Species of aerobic endospore-forming bacteria show a very wide range of colonial morphologies, both within and between species (Fig. 3). After 24 to 48 h of growth, sizes range from 1 to 5 mm. Color commonly ranges from buff or creamy gray to off-white, but some strains may produce orange pigment. Morphology can vary from moist and glossy, through granular, to wrinkled. Shapes can vary from round to irregular, sometimes spreading, with entire, through undulate or crenate, to fimbriate edges. Elevations range from effuse, through raised, to convex. Consistency is usually butyrous, but mucoid and dry, adherent colonies are not uncommon. On blood agar, hemolysis may be absent, slight, marked, partial, or complete. Despite this diversity, *Bacillus* colonies are not generally difficult to recognize. *B. subtilis* and *B. licheniformis* produce similar colonies which are exceptionally variable and often appear to be mixed cultures (Fig. 3i). These colonies are of moderate (2 to 4 mm) diameter, irregular in shape, and range from moist and butyrous or mucoid, with margins varying from undulate to fimbriate through membranous with an underlying mucoid matrix, with or without mucoid beading at the surface, to rough and crusty as they dry. The "licheniform" colonies of *B. licheniformis* tend to be quite adherent. *B. circulans* is another heterogeneous species, and in about 13% of strains, rotating and migrating microcolonies, which may show spreading growth, have been observed (Fig. 3k). However, closer examination of the spreading strains has revealed some of them to be genotypically distinct, such that they are now classified as species of *Paenibacillus*. Despite their variability, colonies of *B. cereus* are readily recognized. They are characteristically large (2 to 7 mm in diameter) and vary in shape from circular to irregular, with entire to undulate, crenate, or fimbriate edges (Fig. 3b). They usually have matte or granular textures, but smooth and moist colonies are not uncommon. When grown on egg yolk agar, strains of the *B. cereus* group, including albeit
to a lesser extent, *B. anthracis*, synthesize lecithinases, which produce opaque zones of precipitation around colonies (i.e., usually after overnight or perhaps 24 h of incubation). The optimum growth temperature is about 37°C, with minima and maxima of 15 to 20°C and 40 to 45°C, respectively. However, routine, reliable differentiation of individual species within the *B. cereus* group can be challenging. Features considered characteristics of individual species, including the anthrax toxin and capsule of *B. anthracis*, and the parasporal crystals of *B. thuringiensis*, are encoded by plasmids.

The acquisition or loss of a plasmid may alter the features of a particular strain and can undermine identification. Colonies of *B. anthracis* and *B. cereus* can be similar in appearance, although those of the former are generally smaller and nonhemolytic and may show more spiking or tailing along the lines of inoculation streaks. Compared with the usually butyrous consistency of *B. cereus* or *B. thuringiensis*, colonies of *B. anthracis* are very tenacious and may be pulled into standing peaks with a loop. *B. anthracis* colonies are also susceptible to diagnostic gamma phage.
B. mycoides produces characteristic rhizoid or hairy-looking, adherent colonies which readily cover the whole agar surface. B. anthracis capsule production is stimulated by plating on nutrient agar containing 0.7% sodium bicarbonate followed by overnight incubation under 5 to 7% CO₂ (candle jars perform well). Colonies of the capsulated organism appear mucoid, and the capsule can be visualized by M'Fadyean or India ink staining of smears.

Phenotypic tests are widely used for species-level identification. For diagnostic purposes, the aerobic endospore formers comprise two groups: the reactive ones, which give positive results in various routine biochemical tests and which are therefore easier to identify (Table 1), and the nonreactive ones, which give few, if any, positive results in such tests. Nonreactive isolates tend to dominate the market, which are therefore easier to identify (Table 1), and the nonreactive ones, which give few, if any, positive results in such tests. Nonreactive isolates tend to dominate the identification requests sent to reference laboratories. In addition to the traditional phenotypic testing methods, convenient miniaturized formats such as API (bioMérieux SA, Marcy-l’Etoile, France) and automated identification systems such as VITEK (bioMérieux, Inc., Durham, NC) and Biolog (Hayward, CA) also exist. With such systems, it is important to keep in mind that, if a species is not included in the database, accurate identification is not possible. These systems also have limited value in distinguishing between some members of the B. cereus group (127), with the exception of the presumptive identification of B. anthracis (128). Both the API 50 CH and API 20 E strips together or the API 50 CH alone, along with API 50 CHB/E medium, can be used for the identification of 38 taxa of Bacillus species and related genera and requires up to 48 h of incubation. A large number of Bacillus and related genera are listed in the Biolog database using the GEN III (63 taxa) or GP2 (53 taxa) microplates. Set-up is minimal, and bacteria can be identified in as little as 2 h. BioMérieux has designed the BCL card for the automated identification of aerobic endospore-forming bacteria of the Baccillaceae family using the VITEK 2 system. A total of 42 species can be identified, and final results are obtained after 14 h (129). The BD Phoenix automated microbiology system (BD Diagnostics, Sparks, MD) lists 12 Bacillus species and related taxa in its Gram-positive panel identification database. The commercially available databases are expanding, and continue to

### Table Notes
- Symbols and abbreviations: -, ≥85% positive; +/w, positive or weakly positive; w, weakly positive; (+), 75 to 84% positive; v, variable (26 to 74% positive); (-), 16 to 25% positive; -, 0 to 15% positive; -/w, negative or weakly positive.
- Results shown in brackets are for the biotype isolated particularly in connection with outbreaks of enteric-type food poisoning and for strains of serovars 1, 3, 5, and 8, which are commonly associated with such outbreaks.
- Spore shape: C, cylindrical; E, ellipsoidal; S, spherical. Spore position: C, central or paracentral; S, subterminal; T, terminal. The most common shapes and positions are listed first, and those shown in parentheses are infrequently observed.
improve, but keeping up with the changing taxonomy and deluge of new aerobic, endospore-forming species is a significant challenge. To be effective in identifying a particular species, a diagnostic database must account for intraspecies variability. Creation of a robust profile requires multiple authentic strains from a range of sources, yet many new species are proposed on the basis of single isolates. As such, commercial kits should always be used in conjunction with other methods.

Nucleic acid-based methods, especially 16S rRNA gene sequencing, may effectively identify strains that cannot be definitively characterized by morphological or biochemical methods. Guidelines for sequencing-based identification of bacteria are outlined in Clinical Laboratory Standards Institute (CLSI) document MM-18A (130). Some species, notably B. cereus, B. thuringiensis, and B. anthracis, are not effectively differentiated by 16S rRNA gene sequencing. B. anthracis-specific single-nucleotide polymorphisms have been identified using the hypervariable 16S-23S internal transcribed spacer region (131), but sequencing of this target for the definitive identification of B. anthracis is not recommended. In the past, there were concerns about the accuracy and availability of reference sequences. However, these have largely been resolved and, for type and reference strains of most species, high quality 16S rRNA gene sequences can be found in public databases (e.g. GenBank).

In recent years, there has been growing interest in the use of MALDI-TOF (MS) platforms for bacterial identification. Three commercial systems, the VITEK-MS (bioMérieux), the MALDI Biotyper (Bruker Corp., Billerica, MA), and the Andromas (Andromas SAS, Paris, France), are currently available. Systems are rapid, easy to use, and facilitate identification of isolates cultured on solid media. Initial instrument cost is high; however, reagent costs are minimal. Methods compatible with liquid media (e.g., blood culture bottles) have been described. As with the phenotypic methods, the key limitation to accurate MS-based identification is the availability of robust databases for interpretation of the MALDI-TOF profiles. Results at the genus level only or misidentifications are still common for this group of organisms (132). These databases may not include recent or uncommon species, and profiles for closely related species (e.g., B. subtilis group or B. cereus sensu lato) may be too similar to differentiate (133). However, analytical methods continue to improve, and effective differentiation of B. subtilis from B. amyloliquefaciens and B. cereus (sensu stricto) from B. thuringiensis has been reported (134). Supplementing commercial databases with locally produced profiles using in-house strains may help improve identification (125).

Other approaches to identification include chemotaxonomic fingerprinting by fatty acid methyl ester profiling, pyrolysis MS, and Fourier transform infrared spectroscopy (135). All of these approaches have been successfully applied either across genera or to small groups, but as with other profiling methods, large databases of authentic strains are necessary for accurate identification. Some databases, such as the Microbial Identification System software (Microbial ID, Inc., Newark, DE) for fatty acid methyl ester analysis, are commercially available.

TYING

Typing schemes have been developed only for a few species of aerobic endospore-forming bacteria, most notably the B. cereus group (including B. anthracis). In the past, this group was differentiated into serovars based on flagellar antigen variations, but serotyping is not commonly used today. Similarly, protein-based multilocus enzyme electrophoresis has been replaced by nucleic acid-based genotyping methods. Many PCR- and DNA sequencing-based typing methods have been described, but only a few have gained widespread acceptance, including multiple-locus variable-number tandem repeat analysis (MLVA), multilocus sequence typing (MLST), and increasingly, whole-genome sequencing.

MLVA is primarily used for typing of B. anthracis. It is a PCR-based fragment analysis method that targets copy number variations among DNA elements located on the B. anthracis chromosome and virulence plasmids. The differences can be resolved by agarose electrophoresis, capillary electrophoresis, or MS (136–139). The MLVA-8 scheme targets eight loci: six chromosomal plus one on each of pXO1 and pXO2 (139). It was the first typing method that could reliably differentiate B. anthracis strains, and during the 2001 bioterror event, MLVA-8 implicated the Ames strains as the cause of the outbreak (114). The resolution of MLVA increases with the number of targets, and schemes that use 15, 25, and 31 loci have been developed (81, 137). MLVAbank (mlva.u-psud.fr/mlvav4/genotyping/index.php) is an online repository of MLVA profiles and a valuable resource for strain comparison.

MLST is a DNA sequencing-based method that exploits nucleotide polymorphisms found in sets of "housekeeping" genes. Because DNA sequences are unequivocal and portable, many view MLST as the gold standard method for B. cereus genotyping. Several MLST schemes have been described, and each targets a different set of six to seven genes. Online databases are available for several of these, including the Priest (pubmlst.org/bcereus) and Tournasse-Helgason (mlstoslo.uio.no) schemes (140, 141), the latter of which provides data on any of five published MLTS schemes for B. cereus. The HyperCat database (also at mlstoslo.uio.no) includes typing data for >2,200 strains and allows comparison of MLST, multilocus enzyme electrophoresis, and amplified fragment length polymorphism data (142). Despite some differences among gene targets, the MLST methods provide a consistent view of the B. cereus group. From the genotypic perspective, B. cereus sensu lato is heterogeneous, and correlation between the phylogenetic clusters and traditional, phenotypic divisions is poor. Some analyses indicate that B. pseudomycoides, B. cytotoxicus (143), and B. toyonensis do comprise distinct clades. B. anthracis is recognized as a pathogenic clone, but B. cereus and B. thuringiensis strains are largely indistinguishable. Although reports have suggested that the B. cereus strains associated with emetic food poisoning exhibit distinct characteristics, the emetic toxin can actually be produced by multiple discrete phylogenetic lineages (144–146).

Whole-genome sequencing has become an increasingly affordable and popular tool for strain typing and molecular epidemiology. Whereas MLST may involve sequencing a few thousand nucleotides, the average genomic dataset includes millions of nucleotides. This provides extraordinary resolution and can reveal single nucleotide polymorphisms among strains that, by other typing methods, appear to be identical (147). This approach has been used to examine the population structure of B. cereus sensu lato (148) and the evolution of B. anthracis (149–151). Increasingly, genomic approaches are also being used to examine phylogenetic relationships among other aerobic endospore-forming bacteria (152).

SEROLOGIC TESTS

Serologic tests for anthrax have been developed, but such assays are not available for infections due to other aerobic
endospore-forming bacteria. In outbreak situations, serologic tests for anthrax are of limited utility because seroconversion takes time, whereas effective treatment and public health response require rapid diagnostics. Moreover, in human anthrax, early treatment sometimes prevents development of a detectable rise in antibody titer (115). However, serologic assays are valuable for retrospective surveillance and epidemiological investigations and can also be used to monitor vaccination effectiveness. After the 2001 bioterror event, serologic assays aided in the effort to confirm cases (153).

The Ascoli test, which dates from 1911, is a precipitin test that uses hyperimmune serum raised to B. anthracis whole-cell antigen to provide rapid, retrospective evidence of infection. Despite its age, the Ascoli test is still used by veterinarians in Eastern Europe and central Asia (154). Anthraxin, a heat-stable extract from a noncapsulated strain of B. anthracis, is the basis for a skin test that has been licensed for human and animal use since 1962. It is widely acclaimed and remains in use in countries of the former USSR (155). If a delayed-type hypersensitivity reaction develops after injection of anthraxin, it is interpreted as indicating cell-mediated immunity to B. anthracis. The test can be used to monitor vaccine-induced immune status after periods of several years or to diagnose anthrax retrospectively. Anthraxin does not contain highly specific antigens and relies on the fact that the only Bacillus species likely to proliferate within and throughout an animal is B. anthracis.

The three protein components of the anthrax toxin (PA, LF, and EF), and antibodies to them, can be used in enzyme immunosassay systems. For routine confirmation of anthrax infection or for monitoring response to anthrax vaccines, antibodies against PA alone appear to be satisfactory and have proved useful for epidemiological investigations with humans and animals. PA, LF, and EF are available commercially (List Biological Laboratories, Inc., Campbell, CA; http://www.lisitabs.com). In cases where culture has failed, serologic assays for the detection of antibody response against PA have been used, in combination with NAAT or immunohistochemistry test results, to confirm the diagnosis of anthrax. During the 2001 outbreak, a quantitative human anti-PA immunoglobulin G (IgG) enzyme-linked immunosorbent assay, performed at the CDC, was positive only with sera from individuals with anthrax or vaccinated with AVA vaccine (153). A qualitative kit (QuickELISA Anthrax-PA kit) for the detection of anti-PA IgG and IgM antibodies in human serum has been developed by ImmunoTech (Boston, MA). It is FDA cleared and CE marked in Europe.

ANTIMICROBIAL SUSCEPTIBILITIES

The Clinical Laboratory Standards Institute (CLSI) has published approved guidelines describing susceptibility testing methods and suggested agents for primary testing in the case of B. anthracis, as well as interpretive criteria for other Bacillus spp. (156). Comparable information is also included in chapter 74 of this Manual. The recommended procedure is broth microdilution. Agar dilution and Etest may also be performed (157–160). LRN sentinel level laboratories do not and should not perform antimicrobial susceptibility testing of B. anthracis. If B. anthracis cannot be ruled out, the sentinel level laboratory submits the isolate to its designated LRN reference laboratory for confirmatory identification; the latter laboratory will forward the isolate to the federal level (CDC) for antimicrobial susceptibility testing, sequencing, and archiving. The same is true for sentinel level food and veterinary laboratories.

Bacillus anthracis

Most strains of B. anthracis are susceptible to penicillin, although exceptions have been reported (157–159). However, the presence of inducible β-lactamases in some isolates precludes the use of penicillin as a single agent in the treatment of systemic anthrax (161). Strains are also susceptible to ciprofloxacin, clindamycin, chloramphenicol, doxycycline, levofloxacin, gentamicin, tetracycline, tobramycin, and vancomycin (157–160, 162, 163). In contrast, the majority of B. anthracis isolates exhibit reduced susceptibility (or “nonsusceptibility”) to some extended- and broad-spectrum cephalosporins, specifically cefuroxime (157), ceftriaxone (158), and cefotaxime (159), rendering these a poor choice for treatment (158), and in vitro results, even if susceptible, may not predict clinical efficacy. Resistance or reduced susceptibility has also been shown for trimethoprim-sulfamethoxazole (TMP-SMX), erythromycin, and azithromycin (158–160). In general, susceptibility testing of B. anthracis is often not required, nor are interpretive breakpoints established (other than susceptible) by the CLSI, with the exception of penicillin (156, 164). Agents for primary testing may include penicillin, doxycycline, tetracycline, and ciprofloxacin and must be performed in a reference laboratory with BSL-3 capacity.

Postexposure prophylaxis can prevent inhalational anthrax following exposure to aerosols containing B. anthracis spores. The recommended regimen is 60 days of oral antimicrobial therapy and three doses of AVA (165). When selecting antimicrobial agents, consideration for the possibility of antimicrobial resistance should be given. For adult and pediatric patients, the recommended first-line antimicrobial agent is ciprofloxacin or doxycycline (166). Levofloxacin is recommended as a second-line antimicrobial for adults (165), although there is limited safety data regarding use beyond 28 days. For pregnant women, ciprofloxacin is recommended over doxycycline, though doxycycline may be used if ciprofloxacin is unavailable (167). Amoxicillin may be used if the isolate at issue is susceptible to penicillin. Amoxicillin is also recommended in the treatment of children and lactating women and when other antimicrobial agents are not considered safe. Clindamycin, chloramphenicol, rifampin, vancomycin, and other fluoroquinolones are also suitable for the treatment of patients unable to tolerate recommended antibiotics (165).

For severe cases of anthrax (e.g., fulminant bacteremia, inhalational, gastrointestinal, or injection anthrax), there is often meningeal involvement and the recommended treatment is intravenous ciprofloxacin for 7 to 10 days plus one or two additional drugs (65, 165). In the presence of inflammation, central nervous system penetration of ciprofloxacin is much higher than that of doxycycline. For cases of uncomplicated, naturally acquired, cutaneous anthrax, a 7- to 10-day course of oral ciprofloxacin or doxycycline is recommended, but penicillin V or amoxicillin may also be used if susceptibility is confirmed. Bioterrorism-related cutaneous anthrax should be subject to treatment as described for postexposure prophylaxis due to the risk of aerosol exposure.

Bacillus cereus Group (Not B. anthracis)

There have been rather few studies of the antimicrobial susceptibility of B. cereus, and most information has to be gleaned from reports of individual cases or outbreaks. B. cereus and B. thuringiensis produce penicillinases and a
broad-spectrum β-lactamase and are thus resistant to penicillins, cephalosporins, and β-lactamase inhibitor combinations (160, 168). Moderate or intermediate susceptibility has been demonstrated for TMP-SMX, clindamycin, and tetracycline in a portion of isolates (160, 168). All strains are susceptible to imipenem and vancomycin, and most are susceptible to chloramphenicol, erythromycin, gentamicin, ciprofloxacin, and daptomycin (160, 168, 169). Despite this, treatment failures have been reported, even for regimens containing vancomycin. Such cases were summarized in the previous version of this chapter (170).

Oral ciprofloxacin has been used successfully in the treatment of B. cereus wound infections, bacteremia, and pulmonary infection. Clindamycin with gentamicin, given early, appears to be the best treatment for ophthalmic infections caused by B. cereus (171). Recommended agents for primary susceptibility testing of Bacillus spp. (not B. anthracis) include vancomycin, fluoroquinolones, and clindamycin, and interpretive criteria are available for many antibiotics (156).

Other Species

There is a paucity of antimicrobial susceptibility data for other Bacillus species and related genera, due to the low frequency at which these are found to be clinically significant. Most of the available information has been derived from individual clinical case studies, where antibiotics were administered empirically and treatment may or may not have been guided by in vitro susceptibility results. As environmental organisms, Bacillus spp. may exhibit a wide array of resistance and susceptibility patterns against commonly used antibiotics (169). When isolated from normally sterile sites and clinically warranted, the laboratory may use the published CLSI approved guidelines (156). The antimicrobial agents suggested for primary testing are vancomycin, clindamycin, and fluoroquinolones. When tested, clinical isolates of non-B. cereus, non-B. anthracis species are typically susceptible to vancomycin, daptomycin, gentamicin, ciprofloxacin, imipenem, erythromycin, and TMP-SMX (168). Variable susceptibility exists for penicillins, cephalosporins, chloramphenicol, clindamycin, and tetracycline (168). Vancomycin resistance is rare, but it has been reported (172, 173).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

The isolation of B. anthracis is always significant and requires urgent reporting, but the majority of aerobic endospore-forming bacteria are innocuous environmental organisms, not professional pathogens. Although frequently encountered in the microbiology laboratory, most isolates are of no clinical relevance. However, opportunistic infections have been reported since the late 19th century, and over the past 30 years, the clinical importance of aerobic endospore formers (most, but not all, of them Bacillus species) has become widely accepted. One must be wary of dismissing any organism as a mere contaminant before considering the clinical context of its isolation. If it is obtained in pure culture (or at least appears to dominate the microbiota), if it is isolated in large numbers, or if it is isolated from more than one clinical specimen, then the organism should be considered of potential clinical significance. Moderate or heavy growth of bacilli from wounds is usually significant, and B. cereus infections of the eye are serious emergencies that should always be reported immediately to the physician. In food-borne illness investigations, qualitative isolation tests are insufficient because low-level contamination of foodstuffs by aerobic endospore-forming bacteria is common, as is transient and asymptomatic fecal carriage. Ideally, to establish that a putative pathogen is the etiological agent of a food poisoning event, the organism should be isolated from the epidemiologically incriminated food in significant numbers (>10^5 CFU/g) and the same strain (genotype, biovar, or plasmid type, etc.) should also be isolated in significant numbers from acute-phase specimens (feces or vomitus) obtained from patients but not from healthy controls. For events associated with B. cereus, it should also be possible to detect emetic toxin and/or enterotoxin in the food.

In cases where clinical significance is suspected or established, but the isolate does not represent a “usual suspect,” it is preferable that the identification be confirmed by DNA sequencing. Ideally, nucleotide sequences associated with rare and potentially novel species should be submitted to public databases, where they will be accessible to other laboratories searching for information about the same aerobic endospore-forming organism.

Listeria

Taxonomy

The genus Listeria consists of Gram-positive, non-sporeforming, facultative anaerobic, regular rod-shaped bacteria with a low G+C content of 36 to 42 mol%. While early phylogenetic studies suggested a close relation between Listeria and the Lactobacillaceae, comparisons of 16S rRNA gene sequences have shown that Listeria is most closely related to Staphylococcus and Bacillus. Listeria belongs to the newly assigned family Listeriaceae within the order Bacillales (1). Synthesis of menaquinones and major amounts of branched-chain fatty acids confirms the taxonomic separation of Listeria from the Lactobacillaceae (2).

Until recently, the genus Listeria comprised six validated species including Listeria monocytogenes as the type species in the genus, L. grayi, L. innocua, L. ivanovii, L. seeligeri, and L. welshimeri. Within L. ivanovii, two subspecies, L. ivanovii subsp. ivanovii and L. ivanovii subsp. londoniensis, are differentiated. In recent years, further Listeria species, i.e., L. marthii, L. rocourtiae, L. fleischmannii, including a recent subspecies L. fleischmannii subsp. coloradensis (3), and L. welshenstephanensis, have been described from the natural environment and from food items (4–7).

Based on the results of multilocus enzyme electrophoresis, DNA-DNA hybridization, and 16S rRNA gene sequencing, a group of species closely related to L. monocytogenes, including L. innocua, L. ivanovii, L. marthii, L. monocytogenes, L. seeligeri, and L. welshimeri, can be differentiated from L. grayi and the remaining recently described species (4–7). Only L. monocytogenes and L. ivanovii are pathogenic for humans and animals.

Description of the Agent

Members of the genus Listeria are Gram-positive, facultative anaerobic, non-spore-forming, nonbranching, regular, short (0.5 to 2 μm by 0.4 to 0.5 μm) rods that occur singly or in short chains. Filaments of 6 to 20 μm in length may occur in older or rough cultures. Temperature-regulated expression of flagellin results in a characteristic tumbling motility at 20 to 28°C by means of one to six peritrichous flagella. At 37°C, the organisms are much less motile. Colonies are small (1 to 2 mm in diameter after 1 or 2 days of incubation at 37°C), smooth, and blue-gray on nutrient agar when examined with obliquely transmitted light and typically show a narrow zone of beta-hemolysis. Listeria spp. show an exceptionally large growth temperature range from 0 to 50°C. The optimum growth temperature is between 30 and 37°C, but at 4°C, growth is also observed within a few days. Catalase is typically produced, but catalase-negative strains causing disease in humans have been described (8, 9). The oxidase test is negative. Acid is produced from D-glucose and other sugars. The Voges-Proskauer and methyl red tests are positive. Esculin is hydrolyzed in a few hours. Urea and gelatin are not hydrolyzed. Neither indole nor H2S is produced. The cell wall contains a directly cross-linked peptidoglycan based on meso-diaminopimelic acid, as well as lipoteichoic acid, but no mycolic acids. The two predominant cellular fatty acids are C15:0 and C17:0 (branched-chain type) (10).

Epidemiology and Transmission

The primary habitat of Listeria species is the environment, where they exhibit a saprophytic lifestyle. L. monocytogenes has been isolated from various animals, like mammals, birds, fish, and crustaceans. Infected animals can asymptptomatically pass the organism or develop clinical disease. Due to its widespread distribution, L. monocytogenes has many opportunities to enter human food production, resulting in contamination of fresh and processed poultry, meat, and vegetables; raw milk; cheese; smoked salmon; etc. Numbers of organisms exceeding 10^3 CFU/g were detected in food products (11). Infection of humans ingesting colonized food is potentiated by the ability of the organism to multiply at 4°C. The intestinal tract of adults is consistently colonized with nonpathogenic Listeria species and, to a lesser extent (1 to 5%), with pathogenic L. monocytogenes. Cervicovaginal carriage in women has not been reported. Apart from food-related infections, nosocomial outbreaks, mainly in neonatal wards, have been described (12, 13).

The number of sporadic cases of listeriosis in countries that report the illness is typically in the range of 0.1 to 0.9 cases per 100,000 persons. While the number of cases and the mortality in the United States have decreased until the end of the last millennium, the incidence remained quite stable in the last decade around 0.27 cases per 100,000 persons (14–17). In contrast, in several European countries, the incidence of sporadic cases of listeriosis has increased, reaching numbers from 0.4 up to 1.0 per 100,000 per year (18–20). People with an underlying condition, like chronic lymphocytic leukemia, myeloproliferative disorder, cancer, organ transplantation, alcoholism, and hepatic disorders;
pregnant women; and individuals ≥60 years have an up to 100 to >1,000-fold increased risk of acquiring listeriosis (15, 17, 18, 20).

Clinical Significance
In adults, L. monocytogenes causes primarily septicemia, meningitis, and encephalitis with a mortality reaching up to 50%. According to a recent study, the rate of unfavorable outcome of Listeria meningitis has increased significantly during the last 15 years and could be linked to infection with L. monocytogenes serotype 6 (21). Focal infections with Listeria spp. have been infrequently described and include endocarditis, pericarditis, arthritis, osteomyelitis, intra-abdominal and brain abscesses, endophthalmitis, (sclero-)keratitis, peritonitis, cholestatis, and intravascular catheter and pleuropulmonary infections (22–24). Among veterinarians and abattoir workers, but recently also in a gardener, primary cutaneous listeriosis with or without bacteremia has been reported (25, 26).

In pregnant women, L. monocytogenes often causes a mild, self-limited influenza-like illness. Transient bacteremia can result in placentalitis and/or amnionitis, and since Listeria is able to cross the placenta, it can infect the fetus, causing abortion, stillbirth, or most commonly, preterm labor (27, 28). In neonates, an early-onset form and a late-onset form of listeriosis occur. The early form is presumably caused by intrauterine infection and manifests as granulomatosis infantisepticum. The organism is widely disseminated in the body, including the central nervous system. The source of the organism in the late-onset cases, which manifest at a mean of 14 days after birth, is unclear and may comprise the mother’s genital tract or environmental sources.

The incubation period for human listeriosis varies between 1 day and 2 to 3 months and is significantly longer for pregnancy-associated cases (median, 28 days) than for central nervous system and bacteremia cases (median of 9 and 2 days, respectively) (29). The infectious dose has not been firmly established, but 10^3 CFU or greater have been reported to cause gastroenteritis in outbreak situations (30).

A dose-response model using rhesus monkeys as a surrogate for pregnant women recently indicated that oral exposure to 10^7 CFU of L. monocytogenes results in about 50% stillbirths (31). In a pregnant guinea pig model, doses of 10^4 to 10^8 CFU have been shown to invade fetal liver and brain tissue in up to 75%, and fetal infection occurred as early as day 2 after maternal infection (32). Thus, the infectious dose may be much less than the extrapolated estimate of 10^13 CFU from the FDA-U.S. Department of Agriculture-CDC risk assessment based on mouse data (33).

Most cases of Listeria gastroenteritis are linked to foodborne outbreaks (34). Typically, patients with Listeria gastroenteritis have no known predisposing risk factors for listeriosis, illness occurs about 24 h after ingestion of a food item that is contaminated with a large number of bacteria (10^3 to 10^9 CFU/g or ml), and illness lasts about 2 days. Apart from gastroenteritis, fever, headache, and pain in joints and muscles are frequently seen.

After ingestion of L. monocytogenes, pathogen and host factors as well as the number of pathogens ingested determine whether invasive infection develops. Immunity to listeriosis is effected primarily via the cell-mediated immune system. Penetration of the epithelial barrier in the gut by L. monocytogenes is facilitated by its ability to escape from the host cell vacuole, intracytoplasmic multiplication, movement via bacterially induced polymerization of host cell actin, and spread to neighboring cells through pseudo-pod-like extensions of the host cell membrane. By N-deacetylation of peptidoglycan of the cell wall, Listeria evades innate immune defenses (35). Virulence genes are clustered on an 8.2-kb pathogenicity island and include genes coding for internalin A and B and listeriolysin, a hemolysin (36). Interaction between internalin and E-cadherin, a receptor of the trophoblast, facilitates the spread of the organism to the fetus.

L. ivanovii is primarily a pathogen of ruminants, but systemic infections in humans with underlying conditions and a case of stillbirth in a pregnant woman have been described (37).

Collection, Transport, and Storage of Specimens
Suitable specimens for detection of listeriosis include blood and cerebrospinal fluid (CSF). In neonates with suspicion of listeriosis, investigation of blood, CSF, amniotic fluid, respiratory secretions, placental or cutaneous swabs, gastric aspirates, or meconium can facilitate detection of the organism. For epidemiologic purposes or rare causes of gastroenteritis, stool specimens are preferred to rectal swabs. In general, specimens for detection of Listeria do not need special handling during collection.

Clinical specimens for culture of L. monocytogenes should be processed as soon as possible or stored and transported at room temperature or 4°C for up to 48 h. At 4°C, even longer storage times may be tolerated due to the specific cold resistance of the organism, but multiplication of Listeria has to be regarded. Stool samples (1 g each) can be inoculated into 100 ml of a selective broth, e.g., University of Vermont, polymyxin-acriflavine-lithium chloride-ceftazi-dine esculin-mannitol (PALCAM), or Listeria enrichment broth (38–41), analogous to the preparation of food samples (see below), and then shipped overnight at room temperature. Nevertheless, the value of enrichment of clinical samples has not been investigated yet. To avoid overgrowth of L. monocytogenes by contaminating microbiota during longer periods of storage, nonsterile-site specimens should be stored at 4°C for 24 to 48 h or frozen at −20°C.

