257
inoculation procedures, 1257
interpretation and reporting of results, 1257–1258
preparation, supplementation, and storage of media, 1257
anaerobic bacteria, 1342–1352
agar dilution, 1342–1344
antibiograms, 1352
broth microdilution method, 1344–1345
commercial test methods, 1345–1346
indications for testing, 1349
MIC gradient diffusion method, 1345
quality control, 1343–1345
reference test methods, 1342–1345
strategies for testing and reporting of susceptibility data, 1352
suggested agents for testing, 1349
automated systems, 33–35, 1274–1281
ability to detect resistance, 1278–1280
advantages, 1277–1278
BD Phoenix system, 1277
disadvantages, 1278
MicroScan WalkAway system, 1276–1277
semiautomated instrumentation for disk diffusion method, 1274–1275
Sensititre ARIS 2X, 1277
VITEK systems, 1275–1276
breakpoint establishment, 1248–1249
clinical and bacteriological response rates, 1248
MIC distributions, 1248, 1253
pharmacokinetics and pharmacodynamics, 1248
broth macrodilution methods, 1258, 1261–1262
advantages and disadvantages, 1262
dilution of antimicrobial agents, 1258
incubation, 1261
inoculation procedures, 1261
interpretation and reporting of results, 1261–1262
preparation, supplementation, and storage of media, 1258, 1261
broth microdilution method, 1262–1263
ability to detect resistance, 1278–1280
advantages and disadvantages, 1263
anaerobic bacteria, 1344–1345
automated, 1275–1280
breakpoint susceptibility tests, 1263
dilution of antimicrobial agents, 1262
fastidious bacteria, 1315, 1317–1318
for aminoglycoside resistance detection in enterococci, 1288
gradient diffusion method, 1263
incubation, 1262–1263
inoculation procedures, 1262
interpretation and reporting of results, 1262

Vibrio furnissii, 765
Vibrio metschekoffi, 766
Wesserella, 431
Bacteria
classification of bacteria, 235–265
identification by nucleic acid sequencing, 75–76
SUBJECT INDEX
β-Lactamase (continued)

Pastoretella, 1331
penicillins and, 1172–1173
Porpholyctus, 1346–1347
Prevotella, 1342, 1346–1347
processing, 1223–1224
Pseudomonas aeruginosa, 781, 1224–1227
resistance, 1220–1228
ROB-1, 1320, 1331
SHV, 1223–1225, 1299, 1383–1384
staphylococcal, 1213–1214, 1289
TEM, 1222–1226, 1299, 1320, 1322
tests for
AmpC, 1299–1300
carbapenemases, 1300–1302
direct tests for β-lactamases, 1302–1303
extended-spectrum β-lactamase (ESBL), 1299
in anaerobes, 1345–1346
molecular, 1383–1384
zone edge test, 1289, 1302
VIM type, 1223–1224, 1226, 1383–1384
β-Lactamase inhibitors, 1177–1178
avlsac, 1178
clavulanic acid, 1177
MK-7655, 1178
sulbactam, 1177–1178
tazobactam, 1178
β-Lactam resistance, 1220–1228
β-lactamase-mediated resistance, 1223–1228
class A β-lactamases, 1224–1226
class B β-lactamases, 1226
class C β-lactamases, 1226–1227
class D β-lactamases, 1227–1228
common associations of resistance mechanisms, 1215
class E β-lactamases, 1229
penicillin-binding protein-mediated, 1212
acquisition of foreign PRPs, 1221–1222
PRP overexpression, 1221
point mutations, 1222–1223
resistance mutations by recombination with foreign DNA, 1222
pneumococci, 1383
Beta-lin, 317
Betamethasone, 2155
Betapenilomatus (genus), 1398, 1783
B-G-0-Star, 1996
BHE media, for fungi, 1951–1952
BHI-V6 screening agar test method, 1295
Biastopora mackinnoni, 1968, 2173–2174, 2330
Bibersteinia trehalosi, 655
Bicho-Dubli test, 1986
Bijldobacterium
antimicrobial susceptibilities, 931, 1348
clinical significance, 925
identification, 438, 926–927, 930
isolation procedures, 926
taxonomy and description, 920–921
Bijldobacterium adenococci, 925
Bijldobacterium breve, 925
Bijldobacterium dentium, 925
Bijldobacterium infantis, 920
Bijldobacterium longum, 920, 925
Bijldobacterium scaidax, 925, 927
Bijldobacterium suis, 920
Big Brushy virus, 1669, 1672
BiOCY (bismuth sulftite-glucose-glycine yeast) agar, 1959
Bigra (phylum), 2406
Bihlavix, 2486
Bile esculin agar, 328
dimorphic fungi causing systemic mycoses, 2117
Ebrhichia chaffensis, 1140
filoviruses, 1674–1675
Franciscella tularensis, 855–856
fungi, 1947
Fusarium, 2068
Influenzae, 1663
influenza viruses, 1479, 1482
prions, 1861–1862
Ricketsia conorii, 1128
specimen collection considerations, 1409
biosafety cabinets, 172–173, 282–283
Biosecurity, dimorphic fungi causing systemic mycoses and, 2117
BioSignal, 1474
Biosynth chromogenic medium for Listeria monocytogenes, 328–329
Bioterrorism, see Biothreat agents
Bioterrorism Act, 219
Biothreat agents, 217–224
antimicrobial susceptibility testing, 1316, 1324–1325
botulism toxin, 947
categories and definitions, 219
category A agents, 219, 221–222
anthrax, 221
botulism, 221
hemorrhagic fever viruses, 222
plague, 221
smallpox, 221–222
tularemia, 222
category B agents, 219, 222–224
brucellosis, 222
tuberculosis, 223
epidemic typhus, 223
epstein toxsin, 223
food and water safety threats, 224
glomer, 222
meliodosis, 222
psittacosis, 223
Q fever, 222–223
staphylococcal enterotoxins, 223
viral encephalitis, 223–224
characteristics, summary of, 220
Federal Select Agent Program, 219
Laboratory Response Network (LRN), 217–219
mycotoxins, 2192
Ricketsia, 1124
Biotyper system, 34, 48, 72
anaerobic Gram-negative rods, 982
Clostridium, 959
FAECK group, 658, 661
Bipolaris, 1940, 2159–2160, 2266–2269
Bipolaris aerubrunis, 2160
Bipolaris haustorius, 2160
Bipolaris specifera, 2160
Bird seed and esculin base medium, 1952
Birdseed agar, 1959, 2000
Birth defects
arenaviruses, 1673
rubella, 1526–1527
Bismuth sulftate agar, 329
Bismuth sulftate-glucose-glycine yeast (BiOCY) agar, 1959
Bite wounds, see also Dog bites; Wound infection
rabies virus, 1635
specimen collection, transport, and storage guidelines, 272
Biting and stinging arthropods, 2518–2521
centipedes and millipedes, 2520
Hymenoptera, 2518
scorpions, 2519–2520
Broth macrodilution method (continued)