Food samples should include a minimum of 100 g of a sample and should be collected aseptically in sterile containers. Food packaged in original containers should always be preferred. Samples should be shipped overnight frozen. Although L. monocytogenes is relatively resistant to freezing, repeated freezing and thawing should be avoided.

Cultures of Listeria spp. should be frozen at −20 to −70°C for long-term storage.

They can be shipped on a non-glucose-containing agar slant and packaged and declared according to the respective national and international requirements.

Because L. monocytogenes can infect the fetus, pregnant women should be particularly careful when working in a laboratory where L. monocytogenes is propagated or handled.

Direct Examination
Direct microscopy should be performed on CSF, positive blood cultures, and if available, tissue samples. Detection of Gram-positive, regular short rods in CSF or blood cultures should lead to the suspicion of listeriosis. Nevertheless, L. monocytogenes may be confused with members of the Coryneform rods (especially in direct slides from positive blood cultures), since the cells may be arranged in V forms or palisades. Commercial tests licensed for antigen detection in clinical specimens are not available.
Sensitive and specific in-house PCR assays have been described for detection of \textit{L. monocytogenes} in CSF, stool, or lung tissue (39, 42–46) and may be particularly useful for specimens from patients with prior antimicrobial therapy. Regarding commercial assays, the Probelia \textit{Listeria monocytogenes} assay (Bio-Rad, Hercules, CA) has been evaluated in clinical stool specimens, while other commercial assays (e.g., LightCycler PCR, Roche Diagnostics, Indianapolis, IN; TaqMan \textit{Listeria monocytogenes} detection kit, Applied Biosystems, Carlsbad, CA; BAX System PCR, DuPont, Wilmington, DE) have been validated only for food specimens.

Recently, a fluorescent in \textit{situ} hybridization assay has been described that allows detection of \textit{L. monocytogenes} in wastewater samples with a sensitivity of 10^{4} cells/ml (47).

### Isolation Procedures

Clinical specimens from normally sterile sites should be plated onto tryptic soy agar containing 5% sheep, horse, or rabbit blood. Plates should be incubated at 35 to 37°C in an atmosphere enriched with 5% CO\textsubscript{2} for a minimum of 48 h. \textit{Listeria} colonies typically show a narrow zone of beta-hemolysis on blood agar. Blood samples should be inoculated into conventional blood culture media. Clinical specimens obtained from nonsterile sites, like stool samples, as well as food and environmental specimens should be plated on \textit{Listeria} spp. selective agars. In addition, enrichment by inoculation into selective broth for \textit{Listeria} spp. should be done before plating.

Selective agars for culture of \textit{Listeria} spp. include lithium chloride-phenylethanol-moxalactam (LPM) (48), Oxford, modified Oxford, and PALCAM agars (39). On LPM agar, colonies have to be examined under a stereomicroscope with Henry illumination (magnification, ×15 to ×25, with oblique lighting directed to the microscope stage by a concave mirror positioned at a 45° angle to the incident light). \textit{Listeria} colonies appear blue, and colonies of other bacteria appear yellowish or orange. Oxford and PALCAM agars contain selective substances that eliminate the need for examination under oblique lighting. On Oxford and modified Oxford agars, \textit{Listeria} colonies appear black due to esculin hydrolysis, are 1 to 3 mm in diameter, and are surrounded by a black halo of 2 to 4 mm of incubation time up to 37°C. On PALCAM agar, \textit{Listeria} colonies appear gray-green, are approximately 2 mm in diameter, and have black sunken centers.

For the detection of \textit{Listeria} spp. in food samples, enrichment methods have to be used. The most widely used reference methods for food and environmental samples are the Food and Drug Administration (FDA) \textit{Bacteriological and Analytical Manual} (41) and the U.S. Department of Agriculture (USDA) method (40) in the United States and the International Organization for Standards (ISO) 11290 method in Europe (49). All methods require enrichment of the samples in a selective broth (buffered \textit{Listeria} enrichment broth in the FDA \textit{Bacteriological and Analytical Manual} method, University of Vermont broth in the USDA method, and Fraser broth in the ISO method) prior to plating onto selective agar (see above; also agar \textit{Listeria} according to Ottaviani and Agosti [ALOA]) and biochemical identification of typical colonies (40, 41). Confirmation of species identification is necessary, since growth of \textit{Bacillus circulans} strains on ALOA has been described (50). A detailed comparison of methods is given by Dever et al. (51).

Chromogenic media allow selective isolation of \textit{Listeria} species (39, 52, 53). Chromogenic media are mainly based on ALOA and include ALOAgar (Bioline, Milan, Italy), BCM \textit{L. monocytogenes} ( Biosynth, Staad, Switzerland), Li-mono-Ident-Agar (Heipha, Eppelheim, Germany), Chromoplate \textit{Listeria} (Merck KGaA, Darmstadt, Germany), Oxoid Chromogenic \textit{Listeria} agar (Oxoid, Basingstoke, United Kingdom), and BBL Chromagar (BD, Sparks, MD) (53–55). However, none of these agars differentiate between \textit{L. monocytogenes} and \textit{L. ivanovii}. Specific detection of \textit{L. monocytogenes} is facilitated on Rapid \textit{L. mono} agar (Bio-Rad, Hercules, CA) (56). Chromogenic media showed sensitivities comparable to those of Oxford and PALCAM agar, but they appeared to be less specific (52, 53, 55, 56).

### Identification

A simplified identification is based on the following tests: Gram staining, observation of tumbling motility in a wet mount, and tests for a positive catalase reaction and esculin hydrolysis. Acid production from d-glucose and a positive Voges-Proskauer test are confirmatory results.

\textit{Listeria} spp. may be confused with other Gram-positive bacteria due to similar morphologic or biochemical characteristics. \textit{Streptococcus} and \textit{Enterococcus} spp. can be differentiated from \textit{Listeria} spp. on the basis of Gram stain morphology, motility, and catalase reaction. \textit{Erysipelothrix} spp. differ from \textit{Listeria} spp. in motility, catalase reaction, and ability to grow at 4°C (\textit{Erysipelothrix} spp. do not grow at that temperature). \textit{Lactobacillus} spp. are usually nonmotile and catalase negative.

Identification of \textit{Listeria} isolates to the species level is crucial, because all species can contaminate foods but only \textit{L. monocytogenes} is of public health concern. A scheme for identification of medically relevant \textit{Listeria} species based on morphological and biochemical characteristics is shown in Table 1. Among these markers, hemolysis is essential for differentiating between \textit{L. monocytogenes} and the most frequently isolated nonpathogenic species, \textit{L. innocua}.

Production of hemolysins is regarded as a key virulence factor of \textit{L. monocytogenes} and is visible on sheep blood agar plates as a narrow zone of beta-hemolysis that frequently does not extend much beyond the edges of the colonies (Fig. 1). Like \textit{L. monocytogenes}, \textit{L. ivanovii} is also hemolytic, but hemolysis alone cannot be used to discriminate pathogenic and nonpathogenic species, since \textit{L. seeligeri} is, besides rare exceptions (57), hemolytic and since hemolytic strains of \textit{L. innocua} have been described as well (58).

The CAMP (Christie, Atkins, Munch-Petersen) test can be used to differentiate among hemolytic \textit{Listeria} species. The test is carried out by streaking a beta-hemolysis-producing \textit{Staphylococcus aureus} strain and \textit{Rhodococcus equi} parallel to each other on a blood agar plate. Suspect cultures are streaked at right angles in between (but not touching) the two streaks. Hemolysis by \textit{L. monocytogenes} and, to a lesser degree, \textit{L. seeligeri} is enhanced in the vicinity of \textit{S. aureus}, and hemolysis by \textit{L. ivanovii} is enhanced in the vicinity of the \textit{R. equi} streak (Fig. 2). However, the reliability of the CAMP test is limited. As recommended in the USDA method (40), commercially available B-lysis disks (Remel, Lenexa, KS) may be used instead.

\textit{L. monocytogenes} is, apart from rare atypical strains, \textit{D}-rhamnose and \textit{α}-methyl-\textit{D}-mannoside positive and \textit{D}-xylose negative. Incubation of test tubes for up to 7 days (37°C, aerobically) may be necessary.

Commercially available miniaturized tests considerably speed up biochemical identification of \textit{Listeria} spp. The API Coryne and \textit{Listeria} (bioMérieux, Durham, NC), Micro-ID \textit{Listeria} (Remel), BBL Crystal Gram-Pos ID (BD, Franklin Lakes, NJ), and Microbact \textit{Listeria} 12L (Oxoid) reliably identify \textit{Listeria} isolates to the genus and species level (59).

doi:10.1128/9781555817381.ch27.f1
The RapID CB Plus system (Oxoid) allows reliable identification of *Listeria* species to the genus level only (60, 61).

Identification of *L. monocytogenes* is possible with the Vitek2 (bioMérieux), MicroScan WalkAway (Siemens Healthcare, Malvern, PA), Micronaut (Merlin, Bornheim-Hesel, Germany), Phoenix (BD), and Biolog (Biolog, Inc., Hayward, CA) systems. All systems allow reliable species identification, while Vitek1 (bioMérieux) facilitates identification of *Listeria* isolates to the genus level only.

A chemiluminescence DNA probe assay (AccuProbe, Hologic Gen-Probe, Bedford, MA) (62) is available for rapid identification of *L. monocytogenes* from primary isolation plates. However, false-positive results were observed with *L. marthi* (5). Recently described peptide nucleic acid fluorescent in situ hybridization probes also allow rapid and specific identification of *L. monocytogenes* and *L. ivanovii* (63).

The matrix-assisted laser desorption ionization–time of flight (mass spectrometry) (MALDI-TOF [MS]) technique is increasingly used, especially in European laboratories, and allows discrimination of the *Listeria* species by use of the respective software (MALDI Biotyper, Bruker Daltonics, Billerica, MA; Vitek MS, bioMérieux; in-house databases) and an optional pretreatment protocol for colonies (64–66). The use of MALDI-TOF (MS) on the Andromas system directly from colony material facilitated species identification of *L. grayi*, while *L. monocytogenes* clustered with all other *Listeria* species and was, thus, identifiable to the genus level only. By use of the Vitek MS v2.0 system, 75% of the tested *L. monocytogenes* isolates could be identified to the species level and 9% to the genus level, while 15% failed to be identified (66). Differentiation of *L. grayi* from a cluster including *L. monocytogenes* and all other *Listeria* species by MALDI-TOF (MS) corroborates molecular and phylogenetic studies of the genus *Listeria* (67).

**Typing Systems**

Subtyping of *L. monocytogenes* is crucial for the workup of disease acquired from food-borne agents. Based on somatic “O” and flagellar “H” antigens, 13 serovars of *L. monocytogenes* are known (1/2a, 1/2b, 1/2c, 3a, 3b, 3c, 4a, 4b, 4b/4bX, 4c, 4d, 4e, and 7). Since the vast majority of *L. monocytogenes* strains that cause sporadic infections or outbreaks belong to the same serotypes, i.e., 1/2a, 1/2b, and 4b, and since serotyping antigens are shared among *L. monocytogenes*, *L. innocua*, *L. welshimeri*, and *L. seeligeri*, reliable discrimination below the level of serotype is necessary. Thus, serotyping is only useful as a first-level discriminator or for the selection of further typing methods in suspected outbreaks. Antisera are commercially available from Difco (Difco Laboratories/BD, Sparks, MD) and Denka Seiken (Tokyo, Japan). Multiplex PCR assays, also validated by interlaboratory comparison, have been described for identification of the four major serovars of *L. monocytogenes* (1/2a, 1/2b, 1/2c, and 4b) (68–72).

Pulsed-field gel electrophoresis (PFGE) is considered the standard typing method for *L. monocytogenes* and is particularly useful for subtyping of serovar 4b isolates. Its discriminatory power and reproducibility of results have been confirmed in a World Health Organization multicenter international typing study (73) as well as in a large number of other studies. To optimize quality and inter-laboratory comparability of PFGE, standardized laboratory protocols should be used. PulseNet USA has published a 1-day protocol (74) (available at http://www.cdc.gov/pulsenet/PDF/listeria-pfge-protocol-508c.pdf) that has recently been optimized and re-evaluated by a multilaboratory study (75). According to the protocol, restriction endonucleases AscI and Ascl are used. A proficiency testing trial of the PulseNet Europe involving 29 national reference laboratories showed a high level of agreement between typing results but also stressed the necessity of adherence to the standardized protocol and revealed failures in DNA extraction (72).

Faster and simpler molecular subtyping methods, like multilocus variable-number tandem-repeat analysis and multilocus sequence typing, have evolved, and their application for subtyping of *L. monocytogenes* is supported by PulseNet. Both methods showed a discriminatory power comparable to that of PFGE (76–79). By multilocus sequence typing and multi-virulence locus sequence typing, the predominant PFGE clone of *L. monocytogenes* involved in recent listeriosis outbreaks in Canada could be further characterized and traced back to 1988 (80). Other molecular typing methods, like single-nucleotide polymorphism-based multilocus genotyping and a mixed-genome DNA microarray, have been developed and also showed results comparable to those of PFGE (81–84). High-throughput genome pyrosequencing allowed rapid molecular characterization of the outbreak strain of *L. monocytogenes* serotype 1/2a in a
large listeriosis outbreak in Canada in 2008, confirming differences in AseI PFGE patterns at the molecular level (86). Altogether, sequence-based molecular methods may further improve subtyping of L. monocytogenes. They may replace typing methods with high discriminatory power but lacking interlaboratory standardization, like random amplification of polymorphic DNA (RAPD), amplified fragment length polymorphism, multilocus single-stand conformation polymorphism, and ribotyping, and may also add relevant molecular information about outbreak strains to the knowledge obtained by PFGE.

As a nonmolecular technique, MALDI-TOF (MS) has been used successfully for rapid typing of L. monocytogenes. It allowed clear discrimination of all lineages and serotypes of L. monocytogenes in one study so far (64).

An overview of the methods used for typing of L. monocytogenes is given by Jadhav et al. (44).

**Serologic Tests**

Antibodies directed against listeriolysin O have been detected in listeriosis patients by blotting techniques with sensitivities from 50 to 96%, but the sensitivity was markedly lower with complement fixation or O-agglutination tests (86, 87). A test based on the detection of antibodies against recombinant truncated forms of listeriolysin O may be more specific (88). Serologic tests cannot be recommended for the detection of past or acute listeriosis.

**Antimicrobial Susceptibilities**

Treatment with an aminopenicillin (ampicillin or amoxicillin) is still regarded as the most effective therapeutic regimen for listeriosis. In vitro resistance of L. monocytogenes isolates to ampicillin has been reported sporadically (89–91), but the methods used in these studies appear to be inadequate for susceptibility testing of Listeria. Therefore, these reports have to be interpreted with great caution. In other studies and reviews, in vitro resistance against ampicillin was not detected (92–94). Since aminoglycosides exhibit a synergistic effect on aminopenicillins, they are usually added for therapy of listeriosis. However, in a retrospective cohort study, addition of gentamicin did not decrease early or late mortality in listeriosis (95). Trimethoprim-sulfamethoxazole is recommended for patients who are allergic to penicillin, and moxifloxacin may be a valuable option for patients with penicillin allergy. Cultures from blood and CSF that were obtained after the initiation of antimicrobial therapy may be negative. In these cases, detection of Listeria DNA may be useful. Commercial kits for PCR-based detection of L. monocytogenes in CSF specimens are not available, but in-house protocols and multiplex PCR formats facilitate rapid and specific detection of L. monocytogenes DNA.

**ERYSIPELOTHRIX**

**Taxonomy**

Erysipelothrix is taxonomically classified within the class Erysipelotrichia (105) in the phylum Firmicutes. The genus Erysipelothrix has three validly published species, E. rhusiopathiae, E. tonsillarum, and E. inopinata. Based on peptidoglycan antigens of the cell wall, several serovars can be distinguished in E. rhusiopathiae (serovars 1a, 1b, 2a, 2b, 3, 4, 5, 6, 8, 9, 11, 12, 15, 16, 17, 19, 21) and E. tonsillarum (serovars 3, 7, 10, 14, 20, 22, and 23) (106). Only E. rhusiopathiae has been detected as a pathogen of humans. The vast majority of infections are caused by serovars 1 and 2.

**Description of the Agent**

Erysipelothrix organisms are facultatively anaerobic, non-spor-forming, non-acid-fast, Gram-positive bacteria that appear microscopically as short rods (0.2 to 0.5 μm by 0.8 to 2.5 μm) with rounded ends and occur singly, in short chains, or in long, nonbranching filaments (60 μm or more in length). Some cells stain unevenly. They are nonmotile and grow in complex media at a wide range of temperatures (5 to 42°C; optimum, 30 to 37°C) and at alkaline pH (pH 6.7 to 9.2; optimum, pH 7.2 to 7.6). Like Listeria organisms, they can grow in the presence of high concentrations of sodium chloride (up to 8.5%). Erysipelothrix organisms are catalase negative and oxidase negative, do not hydrolyze esculin, and weakly ferment glucose without the production of gas. They are methyl red and Voges-Proskauer negative and do not produce indole or hydrolyze urea but distinctively produce H₂S in triple sugar iron agar. Key fatty acids are C₁₆:₀ and C₁₈:₀ω9 (10).

**Epidemiology and Transmission**

E. rhusiopathiae is distributed worldwide in nature and is remarkably stable under varying environmental conditions. The organism is carried by a variety of animals, like mammals, birds, and fish, in their digestive tracts or tonsils but is most frequently associated with pigs. Other domestic animals that are frequently infected include sheep, rabbits, cattle, and turkeys. Infected animals, both sick and asymptomatic,
tomatic, pass the organism by urine and feces, leading to contamination of water and soil.

Human infection with *E. rhusiopathiae* is most likely acquired by ingestion of contaminated matter. Human infection with *E. rhusiopathiae* is a zoonosis. Most cases are related to occupational exposure, occurring most frequently among fish handlers, veterinarians, and butchers. The disease is contracted through direct contact via skin abrasions, injuries, or animal bites (107).

*E. tonsillarum* has been recovered from tonsils of healthy pigs and cattle, water, and seafood. *E. inopinata* has been isolated once from a vegetable-based peptone broth (108).

**Clinical Significance**

*E. rhusiopathiae* has been recognized for more than 100 years as the agent of swine erysipelas, an acute or chronic disease.

In humans, *E. rhusiopathiae* causes erysipelas, a localized cellulitis developing within 2 to 7 days around the inoculation site. The infected area is swollen, and the mostly painful lesion consists of a well-defined, slightly elevated, violaceous zone which spreads peripherally as discoloration of the central area fades. Vesicles may be present, but suppurative draining fluid is not a characteristic feature. Regional lymphangitis is present in one-third of patients, and low-grade fever and arthralgias occur in about 10% of patients. Healing of erysipelas usually takes 2 to 4 weeks and sometimes months, and relapses are frequently seen. Dissemination of the organism can occur and manifests in most of the cases as endocarditis with a poor prognosis (107). Uncommon manifestations of infection with *E. rhusiopathiae* include peritonitis, endophthalmitis, osteomyelitis, intracranial and spinal abscesses, prosthetic joint arthritis, pneumonia, and meningitis (109–111).

Data about *E. rhusiopathiae* pathogenesis are still scarce. *E. rhusiopathiae* has a capsule consisting of polysaccharide antigen that confers increased resistance to phagocytosis. Neuraminidase plays a significant role in bacterial attachment and subsequent invasion into host cells. The 69-kDa surface antigens SpaA, SpaB, and SpaC appear to be the major protective antigens of *E. rhusiopathiae*, and recombinant SpaA and SpaC elicit a protective immune response in pigs and mice, making them potential vaccine candidates (112, 113). A multiplex real-time PCR for detection of *Spa* types has been described (114).

**Collection, Transport, and Storage of Specimens**

Biopsy specimens from erysipeloïd lesions are the best source of *E. rhusiopathiae*. Care should be taken to cleanse and disinfect the skin before sampling. The organisms typically are located deep in the subcutaneous layer of the leading edge of the lesion; hence, a biopsy of the entire thickness of the dermis at the periphery of the lesion should be taken for Gram staining and culture. Swabs from the surface of the skin are not useful. In disseminated disease, the organism can be cultured in standard blood cultures or from aspirates of the respective infected location. For transport and storage of specimens, standard procedures should be followed.

**Direct Examination**

Direct microscopy should be performed with aspirates, biopsy specimens, and positive blood cultures. Gram stain morphology of *E. rhusiopathiae* includes short rods and very long filaments and, thus, is not distinctive. However, the presence of long, slender, Gram-positive rods in tissue from an individual with a known exposure is suggestive of erysipeloïd. It has to be noted that the organism may appear Gram negative in stains from cultures (see below).

Conventional and real-time PCR assays for specific detection of *E. rhusiopathiae* in animal tissue as well as for discrimination of *E. rhusiopathiae* from *E. tonsillarum* have been described, but their application to human samples has not been evaluated yet (115–117).

**Isolation Procedures**

Tissue or biopsy specimens should be processed as described in chapter 18 and plated onto blood agar or chocolate blood agar, placed in tryptic soy, Schaedler, or thioglycolate broth, and incubated at 35 to 37°C aerobically or in 5% CO₂ for 7 days. Special pretreatment of samples is not necessary, but inoculation of an enrichment broth significantly increases the detection rate. Blood from patients with septicemia or endocarditis can be inoculated into commercial blood culture systems. *E. rhusiopathiae* colonies generally develop in 1 to 3 days, appearing as pinpoints (<0.1 to 0.5 mm in diameter) on blood agar plates after 24 h of incubation; at 48 h, two distinct colony types can be observed. The smaller, smooth colonies are 0.3 to 1.5 mm in diameter, transparent, convex, and circular with entire edges. Larger, rough colonies are flatter and more opaque and have a matte surface and an irregular, fimbriated edge. While a temperature of 37°C favors rough colonies, smooth colonies are favored at 30°C. A zone of greenish discoloration frequently develops underneath the colonies on blood agar plates after 2 days of incubation (105).

**Identification**

Cells stain Gram positive but, especially those from rough colonies, can decolorize and appear Gram negative, sometimes with a beaded morphology. Cells from smooth colonies appear as rods or cocccobacilli, sometimes in short chains. Cells from rough colonies appear as long filaments, often more than 60 μm in length. *E. rhusiopathiae* is catalase negative; it also tests negative for nitrate, urease, esculin, gelatin, xylose, mannose, maltose, and sucrose but positive for glucose, lactose, and H₂S. The extent of H₂S production is influenced by the culture medium, and the strongest reaction is found on triple sugar iron agar. Vitex2 and Phoenix automated systems, as well as the API system (API Coryne, API ID 32 Strep), identify *E. rhusiopathiae* reliably. *E. tonsillarum* differs biochemically from *E. rhusiopathiae* by being sucrose and alkaline phosphatase positive.

Identification of *E. rhusiopathiae* is also facilitated by MALDI-TOF (MS), as recently shown for the Andromas (Paris, France) system (67).

**Typing Systems**

Serotyping schemes are available for routine use in clinical laboratories but are of limited value, since most clinical
isolates belong to serovar 1 or 2. RAPD, amplified fragment length polymorphism, and ribotyping methods have proved useful for epidemiological analysis of Erysipelothrix strains (119–121). PFGE using Smal was superior to RAPD and ribotyping in discriminating E. rhusiopathiae isolates (121). Nucleotide sequence analysis of a hypervariable region in the spaA gene also allows discrimination of certain serovars of E. rhusiopathiae (113, 122).

Serologic Tests
Serologic tests for detection of antibodies to E. rhusiopathiae in humans are not available. Vaccines for active immunization of animals are available, and protective antibodies can be measured by enzyme immunoassay.

Antimicrobial Susceptibilities
Penicillin or ampicillin is the treatment of choice for both localized and systemic infections. Broad-spectrum cephalosporins or fluoroquinolones are suitable alternatives, since no resistance has been described yet. E. rhusiopathiae is also usually in vitro susceptible to clindamycin, erythromycin, daptomycin, imipenem, and tetracycline (123, 124). Of note, E. rhusiopathiae is intrinsically resistant to vancomycin and usually also to aminoglycosides and sulfonamides. Although antimicrobial susceptibility testing of isolates is not routinely required, testing of erythromycin and clindamycin, or further substances, may be warranted for patients with penicillin allergy. A CLSI guideline (M45-A2) for broth microdilution antimicrobial susceptibility testing of Erysipelothrix, including interpretative breakpoints for penicillin, ampicillin, cefepime, cefotaxime, ceftriaxone, imipenem, meropenem, erythromycin, ciprofloxacin, gentamicin, levofloxacin, and clindamycin, has been published (104).

Evaluation, Interpretation, and Reporting of Results
Since human infection is rare and clinical knowledge about the disease is scarce, diagnosis of erysipeloid is usually made accidentally by culture of E. rhusiopathiae from tissue biopsy specimens or blood. If there is no clinical suspicion, identification of E. rhusiopathiae in the clinical laboratory may be challenging. Detection of Gram-positive and Gram-variable rods, including decolorized, beaded cells and the presence of cocccobacilli and very long filaments in direct microscopy of the specimens, gives a hint to this organism. A major discriminatory biochemical characteristic of E. rhusiopathiae is the production of H$_2$S.

Detection of E. rhusiopathiae in clinical samples should always be reported. Occurrence of this species in wound or tissue specimen indicates erysipeloid rather than contamination. Species identification is essential to ensure adequate antimicrobial therapy. While penicillin and ampicillin are generally active and recommended as first-line therapy, intrinsic resistance to vancomycin has to be noted.

REFERENCES

This chapter deals with aerobically growing, asporogenous, irregularly shaped, non-partially acid-fast, Gram-positive rods generally called “coryneforms.” The term “coryneform” is actually somewhat misleading, since only true Corynebacterium spp. exhibit a typical club-shaped (“coryne,” meaning “club” in ancient Greek) morphology, whereas all the other bacteria discussed in this chapter show an irregular morphological shape. However, in our experience, the term “coryneforms” is a common and convenient expression used by many clinical microbiologists, and therefore, the term will be used in this chapter.

The coryneform bacteria which were, for didactical reasons, not included in this chapter comprise Actinomyces spp. (in particular, the most frequently encountered species on aerobic plates, A. eutrophus, A. neutii, A. radingae, and A. turicensis), Actinobaculum spp., Propionibacterium spp., and Propioniferax sp. (see chapter 52), whereas the genera Actinomadura and Trueperella are included. Gardnerella vaginalis is included in this chapter but is discussed separately. Regularly shaped aerobically growing or aerotolerant Gram-positive rods (Bacillus, Listeria and Erysipelothrix, Lactobacillus, and Clostridium tertium) are covered in chapters 26, 27, 52, and 53, respectively. Taxa which might be initially misidentified as coryneform bacteria also include partially acid-fast bacteria and other aerobic actinomycetes (chapter 29) as well as rapidly growing mycobacteria (chapter 32).

Features and infections caused by many of the taxa described in this chapter have recently been reviewed (1, 2).

**TAXONOMY**

The genera of the class Actinobacteria and the genera of the class Firmicutes, which belongs to the class Firmicutes, with a low G+C content. The coryneform bacteria are most diverse and are differentiated by chemotaxonomic features (Table 1). Phylogenetic investigations, in particular 16S rRNA gene sequencing, have, in general, confirmed the framework set by chemotaxonomic investigations. The 16S rRNA gene sequencing data demonstrate that the genera Corynebacterium and Turicella are more closely related to the partially acid-fast bacteria and to the genus Mycobacterium than to the other coryneform organisms covered in this chapter (5–7). The genus Arthrobacter, which contains rods, is phylogenetically intermixed with the genus Mycobacterium (and genera formerly called Micrococcus), which contains cocci (chapter 21) (8, 9). The genus Rothia contains both rod-forming organisms, represented by Rothia dentocariosa, and coccal or cocci-forming species, i.e., Rothia mucilaginosa (formerly Stomatococcus mucilaginosus [10]) and Rothia aeria (11). The genus Aaeritalibacter, in the same family (Micrococccaeae) as Arthrobacter and Rothia, contains rod-shaped bacteria (12). Other genera which are phylogenetically closely related include Oerskovia, Cellulosimicrobium, and Cellulomonas (13–15) as well as Arcanobacterium, Trueperella, Actinobaculum, and Actinomyces (16).

**DESCRIPTIONS OF THE GENERA**

**Genus Corynebacterium**

The number of species belonging to the genus Corynebacterium has dramatically increased from 22 in 1990 to 89 species (and one taxon group) at the time of writing, about 54 of which (and one taxon group) are medically relevant. However, clinically relevant Corynebacterium species validly described since the last edition of this Manual comprise only C. aquatimans (17).

The cell wall of corynebacteria contains meso-diaminopimelic acid (m-DAP) as the diamino acid as well as short-chain mycolic acids with 22 to 36 carbon atoms (1). The medically relevant species C. amycolatun, C. kroppenstedtii, and C. atypicum lack mycolates (1, 18–20). Palmitic (C_{16:0}), oleic (C_{18:1}ω9c), and stearic (C_{18:0}) acids are the main cellular fatty acids (CFAs) in all corynebacteria, and tuberculostearic acid (TBSA) can be detected in some medically relevant species (e.g., C. urealyticum, C. kroppenstedtii, C. confusum, C. appendicitis, C. minutissimum) (19, 21–23). The G+C content of Corynebacterium spp. varies from 46 to 74 mol%, indicating the enormous diversity within this genus (1). The phylogenetic relationships within the genus Corynebacterium have been outlined (5, 6), creating an extensive and reliable database for future comparative 16S rRNA gene studies, e.g., for the delimitation of new species. Complete genome sequences of 16 Corynebacterium species, including the medically relevant species C. diphtheriae, C. aurimucosum, C. jekkeitum, C. kroppenstedtii, C. pseudotuberculosis, C. resistens, C. striatum, C. tuberculostearicum, C. ulcerans, and C. urealyticum, have been determined at the time of writing.

Gram staining of corynebacteria shows slightly curved, Gram-positive rods with sides not parallel and sometimes...
slightly wider ends, giving some of the bacteria a typical club shape (Fig. 1a, 1e, 1g). Corynebacteria whose morphologies differ from this morphology include C. canis, C. durum, C. matruchotii (Fig. 1f), and C. sundsvallense (see below under each species). Cells generally stain evenly. If Corynebacte-rium cells are taken from fluid media, they are arranged as single cells, in pairs, in V forms, in palisades, or in clusters with a so-called Chinese letter appearance. It is again emphasized that the club-shaped form of the rods is observed only for true Corynebacterium spp. All medically relevant taxa in the genus Corynebacterium are catalase positive and nonmotile, and the genus Corynebacterium includes both fermenting and nonfermenting species.

**Genus Turicella**

The genus Turicella is phylogenetically closely related to genus Corynebacterium but contains T. otitidis as the only species. The cell wall contains m-DAP, but mycolic acids are not present (7). The main CFAs for T. otitidis are the same as those for Corynebacterium spp., but all T. otitidis strains also contain significant amounts of TBSA (2 to 10% of all CFAs) (7). The G+C content varies between 65 and 72 mol%.

Gram staining shows relatively long Gram-positive rods (Fig. 1b). T. otitidis is catalase positive, nonmotile, and an oxidizer.

**Genus Arthrobacter**

The genera Arthrobacter and Micrococcus are so closely related phylogenetically that it has been stated that micrococci are, in fact, arthrobacters which are unable to express rod forms (8). Presently, the genus Arthrobacter contains at least 70 species, of which only a few have been recovered from human clinical specimens (24). Lysine is the diamino acid of the cell wall, and C15 or C17 is the overall dominating CFA which represents more than 50% of all CFAs in most Arthrobacter species. The G+C content varies between 59 and 70 mol%, indicating the diversity within this genus.

Gram staining may demonstrate a rod-coccus cycle (i.e., rod forms in younger cultures and cocci in older colonies) when cells are grown on rich media (e.g., Columbia base agar). Jointed rods (i.e., rods in a rectangular form, which contributed to the designation of this genus as "arthros" meaning "joint" in ancient Greek) may also be observed in younger cultures (i.e., after 24 h) but may not be demonstrable for every species. Arthrobacters are catalase positive, motility is variable, and they are always oxidizers.

**Genus Brevibacterium**

The genus Brevibacterium presently comprises 30 species, of which 9 species are medically relevant. m-DAP is the diamino acid type found in the cell wall. C15 and C17 usually represent more than 75% of all CFAs (25). The G+C content varies between 60 and 70 mol%.

Gram staining demonstrates relatively short rods which may develop into cocci when cultures are getting older (after 3 days). Brevibacteria are catalase positive, nonmotile, and oxidizers.

**Genus Dermabacter**

The genus Dermabacter presently comprises only one species, D. hominis. m-DAP is the diamino acid of the cell wall, and...
FIGURE 1 Gram stain morphologies of Corynebacterium diphtheriae ATCC 14779 after 48 h of incubation (a), Turicella otitidis DSM 8821 (48 h) (b), Dermabacter hominis ATCC 51325 (48 h) (c), Gardnerella vaginalis ATCC 14018 (48 h) (d), Corynebacterium anycolatum HC-NML 92-0507 (24 h) (e), Corynebacterium matruchoti ATCC 14266 (24 h) (f), Corynebacterium cobleae HC-NML 98-0068 (24 h) (g), and a black-pigmented Rothia dentocariosa HC-NML 77-0298 (24 h) (h). doi:10.1128/9781555817381.ch28.f1
The genus metabolism. Catalase reaction, are nonmotile, and exhibit a fermentative forms are normally not observed. They have a variable can be quite pleomorphic by Gram staining, but filamentous and C. minutissimum but later, using a polyphasic approach, of D. hominis. The Gram stain shows Gram-positive, straight, short (0.7 to 1.0 μm in length by 0.4 to 0.7 μm in diameter), irregular rods. Colonies are pigmented. The type strain is catalase positive, nonmotile, and a glucose fermenter. This taxon is amycolated, with a G+C content of 68.6 mol%, m-DAP as the cell wall diamino acid, and with CFAs C15:0(Δ2) and C16:0 (together ~70% of the total) predominating (17).

**Genus Helcococcus**

The genus *Helcococcus*, part of the family *Dermabacteraceae*, has been described for an isolate recovered from a patient with a cutaneous discharge presenting with an erythrasma. Interestingly, phenotypic features of the bacterium were initially thought to be suggestive of *C. minutissimum* but later, using a polyphasic approach, of *D. hominis*. The Gram stain shows Gram-positive, straight, short (0.7 to 1.0 μm in length by 0.4 to 0.7 μm in diameter), irregular rods. Colonies are pigmented. The type strain is catalase positive, nonmotile, and a glucose fermenter. This taxon is amycolated, with a G+C content of 68.6 mol%, m-DAP as the cell wall diamino acid, and with CFAs C15:0(Δ2) and C16:0 (together ~70% of the total) predominating (27).

**Genus Rothia**

For didactical reasons, the genus *Rothia* is also included in this chapter because some species are rod-like. The genus *Rothia* belongs to the family *Micrococaceae*. Collins and colleagues reclassified *Stomatococcus mucilaginosus* as *Rothia mucilaginosa* (10). Since *R. mucilaginosa* exhibits coccoid forms in the Gram stain, the genus *Rothia* is also covered in chapter 21 (on the catalase-positive, Gram-positive cocci). However, the species *R. dentocariosa* exhibits mainly but not solely (Fig. 1h) rod forms and is, therefore, covered in this chapter on coryneform bacteria. The occasional pathogen *R. aetia* has mainly coccoidal or coccobacillary forms (11).

Lysine is the diamino acid of the cell wall, and C15:0(Δ2) and C17:0(Δ10) usually represent 40 to 60% of all CFAs. The G+C content ranges between 47 and 56 mol%. *Rothia* strains can be quite pleomorphic by Gram staining, but filamentous forms are normally not observed. They have a variable catalase reaction, are nonmotile, and exhibit a fermentative metabolism.

**Genus Auritidibacter**

The genus *Auritidibacter* contains one species, *A. ignavus*, recovered from the ear, which can be observed to have a rod-coccus cycle. Lysine is the diamino acid of the cell wall, with CFAs C15:0(Δ2) and C17:0(Δ10) predominating, and the G+C content is about 60% (12). A novel second species within this genus has been observed which is close but distinguishable from *A. ignavus* (28). Both taxa are minimally reactive biochemically, are motile only if the hanging drop method is used, and are catalase positive but oxidase negative.

**Genus Exiguobacterium**

Presently, 14 species are included in the genus *Exiguobacterium*, of which only *E. acrylicum* and *E. anaerum* have been mentioned in publications as being isolated from human clinical material. Lysine is the diamino acid of the cell wall, and C15:0(Δ2) and C17:0(Δ10) comprise only about 30 to 40% of the total CFAs. *E. acrylicum* contains significant amounts of C13:0 and C11:0(Δ7), which are not found in any other coryneform taxon (21). The G+C content is about 47 mol%.

Exiguobacteria present as relatively short rods in young cultures. Strains are catalase positive and motile and have a fermentative metabolism.

**Genus Oerskovia**

In older textbooks, *Oerskovia* were assigned to the nocardioform group of organisms due to their morphological features. This includes branching vegetative substrate hyphae, penetration into agar, but no aerial hyphae. Current phylogenetic and chemotaxonomic evidence suggests that *Oerskovia*, including the reclassified *Promicromonas*, is more closely related to genera like *Cellulomonas* than to the mycolic acid-containing genera like *Nocardia*. Representatives of the type species, *O. turbae*, were recovered from soil, but human pathogens originally identified as *O. turbae* have now been placed in *Cellulosimicrobium* fuscum (15). Lysine is the diamino acid of the cell wall, and C15:0(Δ2) is the main CFA in *oerskovia*. The G+C content is 70 to 75 mol%.

Gram staining shows coccoid to rod-shaped bacteria which originate from the breaking up of mycelia. *Oerskoviae* strains are catalase positive, motility is variable, and they are fermentative.

**Genus Cellulomonas**

The genus *Cellulomonas* presently comprises 23 species of which only *C. hominis* and *C. denverensis* have been described as being isolated from humans (13, 29). Ornithine is the diamino acid of the cell wall, and C15:0(Δ2) and C16:0 are the main CFAs. The G+C content is 71 to 76 mol%.

Gram staining shows small, thin rods. *All Cellulomonas* spp., except C. fermentans and *C. humilata*, are catalase positive, their motility is variable, the environmental *Cellulomonas* strains are cellulytic (whereas *C. hominis* did not hydrolyze cellulose in the test system used) (13), and they have a fermentative metabolism.

**Genus Cellulosimicrobium**

The genus *Cellulosimicrobium* presently comprises three species. The medically relevant species, *C. funkei* and *C. cellulosi*, had been designated *Cellulosimicrobium cellulosi* or *Oerskovia xanthineolytica* in the past (14). The reason for removing *C. cellulosi* from the genus *Cellulosimicrobium* was that the topology of the 16S rRNA gene dendrogram indicated that the branching point of this taxon was outside *Cellulomonas* proper. In addition, the chemotaxonomic characteristic of lysine as diamino acid supported reclassification. Predominant CFAs include C15:0(Δ2), C15:0, C16:0, and C16:0. The major menaquinone (MK) is MK-9(H4), and the G+C content is 74 mol%. It should be noted that the genus *Cellulosimicrobium* is related to the genus *Oerskovia* but nevertheless distinct.

In young cultures, a mycelium is produced that fragments later into irregular, curved and club-shaped rods. Catalase activity is detected, and strains are motile or nonmotile. All strains have a fermentative metabolism.

**Genus Microbacterium**

The genera *Microbacterium* and *Aureobacterium* were found to be phylogenetically intermixed and were unified in a redefined genus *Microbacterium* (30).

Now, over 80 *Microbacterium* species have been validly named, but only a minority of them has been demonstrated to be of clinical importance (31). Microbacteria are most frequently encountered in environmental specimens (e.g., soil). C15:0(Δ2) and C17:0(Δ10) are the two main CFAs, often representing up to 75% of the total CFAs (30, 32, 33). The G+C content of *Microbacterium* spp. is 65 to 76 mol%, indicating the diversity within the genus.
Gram staining often shows thin or short rods with no branching. Catalase activity and motility are variable. Microbacteria can be either fermenters or oxidizers.

**Genus Curtobacterium**
Curtobacterium spp., like microbacteria, belong to the peptidoglycan type B actinomyceteces (i.e., cross-linkage between positions 2 and 4 of the two peptide subunits). Ornithine is the diamino acid and the only amino acid composing the interpeptide bridge. Curtobacterium have an acetyl peptidoglycan acyl type and MK-9 as the major MK, whereas microbacteria possess a glycolyl type and MK-11 and -12 (Table 1). For most curtobacterium, C<sub>15:0</sub>Δ<sub>9</sub> and C<sub>17:0</sub>Δ<sub>10</sub> represent more than 75% of all CFAs (34). The G+C contents range from 68 to 75 mol%. Presently, nine Curtobacterium species are validly described.

Gram staining shows small and short rods with no branching. Catalase activity is positive, motility is observed in most strains, and all strains show a respiratory metabolism which proceeds slowly in oxidizing carbohydrates.

**Genus Leifsonia**
The former “Corynebacterium aquaticum” had been transferred into the genus Leifsonia as L. aquatica (35) and is the only medically relevant species in this genus. L. aquatica stains blue (to the peptidoglycan B type actinomycetes and, therefore, cannot be true corynebacteria, which actually possess an A type of peptidoglycan (i.e., cross-linkage between positions 3 and 4 of the two peptide subunits). Diaminobutyric acid is the diamino acid of the cell wall peptidoglycan, and C<sub>15:0</sub>Δ<sub>9</sub> and C<sub>17:0</sub>Δ<sub>10</sub> are the main CFAs, similar to microbacteria, but represent <75% of all CFAs (32). The G+C content is about 70 mol%.

Gram staining shows thin rods. The strains are catalase and oxidase positive (the latter is an atypical feature for coryneform bacteria), always motile, and oxidizers.

**Other Unusual Coryneforms**
Examination of coryneform bacteria using primarily sequence-based identification approaches has shown that additional genera could be recovered from human clinical materials.

**Genus Janibacter**
Strains of the genus Janibacter (36) were found to be associated with bacteremia (37, 38; K. A. Bernard, unpublished data), the first medically relevant coryneforms reported from the family Intrasporangiaceae. Janibacter strains have Gram-variable or Gram-positive coccoidal to rod forms in singles, pairs, or irregular clumps. DNA base composition is 69 to 72 mol% G+C, with an unusual CFA profile consisting of significant volumes of CFAs C<sub>16:0</sub>, C<sub>17:1</sub>ω<sub>7</sub>, and C<sub>17:0</sub>ω<sub>6</sub>. These bacteria are described as oxidizers, with white, creamy, or yellowish pigments. They are nonmotile, and optimal growth may occur at 25 to 30°C.

**Genus Pseudoclavibacter**
The genus Pseudoclavibacter was first described in 2004 to accommodate the misidentified type strain of “Brevibacterium hovolucum” (39). P. albipullus strains were recovered from urine and P. bifida from blood cultures and wounds. By Gram staining, these species were short or medium Gram-positive rods, with P. bifida demonstrating some rudimentary branching. The DNA base composition is 62 to 68 mol% G+C. Major CFAs are C<sub>15:0</sub>ω<sub>2</sub>, C<sub>16:0</sub>, C<sub>16:0</sub>ω<sub>5</sub>, and C<sub>17:0</sub>ω<sub>6</sub>. These strains are oxidizers, with white or yellowish colonies. Optimal growth occurs at 30°C.

Genera Brachybacterium and Knoellia
Isolates from the genus Brachybacterium and one strain from the genus Knoellia, all recovered from blood cultures, have been characterized (Bernard, unpublished). There are currently 14 species in the genus Brachybacterium, which is part of the family Dermatobacteraceae, and so they are most closely related to the genus Dermatobacter. Members of this genus grow at 37°C, exhibit Gram-positive coccoidal and rod-like forms, and have a G+C content of 68 to 73 mol%. The Brachybacterium blood culture isolates were metabolically fermentative and had branched-chained type CFAs. The genus Knoellia, like that of the genus Janibacter, is a member of the family Intrasporangiaceae. Cells are irregular Gram-positive rods or cocci, with major CFAs of the branched-chain type, and the G+C content is 68 to 69 mol%. The single Knoellia blood culture isolate was capnophilic, growing best in 5% CO<sub>2</sub> at 37°C.

Genera Arcanobacterium and Trueperella
The genus Arcanobacterium presently contains six species, of which only A. haemolyticum is recovered from human clinical specimens. The main CFAs of arcanobacteria are C<sub>16:0</sub>, C<sub>16:1</sub>ω<sub>7</sub>, and C<sub>18:0</sub> (as in Corynebacterium spp. and T. oitidis), but in contrast to corynebacteria, significant amounts of C<sub>16:0</sub>, C<sub>12:0</sub>, and C<sub>14:0</sub> may also be detected (21). The genus Trueperella comprises five species, of which T. bernardiae (formerly A. bernardiae) and T. pyogenes (formerly A. pyogenes) can be detected in human clinical specimens (40).

Gram staining of A. haemolyticum and Trueperella spp. shows irregular Gram-positive rods. They are all catalase negative, nonmotile, and fermenters. Arcanobacterium species are reverse CAMP or CAMP test positive, whereas Trueperella species are not (40).

**EPIDEMIOLOGY AND TRANSMISSION**
Many species of the corynebacteria are part of the microbiome of the skin and mucous membranes in humans and mammals. The habitat for some medically irrelevant corynebacteria is the environment. It is noteworthy that not all corynebacteria are equally distributed over skin and mucous membranes, but many of them occupy a specific niche. Corynebacteria can be isolated from the nasopharynx as well as from skin lesions, which actually represent a reservoir for the spread of diphtheria. Important opportunistic pathogens like C. amycolatum, C. striatum, and D. hominis are part of the human skin microbiome but have thus far not been recovered from throat swabs from healthy individuals (41). Coryneform bacteria prominent in the oropharynx include C. dorum and R. dentocariosa (41). Corynebacterium auri and T. oitidis seem to have an almost exclusive preference for the external auditory canal (42). In nearly every instance that Corynebacterium macnilyei has been isolated, it has been recovered from eye specimens (43). Another Corynebacterium species with a distinctive niche is C. glucuronolyticum, which is almost exclusively isolated from genital specimens from males (44) and also from animals (45). C. urealyticum, another genitalourinary pathogen, has, like Corynebacterium jeikeium, also been cultured from the intramammary hospital environment.

The natural habitat of arcanobacteria is not fully understood, but A. haemolyticum is recovered from throat as well as from wound swabs, whereas Trueperella bernardiae has mainly been found in abscesses adjacent to skin (G. Funke and K. Bernard, unpublished data). It is unclear whether the two species are part of the skin and/or the gastrointestinal...
microbiome. *Trueperella pyogenes* is found on mucous membranes of cattle, sheep, and swine. Brevibacteria can be found on dairy products (e.g., cheese) but are also inhabitants of the human skin (25). Arthrobacters are some of the most frequently isolated bacteria when soil samples are cultured, but at least *Arthrobacter cumminsi* also seems to be present on human skin (24, 46). Auritidibacters have been recovered from ear specimens (12, 28). Members of the genera *Exiguobacterium*, *Oerskovia*, *Cellulomonas*, *Cellulosimicrobium*, and *Microbacterium* have their habitats in the inanimate environment (e.g., soil and activated sludge). *Microbacterium* spp. have also been recovered from hospital environments (33). Curtobacteria are primarily plant pathogens (34).

**CLINICAL SIGNIFICANCE**

Estimating the clinical significance of coryneform bacteria isolated from clinical specimens is often confusing for clinical microbiologists. This is in part due to the natural habitat of coryneform bacteria, which may lead to their recovery if specimens were not taken correctly. The reader is referred to guidelines on minimal microbiological requirements if specimens were not taken correctly. The reader is referred to review articles (2, 47, 48). The most frequently reported coryneforms as well as their established disease associations are listed in Table 2.

Historically, diphtheria caused by *C. diphtheriae* (or *C. ulcerans*) is the most prominent infectious disease for which coryneform bacteria are responsible. Therefore, special attention is given to that disease in this chapter; a comprehensive review on diphtheria has been recently published (49). Due to immunization programs, the disease has nearly disappeared in countries with high socioeconomic standards. However, the disease is still endemic in some subtropical and tropical countries as well as among individuals of certain ages (2, 47, 48).

For a comprehensive summary of case reports on individual coryneform bacteria, the reader is referred to review articles (2, 47, 48). The most frequently reported coryneforms as well as their established disease associations are listed in Table 2.

</table>
that the sensitivity of the microscopic examination is limited.

Antigen assays for the direct detection of coryneform bacteria are not recommended.

As described previously, *C. diphtheriae*, *C. ulcerans*, and *C. pseudotuberculosis* are the only species able to harbor the bacteriophage which carries the diphtheria tox gene and potentially produce diphtheria toxin. PCR-based, direct detection systems for the diphtheria tox gene have been described, using conventional methods to detect fragment A and/or the entire tox gene (51, 52) or fragment A and B subunits of the tox gene (53). The system described by Nakao et al. had the highest sensitivity when Dacron polyester-tipped swabs were used and when silica gel packages were stored at 4°C rather than at room temperature. Conventional PCR detection of the regulatory dtxR gene has been evaluated (54). Detection of the tox gene using a real-time platform has been outlined (55–57). Real-time detection using primers targeting the *C. diphtheriae* tox gene for *C. ulcerans* strains has required modifications (56–58). Direct detection of the diphtheria tox or dtxR as the sole test of clinical specimens has not been recommended, as expression of diphtheria toxin must be demonstrated, so microbiological culture is essential for confirming diphtheria (59).

**ISOLATION PROCEDURES**

Coryneform bacteria including *C. diphtheriae* can be readily isolated from a 5% sheep blood agar (SBA)-based selective medium containing 102 μg of fosfomycin per ml (plus 12.5 μg of glucose-6-phosphate per ml), since nearly all coryneforms (except *Actinomyces* spp. and *D. hominis*) are highly resistant to this compound (60). It is also possible to put disks containing 50 μg of fosfomycin (plus 50 μg of glucose-6-phosphate [already incorporated in the disk]) (BD Diagnostics, Sparks, MD) on an SBA or a colistin-nalidixic acid (CNA) plate and then examine the colonies which grow around the disk. Selective media for coryneform bacteria containing 50 to 100 μg of furazolidone (Sigma, St. Louis, MO)/ml have also been described. If lipophilic corynebacteria like *C. jeikeium* or *C. urealyticum* are sought, then 0.1 to 1.0% Tween 80 (Merck, Darmstadt, Germany) could be added to an SBA plate (add Tween 80 before pouring the medium). Additional methods to demonstrate lipophilia are described below. Medically relevant coryneforms described to date do not grow on MacConkey agar. However, if “coryneform” bacteria are recovered from this medium, they should be examined carefully to rule out rapidly growing mycobacteria.

With very few exceptions (some arthrobacters, microbacteria, and curtobacteria, which have optimal growth temperatures of between 30 and 35°C), the medically relevant coryneform bacteria all grow at 37°C. It is desirable to culture specimens for coryneform bacteria in a CO₂-enriched atmosphere, since some taxa, e.g., *Rothia*, *Arcanobacterium*, and *T. percolla*, grow much better under those conditions. Nearly all medically relevant coryneform bacteria grow within 48 h, so primary culture plates should not be incubated longer than that. However, if liquid media are used (e.g., for specimens from normally sterile body sites), these should be checked after 5 days by Gram staining for the presence of coryneform bacteria (only if growth is observed with the naked eye) before they are discarded.

It is recommended that urine specimens be incubated for longer than 24 h to check for the presence of *C. urealyti-

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

In general, coryneform bacteria do not need special handling when samples are collected.

*C. diphtheriae*

The diagnosis of diphtheria is primarily a clinical one. The physician should notify the receiving laboratory immediately of suspected diphtheria. In case of respiratory diphtheria, material for culture should be obtained on a swab (either a cotton- or a polyester-tipped swab) from the inflamed areas in the nasopharynx. Multisite sampling (nasopharynx) is thought to increase sensitivity. If membranes are present and can be removed (swabs from beneath the membrane are most valuable), they should also be sent to the microbiology laboratory (although *C. diphtheriae* might not be culturable from those in every instance). Nasopharyngeal swabs should be obtained from suspected carriers. It is preferable that the swabs are immediately transferred to the microbiology laboratory for culturing. If the swabs must be sent to the laboratory for culturing. If the swabs are immediately transferred to the microbiology laboratory, semisolid transport media (e.g., Amies) ensure the maintenance of the bacteria. All coryneform bacteria are relatively resistant to drying and moderate temperature changes. Material from patients with suspected cases of wound diphtheria can be obtained by swab or aspiration.

Long-term preservation in skim milk at ~70°C is applicable to all coryneform bacteria. The same skim milk tube, except for those containing lipophilic corynebacteria, can be thawed and put into the freezer again, and this can be done several times (G. Funke, unpublished data). For both nonlipophilic and lipophilic coryneforms, good results were observed with Microbank tubes (Pro Lab Diagnostics, Austin, TX) (Funke, unpublished). The advantage of using these tubes is that individual beads can be taken out of the tube. Coryneform bacteria can also be stored for decades when they are kept lyophilized in an appropriate medium (e.g., 0.9% NaCl containing 2% bovine serum albumin).

**DIRECT EXAMINATION**

After the appropriate isolation media have been inoculated (see below under “Isolation Procedures”), the swabs taken from diphtheritic membranes may be subjected to Neisser or Loeffler methylene blue staining (positive if metachromatic granules [polar bodies] are seen). However, it is noteworthy
C. diphtheriae

The primary plating media for the cultivation of C. diphtheriae should be SBA plus one selective medium (e.g., cystine-tellurite blood agar [CTBA] or freshly prepared Tinsdale medium) (59, 61). If silica gel is used as a transport medium, the desiccated swabs need to be additionally incubated overnight in broth (supplemented with either plasma or blood), which should then be streaked onto the primary plating medium. The plates are read after 18 to 24 h of incubation at 37°C, preferably in a 5% CO₂-enriched atmosphere. Tellurite inhibits the growth of many noncoryneform bacteria, but even a few C. diphtheriae strains are sensitive to potassium tellurite and will therefore not grow on CTBA but may grow on SBA. It is noteworthy that growth on CTBA and tellurite reduction are not specific for C. diphtheriae, since many other coryneforms may also produce black (albeit smaller) colonies. The best medium for direct culturing of C. diphtheriae is probably Tinsdale medium (61). However, the limitations of Tinsdale medium are its relatively short shelf life (<4 weeks) and the necessity to add horse serum to it. On Tinsdale plates, both tellurite reductase activity (as shown by black colonies) and cystinase activity (as shown by a brown halo around the colonies) can be observed. If neither CTBA nor Tinsdale medium is available, CNA plates are recommended for the isolation of C. diphtheriae or any other coryneform bacterium. It is necessary to pick multiple colonies from CNA plates to rule out C. diphtheriae (first Gram staining, then subculturing, and subsequent biochemical testing or direct application of matrix-assisted laser desorption ionization–time of flight [MALDI-TOF] mass spectrometry on colonies). Nonspecific Loeffler serum slants are no longer recommended for the primary isolation of C. diphtheriae because of overgrowth by other bacteria.

IDENTIFICATION

Basic tests available in every microbiology laboratory are of great value for the identification of coryneform bacteria. The Gram staining morphology of the cells can exclude the assignment to many genera and may even lead to the assignment to the correct genus (e.g., to the genus Corynebacterium, Turicella, or Dermabacter) (Fig. 1). Morphology, size, pigment, odor, and hemolysis of colonies are also valuable criteria in the differential diagnosis of coryneform bacteria.

von Graevenitz and Funke (62) had outlined a biochemical identification system for coryneform bacteria which was based on previous results from the Centers for Disease Control’s Special Bacteriology Reference Laboratory (63). This system includes the following reactions: catalase; test for fermentation or oxidation (in our experience, this is best observed in semisolid cystine Trypticase agar medium [rather than on triple sugar iron or oxidation-fermentation media], with fermentation indicated by acid or alkali production in the entire tube and oxidation found at the surface of the tube); motility; nitrate reduction (24-h incubation); urea hydrolysis (24-h incubation); esculin hydrolysis (up to 48 h of incubation); acid production from glucose, maltose, sucrose, mannitol, and xylose (48-h incubation); CAMP reaction (24-h incubation) with a β-hemolysin-producing strain of Staphylococcus aureus (e.g., strain ATCC 25923), i.e., positive reaction indicated by an augmentation of the effect of S. aureus β-hemolysin on erythrocytes, resulting in a complete hemolysis in an arrowhead configuration (Fig. 2); and a test for lipophilia (24-h incubation), which is performed only for catalase-positive colonies <0.5 mm in diameter. For the test for lipophilia, colonies are subcultured onto ordinary SBA and onto a 0.1 to 1% Tween 80-containing SBA plate. Lipophilic corynebacteria develop colonies up to 2 mm in diameter after 24 h on Tween-supplemented agar. It has also been suggested that growth in brain heart infusion broth with and without supplementation of 1% vol/vol of sterile Tween 80 be compared, and strains which grow only in the supplemented broth can be called lipophilic. The identification protocols given in this chapter are, in principle, based on the identification system of von Graevenitz and Funke (62) (Tables 3 and 4).

Manually performed identification panels include the API (formerly RAPID) Coryne system (bioMérieux, Marcy l’Etoile, France) and the RapID CB Plus system (Remel, Lenexa, KS) which are widely used. The API Coryne system contains 50 taxa in its present database (version 3.0), and comparison to an online database, APIWEB, is available (https://apiweb-.biomerieux.com). In a 1996 study, it was found that 90.5% of the strains belonging to the taxa included were correctly identified, with additional tests needed for correct identification for 55.1% of all strains tested (64). Similar results were

(Continued on next page)
reported in 2006 (65). Reproducible results are best obtained if the manufacturer’s recommendations for use were rigorously followed. The RapID CB Plus system is also used and correctly identified 80.9% of the strains to the genus and the species levels and an additional 12.2% to the genus level but with less accurate species designations (66). An updated version of a panel for the automated Vitek system (bioMérieux) has been described (67); however, this system is not recommended because of its limited database. It is always important to question critically the identifications provided by any commercial identification system and to correlate the results with simple basic characteristics such as macroscopic morphology and Gram staining results. Furthermore, it is important to note that, for both commercially available manual identification systems, the databases have not been updated since the end of the 1990s and, therefore, the recently described taxa are not covered. Limitations found based on the use of the commercial identification systems have been recently reviewed (2).

A reference laboratory may also use chromatographic techniques for further characterization of coryneform bacteria. The analysis of CFAs by means of gas-liquid chromatography with the Sherlock system (MIDI, Inc., Newark, DE) can be a useful method for the identification of coryneform bacteria but has been replaced in many laboratories by other methods such as molecular genetic investigations (see below). This system is, in general, able to correctly identify coryneform bacteria to the genus level, but identification to the species level is, in most cases, impossible, although the commercial database suggests that it is possible. This is due to the very closely similar CFA profiles being obtained for coryneform bacteria belonging to the same genus (21) and because the quantitative profiles observed strongly depend on the incubation conditions. When a laboratory creates an individual data-

encountered in clinical specimens and might even be on the genus level. In general, MALDI-TOF is a useful approach for the identification of true corynebacteria, since most established species exhibit 3% or greater divergence, except for C. afermentans, C. coyleae, and C. mucifaciens (<2%); C. aureus, C. minutissimum, and C. undulatum (<2%); C. pseudodiphtheriticum (<2%); C. xerosis, C. freneyi, and C. hansenii (<2%); C. macrineri and C. acoules (<2%) (1, 2).

In extremely rare cases (i.e., if the 16S rRNA gene divergence is ≤1.3%), quantitative DNA-DNA hybridizations might be necessary, with sequencing of the complete base on its own entries, species identification becomes more likely (Bernard, unpublished).

MALDI-TOF mass spectrometry reliably identifies the potentially toxigenic Corynebacterium strains (68). Two studies including only a limited number of coryneform strains and species showed that about 90% of the isolates were correctly identified to the species level using the MALDI-TOF Bruker system (Bruker Daltonics, Bremen, Germany) applying a score of ≥1.700 as the cutoff (69, 70). Our own MALDI-TOF data using the Bruker system are as follows (Funke, unpublished): of a set of 957 strains of coryneform bacteria representing 10 genera and 53 species, 83.6% were correctly identified to the species level, 90.5% were correctly identified to the same genus level, a wrong species was given in 7.4%, a wrong genus was given in 0.7%, and for 8.8% of the strains, no reliable identification (i.e., no match or a score of <1.700) was observed. A challenge set consisting of 215 strains representing, again, 10 genera and 53 species was cultured on either Columbia blood agar, CNA agar, or chocolate agar, and the strains were correctly identified on the species level in 83.7%, 82.8%, or 82.8% of cases, respectively. The percentage of correct species level identification increased to 87.8% for strains grown on Columbia blood agar if the colonies were treated with 70% formic acid on the MALDI-TOF target plate. Of 509 consecutively isolated (in the author’s routine clinical microbiology laboratory), clinically relevant coryneform bacteria, 86.0% of strains were correctly identified on the species level (compared to 16S rRNA gene and rpoB gene sequencing as the gold standard) and 91.7% were correctly identified on the genus level. In general, MALDI-TOF is a useful tool for identifying the huge variety of coryneform bacteria encountered in clinical specimens and might even be more valuable if the databases are improved by the manufacturers.