- Advantages and disadvantages, 1262
- Automation, 1261
- Interpretation and reporting of results, 1261
- Preparation, supplementation, and storage of media, 1258, 1261

Broth microdilution antimicrobial susceptibility testing, 1262–1263

- Ability to detect resistance, 1278–1280
- Ammonium resistance in Enterococcus, 1278
- Carbapenem resistance, 1279–1280

ESBL-producing Enterobacteriaceae, 1279

- Glycopeptide susceptibility reduction in staphylococci, 1279
- In Gram-negative bacteria, 1280
- In Gram-positive bacteria, 1279
- Inducible clindamycin resistance, 1280
- Linezolid resistance in enterococci and staphylococci, 1278
- Oxacillin resistance in staphylococci, 1278
- Penicillin resistance in staphylococci, 1278

Streptococcus resistance, 1279

Vancomycin resistance in enterococci, 1278

Advantages and disadvantages, 1263

Antifungal susceptibility testing
dermatophytes, 2271

- Molds, 2268, 2270
- Yeasts, 2258–2264

Automated, 1275–1280

- Ability to detect resistance, 1278–1280
- Advantages, 1277–1278
- BD Phoenix system, 1277
- Disadvantages, 1278
- MicroScan WalkAway system, 1276–1277

- Sensititre ARIS 2X, 1277
- VITEK systems, 1275–1276

Breakpoint susceptibility tests, 1263

- Dilution of antimicrobial agents, 1262
- For aminoacetylsresistance detection in enterococci, 1288
- For anaerobic bacteria, 1344–1345
- Commercial panels, 1345
- Incubation conditions, 1344
- Inoculation procedure, 1344
- Inoculation preparation, 1344
- Interpretation and result reporting, 1345
- Medium, 1345
- Quality control, 1344–1345

For extended-spectrum β-lactamase (ESBL) production confirmation, 1266

- Fastidious bacteria, 1315, 1317–1318
- Gradient diffusion method, 1263
- Incubation, 1262–1263
- Inoculation procedures, 1262
- Interpretation and reporting of results, 1263

description of genus, 477
epidemiology and transmission, 479
identification, 438, 495
taxonomy, 474–475
Exiguobacterium acrylyceton, 477, 484, 495
Exiguobacterium anitiansc, 477, 495
Exophiala, 2153–2154, 2157–2158, 2161, 2162, 2165, 2176
Exophiala asiana, 2154, 2158
Exophiala attenuata, 2154, 2158
Exophiala bergeri, 2154, 2157
Exophiala dematitidis, 2154, 2157–2161, 2165, 2167, 2266–2269
Exophiala jeanesnelti, 1968, 1973
Exophiala lacunata, 2154, 2157, 2161–2162, 2173–2176, 2178–2179, 2251, 2254
Exophiala oligosperma, 2154, 2157, 2161–2162
Exophiala phaeoarmafom, 2154, 2158, 2163
Exophiala spinifera, 2154, 2158, 2161, 2163
Exophiala sperculia, 2147
Exophiala xenobiotica, 2154
Exserohilum, 1948, 2153, 2159, 2162, 2164
Exserohilum lungstrostrum, 2161
Exserohilum megaspori, 2161
Exserohilum rostratum, 1978, 2155, 2161
Exserohilum rostratum, 2163–2164
β-lactamase inhibitors, 1178
cephalosporins and, 1173–1175
commercial sources of chromogenic agar media for, 327
Enterobacteriaceae, 324, 327, 722, 727–729, 1299
Escherichia coli, 695–696, 1299
media for detection, 324
molecular detection, 1383
penicillins and, 1172
tests for, 1209
Extension oculomycosis, 1949
Extracellular polysaccharide production, by Streptococcus, 395
Exudate specimen, for fungi, 1945, 1947–1948
Eye fatigue, microscopy and, 13
Eye infection, see also Ocular infection
Bazillicus cereus, 443
Corynebacterium maculatum, 479, 490
Corynebacterium mastitis-like organism, 490
Lactobacillus, 424
Moraxella lacunata, 813–814
ophthalmomyiasis, 2518
parasitology, 2294, 2298
Propionibacterium propionicum, 924
Tropheryma whipplei, 1161
Eye specimen
fungi, 1945, 1947, 1949–1950
parasitology, 2298, 2326, 2330
specimen collection, transport, and handling, 274, 295
viruses, 1413
Eyepiece, 9
EZ One, 1542
Facial edema
Linguatula serrata, 2516
Trichinella, 2495
Facial palys
Borreli, 1041
varicella-zoster virus, 1705, 1709
Falciparum
clinical significance, 425
identification, 425, 426, 428, 429
taxonomy, 423
Falciparum hominis, 423, 428
Falciparum ignorans, 423
Falciparum lunata, 423, 427
Falciparum oocyst, 423
Falciparum malariae, 423
Falciparum ovifertum, 2174, 2176, 2182
Falciparum plasmodium, 2174, 2176
Falciparum resistanc, 1902
False negatives, 81, 92
False positives, 81, 92
Famciclovir
antiviral susceptibility testing, 196
herpes simplex virus (HSV), 1689, 1919
herpesviruses, 1854
varicella-zoster virus, 1706
Famciclovir resistanc, 1917
herpes simplex virus (HSV), 1895
varicella-zoster virus, 1895
Famciclovir resistanc, 2159
Famciclovir resistanc, 2540–2541
Far East scarlet-feverlike, 743
Far Eastern tick-borne rickettsiosis, 1125
Fascicola, 2498, 2499
Fascicoloa, 2481, 2488–2490
Fascicoloa hepatica, 2481, 2488–2489
detection, 2320
epps, 2499
treatment, 2531, 2533
Fasciolasis, 2481, 2488–2490
Fasciolidae (family), 2290, 2481–2482, 2487–2490
Fascioscopias, 2482
Fascioscopias, 2498
Fascioscopias, 2320, 2499, 2498, 2488–2490
Fast Track Referral Model System, 587
FASIDA format, 2523
Fastidious bacteria, antimicrobial susceptibility testing for, 1265, 1314–1332
Fetal familial syndrome (FFS), 1859–1861
Fatigue
Cyclospora cataymensis, 2428
tick paralysis, 2516
FDA, see Food and Drug Administration
Fecal leukocyte examinations, 301
Fecal specimen, see also Stool specimen for Helicobacter, 1018–1020, 1023
Gram stain and smearing methods, 286
specimen collection, transport, and storage guidelines, 275, 281, 301–302
Federal Select Agent Program, 167, 219
Feeley-Gorman agar, 336
Feet, malodorous, 479
Femella, 230
Femella flavipes, 2031, 2034
Femella nivea, 2031
Ferric ammonium citrate, 317
Ferric chloride, 318, 319
Festuclavine, 2190
Fetal death
adenoviruses, 1773
Lujigan virus, 1541
Fetal hydrops, 1819–1820
Fetal infection, see also Congenital infection
genital varicella syndrome, 1412
cytomegalovirus, 1412, 1718–1719
parvovirus B19, 1412
viruses, specimens and methods for detection of, 1407
Fever
adenoviruses, 1771, 1772
Ana plasm phagocytophylum, 1139
arboviruses, 1647
arenaviruses, 1673–1674
Ascants lumbricoides, 2451
Bartellina, 876–877
blackfly fever, 2515
Borrelia, 1041
Clamydiae pesti, 1109
chloramphenicol, 1109
clinidamycin, 1185
Coccidiosis, 2114
coronaviruses, 1569
Corynebacterium diptheriae, 480
Cyclospora cataymenesis, 2428
Cystoispora bellii, 2428
cytomegalovirus, 1718–1719
dirofilaria, 2499
Ehrlichia chaffensis, 1318
Epstein-Barr virus, 1739
floxiviruses, 1674
herpes B virus, 1697
herpes simplex virus (HSV), 1688–1689
F. tricapsula capadomum, 2114
human herpesvirus 6 (HHV-6), 1754–1756
human herpesvirus 7 (HHV-7), 1761
human herpesvirus 8 (HHV-8), 1762–1763
influenza virus, 1471
Leptospora, 1030–1031
liver trematodes, 2489
macrolides, 1183
malari, 2339
Mansonella, 2468
monkeypox virus, 1830
Mycoptasma, 1092
nitrifurantoin, 1196
Oriental, 1124
Paragonimus, 2487
Parasitobacter, 2498
parvovirus B19, 1819
pyamin, 1193
polymaviruses, 1193
respiratory syncytial virus (RSV), 1500
Fusobacterium nucleatum, 968, 973, 979, 981
Fusobacterium necrophorum, 973
Fusobacterium necrophorum subsp. nucleatum, 968, 973, 979, 981
Fusobacterium necrophorum subsp. funduliforme, 973, 976, 979, 981
Fusobacterium necrophorum subsp. fusiforme, 979
Fusobacterium necrophorum subsp. necrophorum, 973, 976, 979, 981
Fusobacterium necrophorum subsp. nucleatum, 979, 981
Fusobacterium nucleatum subsp. polysporum, 979
Fusobacterium necrophorum subsp. vincentii, 979
Fusobacterium nucleatum, 968–969, 973, 975–977, 983, 1057, 1138, 1348, 1351
Fusobacterium perfforstii, 968
Fusobacterium periodonticum, 968, 973, 979, 981, 983
Fusobacterium russii, 968, 973, 979, 981
Fusobacterium sinumae, 968, 973
Fusobacterium nucleatum, see Eubacterium nucleatum
Fusobacterium ulcerans, 968, 973, 979, 981
Fusobacterium varium, 968, 973, 977, 979, 981, 1185