Molecular genetics-based identification systems for coryneform bacteria have been outlined. Restriction fragment length polymorphism analysis of the partly amplified and digested 16S rRNA gene has been demonstrated to be of use for the identification of species, e.g., within the genus Corynebacterium (71). Some corynebacteria may also be identified to the species level by examination of the length of the 16S–23S rRNA intergenic spacer region (72). A very useful approach for the identification of true corynebacteria is the sequencing of a 434- to 452-bp fragment of the rpoB gene (using primers designated C2700F and C3130R), since this particular region of the gene displays a high degree of polymorphism within the genus Corynebacterium (73, 74). A divergence of >5% within this particular part of the rpoB gene of two strains compared suggests that they belong to two different species. For more definitive taxonomic investigations of coryneforms, and in cases of growth of coryneform bacteria from difficult to obtain clinical material (75), full-length 16S rRNA gene sequencing might be indicated. Determination of the complete 16S rRNA gene sequence is a rational approach for identifying corynebacteria, since most established species exhibit 3% or greater divergence, except for C. afermentans, C. coyleae, and C. mucifaciens (<2%); C. aureus, C. minutissimum, and C. undulatum (<2%); C. pseudocorynebacterium (<1% to each other, both <2% to C. diphteriae); C. propinquum and C. pseudodiphtheriticum (<2%); C. xerosis, C. freneyi, and C. hansenii (<2%); C. macrineri and C. acoules (<2%) (1, 2).

In extremely rare cases (i.e., if the 16S rRNA gene divergence is ≤1.3%), quantitative DNA-DNA hybridizations might be necessary, with sequencing of the complete

*Abbreviations and symbols: +, positive reaction; –, negative reaction; v, variable reaction; O, oxidation; F, fermentation. See also references 12, 27, 47, and 48.
Strains belonging to the species in diameter after 24 h. (78) have mainly been isolated from blood cultures as T. otitidis contain mycolates, whereas (C. auris C. auris afermentans T. Gram staining (all strains of this taxon are CAMP reaction positive. Numerical code of 2100004 for this species. About 60% of oxidative metabolism. The API Coryne system provides the h of incubation. C. afermentans subsp. afermentans (Fig. 3a). C. amycolatum actually has a fermentative metabolism, but when cystine Trypticase agar media are used for the observation of acid production from carbohydrates, C. amycolatum appears to resemble an oxidizer (i.e., main acid production at the surface of the medium). Strains of C. amycolatum are remarkable for their variability in basic biochemical reactions (Table 3) and had been often misidentified in the past as the biochemically similar species C. xerosis, C. striatum, or C. minutissimum (80, 82). These species can be differentiated by the following reactions: C. amycolatum and C. minutissimum do not grow at 20°C but C. xerosis and C. striatum do; in addition, C. xerosis does not ferment glucose at 42°C whereas the other three species do; and C. minutissimum and C. striatum produce alkali from formate but C. amycolatum and C. xerosis do not (82). When tested on Mueller-Hinton agar supplemented with 5% sheep blood, nearly all C. amycolatum strains were resistant to the vibriocidal compound O/129 (150-μg disks) (Oxoid, Basingstoke, UK), as indicated by no zone of inhibition around the disk (80). In contrast, only 4% of all C. amycolatum strains were resistant to O/129 when tested on Mueller-Hinton agar with 5% horse blood. The API Coryne system identifies this species well, but in every case, additional reactions must be carried out to confirm the identification of C. amycolatum (64). All C. amycolatum strains produce propionic acid as the major end product of glucose metabolism. In contrast to many other corynebacteria, C. amycolatum exhibits only weak or no leucine arylamidase activity. The identification may also be suggested by the absence of mycolic acids.

C. appendicis The one strain of C. appendicis described in the literature was isolated from a patient with appendicitis accompanied by abscess formation (23). This lipophilic species contains large amounts of TBSA (up to 50% of all CFAs) not seen in any other Corynebacterium species. It is differentiated from CDC coryneform group F-1 bacteria by a positive alkaline phosphatase reaction but negative reactions for nitrate reduction and sucrose fermentation.

C. aquatimens The lipophilic species C. aquatimens was isolated from blood cultures of a patient with bacteremia (17). Its closest phylogenetic neighbor is C. tuscaniense, but phenotypically, it resembles C. argentoratense from which it can be differentiated by negative α-chymotrypsin and cysteine arylamidase tests. C. aquatimens also biochemically resembles C. mucificiens, from which it can be easily separated by its lipophilic colonies and the negative reaction for sucrose fermentation.

C. argentoratense C. argentoratense (83) has been isolated from the human throat as well as from blood cultures (84). Colonies are
FIGURE 3 Colony morphologies of different coryneform bacteria after 48 h of incubation on SBA. (a) C. amycolatum LCDC 91-0077; (b) C. diphtheriae ATCC 14779; (c) C. mucifaciens LCDC 97-0202; (d) C. striatum ATCC 6940; (e) D. hominis ATCC 51325; (f) R. dentocariosa LCDC 95-0154; (g) C. aurimucosum HC-NML 91-0032 (after 96 h); (h) black-pigmented Rothia dentocariosa HC-NML 77-0298 (after 96 h); (i) C. diphtheriae biotype gravis colonies on a Tinsdale agar plate. The latter photo was kindly provided by C. Hinnebusch and M. Cohen, UCLA School of Medicine, Los Angeles. doi:10.1128/9781555817381.ch28.f3
cream colored, nonhemolytic, slightly rough, and 2 mm in diameter after 48 h of incubation. Phenotypically, C. argentoratense may appear to be very similar to (rare) ribose-negative strains of C. coyleae. However, glucose fermentation by C. argentoratense is quite rapid, compared to the slowly fermenting species C. coyleae. As well, CAMP-negative C. argentoratense produces propionic acid as a fermentation product, but CAMP-positive C. coyleae does not (84). C. argentoratense is the only medically relevant Corynebacterium species expressing α-chymotrypsin activity, which can be observed in the API ZYM (bioMérieux) system. Although C. argentoratense is phylogenetically closely related to C. diptheriae, it does not harbor the tox gene coding for the diphtheria toxin.

C. atypicum
Corynomycolic acids, like in C. amycolatum and C. kroppenstedtii, are not detected (20). According to the initial description, C. atypicum is not lipophilic but shows only pinpoint colonies after 48 h of incubation. It is the only medically relevant Corynebacterium not expressing pyrazinamidase but β-glucuronidase activity.

C. aurimucosum
The initial description of C. aurimucosum was based on a single strain which exhibited slightly yellow and sticky colonies on 5% SBA plates but, on Trypticase soy agar without blood, had colorless and slimy colonies (85). Biochemically, this particular C. aurimucosum strain was similar to C. minutissimum. The number of C. aurimucosum strains was enhanced when it was demonstrated that some former CDC coryneform group 4 bacteria actually belong to C. aurimucosum (86). It is important to note that strains of C. aurimucosum exhibit a grayish-black pigment which is not seen in any other Corynebacterium species and that these strains are usually recovered from the female urogenital tract. Synthesis of this pigment, linked to genes on plasmid pET44827, is thought to assist with survival in the high hydrogen peroxide environment of the vagina (87). Strains originally designated “C. nigricans” were shown to be a later synonym of C. aurimucosum (86). Some strains of R. dentocariosa can also exhibit a charcoal-black pigment (86); these strains are differentiated from C. aurimucosum by being constantly nitrate reductase positive, a possible negative catalase reaction, and having branched-chained CFAs as opposed to straight-chained type CFAs for C. aurimucosum. API Coryne codes for pigmented C. aurimucosum strains include 000125, 200125, and 2100327. Phylogenetically, C. aurimucosum is closely related (>98.8% identity) to both C. singulare and C. minutissimum by 16S rRNA gene sequencing but can be readily discerned by partial rpoB gene sequence analysis.

C. auris
C. auris (88) has almost exclusively been isolated from the ear region. Colonies are dryish, slightly adherent to but do not penetrate agar, become slightly yellowish with time, and have diameters ranging from 1 to 2 mm after 48 h of incubation. C. auris does not produce acid from any carbohydrates usually tested. All C. auris strains are strongly CAMP test positive. The API Coryne system provides the numerical code 2100004 for this species. It is noteworthy that the MICs of β-lactam antibiotics for C. auris strains are elevated, but the molecular mechanism for this is not known at present (81).

C. bovis
Occasionally, human infections have been attributed to the lipophilic bovine species C. bovis. Characterization of lipophilic-like corynebacteria based solely on the use of phenotypic tests was probably incorrect, in the absence of modern polyphasic methods or identification schemes (Table 3). An oxidase-positive human blood culture isolate of C. bovis was identified based on a polyphasic approach with an API Coryne code of 0101104 (84) as was an isolate from a prosthetic joint infection.

C. canis
The nonlipophilic C. canis was isolated from a wound infection after a dog bite (89). It has some unusual microscopic features: it exhibits very filamentous rods (>15 μm in length) and some cells even show branching. C. canis is esculinase and α-glucosidase positive and is the only Corynebacterium expressing trypsin activity.

C. confusum
C. confusum has been isolated from patients with foot infections, a blood culture (22), and breast abscess (84). Colonies are whitish, glistening, convex, creamy, and up to 1.5 mm in diameter after 48 h. Acid from glucose is produced only very weakly, becoming visible in the API Coryne or the API 50CH gallery only after 48 to 72 h. Weak growth under anaerobic conditions corresponds to slow fermentative acid production. It is advisable to incubate the API Coryne system after 24 h for another day in those cases in which the results for acid production are ambiguous (i.e., only a slight change in the color of the indicator). After 48 h of incubation, the API Coryne system provides the numerical code 3100304 for this species; the breast abscess strain had a code of 3100104. Interestingly, the breast abscess strain was also CAMP positive, making it potentially more difficult to discern from C. coyleae isolates (84). If glucose fermentation is judged to be negative, C. confusum strains can be misidentified as C. propinquum. However, in contrast to that species, C. confusum does not hydrolyze tyrosine and contains small amounts of TBSA (1 to 3%), whereas C. propinquum hydrolyzes tyrosine but does not contain TBSA. C. confusum is differentiated from C. coyleae and C. argentoratense by its ability to reduce nitrate.

C. coyleae
C. coyleae (90) has mainly been isolated from cultures of blood and other normally sterile body fluids, but it may also be recovered from a variety of sterile body fluids, abscesses, and urogenital specimens (84, 91). Colonies are whitish and slightly glistening, have entire edges, and are about 1 mm in diameter after 24 h. The consistency of the colonies is either creamy or sticky. A slow fermentative acid production from glucose and a strongly positive CAMP reaction are the most significant phenotypic characteristics. C. coyleae is positive for cystine arylamidase, which is not observed for many other corynebacteria. Various API Coryne numerical codes have been observed, especially 2100304 and 6100304. C. coyleae is always positive for ribose fermentation, whereas the biochemically similar species C. argentoratense is variable for this reaction. The API Coryne database lists only 6% glucose-fermenting C. coyleae strains, and therefore, when applying this commercial identification system, the clinical microbiologist may not receive a correct identification (64). However, the two numerical profiles given above combined with a positive CAMP reaction are highly indicative of C. coyleae. Macrolide resistance has been reported (79).
CDC Group F-1 Bacteria

The lipophilic CDC group F-1 bacteria (92) have not been given a species name. Although genetically distinct, no distinguishing phenotypic markers which clearly allow their separation from other defined Corynebacterium spp. have been found. The characteristics of the CDC group F-1 bacteria are consistent with the definition of the genus Corynebacterium in all respects. Of note is the negative alkaline phosphatase reaction (Table 3). CDC group F-1 strains are usually susceptible to penicillin but are often resistant to macrolides.

*C. diphtheriae*

The complete genome sequence of a *Corynebacterium diphtheriae* strain representative for the diphtheria outbreak in the former Soviet Union states in the 1990s was the first *Corynebacterium* genome determined (93). The genome consists of a single circular chromosome of 2,488,635 bp with no plasmids. A complete set of enzymes for the glycolysis, gluconeogenesis, and pentose-phosphate pathways is present, as are all of the de novo amino acid biosynthesis pathways. Fimbrial and fimbria-related genes, sialidase (neuraminidase) genes, and iron-uptake systems have been detected as pathogenicity factors.

*C. diphtheriae* is commonly divided into four biotypes: gravis, mitis, belfanti, and intermedii. Biotype differentiation is recommended by WHO (59, 61), although biotypes cannot be assigned separate subspecies status, nor is biotyping satisfactory for epidemiologic tracking. Initially, these biotypes were defined by differences in colony morphology and biochemical reactions (Table 3). However, only *C. diphtheriae* biotype intermedius can be identified on the basis of colonial morphology (small, gray, or translucent lipophilic colonies) as well as positive dextrin fermentation. Other *C. diphtheriae* biotypes produce larger (up to 2 mm after 24 h) white or opaque colonies (Fig. 3b) which are indistinguishable from each other. The lipophilic *C. diphtheriae* biotype intermedius occurs only rarely in clinical infections, and *C. diphtheriae* biotype belfanti strains rarely express diphtheria toxin.

Presumptive identification of *C. diphtheriae* (as well as of *C. pseudotuberculosis* and *C. ulcerans*) may be made by testing suspicious Gram-positive rods for the presence of cytoxinase (as detected by using freshly prepared Tinsdale medium or diagnostic tablets [Rosco, Taastrup, Denmark]) and the absence of pyrazinamidase (diagnostic tablets are available from Key Scientific Products, Stamford, TX). The API Coryne system identifies *C. diphtheriae* strains, with additional tests needed for the differentiation of *C. diphtheriae* biotype mitis, *C. diphtheriae* biotype belfanti, and *C. diphtheriae* biotype intermedius (64). Usually, *C. diphtheriae* strains do not ferment sucrose, but in Brazil, sucrose-positive strains have been described. Large amounts of propionic acid are produced as the end product of glucose metabolism. *C. diphtheriae* strains are distinct from all other coryneform bacteria (except *C. pseudotuberculosis* and *C. ulcerans*) in their CFA patterns by the presence of a large volume of C16:1ω7t (21).

Diphtheria Toxin Testing

It is recommended that at least 10 colonies of *C. diphtheriae* and related species be tested for diphtheria toxin by the Elek method, modified as described by Engler et al. (94), in a laboratory with skill in performing the test and in interpreting the test results. The modified Elek method as described by the WHO Diphtheria Reference Unit was initially used to characterize strains from the 1990s epidemic in Russia and Ukraine and was found to be faster and less technically problematic than the original version. Antibiotics from various suppliers (Berna Biotech AG, Switzerland; Mikrogen, Russia; Biomed, Russia; Pasteur Merieux/Aventis Pasteur, France; BulBio-NGIPD, Bulgaria; Instituto Butantan, Brazil; Refik Saydam National Hygiene Centre, Turkey), applied to blank filter disks at 10 IU/disk, have been successfully used with the modified Elek test.

PCR-based methods for the detection of the diphtheria toxin gene (tox) in isolated bacteria have been developed and validated (51, 52, 95). Conventional PCR detection of the regulatory dtxR gene has been evaluated (54). Detection of the tox gene using a real-time platform has been described (55–57). Primers targeting the *C. diphtheriae* tox gene for *C. ulcerans* strains perform better with modifications (56–58). A LightCycler PCR assay recognizing tox genes from both *C. diphtheriae* and *C. ulcerans* and differentiating the respective target genes by fluorescence resonance energy transfer hybridization probe melting curve analysis has been developed (96). tox PCR assays applied directly to clinical specimens are acceptable, particularly because isolation is not always possible for patients already receiving antibiotics. However, a PCR-positive patient from whom bacteria are not isolated or without a histopathologic diagnosis and without an epidemiologic linkage to a patient with a laboratory-confirmed case of diphtheria should be classified as a “probable case” of diphtheria, since to date, there are insufficient data to conclude that a PCR-positive result always infers diphtheria. Also, detection of the toxin gene in samples by PCR cannot automatically be attributed to one species because *C. diphtheriae*, as well as *C. ulcerans* and *C. pseudotuberculosis*, may harbor the bacteriophage which carries the diphtheria toxin gene. Furthermore, tox-containing, nontoxigenic isolates have been described and characterized further. Difficulties in identifying *C. diphtheriae* and in correctly performing toxigenicity tests have been demonstrated by an external quality control among 23 National Diphtheria Reference Centers in Europe in which 21% misidentifications and 13% unacceptable toxigenicity reports were observed (97).

Nontoxigenic strains of *C. diphtheriae*, i.e., those which do not express toxin in the Elek test or those which lack a detectable diphtheria toxin gene by PCR, have also caused serious disease, such as cases or outbreaks of skin disease, endocarditis, and occasional mortality among homeless people, alcoholics, and intravenous drug abusers (50, 98). For nontoxigenic *C. diphtheriae* strains circulating in the United Kingdom, it has been shown that the diphtheria toxin repressor (dtxR) genes are functional so that, if these strains are lysogenized by a bacteriophage, they could represent a reservoir for toxigenic *C. diphtheriae* (99).

Antibiotic treatment is required to eliminate *C. diphtheriae* and prevent its spread; however, it is not a substitute for antitoxin prevention, with antibiotics of choice being penicillins or macrolides. Sporadic isolates of *C. diphtheriae* resistant to erythromycin or rifampin have been reported, and multidrug resistance, although extremely rare, has also been reported (100).

*C. durum*

*C. durum* (101) was originally described as being exclusively isolated from respiratory tract specimens. Well-characterized isolates have now been recovered from additional sites, including the gingiva, blood cultures, and abscesses (102). *C. durum* strains were originally isolated after 2 to 3 days from nonselective charcoal-buffered yeast extract plates in-
The species *C. freneyi* tosidase reaction. adherent to blood agar. Distinct biochemical features are in some morphology not observed in other true corynebacteria but The nonlipophilic species *C. freiburgense* has probably been transmitted to a human by a dog bite (104). The 5-day-old strains also express β-

*C. falsenii* strains (103) have mainly been isolated from sterile body fluids. Colonies are whitish, glistening, and smooth with entire edges, and they are 1 to 2 mm in diameter after 24 h. After 72 h, most strains described to date exhibit a yellowish pigment which becomes even more intense after 120 h. The most characteristic biochemical features of *C. falsenii* are a slow but fermentative acid production from glucose, a weak pyrazinamidase reaction, and a weak urease activity which becomes visible in either Christensen's urea broth or the API Coryne system after overnight incubation only. API Coryne codes observed for *C. falsenii* have been 2101104 and 2101304 (84, 103).

**C. freiburgense**

The nonlipophilic species *C. freiburgense* has probably been transmitted to a human by a dog bite (104). The 5-day-old colonies exhibit a very peculiar "spoke-wheel" macroscopic morphology not observed in other true corynebacteria but in some *R. dentocariosa* strains. Colonies are also strongly adherent to blood agar. Distinct biochemical features are the lack of pyrazinamidase activity and a positive β-galactosidase reaction.

**C. freneyi**

The species *C. freneyi* has initially been outlined based on the study of three strains (105) which came from skin-related material. There is now evidence that *C. freneyi* is also isolated from genitourinary specimens (106) and bacteremia. *C. freneyi* is phylogenetically closely related to *C. xerosis*. Colonies are typically wrinkled, whitish, dry, and rough; have irregular edges; and are 0.5 to 1 mm in diameter after 48 h incubation. *C. freneyi* strains are nonlipophilic. The basic biochemical profile (Table 3) is similar to that of *C. xerosis*. All *C. freneyi* strains studied so far exhibit α-glucosidase activity which is not frequently observed in other *Corynebacterium* species (very few *C. amycolatum* and all *C. xerosis* strains express this enzyme). *C. freneyi* can be further differentiated from *C. xerosis* by glucose fermentation at 42°C and growth at 20°C, whereas *C. xerosis* is negative for the latter two reactions. This species is also closely related to *C. hansenii*.

**C. glucuronolyticum**

*C. seminale* is a later synonym of *C. glucuronolyticum* (44, 45). This species is probably part of the genitourinary microbiome of males, while its presence in females is uncertain. Recoveries from blood cultures have been documented (84). Colonies are whitish-yellowish, convex, creamy, and 1 to 1.5 mm in diameter after 24 h. The fermentative species *C. glucuronolyticum* is remarkable for its variability in basic biochemical reactions (Table 3). It is the only medically relevant, large-colony *Corynebacterium* species exhibiting β-glucuronidase activity. When urease activity is present, it is abundant in Christensen's urea broth, becoming positive after only 5 min of incubation at room temperature (44). *C. glucuronolyticum* is also one of the very few corynebacteria which are able to hydrolyze esculin. All *C. glucuronolyticum* strains are CAMP reaction positive (Fig. 2). With the exception of strains which are alkaline phosphatase positive, the API Coryne strip identifies *C. glucuronolyticum* well (64), although profiles obtained from human strains may differ from animal isolates (45). Propionic acid is one of the major end products of glucose metabolism. *C. glucuronolyticum* strains are often tetracycline resistant and may also exhibit resistance to macrolides and lincosamides (81). 16S rRNA gene sequences derived from fluids of patients with prostatitis have been found to be homologous with sequences derived for this species, indicating that *C. glucuronolyticum* might be involved in selected cases of prostatitis (107).

**C. hansenii**

*C. hansenii*, a nonlipophilic species, exhibits yellow and dry colonies (108). Biochemical identification reactions are similar to those of *C. freneyi* and *C. xerosis*. However, *C. hansenii* can be distinguished from these species by being negative for alkaline phosphatase and α-glucosidase reactions. These three species are not well discerned by either 16S rRNA or partial *rpoB* gene sequencing but were found to represent different taxa by DNA-DNA hybridization (108).

**C. imitans**

*C. imitans* was originally isolated from a nasopharyngeal specimen of a child suspected of having throat diphtheria as well as from three adult contacts (109). This was the first well-documented case of the person-to-person transmission of a *Corynebacterium* other than *C. diptheriae* in a nonhospital setting. Additional strains of *C. imitans* have been recovered from blood cultures (84). Colonies are whitish-grayish, glistening with entire edges, creamy, and 1 to 2 mm in diameter. The strain did not produce a brown halo on Tisbury medium but was tellurite reductase positive. Interestingly, Neisser staining was positive for polar bodies.
Pyrazinamidase activity was weak only, as was fermentation of sucrose, which may lead to the initial misidentification as an atypical *C. diphtheriae* strain. It is not unlikely that *C. imitans* may have been misidentified as *C. minutissimum* in the past, since biochemical reactions of both taxa are similar (Table 3). However, *C. imitans* is CAMP reaction positive and does not hydrolyze tyrosine, whereas the opposite reactions are observed for *C. minutissimum*. The API Coryne system provided the numerical codes 1100325, 2100324, and 3100325 for *C. imitans*, indicating a negative α-glucosidase reaction, whereas all *C. diphtheriae* strains express this enzyme. *C. imitans* strains do not produce propionic acid as a fermentation product, unlike *C. diphtheriae* (84). Diphtheria toxin assay using the Elek test and assaying for tox gene by PCR were all negative for *C. imitans* strains (84, 109). *C. imitans* is resistant to O/129, while *C. diphtheriae* is not.

**C. jeikeium**

*C. jeikeium* is a frequently encountered *Corynebacterium* in clinical specimens (47). Nosocomial transmission has been described. The complete genome sequence of a *C. jeikeium* strain has been determined, indicating that the lipophilic phenotype of *C. jeikeium* originates from the absence of fatty acid synthase. *C. jeikeium* is often resistant to multiple antibiotics (including penicillin and gentamicin) (79, 110), but this cannot be used as a taxonomic characteristic because the phenotypically closely related *C. tuberculostearicum* may also demonstrate multidrug resistance. Quantitative DNA-DNA hybridization experiments had shown that *C. jeikeium* includes two genomospecies for which penicillin and gentamicin MICs are low, but as they could otherwise not be differentiated phenotypically from the resistant *C. jeikeium* strains, they were not proposed as independent species (111). Colonies of *C. jeikeium* are tiny, low, entire, and grayish white. *C. jeikeium* is a strict aerobe which may oxidatively produce acid from glucose and sometimes from maltose but not from fructose (C. *tuberculostearicum* is positive for acid production from fructose). The RapID CB Plus system correctly identifies *C. jeikeium*, as does the API Coryne system if ancillary tests are used (64, 66).

**C. kroppenstedtii**

*C. kroppenstedtii* (19), a rarely recovered species, was originally recovered from the sputum of a patient with pulmonary disease. Additional strains have been isolated from lung biopsy specimen, sputum, breast abscess, and patients with granulomatous lobular mastitis (84, 112). Colonies are grayish translucent, slightly dry, and less than 0.5 mm in diameter after 24 h of incubation at 37°C. *C. kroppenstedtii* is lipophilic and is one of the few medically relevant *Corynebacterium* species exhibiting esculinase activity. Other biochemical characteristics are given in Table 3. API codes of *C. kroppenstedtii* include 0101104, 2040104, and 2040105 (84). It can be separated from *C. durum*, *C. matruchotii*, and *C. glucuronolyticum* by colony and Gram stain morphologies and from *C. glucuronolyticum* by its negative CAMP reaction. The determination of the whole-genome sequence revealed that lipophilism is the dominant feature involved in the pathogenicity of *C. kroppenstedtii*.

**C. lipophiloflavum**

Initially, *C. lipophiloflavum* (113) was represented by only a single strain which had been isolated from vaginal discharge from a patient with bacterial vaginosis. Additional strains have now been described from blood cultures (Funke, unpublished). This species contains lipophilic strains, but the majority of strains are nonlipophilic (Funke, unpublished). The lipophilic strains have the same biochemical screening pattern as *C. urealyticum* except that they exhibit a strong yellow pigment and weaker urease activity and slowly produce acid from glucose (Table 3). In contrast to most *C. urealyticum* strains, the *C. lipophiloflavum* strains isolated were not multidrug resistant. The nonlipophilic strains have a biochemical profile similar to that of *C. falsenii* but do not ferment galactose and trehalose.

**C. macginleyi**

*C. macginleyi* (92) has almost exclusively been isolated from eye specimens, whether from diseased (43) or healthy conjunctiva, although extraocular infections have been occasionally reported. Colonies are typical for lipophilic corynebacteria (see above). *C. macginleyi* is one of the very few *Corynebacterium* species not expressing pyrazinamidase activity (Table 3). Most strains ferment mannitol, while the majority of other corynebacteria are unable to do so. The API Coryne system can correctly identify *C. macginleyi* (64). Strains belonging to this species are susceptible to a broad spectrum of antibiotics (43), but high-level fluoroquinolone resistance has been reported (114).

**C. massiliense**

*C. massiliense* was isolated from synovial fluid (115). It does not produce acid from any of the carbohydrates tested in the differentiation of true corynebacteria (Table 3), but its cell wall contained tuberculostearic acid.

**C. mastitidis-like organisms**

Bacteria recovered from ocular specimens (patients with cataracts, diabetic retinopathy, or dry eyes) were, by 16S rRNA gene sequencing, found to be closest to (98.2% identity) *C. mastitidis*, otherwise found to date to cause sheep mastitis. In contrast to *C. macginleyi*, these strains were sensitive to the fluoroquinolones (114). Description of two species nova involving these strains is under way (Bernard, unpublished).

**C. matruchotii**

*C. matruchotii* is thought to be a natural inhabitant of the oral cavity, particularly on calculus and plaque deposits, so it has been much studied by oral microbiologists (102). Otherwise, it is a very rare human pathogen. Microcolonies appear flat, filamentous, and spider-like, but macrocolonies have a variable appearance. *C. matruchotii* demonstrates a very unusual appearance by Gram staining in that so-called whip handles (i.e., filamentous bacteria with a single short bacillus adjacent to the end of the filament, creating the illusion of a whip) are observed (Fig. 1e). This microscopic presentation is consistent even when isolates which had been preserved for many years in a culture collection are stained. It has been demonstrated that heterogeneity existed among *C. matruchotii* strains obtained from international culture collections and that some strains represented were misidentified *C. durum* isolates (102). *C. matruchotii* strains are consistently negative for galactose, whereas *C. durum* strains can be positive. The API Coryne system database does not contain *C. matruchotii*, the numerical codes observed for *C. matruchotii* include 7000325, 7010325, and 7050325.

**C. matruchotii-like strain**

This taxon is represented by a single strain, ATCC 43833 (102). It had been deposited in ATCC as *C. matruchotii*,...
but it is a distinct species, as revealed by dot-blot hybridization and 16S rRNA gene sequencing data (Genbank accession no. AE260434). Colonies are pinpoint to 0.1 mm in diameter, grayish-white, with a smooth, nonadherent texture. Biochemical screening reactions are similar to those of C. minutissimum, except that strain ATCC 43833 exhibits esculinase activity in the API Coryne system, with an API Coryne code of 2140325.

**C. minutissimum**

C. minutissimum is part of human skin microbiome, and its historical association with erythrasma is highly questionable (47). Colonies of C. minutissimum are whitish-grayish, shiny, moist, convex, and circular, have entire edges, and are about 1 to 1.5 mm in diameter after 24 h. Most of the colonies are creamy, but some may also have a sticky consistency. C. minutissimum strains have a fermentative metabolism and produce acid from sucrose variably. Very few C. minutissimum strains are also able to produce acid from mannnitol. The API Coryne system identifies C. minutissimum, with additional tests being necessary for most strains (64). Many C. minutissimum strains are pyrrolidonyl arylamidase positive. C. minutissimum strains exhibit DNase activity, nearly all strains hydrolyze tyrosine, and a very few strains exhibit a positive CAMP reaction. Lactic and succinic acids are major end products of glucose metabolism. Some isolates possess TBSA in their cell membranes. Nearly all C. minutissimum strains are susceptible to O/129 (150 μg disk); i.e., they exhibit an inhibition zone around the disk (usually between 20 and 35 mm in diameter). Phylogenetically, C. minutissimum is closely related (>98.8% identity) to both C. singulare and C. aurimucosum by 16S rRNA gene sequencing, but these are readily discerned by partial rpoB gene sequence analysis.

**C. mucifaciens**

C. mucifaciens (116) has mainly been isolated from blood cultures and other sterile body fluids, but it has also been recovered from abscesses, soft tissue, and dialysate (84). Colonies are very distinct because they are slightly to overtly yellow and very mucoid (Fig. 3c) (with very few strains not being mucoid [Funke, unpublished]). C. mucifaciens is the only presently known Corynebacterium species exhibiting such mucoid colonies; this characteristic strongly reminds the bacteriologist of Rhodococcus equi colonies. An extracellular substance (probably polysaccharides) causing connective filaments between the cells has been demonstrated as the ultrastructural correlate of the mucoid colonies. Colonies are about 1 to 1.5 mm after 24 h of incubation and have entire edges. They appear less mucoid after extended incubation for 96 h. C. mucifaciens has an oxidative metabolism. It consistently produces acid from glucose, but acid production from sucrose is variable. The API Coryne numerical codes 2000004, 2000104, 2000105, 2100104, 2100105, 6000004, 6100104, and 6100105 have been observed for C. mucifaciens, suggesting that occasionally glucose oxidation may be too slow to be observed by that method. C. mucifaciens is enzymatically less active than R. equi which exhibits α- and β-glucosidase activities not observed for C. mucifaciens. In addition, C. mucifaciens produces acid from fructose and may produce acid from glyceral and mannose, but acid production from these sugars is not seen in R. equi strains. Tuberculoesteric acid can be detected in amounts of 1 to 2% of the total CFAs. β-Lactam antibiotics and aminoglycosides show very good activities against C. mucifaciens.

**C. pilbarensis**

The nonlipophilic species C. pilbarensis was isolated from an ankle aspirate of a male thought to be suffering from gout (117). It can be differentiated from C. striatum and C. simulans by being nitrate reduction negative and from C. minutissimum by not fermenting maltose. Phylogenetically, it is closest to (98.7 to 99.0% identity) C. ureidoglycans, C. corlea, C. afermentans, and C. mucifaciens but was discerned from those species by DNA-DNA hybridization and biochemically (Table 3) (117).