G

Gag gene/protein, HIV, 1436–1437
Gallactococcus, 1917–1922, 2038–2040
Gallibacterium anatis, 655
Gallicola, 909
Galligliola harnae, 909
Gamma globulin, hepatitis A virus, 1590
Gamma interferon enzyme-linked immunosorbent (ELISOPOT) assay, 1712
Gammacoronavirus (genus), 1565
Gammadermatobacter (subfamily), 1398, 1718, 1762
Gammamapapillomavirus (genus), 1398, 1783
Garcinioviridae, 1777
antiviral susceptibility testing, 1916
cytomegalovirus, 1720
Epstein-Barr virus, 1739, 1740
herpes B virus, 1697
herpesviruses, 1883, 1885
human herpesvirus 6 (HHV-6), 1760
human herpesvirus 7 (HHV-7), 1761
human herpesvirus 8 (HHV-8), 1763
Garcinioviridae resistance, 1917
cytomegalovirus, 1730, 1895–1896, 1919
human herpesvirus 6 (HHV-6), 1760
Gardasil, 1736
Gastrohedral
antimicrobial susceptibilities, 498
chemotaxonomic features, 475
clinical significance, 479, 497
collection, transport, and storage of specimens, 497
direct examination, isolation, and identification, 497–499
epidemiology and transmission, 497
identification, 438
Gastrohedral vaginalis, 474, 618, 2415
antimicrobial susceptibilities, 498
bacterial vaginosis, 479, 497–498, 925
clinical significance, 479, 497
detection, 2327
direct examination, isolation, and identification, 497–498
epidemiology and transmission, 497
Gram stain morphology, 476
identification, 484
specimen collection, transport, and handling, 296, 497
V agar for, 346
Gastrointestinal disease
Blastoscyphus hominis, 2406
coronaviruses, 1569
Entamoeba histolytica, 2402–2403
etiologies, usual, 290
influenza virus, 1471
Trichosporon, 2495
Gastrointestinal microbe, 229–231
Gastrointestinal tract specimen collection, transport, and handling, 271, 301–302
beta-hemolytic streptococci, 303
Clostridium botulinum, 303
food poisoning, 302
Helicobacter pylori, 303
MRSA, 302–303

Page 82
evaluation, interpretation, and reporting of results, 371–372
identification, 362–367
isolation procedures, 362
serologic tests, 368
taxonomy, 354
typing systems, 367–368
identification of aerobic, 350–352
Gram-positive rods
aerobic actinomycetes, 504–528
identification of, 437–439
antibacterial resistance patterns
non-spore-forming bacilli, 1348
spore-forming bacilli, 1348
Clostridium, 940–959
coryneform, 474–498
identification, algorithm for, 437–439
non-spore-forming anaerobic, 920–932
antimicrobial susceptibilities, 931
clinical significance, 922–925
collection, transport, and storage of specimens, 925
direct examination, 925–926
epidemiology and transmission, 922
evaluation, interpretation, and reporting of results, 931–932
identification, 926–930
isolation procedures, 926
serologic tests, 931
taxonomy and description of agents, 920–922
Gram-Sure, 116
Granule cell neuronopathy, JC polyomavirus
and, 1804
Granules, fungal, 1967–1968
Gram-negative bacteria
identification, 814
Gram-positive rods
anterior lymph nodes, 498
antibacterial resistance patterns, 430, 1352
antimicrobial susceptibility testing, 1317,
1325–1326
clinical significance, 424
description of genus, 423
direct examination, 425
epidemiology and transmission, 423
identification, 426, 428, 429
interpretation of results, 431
isolation procedures, 425
taxonomy, 422–423
Graminella adiacens, 422, 430
antimicrobial susceptibility testing, 1325
blood culture, 18
endocarditis, 229
identification, 426
Graminella elegans, 422
antimicrobial susceptibility testing, 1325
identification, 426
Granuloma, tick, 2515
Granuloma inguinale, Klebsiella pneumoniae
subsp. granulomatis and, 718
Granulomatous alemic encephalitis (GAE),
Acanthamoeba and, 2391, 2394
Granulomatous hepatitis, Mycobacterium
scrofulaceum and, 544
Graphium, 2154, 2159, 2180
Graves’ disease, Yersinia enterocolitica and,
742
Gravity displacement sterilizers, 204
Gray baby syndrome, 1193
Greasy pig syndrome, 360
Green bottle fly, 2517
GreeneChip, 144, 241
Gregg, McAlister, 1526
Grepafloxacin, 1179
Grimontia, 762, 763
Grimontia holliae, 764, 766–769, 996
Griseofulvin, 2145, 2230
Grocott’s modification of the Grosmor
methylene silver stain, 1958
Ground itch, 2456
Group A streptococci (GAS)
clinical significance, 385–386
rectal swab screening for, 303
specimen collection, transport, and handling,
299–300
subtyping, 139
whole-genome sequencing, 245
Group B streptococci (GBS)
clinical significance, 386
isolation procedures, 389–390
screening for, 296
Growth medium with 10% fetal bovine serum,
1430
Growth promoters used in food animals, 1214
Guanylate virus, 1691, 1671, 1674
Guanylosin virus, 1645
Guillain-Barré syndrome (GBS), 1635
arboviruses, 1647
Campylobacter, 1002
Guinea worm, 2507; see also Dracunculus
medinensis
Gulf War Syndrome, Mycoplasma and, 1093
Gum Listeria medium (gum base-nalidixic acid
medium), 337
Gumma, Treponema and, 1059, 1061
Gymnascella, 2062, 2069, 2075, 2076
Gymnascella dankaliensis, 2062
Gymnascella hyalodermis, 2062, 2066, 2070,
2118
Gymnophollieae (family), 2290
Gymnopholxoides (superfamily), 2290
Gymnorrhoeicum, 1941
Gynecologic infections, Clostridium sordelli
and, 946
gyA
Aeromonas, 1326
Campylobacter, 1327
Mycobacterium, 581, 1361
Neisseria gonorrhoeae, 1323, 1383
Neisseria meningitidis, 1324
Vibrio cholerae, 1331
gyB, Mycobacterium, 581, 1361
H
P1941 Quick test, 1019
H antigen, Salmomella, 703–704
H broth, 337
H~S production, 615
HAART (highly active antiretroviral
therapy), 1922, 2442
HACEK group, 676–677
antimicrobial susceptibilities, 661–662
antimicrobial susceptibility testing, 1317,
1328
β-lactamase testing, 1328
clinical significance, 654–655
identification, 653
Haemophilus, 2515
Anaplasma, 1138
Ehrlichia, 1138
key to identification, 2514
Haemophilus vaginalis, 2515
Haemophilus influenzae, 625, 820
Haemophilus parainfluenzae, 632–633, 820
Haemophilus, 652, 661–680
antimicrobial susceptibilities, 678–679,
1172–1174, 1176, 1181
resistance rates, 678–679
testing algorithm, 659
testing methods, 679, 1265
clinical significance, 669–670
collection, transport, and storage of specimens, 670–671
description of genus, 667–668
detection in blood, 20
differentiation of Francizella from, 852
direct examination, 671–672
antigen detection, 671
microscopy, 671
molecular techniques, 671–672
epidemiology and transmission, 668–669
evaluation, interpretation, and reporting of
results, 679–680
identification, 673–677
commercial biochemical systems, 676
conventional biochemical tests, 676
mass spectrometry, 676–677
molecular identification, 677
problem with, 677
X and V factor growth requirements,
675–676
isolation procedures, 656, 672–675
colony appearance, 673–675
media, 672–674
serologic tests, 678
taxonomy, 676–678
typing systems, 677–678
capsular serotyping and biotyping, 677–678
molecular methods, 678
Haemophilus aegyptius, 667–668, 670, 672,
674–675, 679–680, 1063–1064, 1183
Haemophilus aphrophilus, see Aggregatibacter
aphrophilus
Haemophilus ducreyi, 297, 667–668, 670–672,
674–675, 679–680, 1063–1064, 1183
Haemophilus haemolyticus, 667–668, 670, 674
Haemophilus influenzae, 667–680
antibiotic resistance, 1223, 1228, 1231,
1234, 1320–1321
antimicrobial susceptibilities, 678–679,
1174–1175, 1177–1178, 1180,
1182, 1184, 1187, 1190, 1192–
1193, 1195, 1197
BLNR (β-lactamase negative and
ampicillin resistant), 679
resistance rates, 678–679
testing algorithm, 659
testing methods, 679
antimicrobial susceptibility testing, 1320–
1322
commercial test methods, 1322
incidence of resistance, 1320–1321
reference test methods, 1321–1322
strategies for testing and reporting of
results, 1322
β-lactamase, 1302, 1320–1322
β-lactamase tests, 1302
biotype, 669
clinical significance, 669–670
collection, transport, and storage of specimens, 670–671
colony appearance, 673–674
description, 661–668
direct examination, 671–672
antigen detection, 671
microscopy, 671
molecular techniques, 671–672
epidemiology and transmission, 668–669
SUBJECT INDEX
Helicobacter canis, 996, 1013
Helicobacter pylori, 996, 1013–1014
Helicobacter felis, 1013–1017
Helicobacter fennellaeae, 994, 996–997, 1013–1018, 1020–1024
Helicobacter gallinarum, 1014–1016
Helicobacter hephaticus, 1014–1016, 1018