**C. propinquum**

C. propinquum is the closest phylogenetic relative of C. pseudodiphtheriticum (5, 6) and shares the same niche (i.e., the oropharynx) as C. pseudodiphtheriticum. Colonies are whitish and somewhat dryish with entire edges and are 1 to 2 mm in diameter after 24 h of incubation. This species reduces nitrate and hydrolyses tyrosine and was historically described as being unable to hydrolyze urea. However, a recent study demonstrated that some C. propinquum strains are able to produce urease (118). C. propinquum and C. pseudodiphtheriticum can be differentiated by either MALDI-TOF analysis or rpoB sequencing (118). The API Coryne system and the RapID CB Plus system may correctly identify C. propinquum strains if they do not hydrolyze urea.

**C. pseudodiphtheriticum**

C. pseudodiphtheriticum is part of the oropharyngeal microbiome. As described in Table 2, this species has been well documented to cause pneumonia in various patient populations, including an outbreak in cystic fibrosis patients (119). Colonies are whitish, slightly dry with entire edges, and 1 to 2 mm in diameter after 48 h of incubation. This nonfermenting species reduces nitrate and hydrolyzes urea but does not produce acid from any of the commonly tested carbohydrates (Table 3). Some strains hydrolyze tyrosine. C. pseudodiphtheriticum strains are susceptible to β-lactam antibiotics, but resistance to macrolides and lincosamides has been observed.

**C. pseudotuberculosis**

C. pseudotuberculosis is phylogenetically closest to C. ulcerans as well as to C. diphtheriae (5, 6) and so, like those species, may harbor the diphtheria toxin gene. It produces propionic acid as a fermentation product and its cell wall contains large amounts of the CFA C16:1ω7c (21). Colonies are yellowish white, opaque, convex, and about 1 mm in diameter after 24 h. Like C. ulcerans, C. pseudotuberculosis is positive for urease and the CAMP inhibition test (complete inhibition of the effect of S. aureus β-hemolysin on sheep erythrocytes is achieved by streaking the presumed C. pseudotuberculosis strain in a right angle toward S. aureus and incubating overnight; a β-hemolysin inhibition zone in the form of a triangle is observed, as is the case for A. haemolyticus [Fig. 2]). C. pseudotuberculosis is not susceptible to O/129 whereas C. ulcerans strains are. C. pseudotuberculosis is variable for both nitrate reduction and sucrose fermentation. The API Coryne system and the RapID CB Plus panel correctly identify this species (64, 66). Human disease to date has been acquired by handling of infected sheep.

**C. pyruviciproducens**

C. pyruviciproducens was independently isolated from a groin abscess (120) and a urethral swab (Funke, unpublished) as well as from urine, a bone biopsy specimen, synovial fluid, and a blood culture (K. Bernard, unpublished data). It was
initially believed to be a lipophilic variant of *C. glucuronolyticum*, which was β-glucuronidase and CAMP test positive. However, 16S rRNA gene sequence analysis, quantitative DNA-DNA reassociation, and partial rpoB gene sequence analysis clearly demonstrated that this species is distinct from *C. glucuronolyticum* (120).

**C. resistens**

*C. resistens* has entire, grayish-white, and glistening colonies and is lipophilic. It is unusual in having a negative pyrazinamidase reaction which separates it from the phenotypically related *C. jeikeium* or *C. tuberculostearicum*. In addition, *C. resistens* grows slowly under anaerobic conditions, whereas *C. jeikeium* is unable to do so. The *C. resistens* strains reported in the literature were resistant to penicillin, cephalosporins, aminoglycosides, clindamycin, and ciprofloxacin but remained susceptible to glycopeptides (121). It is presently unknown whether true *C. resistens* strains have been misidentified as *C. jeikeium* in the routine laboratory.

**C. riegelii**

*C. riegelii* strains were originally described as being isolated from females with urinary tract infections (122), but additional strains have been recovered from blood cultures, including cord blood (84). Colonies are whitish, glistening, and convex with entire margins and are up to 1.5 mm in diameter after 48 h of incubation. Some colonies are of a creamy consistency, whereas others are sticky. *C. riegelii* strains exhibit a very strong urease activity with Christensen’s urea broth, becoming positive within 5 min at room temperature after inoculation. A very peculiar characteristic of *C. riegelii* is the slow fermentation of maltose but not glucose. No other defined *Corynebacterium* exhibits this feature (Table 3). The weak anaerobic growth of *C. riegelii* corresponds to the weak fermentative metabolism. API Coryne system codes observed for *C. riegelii* include 0101224, 2001224, and 2101224.

**C. simulans**

*C. simulans* was originally delineated from some *C. striatum*-like strains (123). The three strains described in the original publication came from skin-related specimens (foot abscess, lymph node biopsy specimen, and boil). Additional strains have been characterized (84). Colonies of *C. simulans* (greyish-white, glistening, creamy, 1 to 2 mm in diameter) are very similar to *C. minutissimum*, *C. singularare*, and *C. striatum*, its closest phylogenetic neighbors. *C. simulans* is the only valid *Corynebacterium* species described to date which reduces nitrite. Further characteristics which separate *C. simulans* from the closely related nonlipophilic, fermentative corynebacteria are the inability to acidify ethylene glycol and to grow at 20°C (in contrast to *C. striatum*). API Coryne profiles include 0100305, 2100105, 2100301, 2100305, and 3000125 (including the falsely negative nitrate reduction reaction because of the strong nitrite reduction). Nitrate reductase-negative “*C. striatum*” strains should always raise the suspicion of *C. simulans*.

**C. singularare**

*C. singularare* colonies are circular and slightly convex with entire margins and are of a creamy consistency, as observed for *C. minutissimum* and *C. striatum* (124). Key biochemical reactions are like those for *C. minutissimum* except that urease activity is observed (Table 3). The numerical API Coryne system profile is 6101125, indicative that pyrrolidonyl arylamidase activity is observed. Like *C. minutissimum* and *C. striatum*, *C. singularare* also hydrolyzes tyrosine. *C. singularare* does not produce propionic acid as a fermentation product, differentiating it from *C. amycolatum*. Phylogenetically, this species is closely related (>98.8% identity) to both *C. aurimucosum* and *C. minutissimum* by 16S rRNA gene sequencing but can be readily discerned by partial rpoB gene sequence analysis.

**C. sputi**

*C. sputi* is the only true *Corynebacterium* expressing α-glucosidase activity and being positive for tuberculostearic acid (125). It can be differentiated from *C. ulcerans* by being positive for pyrazinamidase but negative for alkaline phosphatase and maltose fermentation. Unlike *C. ulcerans*, this species cannot harbor the bacteriophage which bears the diphtheria tox gene.

**C. stationis**

*C. stationis*, originally called *Brevibacterium stationis*, has recently been reassigned to the genus *Corynebacterium* (126). *B. stationis* ATCC 14403T was originally recovered from seawater, but subsequent studies found two human blood culture isolates plus “*C. ammoniagenes*” ATCC 6872, recovered from an infant’s stools, had formed a single taxon group now designated *C. stationis* comb. nov. Strains of *C. stationis* and *C. ammoniagenes* sensu stricto both demonstrate the ability to alkalize citrate, using either Simon’s citrate or a heavy (not light) inoculum in the citrate cupule found in an API 20E strip, a feature not previously associated with members of the genus *Corynebacterium*. Colonies of *C. stationis* grow well in 24 h, that is, they are not lipophilic, are yellow or yellowish, and are fermentative, being reactive with glucose, fructose, ribose, and mannose. All are positive for alkalization of citrate, produce urease, reduce nitrate, and hydrolyze tyrosine, with other features shown in Table 3. API Coryne codes generated were 1001304 and 3001304 (that is, the enzyme PYZ is variably detected). Strains of this species were susceptible to all antimicrobials, except one blood culture isolate was resistant to erythromycin.

**C. striatum**

*C. striatum* is part of the human skin microbiome. Nosocomial transmission or outbreaks of *C. striatum* have been documented (127, 128). Colonies are convex, circular, shiny, moist, and creamy, have entire edges, and are about 1 to 1.5 mm in diameter after 24 h of incubation. Some investigators have described *C. striatum* colonies as being somewhat like those of small coagulase-negative staphylococci. *C. striatum* has a fermentative metabolism, and acid production from sucrose is variable. The API Coryne system identifies *C. striatum*, but additional tests are needed in most of the cases (64). All *C. striatum* strains hydrolyze tyrosine, and some strains are CAMP reaction positive; however, the CAMP reaction of *C. striatum* strains is usually not as strong as that of other CAMP test-positive species (e.g., *C. aers* or *C. glucuronolyticum*). Lactic and succinic acids are the major end products of glucose metabolism. All *C. striatum* strains are susceptible to O/129. Resistance to macrolides and lincosamides due to the presence of an rRNA methylase has been described. *C. striatum* may also be resistant to quinolones and tetracyclines (79, 110), which has led to a renewed interest in this agent as an emerging pathogen.

**C. sundsvallense**

*C. sundsvallense* (84, 129) has been isolated from blood cultures, a vaginal swab, and sinus drainage from an infected
Coryneform Gram-Positive Rods

C. thomssenii

C. thomssenii (130) is a rarely found species, originally repeatedly isolated from a patient with pleural effusion and a second strain recovered from the environment in Canada (84). This species is fastidious and slowly growing, resulting in colonies <0.5 mm after 48 h, but it is not lipophilic. After 96 h, colonies are molar tooth-like, very sticky, and slightly adherent to agar. The clinical strain of C. thomssenii is the only Corynebacterium species expressing N-acetyl-β-glucosaminidase activity, which can be observed either in the API Coryne or API ZYM systems. Acid is slowly and fermentatively produced from glucose, maltose, and sucrose, and the resulting API Coryne code for C. thomssenii is 2121125.

C. timonense

C. timonense was isolated from blood cultures of a patient with endocarditis. Its most peculiar feature is a weakly positive esculinase reaction. It can be differentiated from other esculinase-positive corynebacteria by having negative reactions for maltose and sucrose fermentation as well as a negative CAMP reaction (115).

C. tuberculostearicum

C. tuberculostearicum was revived for a never validly published taxon and also included a strain of the unvalidated species "C. pseudogenitalium" (131). Nearly all "CDC group O" bacteria can be assigned to C. tuberculostearicum (K. A. Bernard and G. Funke, unpublished data). Unfortunately, the effective publication on C. tuberculostearicum did not include any strains of CDC group G bacteria (131). Recently, a comprehensive study on 18 C. tuberculostearicum strains has been published (132). C. tuberculostearicum has some variable biochemical key reactions and can be differentiated from C. accolens if TBSA is detected as one of its CFAs. It can be separated from C. jeikeium by anaerobic growth and fermentative acid production from fructose. C. tuberculostearicum can be multidrug resistant, but the most frequently observed resistance is to macrolides and lincosamides.

C. tuscaniense

C. tuscaniense has been isolated from blood cultures of a patient suffering from endocarditis. C. tuscaniense does not grow under anaerobic conditions, which distinguishes this species from the phenotypically similar C. minutissimum. In addition, C. tuscaniense hydrolyzes hippurate but not tryptophane, whereas C. minutissimum has opposite reactions (Table 3). C. tuscaniense colonies are rounded and regular, in contrast to the biochemically similar C. amycolatum colonies, which exhibit irregular edges (133).

C. ulcerans

Phylogenetically, C. ulcerans (134) is closely related to C. pseudotuberculosis, and both species are the closest relatives to C. diphtheriae (5, 6). As described previously, C. ulcerans can harbor the diphtheria toxin gene, but differences in the receptor-binding and translocation domains have been described, so C. ulcerans diphtheria toxin-specific PCR has been developed for conventional (135) or real-time PCR. Pharyngitis associated with this bacterium is rare but, if recovered from pseudomembranous material, must be treated like a case of diphtheria (59, 61). Recent reports have described the transmission of C. ulcerans from companion pets to humans (49), so expanded national case definitions for diphtheria-like disease, which includes cases involving toxigenic strains of C. ulcerans or C. pseudotuberculosis, have formally occurred in some countries. C. ulcerans colonies are somewhat dry, waxy, and gray-white, with light hemolysis, and are 1 to 2 mm in diameter after 24 h. C. ulcerans may be differentiated from C. diphtheriae by urease activity and a CAMP inhibition reaction and from C. pseudotuberculosis by source, biochemically, and by partial rpoB gene but not 16S rRNA gene sequencing. Strains of C. ulcerans are positive for glycogen, starch, and trehalose fermentation. The API Coryne system and the RapID CB Plus identification strip correctly identify C. ulcerans (64, 66).

C. urealyticum

C. urealyticum is strongly associated with urinary tract infections. Recovery of this bacterium is often associated with urine with an alkaline pH, resulting in struvite crystals. As for all other lipophilic corynebacteria, colonies are pinpoint, convex, smooth, and whitish-grayish on regular SBA. C. urealyticum is a strict aerobe and has very strong urease activity (Table 3). Commercial identification systems correctly identify C. urealyticum. C. urealyticum is almost always multidrug resistant (47, 79, 136). Sequencing of the whole C. urealyticum genome indicated that the multidrug resistance is mediated by transposable elements.

C. ureicelerivorans

The lipophilic species C. ureicelerivorans first described from a blood culture has very strong and rapidly detected (~60 s) urease activity as its most prominent feature (137). Subsequently, recovery of this organism from ascites and multiple blood cultures from immunocompromised patients or those with digestive disorders has been described (138). It can be differentiated from CDC group F-1 bacteria by a positive alkaline phosphatase reaction and having negative reactions for acid production from maltose and sucrose. By 16S rRNA and partial rpoB gene sequencing, this species is closest to C. mucificiens; C. ureicelerivorans can be readily discerned from that species by having a smooth rather than mucoid yellowish colony as well as by observation of rapid urease activity.

C. xerosis

Colonies of C. xerosis are dry, granular, and yellowish with irregular edges and are of 1 to 1.5 mm in diameter after 24 h. It must be emphasized that nearly all "C. xerosis" strains which have been described in the literature before the mid-1990s may have been misidentified C. amycolatum strains (80). C. striatum strains were also misidentified as C. xerosis in the past. C. xerosis has a fermentative metabolism, is variable for the presence of nitrate reductase, but always expresses α-glucosidase as well as leucine arylamidase activities. Because C. xerosis was thought to be rarely encountered in clinical specimens, it was not included in the API Coryne system version 3.0 database. The numerical profiles observed for C. xerosis strains, such as 2110325 and 3110325, provide,
using API Web, responses including “C. striatum/C. amycolatum.” Lactic acid is the major end product of glucose metabolism, and strains are susceptible to O/I29. As described previously, C. xenos is phylogenetically closely related to C. freneyi and C. hansenii (108), so if definitive identification is required, characterization must include genetic testing.

Genus Turicella

*T. otitidis* is almost exclusively isolated from clinical specimens from the ear region, but it does not cause otitis media with effusion in children (42). Colonies are whitish, convex, and creamy with entire edges and are 1 to 1.5 mm in diameter after 48 h of incubation. Some young colonies show a greenish appearance when taken away from the plates with a swab. The distinctive Gram stain morphology seems to be a normal commensal in humans and appears to be the most frequently isolated *Arthrobacter* species in human clinical specimens (24, 46), and *A. oxydans* is the second most frequently encountered species (24). *Arthrobacter* colonies are usually whitish-grayish, slightly glistening, creamy, and 2 mm or greater in diameter after 24 h. *A. cumminsi* may also exhibit a sticky consistency (46). *Arthrobacter* spp. usually do not oxidize any of the carbohydrates routinely tested and do not express a cheese-like smell, as often found for the phenotypically closely related brevibacteria. Some arthrobacters are motile, whereas brevibacteria are always nonmotile. Like brevibacteria, *Arthrobacter* spp. express DNase and have gelatinase activity (9). The identification of arthrobacters on the species level might be achieved by carbohydrate utilization tests, but this is recommended for the reference laboratory only. *A. albus* (140) is phylogenetically most closely related to *A. cumminsi* but might be differentiated phenotypically by being resistant to desferroxamine, whereas *A. cumminsi* is susceptible. *A. cumminsi* has a distinctive CFA pattern with C14:0 and C16:0, each representing 2 to 4% of all CFAs (9). Penicillin MICs for most *Arthrobacter* strains are low, with quinolones showing only weak activities against *Arthrobacter* spp. (9, 24).

Genus Brevibacterium

Some *Brevibacterium* spp. are part of the human skin microbiome. Colonies are whitish-grayish (or yellowish like *B. luteolatum*), convex, mostly creamy, and 2 mm or greater in diameter after 24 h. *B. mbieleneri* colonies have a more granular appearance and are drier than those of other brevibacteria. Some brevibacteria may develop a yellowish or greenish pigment after prolonged incubation. Many *Brevibacterium* strains isolated from human clinical material give off a distinctive cheese-like odor. Brevibacteria are nonmotile, are halotolerant (6.5% NaCl), and form methanethiol from methionine, but this test is specific for brevibacteria only when it is read within 2 h (25). Brevibacteria can be differentiated from the species level by carbohydrate utilization tests. More than 80% of all clinical *Brevibacterium* isolates are *B. casei* (25). *B. sanguinis* is very similar to *B. casei* and can be differentiated from this species by susceptibility to thallium acetate. The MICs of β-lactam antibiotics for brevibacteria are often elevated (81).

Genus Dermabacter

*D. hominis* strains are part of the human skin microbiome. Colonies are whitish, convex, of a creamy or sticky consistency, and 1 to 1.5 mm in diameter after 48 h (Fig. 3e). *D. hominis* strains are sometimes mistaken for small-colony coagulase-negative staphylococci. The Gram staining result is distinctive, with cococcabacillary or coccoidal forms (Fig. 1c). The key biochemical reactions are given in Table 4. *D. hominis* is one of the few coryneform bacteria with a variable reaction for xylose fermentation. It is the only catalase-positive coryneform bacterium (except *Actinomyces neuii*) that is able to decarboxylate lysine and ornithine (141). The API Coryne system and the RapID CB Plus panel correctly identify this species (64, 66). *D. hominis* strains may be resistant to aminoglycosides (60, 81).

Genus Helcocobacillus

The genus *Helcocobacillus* contains one species, *H. massiliensis*, which by phenotypic testing, resembles *D. hominis*. However, when using substrates found in the API Coryne or API 50CH panel, *H. massiliensis* can be differentiated from *D. hominis* by several key reactions, including being able to ferment erythritol, arabinose, xylose, inositol, and mannitol and reduce nitrate (27).

Genus Rothia

The genus *Rothia* presently comprises six validly named species, three of which are deemed to be clinically relevant: *R. mucilaginosus* (formerly designated *Stomatococcus mucilaginosus*) (10); *R. dentocariosa*, as emended by Daneshvar et al. (86); and *R. aeria*, initially recovered from the environment (11), which has been recovered from a variety of clinical materials (142). Some strains formerly designated as CDC coryneform group 4 (Fig. 3h) have been shown to representatives of *R. dentocariosa* (86). These grayish-black pigmented strains were isolated primarily from respiratory materials, pus, or blood cultures (Fig. 3h), in contrast to blackish pigmented *C. aurimucosum* strains derived from the female urogenital tract (Fig. 3g).

Colonies of *R. dentocariosa* are typically whitish (or more rarely grayish-black), raised, smooth or rough, or have a “spoke-wheel” form (Fig. 3f), and they are up to 2 mm in diameter after 48 h. *Rothia* strains usually grow slightly better in a CO2-enriched atmosphere. The biochemical features of *R. dentocariosa* are given in Table 4. The API Coryne system correctly identifies *R. dentocariosa* (64). Its CFA composition is of the branched-chain type (15), which allows differentiation from the biochemically similar species *C. durrum*, *C. mucrochiti*, and *Actinomyces viscosus* (chapter 52), all of which also occupy the oropharynx. *R. dentocariosa* may also be confused with *D. hominis* and *Propionibacterium avidum* (chapter 52) (143), both of which, in contrast, always exhibit smooth colonies. As shown in a study on the pharyngeal bacterial flora of healthy adults, one-third of all *R. dentocariosa* strains isolated were negative for the key biochemical reaction, catalase (41). The MICs of aminoglyco-
cosides for some R. dentocariosa strains are elevated, whereas penicillins usually show good in vitro activities against Rothia strains. It may be difficult to achieve acceptable growth while performing antimicrobial susceptibility testing on R. dentocariosa strains which are overly sticky or grow poorly in air.

**Genus Exiguobacterium**

It is not known whether exiguobacteria are part of the indigenous bacterial flora of humans. Colonies of *E. acetylicum* are smooth, golden-yellow to orange, and up to 2 mm in diameter after 24 h of incubation. Oxidase is positive, and acid from carbohydrates, except for xylose, is rapidly produced by fermentative metabolism. Exiguobacteria are motile. They might be confused with microbacteria, but CFA and phylogenetic analyses provide a clear-cut distinction between the two genera (Table 1). The pathogenic potential of *E. acetylicum* seems to be rather low; this species has been isolated from different sources (e.g., skin, wounds, and cerebrospinal fluid) (63). Cases of pseudobacteremia due to *E. acetylicum* have been observed. Six *E. aurantiacum* strains isolated from blood cultures had been received by a National Reference Center over a 10-year period, which, although biochemically similar to *E. acetylicum*, are oxidase negative and positive or variably positive for DNase and xylase, with strains being susceptible to all drug classes as tested by E-test (bioMérieux) (144).

**Genus Oerskia**

*O. turbata*, a very rare human pathogen, is usually acquired from the environment (e.g., soil). Colonies are pale yellow to phosphorous yellow, convex, and creamy; they penetrate into the agar (“substrate hyphae”); and they are approximately 1 to 2 mm in diameter after 24 h. *O. turbata* rapidly produces acid from sugars by fermentation; it also exhibits a very strong esculin reaction. The genus is identified by the API Coryne system (64). *O. turbata* liquefies gelatin but is able to hydrolyze xanthine and hypoxanthine. In contrast, the related *Cellulomonas cellulans* (below) does not liquefy gelatin but is able to hydrolyze xanthine and hypoxanthine (15).

**Genus Cellulomonas**

*Cellulomonas* strains are usually acquired from the environment. Colonies are first whitish or pale or bright yellow, but after 7 days, nearly all *Cellulomonas* strains are somewhat yellow. Colonies vary between 0.5 and 1.5 mm in diameter after 24 h, are convex and creamy, and have entire edges but do not demonstrate substrate hyphae (29). *Cellulomonas* spp. are variable for the fermentation of mannitol. Other key biochemical reactions are given in Table 4. The majority of *Cellulomonas* strains express cellulase activity, as demonstrated by incubating a heavy bacterial suspension (McFarland no. 6 standard) with a piece of sterile copy paper in a 0.9% NaCl solution for 10 days, resulting in dissolution of the paper (13). Medically relevant species *C. denverensis* can be differentiated from *C. hominis* by its positive reaction for D-sorbitol fermentation (29).

**Genus Cellulosimicrobium**

Colonies of *C. cellulans* are similar to *O. turbata* (see above) and also pit the agar. In addition, *C. cellulans* exhibits a biochemical screening profile which is very similar to that of *O. turbata* (Table 4). However, *C. cellulans* hydrolyzes either xanthine or hypoxanthine, whereas *O. turbata* does not, and *O. turbata* strains might be motile, whereas *C. cellulans* strains are not (63). *C. funkei* strains can be differentiated from *C. cellulans* (formerly *O. xanthineolytica*) by their negative inulin and raffinose fermentation reactions (15); in addition, *C. funkei* strains are motile but *C. cellulans* strains are not.

**Genus Microbacterium**

Microbacteria account for the majority of yellow-pigmented coryneform bacteria isolated from clinical specimens. All shades of yellow pigment are observed, ranging from pale to bright yellow and orange. Most of the strains are catalase positive, but catalase-negative strains might be observed. Some microbacteria grow under anaerobic conditions but only weakly. Motility is variable. Some microbacteria are nitrate reductase negative, which separates them from the phenotypically closely related genus *Cellulomonas*, where all presently defined species are nitrate reductase positive (Table 4). Microbacteria may ferment mannitol and xylose. In contrast, no *Cellulomonas* strain was observed to ferment mannitol and all fermented xylose.

Species identification is almost impossible by phenotypic analysis alone since the type strain is the only representative for many defined *Microbacterium* species, preventing the creation of a comprehensive database. Final identification to the species level is best achieved by molecular investigations (e.g., using 16S rRNA gene sequencing). The most frequently isolated, validated microbacteria in clinical specimens include *M. oxydans*, *M. paraoxydans*, and *M. foliorum* (31).

Microbacteria are usually susceptible to meropenem, linezolid, doxycycline, and vancomycin (except *M. resistens*, which is resistant to vancomycin but susceptible to teicoplanin) (145), but susceptibility to other antimicrobial agents is unpredictable and, therefore, every individual clinically significant strain must be tested (31, 146).

**Genus Curtobacterium**

Curtobacteria are very infrequently isolated yellow- or yellow-orange-pigmented oxidative coryneform bacteria. In contrast to most microbacteria, they produce acid from carbohydrates very slowly (within 4 to 7 days) (34). Curtobacteria are usually nitrate reductase negative but strongly hydrolyze esculin (Table 4). Again, the differentiation of curtobacteria is very difficult and should only be performed in a reference laboratory using primarily molecular methods. The MICs of macrolides and rifampin for curtobacteria are very low.

**Genus Leifsonia**

*Leifsonia aquatica* is very rarely encountered in clinical specimens. It is always motile, does not hydrolyze either gelatin or casein, and has a stronger DNase activity than most microbacteria (32). *L. aquatica* is the only species within the genus *Leifsonia* which is able to grow in broth enriched with 5% NaCl (35). Its yellow pigment develops relatively slowly within 3 to 4 days. The MICs of vancomycin for some *L. aquatica* strains were shown to be elevated (8 μg/ml) (32), but the precise mechanism of this resistance is not known.

**Genera Janibacter, Pseudoclavibacter (Zimmermannella), Brachybacterium, and Knoellia**

Strains belonging to the genera *Janibacter*, *Pseudoclavibacter (Zimmermannella)*, *Brachybacterium*, and *Knoellia* have been derived from the environment, foods, or animals but also have been recovered recently from clinical materials and
characterized using 16S rRNA gene sequencing. These taxa were described as having white, creamy, or yellowish pigment and all were nonmotile. *Janibacter, Pseudoclasticibacter* (later synonym *Zimmermannella*), and *Klosteria* were oxidative, and *Brachybacterium* strains were fermentative. All strains tested so far were susceptible to vancomycin. Since no comprehensive biochemical data based on a large number of strains are available at present, these genera were not included in Table 4.

**Genera Arcanobacterium and Trueperella**

The three medically relevant species *A. haemolyticum*, *T. pyogenes*, and *T. bernardiae* are all catalase negative and exhibit beta-hemolysis on SBA. All species show a fermentative glucose metabolism, with succinic and lactic acids as their major end products. All grow and express hemolysis best in a CO₂-enriched atmosphere.

The colonies of the type species, *A. haemolyticum*, are 0.5 mm in diameter after 48 h of incubation at 37°C. The biochemical reactions of *A. haemolyticum* are given in Table 4. Of major value for the identification of *A. haemolyticum* is the so-called CAMP inhibition test (see the description of the CAMP inhibition test in the section on *C. pseudotuberculosis* (Fig. 2). The protein responsible for this phenomenon is a phospholipase D excreted by *A. haemolyticum*, and this protein is genetically and functionally similar to the ones expressed by *C. ulcerans* and *C. pseudotuberculosis*.

*A. haemolyticum* and the two other medically relevant arcanobacteria are correctly identified by the API Coryne system (64).

*T. pyogenes* colonies are the largest of all former arcanobacteria, with diameters of up to 1 mm after 48 h of incubation. Of all the previous arcanobacteria, this species also shows the sharpest zone of beta-hemolysis on SBA. The protein responsible for hemolysis, named pyolysin, is also an important virulence factor in vivo. Gram stains may show some branching rods. *T. pyogenes* is the only *Arcanobacterium/Trueperella* species of medical relevance that expresses β-glucuronidase activity and that is capable of fermenting xylose.

*T. bernardiae* (40, 147) shows glasy, whitish colonies of <0.5 mm in diameter after 48 h. Some colonies have a creamy consistency, whereas others are sticky. Gram staining shows relatively short rods without branching. Most *T. bernardiae* strains belong to the very few coryneform bacteria that are able to ferment glycogen. Another peculiar feature of *T. bernardiae* strains is their ability to produce acid faster from maltose than from glucose.

The MICs of all β-lactams, rifampin, and tetracycline for *A. haemolyticum* and *Trueperella* spp. are very low, whereas aminoglycosides and quinolones have reduced activities (Funke, unpublished). Macrolides also exhibit excellent activities and are an alternative to β-lactam antibiotics for the treatment of infections. Treatment failures due to β-lactam antibiotics because of the inability of β-lactam antibiotics to act intracellularly have been reported.

**Typing Systems**

Outbreaks of *C. diphtheriae* in the states of the former Soviet Union and other locations have been studied by whole-cell ribotyping, pulsed-field gel electrophoresis, PCR–single-strand conformation polymorphism, analysis of tox and dtxR as well as of the 16S-23S rRNA spacer region, amplified fragment length polymorphisms, random amplification of polymorphic DNA, and multilocus enzyme electrophoresis (148, 149). An international database for *C. diphtheriae* ribotypes using endonuclease BstEII has been established (150). Ribotyping is regarded as being highly discriminatory and, based on a comprehensive comparison of methods, was found to be a preferred typing method for *C. diphtheriae* (149). Other methods, including a spoligotyping system (similar to the spacer oligonucleotide typing for *Mycobacterium tuberculosis*), have been described (151). Sequencing studies with *C. diphtheriae* strains from the epidemic in the former Soviet Union have shown that point mutations within the tox gene were silent mutations, whereas multiple-point mutations (which even led to amino acid substitutions) were observed for the dtxR gene, corresponding to the heterogeneity of outbreak strains as revealed by PCR–single-strand conformation polymorphism, analysis (152). Isolates derived from specific populations in the United States and Canada and characterized using multilocus enzyme electrophoresis, ribotyping, and random amplification of polymorphic DNA were found to be members of persistent endemic strains, rather than being imported from other countries where diphtheria is endemic. A standardized multilocus sequence typing method based on analysis of short sequences derived from seven housekeeping alleles has been developed (153). The technical simplicity of this approach and the ease of comparison of strain data internationally have made this a useful typing method (50). The multilocus sequence typing technique has also been effectively applied to an outbreak investigation involving *C. maginleyi* and *C. masnidiis*-like isolates (114).

Typing methods have occasionally been developed for taxa other than *Corynebacterium* species. Pulsed-field gel electrophoresis has been used to study clinical isolates of *A. haemolyticum* (154).

**SEROLOGIC TESTS**

Detection of antibodies directed against diphtheria toxin is the only established serologic test for coryneform bacteria. Toxin neutralization assays using Vero cell culture system have mainly been replaced by enzyme immune assays. Levels of ≥0.1 IU/ml serum are thought to confer protection, whereas levels of <0.01 IU/ml indicate a susceptible host (149). Other methods, including PCR–single-strand conformation polymorphism, analysis of tox and dtxR, have been developed (150). Booster doses of toxoid should be administered at 10-year intervals.

**Antimicrobial Susceptibilities**

The susceptibility patterns for each taxon were given with the descriptions of each taxon (see above). Since the antimicrobial susceptibility of coryneform bacteria is not predictable in every case, susceptibility testing should always be performed with clinically significant isolates (see "Clinical Significance" above). Due to the emergence of vancomycin-resistant Gram-positive organisms, it has become inappropriate to recommend glycopeptides as first-line drugs for the treatment of infections caused by coryneform bacteria. It is also noteworthy that some coryneform bacteria (e.g., *Microbacterium resistens*) are intrinsically vancomycin resistant.
The Clinical Laboratory Standards Institute has published testing conditions and interpretive criteria for susceptibility testing of coryneform bacteria using a broth microdilution method (156). Direct colony suspensions equivalent to a 0.5 McFarland standard are prepared, and strains are incubated in cation-adjusted Mueller-Hinton broth with 2 to 5% vol/vol lysed horse blood at 35°C in ambient air for up to 48 h. Interpretative categories for the MICs obtained are presently available for 16 antimicrobial agents. In summary, using the broth microdilution method, it has been recently established that multidrug resistance was found for four or more drug classes (out of 16 classes tested) for some or most strains of C. amycolatum, C. jeikeium, C. urealyticum, C. resistent, C. tuberculostearicum, and C. striatum as well as representatives of C. afermentans and C. aurimucosum found in one national culture collection (C. Singh, T. Burdz, and K. Bernard, unpublished data). Very few studies have been performed comparing broth microdilution and disk diffusion results for susceptibility testing of coryneform bacteria (157).

In the past, MICs have been determined by either the E-test or the agar dilution or broth microdilution method. The results of the E-test have been shown to correlate reasonably well with those of both the broth microdilution and the agar dilution methods for Corynebacterium spp. (158, 159). The E-test should be carried out on Mueller-Hinton agar supplemented with 5% sheep blood.

**APPENDIX**

**Genus Gardnerella**

G. vaginalis does not have a particular phylogenetic relationship to any of the established genera described in this chapter. It is remotely related to the genus Bifidobacterium, and these genera share some important features, such as production of acetic and lactic acids as fermentation products. G. vaginalis is the only species belonging to the genus Gardnerella. Studies on the ultrastructure of the cell wall of G. vaginalis have demonstrated that it has a cell wall similar to but much thinner than the cell walls of other Gram-positive bacteria (i.e., there is a smaller peptidoglycan layer) (160). Lysine is the diamino acid of the cell wall, and CFAs are similar to those detected in Actinomyces spp., Arcanobacterium spp., Traubergella spp., and Corynebacterium spp., with C16:0 and C18:1ω9c predominating. The G+C content of 42 to 44 mol% is lower than that of every other genus described in this chapter.

Gram stains show thin Gram-variable rods or cocccobacilli (Fig. 1d). Catalase is not produced, and cells are nonmotile and have a slow fermentative metabolism.

**Epidemiology and Transmission**

G. vaginalis can be found in the anorectal microbiome of healthy adults of both sexes as well as that of children (161). It is also part of the endogenous vaginal flora in women of reproductive age. The optimal pH for the growth of G. vaginalis is between 6 and 7, i.e., at elevated pH in the vagina. The organism can also be recovered from the urethras of the male partners of women with bacterial vaginosis (BV) (161).

**Clinical Significance**

G. vaginalis is associated with BV. Its causative role in the syndrome is controversial (162, 163) as it is certainly not the sole cause; other bacteria like Atopobium vaginae, Lepotrichia/Sneathia, and Megaspheera-like bacterium are also involved in BV (164, 165). Recurrent BV is due to reinfection rather than to relapse (i.e., overgrowth of the previously colonizing biotype). In pregnant women, BV may lead to preterm birth, premature rupture of membranes, and chorioamnionitis (161). G. vaginalis may also be recovered from cultures of blood from patients with postpartum or postabortal fever and may also cause infections in newborns. Although it might be recovered from the urethras of males, its disease association in males is usually questionable. Cases involving serious infections (septicemia, wound infections) in sites other than those associated with the genital tract or obstetrics are very rare but have been reported, including in men (166).

**Collection, Transport, and Storage of Specimens**

Vaginal and extravaginal specimens can be collected with cotton-tipped swabs. It is best to take one swab for direct examination and to take another swab for culture if necessary, such as for epidemiologic studies. If culture media cannot be directly inoculated, then the swab should be placed in a transport medium (e.g., Amies) and culture should be done within 24 h. It is noteworthy that G. vaginalis is susceptible to sodium polyanethol sulfonate (SFS), so an SFS-free medium (or an SFS medium supplemented with gelatin) should be used to achieve optimal recovery of G. vaginalis from blood culture systems whenever G. vaginalis is suspected.

**Direct Examination, Isolation, and Identification**

The gold standard for the diagnosis of BV is direct examination of vaginal secretions and not the culture of G. vaginalis, since G. vaginalis can also be recovered from healthy women. A bedside test for BV is examination of the vaginal discharge to detect the typical “fishy” trimethylamine odor which is enhanced after alkalization with 10% KOH (but G. vaginalis is not responsible for the amine production). The typical smear of vaginal discharge from BV patients shows “clue cells” (bacteria covering epithelial cell margins) together with mixed flora consisting of large numbers of Gram-negative (predominantly Prevotella spp.) and Gram-variable (G. vaginalis) rods and cocccobacilli, whereas lactobacilli are almost always absent. It is recommended
that a standardized Gram staining interpretative scheme be used to improve the reproducibility of this method (163, 167). Although not recommended for routine laboratory procedures, the isolation of G. vaginalis can support the diagnosis of BV. Vaginal swabs are cultured on Vaginalis agar (see chapter 19 for the preparation) and should be semiquantitatively streaked out with a loop. Incubation is at 35 to 37°C in a 5% CO₂-enriched atmosphere or in a candle jar. Slight beta-hemolysis is observed on human or rabbit blood-containing media but not on SBA (on which G. vaginalis can also grow, exhibiting alpha-hemolysis). Plates may be checked for the growth of diffuse beta-hemolytic colonies of <0.5 mm in diameter after 24 h, but very often, G. vaginalis is best observed after 48 h. Gram staining of the suspected colonies confirms the diagnosis of G. vaginalis.

G. vaginalis strains are consistently α-glucosidase, starch hydrolysis, and prolīne aminopeptidase positive, but only 90% of all G. vaginalis strains hydrolyze hippurate. Both the API Stript and API Coryne systems identify G. vaginalis well (64). Confirmation of the identification of G. vaginalis can also be achieved by antimicrobial agent disk inhibition tests with 50 μg of metronidazole (inhibition present), 5 μg of trimethoprim (inhibition present), and 1 mg of sulfonamide (inhibition absent).

Antimicrobial Susceptibilities

Metronidazole is the drug of choice both for local therapy of BV and for systemic therapy of extravaginal infections caused by BV-associated flora. Systemic infections due to BV should be semiquantitatively streaked out with a loop. Incubation is best observed after 48 h. Gram staining of the suspected colonies confirms the diagnosis of G. vaginalis.

G. vaginalis strains are consistently α-glucosidase, starch hydrolysis, and prolīne aminopeptidase positive, but only 90% of all G. vaginalis strains hydrolyze hippurate. Both the API Stript and API Coryne systems identify G. vaginalis well (64). Confirmation of the identification of G. vaginalis can also be achieved by antimicrobial agent disk inhibition tests with 50 μg of metronidazole (inhibition present), 5 μg of trimethoprim (inhibition present), and 1 mg of sulfonamide (inhibition absent).

28. Coryneform Gram-Positive Rods

**Nocardia, Rhodococcus, Gordonia, Actinomadura, Streptomyces, and Other Aerobic Actinomycetes**

PATRICIA S. CONVILLE AND FRANK G. WITEBSKY

**TAXONOMY**

The word "actinomycete" is derived from two Greek roots (actin- and -mycete) meaning "ray" (and hence also "rod") and "fungus," respectively. The anaerobic organisms now in the genus Actinomyces and the aerobic organisms grouped together as the "aerobic actinomycetes" were previously presumed to be related to one another on the basis of shared features of microscopic and colonial morphology. The aerobic actinomycetes, a group for which no agreed-upon operational definition currently exists, are now known to be an evolutionarily heterogeneous assemblage of genera. At some stage, they all form Gram-positive rods, and most of the more commonly isolated species exhibit at least rudimentary branching under certain growth conditions; all grow better under aerobic than anaerobic conditions, a feature distinguishing them from most organisms in the genus Actinomyces. Figure 1 shows the current classification of genera included in this chapter according to the List of Prokaryotic Names with Standing in Nomenclature (LPSN http://www.bacterio.net/).

The organisms containing mycolic acids in their cell walls (included in the genera Dietzia, Gordonia, Nocardia, Rhodococcus, Segniliparus, Tsukamurella, and Williamsia) are rather closely related on the basis of molecular genetic studies (1, 2); these mycolic-acid-containing genera appear phylogenetically more closely related to the genera Corynebacterium and Mycobacterium (both of which are sometimes considered aerobic actinomycetes) than to the other nonmycolic-acid-containing genera usually also included with the aerobic actinomycetes. According to a recent classification scheme, these seven genera of actinomycetes, along with the genera Corynebacterium and Mycobacterium, are classified together in the suborder Corynebacterineae (LPSN). Note in Fig. 1 that the genera in the suborder Corynebacterineae are at least weakly acid fast, with the exception of Corynebacterium, Williamsia, and possibly Dietzia.

The number of recognized pathogenic species of aerobic actinomycetes has been rising rapidly. With the exception of the genus Kroppenstedtia (see below), only genera containing species of documented clinical significance are dealt with in this chapter. Unfortunately, the increasingly fine discrimination of species has made it difficult to delineate important species-specific differences in geographic distributions, pathogenic and other biological mechanisms, disease associations, and antimicrobial susceptibility patterns. This enormous proliferation of distinct species for which association with human disease has been claimed presents several problems for the clinical microbiologist. First, phenotypic testing has been rendered virtually useless for accurate discrimination among species. Particularly for the aerobic actinomycetes, the number of phenotypic tests available in clinical laboratories (and in most research laboratories) is far too small for accurate differentiation among so many species, and often, information on the percent positivity for a specific reaction in a given species is not known. Furthermore, precisely the same biochemical testing format has generally not been employed with isolates of all the species, making the usefulness of multistudy comparisons uncertain. Second, some types of testing, such as analysis of cell wall constituents and of whole-cell sugars, are available in only a few research settings and are rarely of use for species-level identification. Some general information regarding these features is provided herein, but the references should be consulted for performance procedures and additional details. Third, only gene sequencing is currently adequately discriminatory, reproducible, and sufficiently available to be useful for precise species identifications in clinical laboratories. Fourth, because of the growing problems with accurate species determinations, the clinical literature is rife with erroneous identifications; nowhere is this problem more apparent than with organisms in the genus Nocardia. Additionally, as some species have been described on the basis of only a single isolate, and for others only a few reports exist, little if any meaningful clinical information can be associated with many species names. Particularly when molecular methods are not available, precise identification of isolates may be impossible and is also frequently not of immediate clinical utility.

There are a few terminology issues that, while they pertain to all bacteria, seem to cause confusion particularly frequently with regard to the aerobic actinomycetes. First, for every bacterial species, there is only one "type strain," the strain on which the original description of the species was based. Other strains contained in culture collections that are thought to belong to the same species as a given type strain can be referred to as "reference strains," but they are not type strains. Second, the term "sensu stricto" means...
FIGURE 1 Classification of genera of aerobic actinomycetes considered to be human pathogens, not including members of the family Thermoactinomycetaceae. Information from LPSN (http://www.bacterio.net/).

doi:10.1128/9781555817381.ch29.f1
“in the strict sense.” The term, when used with a species name, should be restricted to mean organisms belonging to that particular species, as determined by the best available methods. So, to refer to isolates that are “Nocardia asteroides sensu stricto” should mean isolates that by gene sequencing are identical to the type strain of N. asteroides (ATCC 19247).

**DESCRIPTION OF THE GENERA**

Basic information about specific microscopic and colonial morphologies of the following genera is presented in Table 1; additional information is included in the text below for some genera. See Table 2 for a comparison of the chemotaxonomic characteristics and lysozyme resistance (a phenotypic test, the results of which may vary among the genera) that distinguish these genera. In the listings that follow, enumeration of species within a genus is taken from the LPSN.

**Actinomadura**

The microscopic and colonial morphologies of organisms in the genus Actinomadura, which contains approximately 52 validly named species or subspecies, are very similar to those in the genus Streptomyces (Fig. 2A and B and 3A). Among the species transferred to the genus Actinomadura was Nocardia orientalis, two isolates of which were reported from clinical specimens (4). A study based on 16S rRNA gene sequences recommended combining the genera Amycolatopsis and Pseudonocardia into an emended genus, Pseudonocardia (5). Currently, there are 4 validly named species in the genus Amycolatopsis and approximately 52 validly named species or subspecies in the genus Amycolatopsis.

**Dermatophilus**

The two species currently making up the genus Dermatophilus are probably not closely related to most of the other organisms considered in this chapter. Aerial mycelia may be produced by colonies if the organism is grown in an atmosphere of increased CO$_2$; the organisms are facultatively anaerobic (6). The microscopic morphology is unusual and striking; this branching organism develops both longitudinal and transverse septa (Fig. 3D). The resulting chains of coccoid cells may occur in as many as eight parallel rows (7). The coccoid cells may develop into motile zoospores under favorable environmental conditions.

**Desmopora**

Desmopora activa is currently the only species in the recently described genus Desmopora. It is related to species in the genus Thermoactinomyces. This species is a filamentous, thermotolerant bacterium that was isolated from the sputum of a patient suspected of having tuberculosis, but it is unclear if it was the cause of the patient’s pulmonary disease (8).

**Dietzia**

The species Dietzia maris was removed from the genus Rhodococcus because of chemotaxonomic and 16S rRNA gene sequence differences from Rhodococcus species (9). Dietzia isolates apparently rarely, if ever, branch but may show coccoid and rod forms. There are approximately 13 species included in the genus Dietzia; however, discrimination among these species may be extremely difficult, even with gene sequencing methods.

**Gordonia**

Upon Gram staining, Gordonia species appear coryneform and could easily be mistaken for a component of the normal oral biota in sputum specimens (Fig. 3C). The genus “Gordona” (now Gordonia), originally described by Tsukamura, was revived in 1988 by Stackebrandt et al. (10) to contain species with mycolic acids of approximately 46 to 66 carbon atoms in length (11) and a predominant menaquinone of nine isoprene units. Gordonia and Rhodococcus were also found to be separable on the basis of their 16S rRNA gene sequences. The biology of the genus Gordonia has been reviewed (12). There are approximately 35 validly named species in the genus (Fig. 21 and 3C).

**Kroppenstedtia**

Kroppenstedtia was defined on the basis of an isolate found during environmental screening of a plastic surface in a manufacturing organization, but Kroppenstedtia eburnea has since been recovered from a variety of clinical specimens. There are two validly described species in the genus. K. eburnea has chemotaxonomic and molecular features typical of members of the family Thermoactinomycetaceae, except for containing LL-diaminopimelic acid in its cell wall peptidoglycan. (Diaminopimelic acid is in the meso conformation in the other members of the family [13]).

**Nocardia**

The most commonly isolated aerobic-actinomycete human pathogens belong to the genus Nocardia; there are approximately 87 validly named species included in this genus. In direct Gram smears, organisms generally appear as very long, obviously branching, thin, and finely beaded Gram-positive rods (Fig. 3E and K). Unlike the individual cells composing a streptococcal chain, the beads generally do not abut one another (Fig. 3H and O). Particularly when prepared from cultures, smears may show streptococcus-like chains or small branching filaments, probably as a result of the fragile nocardial mycelium breaking during smear preparation (14, 15) (Fig. 3E, F, G, K, and L).

Colonial morphology varies from species to species and frequently varies from isolate to isolate within a species (Fig. 2D, E, G, and L). Colony color may best be seen on the reverse when colonies are grown on translucent media (such as Sabouraud agar), as color may become obscured on the surface by the powdery aerial hyphae typically produced by members of this genus.

A brief account of the nomenclatural history of the designation “Nocardia asteroides” is necessary to clarify a confusing and widely unappreciated taxonomic issue. In 1888, Edmond Nocard obtained an isolate of an organism thought to be the causative agent of bovine farcy. This organism was given the name Nocardia farcinica by Trevisan in 1889, and thereupon, it became the type strain for both the genus and species. Gordon and Mihn (16) found, using their battery of phenotypic tests, that N. farcinica could not be distinguished from isolates to

fThe original description was positive.
gSparse aerial hyphae may be produced by Godona amarae.
hOccasionally no aerial hyphae are produced.
iOccasionally rudimentary aerial hyphae are seen.

which the name Nocardia asteroides had been applied. Because of some uncertainty relating to the isolate obtained by Nocard and what was presumed to be the conspecificity of the organisms then known as N. farcinica and N. asteroides, an appeal was made to the Judicial Commission to have the type species of the genus changed to N. asteroides, with strain ATCC 19247 selected as the type strain of the species. The appeal was accepted, but the isolate of N. farcinica was retained as the type strain for that particular species, as not all were convinced that the two species were truly identical.

**Nocardidiopsis**
The genus Nocardidiopsis was originally described by Meyer to accommodate an organism that at the time was called Actinomadura dassonvillei but that differed chemotaxonomically and in certain colonial morphologic features from other organisms in the genus Actinomadura (17). The cell wall of this organism does not contain madurose. The substrate mycelium fragments into coccal forms, and the aerial hyphae fragment into variously sized spores (17). Currently, there are approximately 39 named species or subspecies in the genus.

**Pseudonocardia**
Pseudonocardia spp. are characterized by the microscopic morphology of their aerial hyphae, which are segmented as a result of elongation by budding. Aerial and substrate hyphae are often zigzag shaped (18). Currently, there are approximately 48 published species in the genus.

\(^a\)Abbreviations: V, variable; Neg, negative; NA, not applicable; Pos, positive; NF, test result not found.

\(^b\)Cell wall types are as follows: I, t-DAP, no sugars; II, meso-DAP, madurose or no sugars; IV, meso-DAP, arabinose, and galactose.

\(^c\)The lysozyme test may assist in initial genus assignment.

\(^d\)Included for completeness; some consider Corynebacterium and Mycobacterium to be aerobic actinomycetes.

\(^e\)Cell wall chemotype I is implied, as sugars were not detected in whole-cell hydrolysates.

\(^f\)The cell wall contains meso-DAP; no data regarding cell wall sugars were found.

Rhodococcus

The microscopic morphology of rhodococci can range from coccoid to bacillary depending on species and specimen type and on the stage of growth of the organism (19). The organisms exhibit a rod-to-coccus growth cycle. Rod forms are best visualized by growing isolates in a liquid medium, and under such conditions, some branching of individual cells may be found. Generally, however, the organisms appear as Gram-positive coccobacilli which may be solidly stained or have a beaded appearance (Fig. 3H). Modified acid-fast staining must be performed and interpreted with particular care when dealing with isolates that may belong to this genus, as only a tiny fraction of the cells may retain the stain (Fig. 3I). Modified acid-fast smears prepared from isolates growing on Trypticase soy agar with 5% sheep blood or chocolate agar may appear to be acid-fast stain negative (20). Rhodococcus species can easily be dismissed as "diphtheroids" because of their Gram stain morphology (Fig. 3H) and their frequent failure to develop obvious pigmentation during the first few days of growth. At 37°C, colonies may be only about 1 mm in diameter after 24 h of incubation. An aerial mycelium is generally not macroscopically visible but may occasionally be seen microscopically (21). Rhodococcus has been the subject of several reviews (22, 23). Some data suggest that it may be justifiable to separate the genus into several additional genera (23). There are approximately 35 named species in the genus. There has been a recent proposal that Rhodococcus equi be transferred to a new genus, Prescottella, which to date has been effectively but not validly described in the LPSN. The new genus contains only the species P. equi (24, 25).

Saccharomonospora

The approximately nine described species of the genus Saccharomonospora are characterized by the presence of single spores tightly packed on aerial hyphae. The organisms are commonly found in soil, lake sediment, peat, compost, and manure. They are moderately thermophilic, with optimum growth occurring at 35 to 50°C (26).

Saccharopolyspora

Species in the genus Saccharopolyspora were initially thought to be related to Nocardia and Streptomyces by biochemical characteristics but are phylogenetically distinct from those genera. The organism was originally isolated from sugar cane and has a microscopic morphology similar to that of species in the genus Nocardiosis. It is so named because of the presence of bead-like chains of sheath-enclosed spores formed by segmentation of the aerial hyphae. The organism grows at temperatures between 25 and 50°C, with optimum growth at 37 to 40°C (27). There are approximately 21 described species and subspecies in the genus.

Segniliparus

The presence of unique high-pressure liquid chromatography mycolic acid patterns in four clinical isolates thought to belong to the genus Mycobacterium initiated an investigation into the characteristics of this recently described genus. By 16S rRNA gene sequencing, the genus is most closely related to members of the genus Rhodococcus, and cell wall chemistry places it in the suborder Corynebacterineae with Rhodococcus and other related genera (28). Segniliparus is the only aerobic actinomycete (besides Mycobacterium) that is strongly acid...
fast (Fig. 2M and 3M and N). There are two validly described species in this genus.

**Streptomycetes**
The genus-level taxonomy of this huge group, which contains approximately 525 named species or subspecies, remains problematic (29, 30). Many of these species have been patented because of the commercially useful products that they synthesize (29) (Fig. 2C).

**Thermoactinomycetes**
The approximately three species of the genus Thermoactinomycetes are characterized by their production of abundant endospores that are resistant to heat and easily become airborne. Organisms are found in soil, moldy and decaying plant materials, and composts. By their 16S rRNA gene sequences and G+C contents, members of this genus are more closely related to the genus Bacillus than they are to the other genera considered aerobic actinomycetes, but they are considered with this group because of their similar morphologic features. Optimum growth temperatures vary by species, but most species grow between 35 and 58°C (31).

**Tsukamurella**
The genus Tsukamurella was created to accommodate organisms with a specific cell wall chemistry that separated them from other aerobic actinomycetes (32). The type species of the genus, Tsukamurella paurometabola, was previously known as Corynebacterium paurometabolum. There are approximately 12 named species in the genus. The taxonomy of the genus remains confusing; see below for additional details (Fig. 2J and K and 3J).

**Williamsia**
The genus Williamsia was recently established to include environmental organisms that resembled those in genera belonging to the family Nocardiaceae but that had unusual cell morphology. When examined by electron microscopy, cells of Williamsia show hairy structures distributed over the whole surface of the cell. These structures are not visible in negatively staining preparations, indicating that the structures are composed of fibrillar capsular material and not true fimbriae (33). The genus contains approximately eight species (Fig. 2N and O and 3O).

**EPIDEMIOLOGY AND TRANSMISSION**
While the aerobic actinomycetes are widely distributed in the environment, the extent to which particular species are geographically restricted is not well known. Their primary ecological niche is probably the decomposition of plant material (30).

The majority of infections caused by aerobic actinomycetes stem from environmental sources, and even most nosocomial infections appear attributable to an environmental source, such as dust from construction work (34). There has not yet been a documented case of direct patient-to-patient spread of an aerobic actinomycete infection without the intermediation of another human agent or of environmental contamination.

Two outbreaks of Gordonia bronchialis sternal wound infections were traced to nurses from whose hands and other body sites the organism was isolated. In one case, the organism was also isolated from two of the nurse’s dogs (35, 36).

An outbreak of pseudo-infection attributed to T. paurometabola, involving specimens from 10 different patients and attributed to a common source somewhere in the laboratory, has also been reported (37). See the 9th edition of the Manual of Clinical Microbiology for a discussion of additional outbreaks and pseudo-outbreaks (38).

**CLINICAL SIGNIFICANCE**
While the number of recognized species of aerobic actinomycetes is rapidly increasing, assessment of the clinical significance of many species is becoming increasingly difficult. In some cases, a new species is described on the basis of a single isolate, and while careful attention is paid to its molecular features, little or no information may be provided to document that the isolate was actually a cause of disease in the patient from whom it was isolated. On the other hand, reports continue to be published regarding organisms that, while unquestionably the cause of disease, have been misidentified because of failure to use molecular methods; in other cases, even when molecular methods have been used, the accuracy of the reported identifications may be in doubt because of the provision of inadequate detail regarding the molecular technique used and the methods of interpretation used. Furthermore, many identifications reported in the older literature would be considered incorrect by currently accepted species criteria; perhaps the best example is that of Nocardia asteroides, which has only rarely been documented to be a human pathogen using currently accepted taxonomy.

Unfortunately, all these factors hinder the accurate association of clinically useful information with a given species. There is perhaps a growing tendency to assemble species into “groups” on the basis of certain features, such as antimicrobial susceptibility, as was originally done by Wallace et al. for what were considered antibiogram types of N. asteri-

FIGURE 3  Microscopic morphology of various aerobic actinomycetes. All photomicrographs were taken at a ×1,000 magnification. (A) Actinomadura latina (Gram stain from Tween-albumin broth [TAB] at 4 days, with long, branching, relatively solidly staining rods); (B) Amycolata autotrophica (Gram stain from TAB at 4 days, with long beaded rods with some branching); (C) Gordonia bronchialis (Gram stain from TAB at 4 days, showing coryneform rods with no obvious branching); (D) Dermatophilus congolensis (Gram stain from Sabouraud dextrose agar at 14 days in CO₂, with dense aggregates of cells of various sizes [note the chains of longitudinally and transversely dividing cells near the top]); (E) Nocardia abscessus (Gram stain from TAB at 10 days, with long, beaded, branching rods [note that the beads generally do not abut one another]); (F) Nocardia farcinica (modified acid-fast stain from horse blood agar at 2 to 3 days showing many coccal forms [it is mostly these that are modified acid-fast stain positive]); (G) N. veterana (modified acid-fast stain from TAB at 25 days showing some long, branching forms that are modified acid-fast stain positive); (H) Rhodococcus equi (Gram stain from TAB at 4 days showing coccobacilli and short coryneform rods without obvious branching); (I) Rhodococcus equi (modified acid-fast stain from charcoal yeast extract [CYE] agar at 10 days, on which only a small percentage of the cells stain positive); (J) Tsukamurella pulmonis (modified acid-fast stain from Lowenstein-Jensen medium at 4 days showing thin rods, many of which stain positive); (K) direct Gram stain of sputum that grew a Nocardia species (note the lacy network of long, thin, branching, beaded rods [courtesy of Daniel P. Fedorko]); (L) direct modified acid-fast stain of the same specimen as in panel K (the beads are purplish, but the intervening areas of the organism stain positive [courtesy of Daniel P. Fedorko]); (M) Segniliparus rotundus (Kinyoun stain from Middlebrook at 12 days); (N) Segniliparus rugosus (Gram stain from TAB at 7 days); (O) Williamsia deligenus (Gram stain from TAB at 5 days). doi:10.1128/9781555817381.ch.29.f3

not seem well established, and there are no recent reports for many of them. Tables 5 and 6 should by no means be considered exhaustive. Whenever a laboratory isolates an aerobic actinomycete whose sequence indicates that the organism belongs to a species that has rarely been isolated, the circumstances surrounding the isolation of the organism should be carefully evaluated to assess its potential clinical significance. A search of the current literature may be conducted to determine what is already established regarding that species, including its known pathogenicity and antibiotic susceptibilities. For such searches, the LPSN and PubMed (http://www.ncbi.nlm.nih.gov/pubmed/) may be good starting points; current nomenclature and taxonomic standing should be followed as stated in the LPSN.

Actinomadura

A useful clue to the identification of organisms in the genus Actinomadura is the nature of the lesion from which an isolate originates. Most commonly, this organism causes a mycetoma, a chronic, invasive, slowly progressive infection usually occurring in the foot (Madura foot) and nearby anatomic structures and nearly always resulting from traumatic implantation of the organism. Draining sinuses are typically present in a mycetoma; macroscopically visible grains (organism aggregates or microcolonies) may be visible in the discharge from the lesions. The infection occurs most frequently in tropical regions, where people are more likely to walk barefoot. The word "mycetoma" is used only to describe the clinical nature of the infection, not the etiologic agent. Actinomycotic mycetomas are caused by aerobic actinomycetes but which are now divided into different species (39). While currently "species" are delineated and identified primarily, if not entirely, on the basis of molecular features, possibly a separate but more relevant clinically based taxonomy may emerge, based not only on molecular features but also on such aspects as pathogenicity, antimicrobial susceptibility, and type of disease produced, all of which presumably have a basis in the fundamental molecular features of the organism.

Tables 3 and 4 list species of aerobic actinomycetes other than those in the genus Nocardia and those in the genus Actinomadura, respectively, that are considered relatively frequent human pathogens or, in a few cases, are clearly established pathogens but probably have previously been unrecognized as separate species. Tables 5 and 6 list species of aerobic actinomycetes other than those in the genus Nocardia and species in the genus Actinomadura, respectively, that have only rarely (often only once) been reported as human isolates; their actual causative role in human disease does probably have a basis in the fundamental molecular features of the organism.
nomyces; eumycotic mycetomas are caused by true fungi. Organisms in the genus Actinomadura have very rarely been implicated in other types of infection. Actinomadura madurae and Actinomadura pelletieri have been the two species most frequently reported as pathogens. In many reports mentioning the species causing mycetomas, identification has been made solely on the basis of the histological appearance of

<sup>a</sup>Type strains of these species are known to contain multiple differing copies of the 16S rRNA gene (see the text).

<sup>b</sup>The later synonym of *Rhodococcus corynebacterioides*.

the grains, on the basis of a small number of phenotypic tests, or in ways not specified in any detail (40–43). As with virtually all the aerobic actinomycetes, molecular methods are the only procedures that allow definitive species-level identification of organisms in this genus.

**Amycolata and Amycolatopsis**

There are no recent reports documenting human infection caused by species in either the genus *Amycolata* or the genus *Amycolatopsis*. Three species in the genus *Amycolatopsis* and several other aerobic actinomycete species may be causative agents of equine placental infection and abortion (44).

**Dermatophilus**

Dermatophilus congolensis causes dermatitis in a wide variety of animals worldwide, including cattle, horses, goats, and
sheep, but has only rarely been noted as a cause of human infection (45). In humans, the organism has been reported to cause a variety of cutaneous manifestations, including scaling and exudative lesions, pustules, pitted keratolysis (46), and hairy leukoplakia of the tongue (47). Filamentous and coccoid forms of the organism may be visualized directly in tissue specimens. Optimal therapy has not been defined, but infections may be self-limiting. This organism should be considered in travelers returning from tropical areas, particularly if lesions develop subsequent to animal contact at a site of previous skin trauma (48).