cytomegalovirus, 1719
enteric adenoviruses, 1622
epidemic, 1841
Epstein-Barr virus, 1739
hepatitis A virus, 1589–1591
hepatitis B virus, 1844–1845, 1852–1853
hepatitis C virus, 1599–1601
hepatitis D virus, 1854–1855
hepatitis E virus, 1589–1591
herpes simplex virus (HSV), 1689
Histoplasma capsulatum, 2114
human herpesvirus 6 (HHV-6), 1755–1756
liver transplant, 2489
macrophages, 1183
Mannosatina, 2468
measles, 1521
microsporidia, 2210, 2213
nitrofurantoin, 1196
penicillins, 1173
rifampin, 1195
varicella-zoster virus, 1705
viruses, specimens and methods for detection of, 1406
Hepatitis A infection, 1589–1591
Hepatitis A virus (HAV), 1584–1594
antigen detection, 1591
clinical significance, 1589–1591
clinical presentation and course, 1589–1590
dose response to infection, 1590
vaccines and antiviral agents, 1590–1591
description of agent, 1584–1585
detection and identification methods, 1433
direct examination, 1591
electron microscopy, 1591
epidemiology and transmission, 1586–1588
export from hepatocytes, 1586
genome replication and proteins, 1585
identification and typing systems, 1592
isolation procedures, 1592
laboratory tests suggested for, 125
nucleic acid detection, 1591
serologic tests, 1588–1590
specimen collection and handling, 1406, 1413, 1591
taxonomy, 1584
vaccine, 1595–1585, 1589–1590
Hepatitis B infection
acute, 1843–1844, 1852
chronic, 1843–1845, 1852–1853, 1880
epidemiology and transmission, 1843–1844
laboratory techniques and control interventions used in significant outbreaks, 126
laboratory tests suggested for, 125
laboratory-acquired infections, 177
worldwide distribution of chronic, 1844
Hepatitis B virus (HBV)
antigen detection, 1845–1848
antiviral agents, 1880–1882
nucleotide/nucleoside analogues, 1880–1882
antiviral resistance, 1917, 1923–1924
antiviral resistance mechanisms, 1899–1900
antiviral susceptibility testing, 1851–1852, 1920–1921
clinical significance, 1844–1845
collect, transport, and storage of specimens, 1406–1407, 1412, 1845
description of agent, 1841–1843
detection and identification methods, 1433
direct examination, 1845–1849
epidemiology and transmission, 1843–1844
evaluation, interpretation, and reporting of results, 1852–1854
genome, 1841–1842
genotypes, 1849–1850, 1900
HBeAg (hepatitis B core protein antigen), 1841–1843, 1845, 1848–1850
HBeAg (hepatitis B e antigen), 1841–1845, 1845, 1851–1853
HBeAg (hepatitis B surface antigen), 1841–1847, 1850–1853
HDV coinfection, 1854–1855
history, 1841
identification, 1849
isolation, 1849
markers, 1843, 1852
microscopy, 1845
nucleic acid detection, 1411, 1846, 1849
occupational exposure, 1845
serologic tests, 1847–1851
anti-HBs, 1851
anti-HBc, 1850–1851
commercial systems, 1847–1848
lgM anti-HBe, 1849–1850
total anti-HBc, 1850
taxonomy, 1841
typing systems, 1849–1850
vaccine, 1855, 1883, 1845, 1849–1851, 1853
virology, 1841–1842
Hepatitis C infection, 1599–1601
acute
clinical features of, 1599–1600
diagnosis, 1599–1600
interpretation of results in, 1609–1610
antiviral resistance, 1901–1903, 1917, 1923–1924
antiviral susceptibility, 1609
chronic
clinical features, 1600–1601
diagnosis, 1603
interpretation of results in, 1610–1611
screening recommendations, 1607
diagnosis, 1602–1609
epidemiology and transmission, 1599
laboratory-acquired infections, 177
treatment, 1601–1602, 1901
direct-acting antiviral drugs (DAAs), 1601–1602, 1610–1611
HCV RNA quantification to define therapeutic response, 1610–1611
nucleic acid tests (NATs) in management of chronic hepatitis C therapy, 1603–1605
viral load, 1601–1602, 1610
Hepatitis C virus (HCV), 1599–1611
antibody testing, 1409
antigen detection, 1603
antiviral agents, 1878–1880
combination therapies, 1880
interferon, 1878–1879
polymerase inhibitors, 1879–1880
protease inhibitors, 1879
ribavirin, 1878–1879
table of agents, 1879
antiviral resistance, 1917, 1923–1924
antiviral resistance mechanisms, 1900–1903
interferon resistance, 1901–1902
nonnucleoside inhibitor (NNI) resistance, 1902–1903
NSSA inhibitor resistance, 1902–1903
nucleoside inhibitor resistance, 1902–1903
protease inhibitor resistance, 1901–1902
ribavirin resistance, 1901–1902
antiviral susceptibility, 1609
antiviral susceptibility testing, 1921
clinical significance, 1599–1601
collection, transport, and storage of specimens, 1406, 1411–1412, 1414, 1602
description, 1599
detection and identification methods, 1433
direct examination, 1602–1605
discovery of, 1600
endosome contamination outbreak, 199
epidemiology and transmission, 1599
evaluation, interpretation, and reporting of results, 1609–1611
in acute hepatitis C, 1609–1610
in chronic hepatitis C, 1610–1611
gene and protein coding scheme, 1599–1600
genotypes, 1599, 1605–1606, 1610, 1901
nucleic acid detection, 1605–1607
identification, 1605
isolation procedures, 1605
microscopy, 1602–1603
nucleic acid tests (NATs), 1411, 1603–1605
commercial HCV RNA qualitative tests, 1603–1604
commercial HCV RNA quantitative tests, 1604–1605
diagnosis of acute infection, 1603
diagnosis of chronic infection, 1603
management of chronic hepatitis C therapy, 1603–1605
nucleic acid preparation for, 1604
serologic tests, 1606–1609
taxonomy, 1599
testing algorithm, 1609
tool, 1601–1602, 1901
molecular methods of monitoring response, 76–77
Hepatitis D infection, 1854–1855
Hepatitis D virus (HDV), 1854–1855
clinical significance, 1854–1855
collection, transport, and storage of specimens, 1406, 1585
description of agent, 1854
detection and identification methods, 1433
direct detection, 1855
epidemiology and transmission, 1854
evaluation, interpretation, and reporting of results, 1855
HBV coinfection, 1854–1855
serologic tests, 1855
taxonomy, 1854
typing, 1855
Hepatitis E infection, 1859–1951
Hepatitis E virus (HEV), 1859–1954
antigen detection, 1991
clinical significance, 1589–1591
clinical presentation and course, 1589–1590
dose response to infection, 1590
vaccines and antiviral agents, 1590–1591
collection, transport, and storage of specimens, 1406, 1591
description of agent, 1585–1586
detection and identification methods, 1433
direct examination, 1591–1592
electron microscopy, 1591
epidemiology and transmission, 1586–1589
genome replication and proteins, 1585
genotypes, 1586
identification and typing systems, 1592
isolation procedures, 1592
laboratory tests suggested for, 125
nucleic acid detection, 1591–1592
serologic tests, 1592–1594
taxonomy, 1584
vaccine (candidate), 1586, 1590
Hepatobiliary disease, Helicobacter and, 1018
Hepatocellular carcinoma (HCC), hepatitis B virus and, 1884–1845, 1892
Hepatomegaly
Leishmania, 2159
Trypanosoma brucei, 2366
Trypanosoma cruzi, 2362
Trypanosoma lewisi, 2368
Hepatosplenic schistosomiasis, 2479, 2484
Hepatosplenomegaly, HHV-6, 1755
Hepatotoxicity
nitrofurantoin, 1196
telithromycin, 1185