**Dietzia**

Until recently, the few reported cases of infection attributed to Dietzia species have been attributed to Dietzia maris; these include isolates from blood and an intravascular catheter (49), from an infection associated with a hip prosthesis (50), and in a case of aortic dissection (51). However, recent reports highlight the problems of distinguishing between Dietzia species and Rhodococcus equi using traditional biochemicals or with the use of commercially available Gram-positive rod identification panels (52, 53). One of these reports also notes the impossibility of distinguishing between certain pairs of Dietzia species (e.g., D. maris and D. schimae), even with the use of gene sequencing of two different molecular targets (52). Until the distinctions among the various species are resolved by molecular methods, it may be most useful to refer to all isolates as Dietzia species.

**Gordonia**

There have been relatively few reports of infections attributed to species in the genus Gordonia. However, an unknown number of Gordonia infections may be missed, either because the isolate is considered an insignificant coryneform Gram-positive rod or the isolate is misidentified as belonging to another genus, such as Nocardia or Rhodococcus (54). In five patients with catheter-related Gordonia species infection, the organism was correctly identified to the genus level in only one case until 16S rRNA gene sequencing was employed (54). In three of these five patients, Gordonia terrae was the infecting organism, one was Gordonia bronchialis, and one was Gordonia oitidis. There has been a review published on medical-device-associated Gordonia infections in connection with a report of infection of an orthopedic device caused by Gordonia avuti; most of the infections reviewed were attributed to G. terrae (55). Two of the very few clusters of infection attributable to any aerobic actinomycete involved patients who developed sternal-wound infections following coronary artery bypass surgery (35, 36). In one of these outbreaks, the organism involved, Gordonia bronchialis, was identified by biochemical testing and cell wall mycolic acid analysis only. Immunocompromise and/or the presence of foreign bodies appears to have been a contributing factor in many of the infections caused by Gordonia species.

**Kroppenstedtia**

Fourteen clinical isolates of K. ehmea have been reported, mostly from blood (11) or other sterile fluids, and one from skin. It is not clear that any of the isolates were of clinical significance. However, as most isolates were recovered from sterile fluids, this genus is included here, pending future determination of its true clinical significance.

The isolates were identified by partial 16S sequencing and matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) mass spectrometry. Of the 11 isolates available for antimicrobial susceptibility testing, all were susceptible to most agents tested but resistant to clarithromycin. The authors of that report noted that the organisms were not acid fast and did not stain with auramine O. No mention was made in their report of the presence of an aerial mycelium (56).

**Nocardia**

Nocardia infections generally result either from trauma-related introduction of the organism or, particularly in immunocompromised patients, from inhalation and the resulting establishment of a pulmonary focus. Nocardia species have also been implicated in extrapulmonary disease in a variety of body sites which usually results from hematogenous spread from a pulmonary site (57). The brain is one of the most common secondary sites of infection (57). Various Nocardia species have also been implicated as the causal agents of keratitis and other ocular infections, but the accuracy of the species-level identification is not always clear (58, 59). In addition, a few cases of catheter-related Nocardia infections have been reported, but the precise species involved has not always been clearly identified (60). A well-documented case of catheter-related infection caused by N. farcinica was recently reported (61).

In 1988, a breakthrough in the clinically useful categorization of pathogenic nocardial isolates was provided by Wallace and his coworkers (39). They divided organisms phenotypically resembling N. asteroides into six different drug pattern types and one additional miscellaneous group. With more-recent molecular characterizations, numerous different species have been described within this set of organisms, which came to be known as the Nocardia asteroides complex. These include Nocardia abscessus (drug pattern I), Nocardia cyriacigeorgica (drug pattern VI), N. farcinica (drug pattern V), Nocardia nova (drug pattern III), Nocardia wallaci (drug pattern IV), and isolates of drug pattern II. Other new Nocardia species are continually being described, and undoubtedly, by current species definition criteria, many more will be described in the future.

Given the current state of the literature, it is possible to make only the most tentative statements regarding geographic distribution and disease correlates of different species. While accurate species assignment allows one to make some predictions regarding likely antimicrobial susceptibility patterns, such a species assignment today requires the use of molecular methods (57). Nonetheless, susceptibility testing of all clinically significant isolates is recommended, whether or not molecular techniques have been used for their identification. The current Clinical and Laboratory Standards Institute (CLSI) document lists typical susceptibility patterns of the most commonly isolated Nocardia species (62).

Of the 84 species of Nocardia currently recognized, 49 have been reported as human isolates, and several others have been reported as pathogens of animals. Importantly, isolates in many reports of infection, even in the recent literature, are incorrectly identified because of failure to use optimal identification methods.

**Nocardia abscessus**

Nocardia abscessus was formally named in 2000 by Yassin et al. (63). ATCC strain 23824, the reference strain of N. asteroides drug pattern type I (64), was one of the isolates found to be N. abscessus on the basis of 16S rRNA sequencing and DNA-DNA hybridization. In their description in 1988 of the antimicrobial susceptibility patterns of 78 clinical isolates of Nocardia from various sources, Wallace et al.
noted that 20% of the isolates had this drug pattern type (39). Several of the strains in the report naming the species were from abscesses; a subsequent report from Japan reported several isolates from pulmonary sources and one from a brain abscess (65). Two isolates have been reported from Germany, one from pericardial fluid (66) and the other from a posttraumatic wound (67). More-recent cases have included a report of disseminated infection in an AIDS patient (68).

According to the CLSI, the expected antimicrobial susceptibility pattern of \textit{N. abscessus} is as follows: susceptibility to amikacin, amoxicillin-clavulanic acid, ceftriaxone, linezolid, and sulfonamides and resistance to ciprofloxacin, clarithromycin, and imipenem (62).

\textbf{\textit{Nocardia asteroides}} and the “\textit{N. asteroides} Complex”

There are innumerable reports of human infection attributed to \textit{N. asteroides} (38); it has probably been considered the most commonly isolated human-pathogenic \textit{Nocardia} species. However, molecular analyses of the pathogenic isolates attributed to this species that have been conducted thus far have indicated that all belong to some other named or as-yet-unnamed species. It is currently believed that \textit{N. asteroides sensu stricto} is rarely pathogenic.

The term “\textit{N. asteroides} complex” has been used for organisms phenotypically resembling the \textit{N. asteroides} type strain. However, several distinct species have now been described within that complex, and precisely what the complex is intended to designate is usually unclear. Given the current inability to identify \textit{Nocardia} isolates molecularly, the phrase “\textit{N. asteroides} complex” should be avoided. The term “complex” is best restricted to groups of species that are related on a molecular basis and have similar phenotypic features. Such groups would include the \textit{N. nova} complex and the \textit{Nocardia translucens} complex. Whenever the term “complex” is used, it is best to state initially precisely which species are intended to be included in the complex.

\textbf{\textit{Nocardia brasiliensis}}

\textit{N. brasiliensis} appears to be the most common cause of actinomycotic mycetoma (see “\textit{Actinomadura}” above) in the Western Hemisphere, especially in Mexico (46, 69). The organism probably occurs worldwide; there are reports of infection from Australia (70), West Bengal (71), and Europe (71) and many reports from North America (72). A variety of cutaneous manifestations in addition to mycetoma, including cellulitis, abscesses, and lymphocutaneous infection, have been reported. Nearly all cases are a result of trauma, including that caused by thorns (71), cat scratch (73), and insect bite (74). Most of the trauma-related infections have occurred in immunocompetent individuals. Disseminated infection, usually originating from a pulmonary focus, has also been reported (72); such infections are more likely to occur in immunocompromised patients (75). Some cases, such as one of a brain abscess resulting from dissemination from a pulmonary focus (76), occur in patients who appear to be immunocompetent. However, most of the cases of invasive disease, as well as some of the cases of cutaneous infection, attributed to \textit{N. brasiliensis} (prior to 1995) almost certainly have been caused by \textit{Nocardia pseudobrasiliensis} (see below).

According to the CLSI, the expected antimicrobial susceptibility pattern of \textit{N. brasiliensis} is as follows: susceptibility to amikacin, amoxicillin-clavulanic acid, linezolid, minocycline, sulfonamides, and tobramycin and resistance to ciprofloxacin, clarithromycin, and imipenem (62).

\textbf{\textit{Nocardia brevicateni/Nocardia paucivorans}}

Brown et al. suggested in 1997 that \textit{Nocardia} isolates sharing both an unusual drug susceptibility pattern and one or another of three different restriction fragment length polymorphism (RFLP) patterns of an amplified portion of the 65-kDa heat shock protein (HSP) gene should be considered to form the \textit{Nocardia brevicateni} complex (B. A. Brown, R. W. Wilson, V. A. Steingrube, Z. Blacklock, and R. J. Wallace, Jr., Abstracts of the 97th General Meeting of the American Society for Microbiology, 1997, abstr. C-65, p. 131, 1997). These organisms included 19 clinical isolates from the United States, 10 clinical isolates from Australia, and three ATCC reference strains of \textit{N. brevicateni}. There have been no subsequent reports of clinical isolates or taxonomic studies of these organisms.

The species \textit{N. paucivorans} was described by Yassin et al. in 2000 on the basis of a respiratory isolate from a patient with chronic lung disease (77). By 16S rRNA gene sequencing, this organism showed 99.6% sequence similarity to \textit{N. brevicateni}; results of DNA-DNA hybridization indicated that they were distinct species. \textit{N. paucivorans} and \textit{N. brevicateni}, along with isolates belonging to the unnamed group \textit{N. asteroides} drug pattern II (39), are sometimes considered to belong to the \textit{N. paucivorans/N. brevicateni} complex based on similar phenotypic characteristics and antibiograms (57).

\textit{N. paucivorans} has been recovered from cerebrospinal fluid in a case of cerebral nocardiosis in an immunocompromised individual (78), an intracerebral abscess in an immunocompetent patient (79), and a mitral valve (80). Two of 86 (2.3%) clinical \textit{Nocardia} isolates from Belgium were identified as belonging to this species (81).

\textbf{\textit{Nocardia cyriacigeorgica}}

\textit{N. cyriacigeorgica} was described on the basis of an isolate obtained from the sputum of a patient with chronic bronchitis (82). Subsequent isolates were obtained from brain abscesses in an immunocompromised patient (83) and from a patient with pneumonia following a near-drowning incident, from whom \textit{N. farcinica} and several other pathogens were isolated (84). Isolates of this species were reported to constitute 13 of 96 (14%) clinical \textit{Nocardia} isolates from Thailand (85) and 13 of 86 (15%) such isolates from Belgium (81). The 16S rRNA sequence of the type strain of this species (1,400 bp) was found to be identical to that of the reference strain of \textit{N. asteroides} drug pattern VI (ATCC 14759) (64, 86). DNA-DNA hybridization studies subsequently established that this drug pattern type VI reference strain and \textit{N. cyriacigeorgica} belong to the same species (87). In the original work describing the different \textit{N. asteroides} drug pattern types, type VI strains were the most commonly isolated strains (35%) (39). \textit{N. cyriacigeorgica} is probably the most frequent human nocardial pathogen, at least in areas where actinomycotic mycetomas are relatively rare. While the species \textit{N. cyriacigeorgica} has been designated an emerging pathogen (88), it is actually a relatively common and long-recognized pathogen that has recently acquired a valid name. In fact, many isolates previously reported as \textit{N. asteroides} almost certainly belong to this species.

According to the CLSI, the expected antimicrobial susceptibility pattern of \textit{N. cyriacigeorgica} is as follows: susceptibility to amikacin, ceftriaxone, imipenem, linezolid, and sulfonamides and resistance to amoxicillin-clavulanic acid, ciprofloxacin, and clarithromycin (62).

\textbf{\textit{Nocardia farcinica}}

The organisms initially described by Wallace et al. belonging to the group \textit{N. asteroides} drug pattern type V (39)
were subsequently found to belong to N. farcinica (89). N. farcinica isolates that showed in vitro resistance to trimethoprim-sulfamethoxazole have been reported to respond to meropenem alone (90) and to the combination of linezolid and minocycline (91). This species may have a particular propensity for causing disseminated disease; Wallace et al. reported that among 30 patients for which the disease extent was known, 57% had disseminated disease and one-third had central nervous system (CNS) involvement (89). Most patients infected by this species, especially those with disseminated disease, have some type of immunocompromise (89), but cutaneous and other infections have been reported to occur in the apparently immunocompetent as well (92). The lung is a common site of involvement, affecting 39.7% of patients according to one review (92). As verified by molecular analysis, N. farcinica has been isolated from brain abscesses (93), blood (93), cases of keratitis (94), and an infected cochlear implant (95). N. farcinica has also been isolated from the bronchoalveolar wash fluid of a cystic fibrosis patient (96). Isolates of this species were reported to make up 34 of 96 (35%) clinical Nocardia isolates from Thailand (85) and 38 of 86 (44%) such isolates from Belgium (81).

According to the CLSI, the expected antimicrobial susceptibility pattern of N. farcinica is as follows: susceptibility to amikacin, amoxicillin-clavulanic acid, ciprofloxacin, linezolid, and sulfonamides and resistance to ceftriaxone, clarithromycin, and tobramycin (62).

**Nocardia nova**

N. nova was described by Tsukamura in 1982, distinguished from N. asteroides by several phenotypic tests (97), and confirmed to be a separate and distinct species by DNA-DNA hybridization (98). Wallace et al. found that 18% of 78 clinical isolates fell into their type III drug susceptibility pattern, characterized by susceptibility to ampicillin and erythromycin and resistance to cefamandole (39). In a subsequent study of 223 clinical isolates, by both biochemical and susceptibility testing procedures, 17% of the isolates, as well as the type strain of N. nova, had similar characteristics, including the type III drug pattern; these isolates were all termed N. nova strains (99). Of the patients for whom clinical information was available, 35% were thought to have disseminated disease; organisms were obtained from many sites, including blood, lung, CNS, skin and soft tissue, joints, and cornea. An upper extremity sporotrichoid form of nocardiosis attributed to N. nova in a human immunodeficiency virus (HIV)-positive patient who sustained a thumb injury while working in a field has been reported (100). Hamed et al. reported the isolation of N. nova, identified by 16S rRNA gene sequencing, from a case of spondylodiscitis and psoas abscess (101).

Recent investigations have revealed that the organisms identified as N. nova by phenotypic testing, including antibiogramming, as well as by the RFLP patterns obtainable from the hsp65 gene, actually may belong to other species in addition to N. nova, including Nocardia africana, Nocardia krusei, and Nocardia veterana (102). These species can be distinguished from one another and from N. nova sensu stricto only by gene sequencing. Phylogenetic analysis using sequence data of the HSP and secA genes consistently place these species in the same clade as N. nova sensu stricto, indicating the close relationship among these species (P. S. Convile and F. G. Witebsky, unpublished data). Phylogenetic analysis of the 16S rRNA, HSP, and secA genes also places Nocardia aobensis and Nocardia elegans in the N. nova complex clade; no phenotypic characteristics of these two species have been examined to determine their similarity to other species in the complex. All species included in the N. nova complex (including N. aobensis and N. elegans) have been isolated from humans or implicated in human disease. Isolates identified only by phenotypic testing as belonging to one or another of these species are probably best reported as members of the N. nova complex.

According to the CLSI, the expected antimicrobial susceptibility pattern of members of the N. nova complex is as follows: susceptibility to amikacin, ceftriaxone, clarithromycin, imipenem, linezolid, and sulfonamides and resistance to amoxicillin-clavulanic acid and ciprofloxacin (62).

**Nocardia oitidiscaviarum**

The initial isolate of the species N. oitidiscaviarum, described by Snijders in 1924, was obtained from the infected middle ear of a guinea pig; for a time this species was known as N. caviae (103). Clark et al. reviewed 28 cases of cutaneous infection, including several mycetoma cases, attributed to this species; many of those for which information was available were considered trauma related (104). There are a few reports of infection at other sites, including a brain abscess (105), a pyothorax infection (106), a catheter-related infection (107), disseminated infection (108), and cavitary pneumonia (109). This species is relatively reliably identified on the basis of its decomposition reactions; it decomposes xanthine and hypoxanthine but not casein or tyrosine. In a molecular study of numerous clinical isolates, several different sequences were obtained from nine different strains that had been phenotypically identified as N. oitidiscaviarum (110). These results were interpreted as suggesting the presence of several different species within this group, but some of the results also suggested that individual isolates might contain two or more differing copies of the 16S rRNA gene.

According to the CLSI, the expected antimicrobial susceptibility pattern of N. oitidiscaviarum is as follows: susceptibility to amikacin, ceftriaxone, linezolid, and sulfonamides and resistance to amoxicillin-clavulanic acid, ceftriaxone, and imipenem (62).

**Nocardia pseudobrasiliensis**

In 1995, Wallace et al. (111) reported on a subset of organisms that had been identified as N. brasiliensis that were sometimes isolated from cutaneous infections but were predominantly associated with noncutaneous invasive disease. This subset of isolates appeared to belong to another taxon, formally named N. pseudobrasiliensis the following year (112). Most infections have occurred in immunocompromised patients; cases have been reported from North and South America, Japan, and Australia (111, 113, 114).

Unlike true N. brasiliensis isolates, most N. pseudobrasiliensis isolates hydrolyze adenine, are susceptible to ciprofloxacin and clarithromycin, and are resistant to minocycline. The two species also differ in their mycolic acid patterns and 16S rRNA, HSP, and secA gene sequences. Most cases of infectious disease of a nonmycetomatous nature previously attributed to N. brasiliensis have probably been caused by this species (see “Nocardia brasiliensis” above).

According to the CLSI, the expected antimicrobial susceptibility pattern of N. pseudobrasiliensis is as follows: susceptibility to amikacin, ceftriaxone, clarithromycin, linezolid, sulfonamides, and tobramycin and resistance to amoxicillin-clavulanic acid, imipenem, and minocycline (62).
Nocardia transvalensis and the N. transvalensis Complex

N. transvalensis was originally described in 1927 on the basis of an isolate from an African patient with a mycetoma (115). In 1997, Wilson et al. published a study of 58 clinical isolates from the United States and Australia that showed resistance to amikacin (116). Using biochemical and molecular methods, these authors were able to separate the isolates into four distinct groups. One group comprised 53% of the isolates studied, were all recovered from patients in the United States, and were similar to isolates classified as N. asteroides drug pattern type IV as defined by Wallace et al. (39). Isolates belonging to this group were later officially designated Nocardia wallacei (117) (see below). Another group (17% of isolates) included organisms similar to the type strain of N. transvalensis. Two additional groups, new taxon 1 (14% of isolates) and new taxon 2 (16% of isolates), were also defined. Australian isolates belonged to the N. transvalensis sensu stricto group and to new taxon 1. Isolates belonging to new taxon 1 have been given the species designation Nocardia blacklockiae (117). Because of their similar phenotypic and molecular characteristics, Wilson proposed that these three species and the unnamed new taxon 2 be considered to belong to the N. transvalensis complex.

There have been numerous reports in the literature describing the isolation of N. transvalensis from clinical specimens; many of these reports base the identification of the isolate on a small number of phenotypic tests. It is unclear if these reports represent accurate species assignments, given the similarity of related species as described above. McNeil et al. reported on 16 patients from whom isolates attributed to this species had been obtained (118). The isolates from 10 of the patients were considered clinically significant; the other isolates were considered colonizers or of uncertain significance. A variety of sites of infection were involved, some of the infections were disseminated, and several patients were known to be immunocompromised. There are a few other case reports of molecularly characterized disseminated infection attributed to the N. transvalensis complex, including a brain abscess in a cancer patient (119), brain and cutaneous infection in a heart transplant patient (120), and pulmonary infection and subcutaneous abscess in a patient with histiocytosis X (121). Three clinical isolates assigned to this species complex have been reported from Japan (122). A well-documented case of Nocardia transvalensis has also been reported in a case of pneumonia in a patient with cystic fibrosis (123).

Those using 16S rRNA gene sequencing for identification of members of the N. transvalensis complex should be aware that numerous sequences for N. transvalensis have been submitted to GenBank. Many of these sequences are more closely related to the type strain of N. wallacei than to the type strain of N. transvalensis.

According to the CLSI, the expected antimicrobial susceptibility pattern of members of the N. transvalensis complex is as follows: susceptibility to ceftriaxone, ciprofloxacin, linezolid, and sulfonamides and resistance to amikacin, clarithromycin, and tobramycin (62).

Nocardia veterana

N. veterana was first described on the basis of an isolate obtained from the bronchial lavage fluid of a patient with pulmonary lesions, but that isolate was thought not to be clinically significant (124). Subsequently, N. veterana has been implicated as the causative agent in cases of mycetomas (125), three patients with pulmonary disease (126), ascitic fluid infection in an HIV patient (127), brain abscess in a diabetic patient (128), and bloodstream infection in a cancer patient (129). In a report of three additional clinical isolates, two of which were shown to have been causative agents of pulmonary disease, it was noted that the isolates had an antimicrobial susceptibility pattern essentially identical to the patterns of N. africana and N. nova (130), demonstrating that species identification could not be definitively established by susceptibility testing alone. It was also noted that the isolates of this species that were studied showed 16S rRNA gene similarities to the type strains of N. africana and N. nova of 99.0 and 97.7%, respectively. N. veterana is one of the species included in the N. nova complex (see “Nocardia nova” above). HSP, secA1, and 16S rRNA gene sequencing place N. veterana in a clade with other members of the complex. The expected antimicrobial susceptibility pattern of N. veterana is consistent with the susceptibility pattern of members of the N. nova complex (see above).

Nocardia wallacei

Officially described in 2008, N. wallacei is the most commonly isolated member of the N. transvalensis complex (117). 16S rRNA, HSP, and secA1 gene sequencing showed >99.8% sequence similarity among five clinical isolates obtained from sputum samples; one of these was also recovered from pleural fluid. This species was initially designated N. asteroides drug pattern IV by Wallace et al. and comprised 5% of 78 isolates identified as N. asteroides by phenotypic methods but unique in their resistance to amikacin (39). The expected antimicrobial susceptibility pattern of N. wallacei is consistent with the susceptibility pattern of members of the N. transvalensis complex (see above).

Nocardioopsis

Nearly all of the very few infections attributed to organisms in the genus Nocardioopsis have been attributed to Nocardio-opsis dassonnevillei. In a letter to the editor regarding a case of actinomycetoma attributed to this species, it was stated that N. dassonnevillei was “regularly encountered” at the Centers for Disease Control and Prevention, with 21 isolates having been identified from 1981 through 1986; no clinical details were provided (131). In the case of a blood isolate, a variety of methods, including 16S RNA gene sequencing, were used to identify the isolate; the same report provided references to a number of other cases of infection, including mycetomas and cutaneous infections, attributed to this species (132).

Rhodococcus

As described previously, reassignment of Rhodococcus equi to the genus Prescottiella has been proposed (24, 25). However, since this change had not been validated at the time of writing, the name Rhodococcus equi is used in the text here. The most commonly isolated pathogen in the genus Rhodo-occus is R. equi. While other species have occasionally been reported to cause disease, in most but not all of these reports, gene sequencing was not used, and it is impossible to obtain reliable species-level identifications without this technique (22, 133). There is some evidence that R. equi itself may be a complex of several different species (134). Infections caused by R. equi have been the subject of several reviews (135–137). The organism has long been known as a significant pulmonary pathogen in horses (hence the species name) (138). The initial report of human disease caused
by the organism (reported as Corynebacterium equi) involved a patient on high-dose steroids with a pulmonary abscess; he had worked briefly in stockyards contaminated with animal feces shortly before the onset of his illness (139). Herbivore manure provides an ideal growth medium for the organism, and inhalation of the organism is presumed to be the major mode of infection in horses (138) and is probably also the principal mechanism for human infections. Direct inoculation and oral ingestion are other possible routes of infection (140). Most patients who develop R. equi infection are immunocompromised, and at least until recently, approximately two-thirds of infected patients were also HIV infected (140). Essentially any body site can be involved, but the lung is a site of involvement in approximately 80% of immunocompromised patients and at least 40% of immunocompetent patients. Bacteremia has been reported in >80% of immunocompromised patients and approximately 30% of immunocompetent patients (140). Pulmonary cavitation is a frequent finding. Malacoplakia, an aggregation of histiocytes containing concentrically layered basophilic structures known as Michaelis-Gutmann bodies, has been noted as a histopathologic finding in several studies (137, 141). Two virulence-associated antigens (VapA and VapB) encoded by plasmids have been identified. Isolates producing the VapA antigen are the predominant, possibly the sole, cause of disease in horses, but isolates producing the VapA antigen, the VapB antigen, or neither antigen have been isolated from human cases of infection (142). A combination of antimicrobials is generally used for the treatment of infections. Agents used include aminoglycosides, erythromycin, imipenem, quinolones, rifampin, and vancomycin. The current CLSI document Susceptibility Testing of Mycobacteria, Nocardiae, and Other Aerobic Actinomycetes, Approved Standard, Second Edition, recommends that a regular Gram-positive panel be inoculated (if such panels include vancomycin and rifampin, critical antimicrobials for this species) (62). Linezolid may also be efficacious (140); in an in vitro study of 102 R. equi isolates obtained from humans and animals, the linezolid MIC ranged from 0.5 to 2.0 μg/ml (143). Some rifampin-resistant strains with 16S gene mutations have been reported (144). Without careful assessment, R. equi isolates can easily be mistaken for coryneform bacteria and dismissed as insignificant (Fig. 2H). One report describes two patients who died of overwhelming R. equi infection; for both patients, isolates from multiple positive blood cultures were initially misidentified as a Corynebacterium species (145).

Segniliparus

Although the two species that make up this genus (Segniliparus rotundus and Segniliparus rugosus) were originally recovered from clinical material, no information was provided concerning the significance of these isolates except that they were from “nonsterile human sources” (28). Subsequent reports of the recovery of S. rugosus seem to indicate the predilection of this organism for patients with cystic fibrosis. A report of the recovery of S. rugosus from the bronchoalveolar lavage fluid or induced sputum of three cystic fibrosis patients emphasized the microscopic and colonial similarities of this species with those of rapidly growing mycobacteria (Fig. 2M and 3M and N). In a subsequent report from Australia, S. rugosus was isolated from the mycobacterial culture of sputum from a cystic fibrosis patient (146). A case of S. rotundus pneumonia in a non-cystic fibrosis patient with bronchiectasis has recently been reported (147).

Streptomyces

The most common type of infection attributed to species in the genus Streptomyces is mycetoma (see “Actinomadura” above), and the most commonly mentioned etiologic agent is Streptomyces somaliensis, although in many reports the identification procedures employed could not have ensured that other species were not involved. There are a few reports implicating other species in the genus as occasional pathogens. In case reports of bacteremia attributed to Streptomyces lividans (148) and Streptomyces thermovulgaris (149), molecular methods were used in identifying the isolates, and such methods were described in detail in a case report of a mycetoma attributed to Streptomyces albus (150). While the majority of isolates from nonmycetomatosus lesions probably represent either contamination or colonization, these organisms are capable of occasionally causing disease other than mycetoma. Six cases of invasive Streptomyces infections have been reported, and there is a literature review of such infections (151). Because of the huge number of validly described species of Streptomyces and the lack of information about the clinical significance of many of these species, identification to the genus level is probably sufficient in most cases. In a study of the susceptibility of 92 Streptomyces species from clinical specimens, 100% of those tested were found to be susceptible to amikacin and linezolid, 77% to minocycline, 67% to imipenem, and 51% to clarithromycin and amoxicillin-clavulanate (152).

Tsukamurella

Tsukamurella infections have been most commonly reported in connection with a foreign body, such as an intravenous catheter (153), but have also been reported even in apparently immunologically normal patients in the absence of any foreign body (154). The literature on catheter-related infections caused by Tsukamurella species has recently been reviewed in connection with two additional reports of such infection (153); several other of the relatively few infections reportedly caused by Tsukamurella species are also briefly mentioned in that review. Tsukamurella tyrosinosolvens has been implicated in cases of keratitis, bacteremia, and catheter-related infections (155). Rhodococcus aurantiacus ATCC 25938 (the initial type strain of the species), which has had a convoluted taxonomic history, has been placed in the species Tsukamurella paromometa (32). In the older literature, there are a few reports of infection attributed to R. aurantiacus, such as pulmonary infection, meningitis, peritonitis, and subcutaneous abscesses (156). Organisms isolated from clinical material have generally been found to resemble strain ATCC 25938. Pseudo-outbreaks attributed to T. paromometa (37) and T. tyrosinosolvens (due to improperly wrapped specimen processing equipment) have been reported (157).

Williamsia

The first clinical isolate of the genus Williamsia was recovered from a protected bronchial brush sample of a patient with bilateral alveolar infiltrates following aortic valve replacement. A Gram stain of the sample showed numerous Gram-positive rods, and culture of the fluid grew >1,000 CFU/ml of an organism identified by 16S rRNA gene sequencing as Williamsia muralis (99.9% sequence similarity). Using breakpoints established for Nocardia species, susceptibility testing of the W. muralis isolate indicated that the isolate was susceptible to amoxicillin-clavulanate, cefotaxime, imipenem, ciprofloxacin, tobramycin, gentamicin, and trimethoprim-sulfamethoxazole (158). The recovery of W.
isolated organism (11). May help to establish the clinical significance of the organism. Sputum is the most easily collected, transported, and stored. In temperate climates, the respiratory tract is the most likely portal of entry for the aerobic actinomycetes and therefore the primary site of nocardial infections in immunocompromised hosts. Sputum is the most easily obtained pulmonary specimen, and examination of several fresh early-morning samples collected on separate days (163) may maximize the chances of organism recovery; isolation of an aerobic actinomycete from multiple samples may help to establish the clinical significance of the isolated organism (11). Nocardia species and other aerobic actinomycetes may, however, be difficult to recover from sputum even in documented cases of pulmonary infection (15), either because of low numbers of organisms present in the sample or because they may be overgrown by more rapidly growing bacteria in the specimen. More-invasive procedures, such as bronchoalveolar lavage or fine needle or open lung biopsy, may be required to obtain a definitive diagnosis (15). These more-invasive procedures may be necessary for diagnosis of as many as 44% of primary pulmonary infections (70); macrophage-rich samples may be necessary to maximize recovery of organisms such as rhodococci, which tend to localize within these cells (19).

Exudates from abscesses or mycetomas should be delivered to the laboratory in a sterile container for macroscopic and microscopic examination for characteristic granules and for smear tests and culture. In the case of disseminated cutaneous lesions or small lesions secondary to trauma, a skin biopsy can be useful. The use of swabs is not recommended, as fibers can make smear interpretation difficult (163). In immunocompromised patients, the aerobic actinomycetes, especially Nocardia, can disseminate to almost any organ. A biopsy sample or aspirate, when obtainable, may be the best specimen to evaluate for the presence of such organisms. Normally sterile body fluids should be collected in a sterile container and sent immediately to the laboratory. Nocardia isolates are infrequently recovered from cerebrospinal fluid, even if numerous brain lesions are present, because the organisms may be confined to the brain abscess itself. Blood should be inoculated directly into blood culture media; many commercially available blood culture systems have been shown to support the growth of Nocardia species. Nocardia and Tsukamurella spp. have been implicated as causes of catheter-related bacteremia; it is likely that other aerobic actinomycetes are also involved in catheter-related infections. Potentially infected catheter tips should be transported to the laboratory in a sterile container and cultured by appropriate methods.