antibody detection, 1971
antifungal susceptibilities, 2121–2122, 2224
antigen detection, 1977–1978, 2116

SUBJECT INDEX
Subject Index

Histoplasma capsulatum (continued)
- bioassay, 2117
- blood culture, 18
- blood specimens, 2307
- clinical significance, 2114
- culture for mold phase, 2117
- culture for yeast phase, 2118
- description of agents, 2110–2111
- detection in blood, 21, 2356
- direct examination, 2115–2117
- endocardialmsis, 1949
- epidemiology and transmission, 2113
- evaluation, interpretation, and reporting of results, 2121–2123
- identification, 2118
- isolation, 2117–2118
- media, 1959
- nucleic acid detection, 2117
- serologic tests, 2120
- specimen collection, transport, and processing, 1948–1949, 1951, 2115
- staining, 1957
- taxonomy, 2109
- typing systems, 2119
- Histoplasma capsulatum var. capsulatum, 2109
- Histoplasma capsulatum var. duboisii, 2109
- Histoplasma capsulatum var. farciminosum, 2109
- Histoplasma polychromatoid antigen (HPA), 2116, 2121
- Histoplasmin, 1971
- African, 2114
- antigen detection, 2116
- clinical significance, 2114
- description of agents, 2110–2111
- epidemiology and transmission, 2113
- evaluation, interpretation, and reporting of results, 2121–2123
- nucleic acid detection, 2117
- serologic tests, 2120
- specimens for, 1947, 1949–1950, 2115
- Histotoxic skin and soft tissue infections, 944–946
- HIV, see Human immunodeficiency virus (HIV)
- HIV RNA assay, 1409
- HME (human monocytic ehrlichiosis), 1138–1142, 1144–1145
- HMP Reference Genomes Catalog, 233
- HPMPV, see Human metapneumovirus
- Hodgkin's lymphoma, Epstein-Barr virus and, 1738, 1740–1741
- Holdemania, 921
- Holdemania filiformis, 922, 927, 930
- Holoblastic, 1940–1941, 1941
- Holoblastic conidiogenesis, 2058
- Holocyclotoxain, 2516
- Hologic/Xen-Probe assay, for Trichomonas vaginalis, 2415
- Holometabolous development, 2505
- Holothryrida (order), 2511
- Holotrichosis (division), 1936
- Homalomyia, 1936, 1941
- Homalothric ascomyetaes, 2075
- clinical significance, 2075
- description, 2069
- key phenotypic features, 2062
- Honeybees, 2518
- Hook effect, 99–100
- Hook, Robert, 5
- Hookworm, 2454–2456
- clinical significance, 2456
- description, 2454
- eggs, 2449, 2452, 2454
- larvae, 2452, 2454
- worms, 2454
- detection, 2320, 2323, 2329, 2331
- diagnosis, 2456
- epidemiology and prevention, 2454
- taxonomy, 2454
- transmission and life cycle, 2454, 2456
- treatment, 2455–2456, 2531–2532
- Horie arabinose ethyl violet broth, 338
- Hormaphleia species, 2062, 2071
- Hormaphleia sp., 2062, 2075
- Hormaphleia spec, 2062
- Hormonaema, 2153, 2159
- Hormonaema dematioides, 2155, 2158, 2163
- Hornets, 2515, 2527
- Horse/deerflies, 2505
- Horeana, 2135–2138
- Hornia spec., 2144, 2147–2148, 2154, 2156, 2161–2162
- Hospital Infection Control Practices Advisory Committee, 406
- Hospitalized adults, herpes simplex virus (HSV) in, 1689
- HotShot DNA extraction, 2523
- House mouse mite, 2511
- Housefly, 2513, 2517
- Hoverfly, 2517
- Holywell medium, 338
- HPEV, see Poxviruses
- HIPLC identification of Mycobacterium, 601

diagnosis, 2464
direct examination, 2464-2465
epidemiology and transmission, 2461-2462
microscopy, 2464-2465
nucleic acid detection, 2465
prevention, 2465
taxonomy, 2461
treatment, 2465, 2531, 2534-2535, 2544
Wakapolymavirus (genus), 1803
X factor, 667, 672-673, 675
Xanthomonas, 792
Xenodiagnosis, for parasites, 2307, 2365
Xenon vapor (XBO) lamps, 10
Xenopsylla, 2507
Xenopsylla cheopis, 2509-2510
X-linked inhibitor of apoptosis gene (XIAP), 1740
X-linked lymphoproliferative syndrome, 1740, 1747
xMAP system, 59-60, 145, 2042
Xpect Cryptosporidium, 2295, 2441
Xpect Flu A&B, 1474
Xpect Giardia, 2293
Xpect Giardia/Cryptosporidium, 2295, 2441
Xpect Rotavirus, 1624
Xpect RSV, 1504
Xpect EV, 1542
Xpect Flu A, 1477
Xpect HPV assay, 1790
Xpect MRSA, 361, 1293, 1381-1382
Xpect MRSA/SA SSTI test, 361, 1381
Xpect MTBRIEF test, 23, 575-576, 587
Xpect VAM, 1381
Xpect van/Amb assay, 407
xTAG gastrointestinal pathogen panel, 690, 1002, 1627, 2320
Cryptosporidium, 2441
Entamoeba histolytica, 2405
xTAG multiplex PCR assay for yeasts, 1997
xTAG respiratory viral panel (RVP), 1478, 1506, 1511, 1543
adenovirus, 1775
parainfluenza virus, 1490
rhinoviruses, 1554-1555
xTAO respiratory viral panel (RVP) fast, 1478, 1506, 1554-1555
xTAG RVP/RVP Fast/RVP Fast v2, 1575
xTAG RVP/VP1, 1990
Xylose-lactose-Tergitol 4, 347
Xylose-lactose-Tergitol 4, 347
Xylose-lactose-Tergitol 4, 347
Xanthomonas, 2465
Wuchereria bancrofti, 1139, 2461-2465
evaluation, interpretation, and reporting
of results, 1837
identification, 1835
isolation, 1835
microscopy, 1832-1833
nucleic acid detection, 1835
serologic tests, 1837
taxonomy, 1828-1829
Yaws, 1055-1056, 1058, 1061
Yeager’s LIT (liver infusion tryptose) medium, 2315
Yeast(s), 1935, 1984-2006; see also specific species
antifungal susceptibilities, 2004-2006
antifungal susceptibility testing
broth microdilution method, 2262
broth microdilution method, 2258-2264
clinical breakpoints, 2263-2264
colorimetric methods, 2264-2265
direct testing on blood samples, 2267
disk diffusion method, 2266
Etest, 2267
flow cytometry methods, 2265-2266
gradient strip testing, 2267
MALDI-TOF MS, 2267
molecular methods, 2267-2268
Neosensitabs, 2267
proteinic methods, 2267
Vitek 2 method, 2265
antigen detection, 1996-1997
ascomycetous, 1938
basidimycetous, 1937
black, 1939, 2204
clinical significance, 1992-1994
collection, transport, and storage of specimens, 1994
cultural and biochemical characteristics, 1989
description of agents, 1985-1991
ascomycetous yeasts, 1986-1988
basidimycetous yeasts, 1988-1991
direct examination, 1994-1998
India ink, 1996
KOH, 1995
microscopy, 1995-1996
yeast in tissue sections, 1996
epidemiology and transmission, 1991-1992
evaluation, interpretation, and reporting
of results, 2006
identification, 1998-2004
ascospore formation, 2000
carbohydrate assimilation tests, 2001
carbohydrate fermentation tests, 2001
chromogenic agar, 1999
germ tube test, 1999-2000
microscopic characteristics, 1998
microscopic characteristics, 1998-1999
molecular methods, 2002-2003
morphology studies, 1999
nitrate tests, 2001
phenol oxidase test, 2000
phenotypic systems, 2001
purity of cultures, 1999
rapid identification, 2001-2002
rapid trehalase test, 2001
scheme, 1995
troubleshooting, 2003-2004
urease test, 2000-2001
identification of, 1939
in tissue sections, 1996