In all cases where infection with an aerobic actinomycete is suspected, it is of utmost importance that the laboratory be notified of the suspected diagnosis. This will ensure that samples will receive appropriate handling, that the correct direct smears will be prepared, and that the sample will be inoculated onto the appropriate media and incubated for an extended period of time (a minimum of 2 weeks, preferably for up to 3 weeks) at the appropriate temperature.

All samples should be transported promptly to the laboratory following the specimen collection and handling procedures outlined in chapter 18.

**DIRECT EXAMINATION**

**Microscopy** Careful microscopic examination of clinical specimens suspected of containing aerobic actinomycetes is extremely important. The observation of organisms characteristic of Nocardia species and other aerobic actinomycetes should alert laboratory personnel to inoculate appropriate media and to extend incubation at the appropriate temperature. In addition, the detection of organisms directly in the specimen may assist in the interpretation of culture results; smears of such specimens may show more-characteristic diagnostic morphologies of organisms than smears from colonial growth.

Smears can be made directly from sputum, drainages, and aspirates; however, liquid specimens, such as bronchoalveolar lavage fluid or normally sterile body fluids that are not excessively cellular, should be concentrated before smear preparation and medium inoculation. For example, a 5-ml aliquot of the sample can be centrifuged for 10 min at 2,800 × g and the pellet can be used for smears and medium inoculation. Alternatively, smears can be prepared using a cytocentrifuge. For tissue samples, smears should be made from ground material and from touch prep. Two important stains that should be used in clinical laboratories for direct samples are the Gram stain and the modified acid-fast stain. Histopathologic examination of fixed tissue by use of special stains (including Fite stain and Grocott-Gomori methena-mine silver stain) may also reveal the presence of organisms belonging to these genera (164).

Gram stain morphologies of the aerobic actinomycetes vary by genus; organisms appear as Gram-positive rods ranging in shape from coccoid to bacillary. Filamentous and branching forms may be present, depending on the species involved and the stage of growth in infected tissues (Fig. 3). See Table 1 for a summary of the microscopic morphologies of the aerobic actinomycetes. The modified acid-fast stain used on direct specimens may more accurately reflect the true partially acid-fast nature of the organisms than do modified acid-fast stains prepared from colonial growth. The modified acid-fast stain uses a weaker decolorizer (1% H$_3$SO$_4$) than does the mycobacterial stain (3% HC1). The decolorization step of the staining process should be carefully monitored to reduce the risk of over- or underdecolorization. See chapter 19 for details on reagent preparation and staining methodology. Because of the difficulty of standardizing the modified acid-fast staining technique, it is imperative that positive and negative controls be run simultaneously with patient smears. The control slides can be made from growing suspensions of Streptomyces
species (negative control) and Nocardia species (positive control). Smears should be evaluated by experienced laboratory personnel, and the quality of the stain itself should be evaluated before results are reported. Gordonia, Nocardia, Rhodococcus, and Tsukamurella (and possibly Dietzia) is known to be partially acid fast with this stain; *Segniliparus* is strongly acid fast.

When smears are read, careful attention should be paid to the cellular material present in the sample (Fig. 3K and L). Nocardia species are frequently seen in association with polymorphonuclear leukocytes (57). Phagocytized Gram-positive or modified-acid-fast-stain-positive organisms can sometimes be seen within macrophages and mononuclear cells; in the modified acid-fast smear, these may appear as “beaded” cells with strongly acid-fast granules within non-acid-fast or weakly acid-fast rods (14, 19).

In cases of suspected actinomycetoma, aspirated material should be examined grossly for the presence of granules by spreading the sample in a sterile petri dish. Granules in infections caused by Nocardia species are small (80 to 130 μm), may be kidney-shaped with club-like structures in the periphery, and are usually yellow to orange in color (165, 166). In infections caused by *A. madurae*, granules can be yellowish-white and large enough to be seen with the naked eye. Microscopically, a zone of pseudoclubs can be seen in the periphery (165). Granules in infections caused by *A. pelletieri* are red to pink in color (165). Granules should be washed and crushed, smears prepared from the crushed material, and appropriate media inoculated. Granules are most often seen in infections caused by *N. brasiliensis* or Actinomyces species but can also be seen in infections caused by other species of *Nocardia* (57). Adequate data are not available to allow using the presence of granules or granule color for precise species or even genus-level discrimination of the etiologic agent.

**Nucleic Acid Detection**

Several authors have reported the use of molecular methodologies for the detection of *Nocardia* directly from clinical specimens. Targets include the 65-kDa HSP gene (167), the 16S rRNA gene (168, 169), and the secA1 gene (172). Fragments of these genes have the potential to provide rapid diagnosis of nocardiosis from samples exhibiting bacterial morphologies suggestive of this genus. Further assessment of these techniques will be needed to assess their sensitivities and overall clinical utility.

Isotalo et al. describe a method using in situ hybridization for detection of *Nocardia* species in formalin-fixed, paraffin-embedded tissue specimens. Their procedure showed 77% sensitivity compared to that of standard histologic stains (170).

**ISOLATION PROCEDURES**

Blood agar, chocolate agar, brain heart infusion agar, S. bourraud dextrose agar, and Lowenstein-Jensen medium support the growth of most aerobic actinomycetes; *Dermatophilus congolensis* may not grow on Sabouraud dextrose agar or Lowenstein-Jensen medium (7). Buffered charcoal yeast extract agar (BCYE) is particularly useful for the recovery of *Nocardia* species. Specimens from sterile sites or concentrated sterile body fluids can be inoculated directly onto these media. Specimens from respiratory sites, skin, and other potentially contaminated sites, such as mycetomas, should additionally be inoculated onto selective media, such as modified Thayer-Martin agar (171) and selective BCYE (containing polymyxin B, anisomycin, and either vancomycin or cefamandole) (172). Sabouraud agar with added chloramphenicol may not be useful, as it may also suppress the growth of some Nocardia species (173). A specialized medium for the recovery of *R. equi* using a Mueller-Hinton agar-based medium with added cefazidime and novobiocin has been described (174). Members of the aerobic actinomyces may also grow in liquid media (such as broth media for mycobacterial cultures), in which they may appear as solid granules. These particles may be captured with a pipette and plated to solid media. Such granules may also be crushed between two slides, dried, and stained (Y. Shea, personal communication).

Cultures for aerobic actinomycetes should be handled as fungal cultures, thus ensuring that the cultures will be incubated and regularly examined over an extended period. Two BCYE plates (for samples from sterile sites) or selective BCYE plates (for respiratory or other potentially contaminated sites) should be inoculated. One BCYE or selective BCYE plate should be incubated at 30°C and the other at 35°C, both in ambient air. It should be noted, however, that Streptomyces species may show best growth at 25°C and that *Dermatophilus* species grow better and shows enhanced production of aerial hyphae in increased CO<sub>2</sub> (7). For all cultures, plates should be held for a minimum of 2 weeks, preferably for up to 3 weeks, and should be sealed to prevent dehydration.

A low-pH decontamination procedure has been successfully used for pretreatment of heavily contaminated specimens suspected of harboring *Nocardia* species. The sample is diluted 1:10 in 0.2 M HCl-0.2 M KCl at pH 2.2, mixed, and allowed to stand for 3 to 5 min, after which it is inoculated onto selective and nonselective media (172, 175). Murray et al. reported a drop in the viability of *Nocardia* species after 30-min exposures to N-acetyl-L-cysteine (NALC), NaOH-NALC, or benzalkonium chloride (Zephiran)-trisodium phosphate (176). The key to improved recovery of *Nocardia* spp. from NaOH-NALC-treated specimens may be a shorter exposure to the decontaminating reagents (15 min), as is in fact also recommended for the recovery of mycobacteria (177).

Aerobic actinomycetes have been recovered from blood using a variety of commercially available blood culture systems, including conventional 2-bottle systems, biphasic bottles, automated blood culturing systems, and lysis-centrifugation systems. Using various blood culture systems, aerobic actinomycetes have been recovered after 3 to 19 days of incubation, which in some cases included the incubation times of terminal subcultures (148, 178). Studies employing newer blood culture systems have resulted in recommendations that extended incubation is no longer necessary (179); however, such studies have not established that such shorter incubation would generally be adequate for the isolation of aerobic actinomycetes. If the possibility of bacteremia with a member of one of these genera is suspected, it would be advisable to perform fungal blood cultures (for the expanded incubation period, at least 3 weeks) or to perform terminal subcultures if the incubation period of routine blood cultures cannot be extended.

Plated cultures from all sources should be examined daily for the first week of incubation and then weekly thereafter, preferably using a dissecting microscope, which will allow detection of tiny colonies. Such microscopic examination is particularly important for specimens that contain contaminating microbiota, as an aerobic actinomycte can be quickly overgrown by more rapidly growing organisms. Care should also be exercised when Lowenstein-Jensen or Middlebrook media are examined for mycobac-
teria or when BCYE plates are examined for Legionella species, as Nocardia and other aerobic actinomycetes can grow on these media.

IDENTIFICATION

Microscopic Morphology

Evaluation of the Gram stain morphology of a suspected aerobic actinomycete should be the initial step in organism identification, as microscopic morphologies can vary among the genera (Table 1 and Fig. 3). A sufficient number of fields should be reviewed to allow determination of the most prevalent morphology and to detect the sometimes-rare branching forms. Care should be taken not to confuse perpendicular aligning of the organisms with true branching. Smears made from colonial growth of filamentous isolates may fragment and appear as bacillary or coccoid forms (37).

A properly prepared and carefully interpreted modified acid-fast smear can assist in the preliminary identification of the organism (Fig. 3F, G, I, J, and L). Quality control slides should be stained along with stains of colonies from cultures. With the modified acid-fast stain, the background should be blue; slides that have a pink background may be inadequately decolorized and should be repeated. The smear should be scanned for areas where individual bacterial cells can be seen or areas where single layers of cells allow clear differentiation of cell borders. The acid-fast reaction of tightly packed clumps of organisms may not represent the true partially acid-fast nature of the cells; be wary of large clumps of cells which all appear to be acid-fast stain positive. Acid-fast cells will clearly be red; cells that stain purple or light pink may or may not be truly acid fast. A stain that shows an unambiguous positive acid-fast reaction may frequently show only a few clearly red cells, with a majority of blue cells. Frequently, only the beads appear acid-fast positive. If modified-acid-fast-stain results are ambiguous, transfer of the organism to a lipid-rich medium, such as Lowenstein-Jensen medium or Middlebrook 7H11 agar (to increase the organism’s lipid content), and repeat staining may give a more clear-cut stain result. Acid fastness may become more evident as colonies age; the acid-fast reaction has been reported to be most reliable when the test is performed with colonies after 1 to 4 weeks of growth (180). Occasionally, coccoid forms of Streptomyces may appear partially acid fast; hyphae, however, are acid-fast negative. Because of the difficulties of interpretation of the modified acid-fast smear, results of this stain should be considered preliminary and must be used only in conjunction with results from other tests. Very rarely, an isolate of a species that is considered to be modified-acid-fast-stain positive may not give a positive stain reaction. If the microscopic and colonial morphology is consistent with an aerobic actinomycete, and if the isolate might be clinically significant, an attempt should be made to determine the identification of the isolate.

Slide Cultures

Slide cultures are probably the best way to evaluate the morphology of some genera, such as Amycolata, Amycolatopsis, and Nocardiosis. Differences among the genera of aerobic actinomycetes in the growth characteristics seen on slide culture may be subtle; experience in recognizing these morphologic differences is required for correct interpretation of these tests. Further information on characteristic slide culture morphologies can be found in references 181 and 182.

Colonial Morphology

The colonial appearance of members of the aerobic actinomycetes is extremely variable among genera and even between isolates of the same species (Fig. 2). Environmental factors, such as growth medium, incubation temperature, air circulation, presence of CO₂, and age of culture, can affect the size and consistency of the colonies and the production of aerial hyphae (183). Some species produce a diffusable pigment that can vary from strain to strain. See Table 1 for information on specific colonial morphologies.

Aerial Hyphae

Aerial hyphae project away from the surface of the colony into the air but may not be apparent until 7 to 14 days for some species that form such hyphae. The use of a dissecting microscope for observation of aerial hyphae is recommended. Nocardia species and Streptomyces species usually produce abundant aerial hyphae that give the colonies their characteristic powdery or velvety appearance (Fig. 2C, E, and L); rare strains of Nocardia produce sparse or no aerial hyphae (Fig. 2D and G). Of the genera that are partially acid-fast, only Nocardia species regularly produce aerial hyphae. For some genera of aerobic actinomycetes, the presence of spores and their relative numbers and arrangement on the aerial hyphae can also give some clue to genus identification (182).

Genus Assignment

To determine the genus of an unknown isolate, observation of microscopic and colonial morphology is especially important (Table 1 and Fig. 2 and 3). In assessing the characteristics of colonial growth, the presence or absence of aerial hyphae should be determined. Nocardia species and Streptomyces species generally produce aerial hyphae, with other less commonly isolated genera also showing this morphologic trait (Table 1). Positive results of a carefully prepared and interpreted modified acid-fast smear combined with the presence of aerial hyphae help to distinguish Nocardia from other genera.

Some recent reports have documented the inadequacy of traditional and commercial biochemical methods in identifying isolates correctly to the genus level. For example, isolates initially misidentified as Rhodococcus equi using commercial test strips have on further study been found to belong to the genus Dietzia (52); isolates initially identified as Rhodococcus species have been found to belong to the genus Tsukamurella (155).

Laurent et al. describe a PCR-based method that allows differentiation of members of the genus Nocardia from other genera of aerobic actinomycetes (184). It is not known if this method is applicable for the discrimination of newly described Nocardia species from other genera.

Species Assignment

Limitations

Given the increasing number of species of aerobic actinomycetes, the use of phenotypic or biochemical tests to obtain exact species or even genus-level identification has become impossible. In addition, phenotypic attributes may be unstable based on environmental and procedural variation. Among the Nocardia, most species are nonreactive in most commercially available biochemistries, precluding the definitive identification of these isolates by these methods. For laboratories without molecular capabilities, assignment to the genus level should be attempted. When a precise identi-
fication is required for a significant patient isolate, molecular testing is generally required.

Some new species have been described based on a single isolate; such species present problems for laboratories attempting to make identification decisions phenotypically, as characteristics described may not reflect the typical reactions of the species that would be determined if more isolates were analyzed (185).

Biochemicals
Because of the increasing number of described species and the low discrimination power and small number of commercially available phenotypic tests, biochemical testing is not recommended for definitive identification of the aerobic actinomycetes. For laboratories without molecular capabilities, the use of antibiotic susceptibility patterns and basic biochemical results may provide preliminary identifications of frequently isolated Nocardia species or complexes obtained from clinical specimens. See the 9th and 10th editions of the *Manual of Clinical Microbiology* for information on species discrimination based on biochemical testing (38, 186) and CLSI document M24-A2 (62) for a list of expected susceptibility results for various Nocardia species. When biochemical tests are performed, it is extremely important to include appropriate positive and negative controls to ensure that tests are inoculated, incubated, and interpreted correctly. See Evaluation, Interpretation, and Reporting of Results below for recommendations on reporting preliminary identifications obtained using these methods.

Susceptibility Testing
For *Nocardia* species, basic biochemical testing may be paired with susceptibility testing to achieve preliminary identifications. Some species or species complexes have predictable susceptibility patterns that may assist in isolate characterization (57, 62). These patterns should not be used exclusively as identification techniques, as many newly described species have not been tested for their antibiotic susceptibilities, and some intraspecies variability has been noted.

Cell Wall and Cell Membrane Analysis

Analysis of the cell wall chemistry of the aerobic actinomycetes can aid in the identification of isolates to the genus level (Table 2). While these organisms have distinct cell walls that are characteristic for each genus, methodologies for the investigation of these chemical structures are generally available only in research or reference laboratories. Cell wall analysis is not useful for species-level identification.

Analysis of whole-cell hydrolysates has been used to identify various forms of diaminopimelic acid (DAP) and sugars present in the peptidoglycan layer of the cell walls. The form of DAP combined with the type of sugars present in the peptidoglycan layer of the cell walls allows classification of the various genera among the aerobic actinomycetes, vary among genera in the numbers of their isoprene units and in the degrees of unsaturation of the C \(_2\) isoprenyl side chain (192, 193) (Table 2). Menaquinone analysis has been particularly useful for distinguishing *Nocardia* species from other mycolic acid-containing aerobic actinomycetes (Table 2).

**Molecular Identification**

Molecular techniques, particularly gene sequencing, are currently the only methods that can provide definitive identification of most isolates of aerobic actinomycetes. These methods have the added benefit of providing identifications in a fraction of the time needed for biochemical tests.

**PCR with Amplicon Detection**
The use of PCR and amplicon detection by gel electrophoresis, with genus- or species-specific primers, enables the identification of aerobic actinomycetes that have unique gene regions. Regions of the 16S rRNA gene have been targeted for the genus-level identification of *Nocardia* (184), *Pseudonocardia* and *Saccharopolyspora* (194), *Gordonia* (195), and *Nocardiosis* (196). PCR and amplicon detection of the 16S rRNA and choE genes have also been used for the species-level identification of *Rhodococcus* species (197, 198).

Wehrhahn et al. describe the use of capillary gel electrophoresis to evaluate amplified regions of the 16S-23S intergenic spacer region for identification of *Nocardia* species. The resulting electropherogram is examined for the presence and pattern of peaks indicating amplified fragments of various sizes. The type strains studied showed unique peak patterns; however, there was significant intraspecies heterogeneity observed (199). The usefulness of this methodology with unknown clinical isolates remains to be determined.

**PCR with REA**

PCR paired with restriction endonuclease analysis (REA) has been used for the identification of commonly isolated *Nocardia* species. The procedure takes advantage of the presence of restriction endonuclease recognition sites within the variable regions of an organism’s gene sequence (38). However, because of the increasing number of recognized *Nocardia* species, and because these REA methodologies are able to detect alterations only within the relatively short restriction endonuclease recognition sequence, the usefulness of these techniques is limited to the identification of only a few species. If a laboratory decides to use REA of any gene as an identification tool, the RFLP patterns for the specific gene and endonuclease combinations for each species newly described must be determined (experimentally or by in silico analysis) to prevent misidentifications. The assessment of each newly described species is necessary to ensure that the pattern obtained from a newly described species is different from that obtained from all other species. For information on which species were presumptively identifiable by the use of REA of the HSP gene, see the report by Rodriguez-Navas et al. (200). Presumptive identification of *N. abscessus*, *N. brasiliensis*, *N. caviae*, and *N. otitidiscauriare* was achievable using REA of the 16S rRNA gene for isolates described prior to 2009; see edition 9 of the *Manual of Clinical Microbiology* (38) for information on this technique.

In addition to being used for the identification of *Nocardia* species, REA has been used for differentiating among numerous genera of aerobic actinomycetes andidentifica-
tion of some species of thermophilic actinomycetes (161, 201). It is likely that the usefulness of these procedures, too, will be limited as the number of recognized species within these genera increases.

**Gene Sequencing**

Gene sequencing has become a powerful and, currently, a necessary tool for the identification of isolates within this complex group of organisms. Sequence analysis of the 16S rRNA gene has been used for the species-level identification of members of nearly all genera of the aerobic actinomycetes (12, 33, 86, 132, 150, 162, 202–205).

Several genes have been shown to discriminate adequately among Nocardia species. By far the most sequence information is available for the 16S rRNA gene sequences of members of this genus. See chapter 6 for a discussion of the phylogenetic attributes of this gene. The presence of a variable sequence region, located near the 5' terminus of the gene (206), has made partial 16S rRNA sequencing of a 500-bp region of the gene a useful method for the identification of many Nocardia species. Cloud et al. (207) compared identifications obtained with a commercial 16S rRNA gene sequencing kit and an expanded database with results obtained using phenotypic identifications and with sequencing results from a 999-bp region of the same gene. The 500-bp-based identification of 94 clinical isolates representing 10 species showed 72% agreement with identifications obtained by phenotypic methods and 90% agreement with identifications obtained by sequencing a larger portion of the gene. At present, this commercial system is capable of distinguishing among the more commonly isolated Nocardia species and was also shown to be useful for the genus-level identification of Gordonia, Rhodococcus, Streptomyces, and Tsukamuraella (110).

Sequencing a region of the 16S rRNA gene larger than 500 bp is necessary for the separation of some species that have identical or nearly identical sequences within the 500-bp region (for example, N. abscessus, Nocardia asiatica, and Nocardia arhinitidis; N. elegans and N. veterana; and Nocardia higoensis and Nocardia shimosensis). These species are clearly distinguished with sequence analysis of 1,300 bases. If the various copies of a particular gene are different, it is impossible to determine the identification of an unknown isolate using the sequence of this gene. Unfortunately, the type strains of several species contain multiple copies of the 16S rRNA gene (Table 6) (209). The sequences initially deposited in GenBank at the time the species were described do not indicate the presence of ambiguous bases in the 16S rRNA gene sequence and, therefore, do not reflect the presence of multiple gene copies. It is unclear how the ambiguous base sequences were resolved prior to the deposition of the sequence in GenBank. If the sequences of unknown isolates are compared to these type strain sequences, an acceptable match could not occur. There have been several reports of isolation of species for which the type strain contains multiple copies; in these reports, the authors have sometimes reported 100% agreement of their 16S rRNA gene sequences with that the type strain, but given the presence of multiple differing copies, the resulting identification is questionable.

Other gene targets have been examined for their ability to discriminate among closely related Nocardia species. Rodríguez-Nava et al. evaluated a 441-bp region of the HSP gene for its discriminatory ability for the identification of 44 Nocardia species (200). They found this gene to have more variable sequence regions than found in the 16S rRNA gene, resulting in more sequence dissimilarity among species. This level of sequence heterogeneity will allow discrimination of some species that are very similar by 16S rRNA gene sequencing.

The secA1 gene is a housekeeping gene that codes for the SecA1 protein. This protein is essential for the export of proteins across the bacterial cytoplasmic membrane (211).

Sequence analysis of a 468-bp region of the secA1 gene has been shown to give good discrimination among Nocardia species (212). In a study of 30 type or reference strains of clinical significance, clear differentiation of all species was obtained. In addition, alignment of the deduced amino acid sequence (156 amino acid residues) showed good separation of all type and reference strains and eliminated some within-species microheterogeneities seen in the gene sequences. The deduced amino acid sequences of 38 of 40 clinical isolates tested were identical to that of the type strain of the species to which that isolate was assigned. Kang et al. reported that the analysis of the gyrB gene and the secA1 gene sequences of Gordonia species allow greater discrimination among species than does the 16S rRNA gene (213).

In a study of 120 Nocardia isolates (10 ATCC strains and 110 clinical isolates), Kong et al. noted some discordant identifications with the secA1 genes from clinical isolates compared to the 5' ends of 606-bp 16S rRNA gene sequences, especially with isolates identified as N. nova on the basis of 16S rRNA sequences (214). With the secA1 gene target, the authors noted a high level of intraspecies diversity, especially among N. nova, N. cyriacigeorgica, N. farcinica, and N. veterana. The authors suggest that the diversity of this gene may make it a useful target for epidemiologic investigations.

The gyrB gene may also be a useful target for the identification of Nocardia species, although it has been noted to be present in multiple copies in some strains (215). This gene encodes the β-subunit of DNA gyrase, a type II topoisomerase. In an evaluation of 56 Nocardia type strains, Takeda et al. (216) noted that with the gyrB gene,
interspecies variation ranged from 82.4% to 99.9% (270 to 2 base differences) in sequences of 1,200 bp. The 16S rRNA gene sequences of the same species (as determined from GenBank entries) showed 94.4 to 100% interspecies variation, indicating that sequencing of the glyB gene may enable the discrimination of some closely related species. Phylogenetic trees created using this gene were similar to trees created using the 16S rRNA gene. This gene also clearly discriminated Nocardia species from other related genera.

The glyB gene codes for the β-subunit of RNA polymerase and has also been used for the identification of Nocardia species. While there are glyB gene sequences for Nocardia species in the GenBank database, we are not aware of any publication documenting the usefulness of this gene for identification. Tamura et al. (215) noted that some Nocardia strains may harbor multiple copies of the glyB gene.

For some genera, such as Nocardia, sequence analysis of more than one gene may be useful for unambiguous identification of a clinical isolate and for the recognition of an unusual species. Rodríguez-Nava et al. (200) noted that a combined analysis using both the 16S rRNA and the HSP65 gene resulted in identification inconsistencies of some Nocardia isolates.

Multilocus sequence analysis (MLSA) may also help clarify taxonomic relationships of other members of the aerobic actinomycetes. In 2010, McTaggart et al. reported the usefulness of MLSA for identification and phylogenetic studies of Nocardia species and noted that MLSA may soon surpass the use of DNA-DNA hybridization as the gold standard for bacterial taxonomy (217). The authors created sequence-based phylogenetic clusters using concatenated partial sequences of five genes, glyB, 16S rRNA gene, secA1, hsp65, and glyB, in a study of 36 type and reference strains and 190 clinical isolates. The results showed that 71.3% of the clinical isolates clustered with type strains and were thus identified to the species level. The authors noted that when target sequences of individual genes were evaluated, the resulting identification differed from that obtained using MLSA. This was especially evident for sequences targeting hsp65 and glyB. The authors noted that the sequences from multiple genes appeared to “buffer” the effect of discrepant alleles in the sequences of the individual genes. The authors indicate that results using a 4-locus (glyB, 16S rRNA gene, secA1, hsp65) or a 3-locus (glyB-16S rRNA, secA1) scheme were nearly as reliable results using a 5-locus scheme.

An important component of identification of isolates by gene sequencing is the quality of the database used for sequence comparison. Users of any sequence database should be aware of the limitations inherent in that database. The public database GenBank (NCBI, National Center for Biotechnology Information) (http://www.ncbi.nlm.nih.gov/) includes the most extensive collection of sequences from many gene targets. The drawback to its use is that entries in the general database are not curated, and comparison of an unknown sequence with some poor-quality entries may result in an erroneous identification. GenBank contains a reference sequence (RefSeq) collection that contains nonredundant, annotated sequences that are curated by NCBI staff and collaborators (http://www.ncbi.nlm.nih.gov/refseq/). See Tables 3 through 6 for GenBank type strain sequences deemed to be reliable for the identification of Nocardia and other aerobic actinomycetes. For organisms not listed in those tables, laboratories may want to obtain specific type strains and determine the sequence of that isolate themselves to use as a comparison for unknown patient isolates. Proprietary 16S rRNA gene databases for the identification of Nocardia species may be limited in the number of species represented and in the number of sequences of each species included. Cloud et al. expanded a proprietary database with additional entries to obtain more-reliable matches for query organisms (207). Other useful databases include the Ribosomal Database Project (http://rdp.cme.msu.edu/) for 16S rRNA gene sequences, BiBi (https://umr5558-bibiserv.univ-lyon1.fr/lebibi/lebibi.cgi), which includes sequences from a variety of gene targets, and a commercially available database which includes curated 16S rRNA and secA1 gene sequences.

Other Molecular Methods

Pyrosequencing provides sequence information for short regions of a DNA target and takes advantage of variable regions of otherwise conserved genes. The usefulness of pyrosequencing is limited due to the short region sequenced, the difficulty of interpretation of results from G+C-rich organisms, and the inability of this technique to easily distinguish among some closely related species. There is some evidence that the use of pyrosequencing may be useful for the identification of Nocardia to the genus level (218).

A PCR and reverse line blot hybridization assay was evaluated by Xiao et al. using a total of 135 reference and clinical Nocardia isolates encompassing 14 species. Amplification of a region of the 16S rRNA gene and a region of the 16S-23S gene spacer region was followed by hybridization with a panel of species- or group-specific probes. The assay correctly identified 91.8% of the clinical isolates as determined by 16S rRNA gene sequencing (219).

Yassin and Muller recently reported a real-time PCR assay that enables the identification of members of the genus Tsukamurella from colonial growth. This method is able to discriminate Tsukamurella from other aerobic actinomycetes (220).

Proteomics

MALDI-TOF mass spectrometry is a novel methodology that is being used to identify species of numerous genera of bacteria, especially isolates from clinical specimens. Identifications are based on proteomic profiling by mass spectral analysis, and results obtained from individual isolates are compared to spectra included in databases. There have been only a few published reports describing the use of this technology with the aerobic actinomycetes. Verroken et al. describe the use of MALDI-TOF for the identification of clinical isolates of Nocardia species initially identified using a combination of phenotypic and enzymatic tests and 16S rRNA gene sequencing (221). The nocardial proteins were first extracted using a process involving boiling, centrifugation, and the addition of ethanol, formic acid, and acetonitrile prior to spotting. Using the conventional database, the authors were able to identify only 28/43 isolates (65%) to the species or genus level; 15 isolates (35%) were misidentified. With the addition of the spectra of 100 additional isolates to the database, the authors were able to increase the percentage of isolates identified to the species or genus level to 95% (41/43 isolates correctly identified), with only 2 misidentifications. Analysis of resulting dendrograms indicated that some species contained isolates with very diverse spectra but still clustered together. Farfou et al. reported the accurate identification of 44 isolates of Nocardia (42 to the species level and 2 to the genus level) and 2 isolates of Rhodococcus equi (222). This study utilized an alternate database that was built using direct-colony testing, with no extraction process involved.

As indicated above, one of the limitations of the use of MALDI-TOF for the identification of aerobic actinomyc-
mycobacteria and aerobic actinomycetes (62). The recom-}

mented procedure for susceptibility testing of Nocardia and

the other aerobic actinomycetes is broth microdilution;}

panels containing the appropriate dilutions of antimicro-

bials specifically active against these genera are commercially

available, but at the time of this writing, none are cleared

for use in the United States. The CLSI document outlines

methods for inoculum preparation, panel inoculation, incu-

bation, and result interpretation. For Nocardia species,

panels are read after 3 to 5 days of incubation, with the

incubation duration dependent on the particular species

being tested. Antimicrobial agents recommended for pri-

mary susceptibility testing of all aerobic actinomycete gen-

era include amikacin, amoxicillin-clavulanic acid, ceftria-

xone, ciprofloxacin, clarithromycin, imipenem, linezolid,

minocycline, trimethoprim-sulfamethoxazole, and tobra-

mycin. Agents to be considered for secondary testing include

cefepime, cefotaxime, and doxycycline. The CLSI docu-

ment lists both the breakpoints and the interpretive criteria

for all drugs to be tested for Nocardia isolates; both an MIC

and an interpretation of the MIC result should be provided

in the report to the physician. The document also indicates

that the breakpoints listed for Nocardia species can be used

for other aerobic actinomycetes but should be reported as

tentative pending accumulation of further information on

these drug/organism combinations (62).

Among the aerobic actinomycetes, reports on various strain

typing methodologies are limited to studies on Rhodococcus

species, Tsukamurella species, and Nocardia species. For No-
cardia, there is no consensus on the best method for perform-
ing strain typing. Lack of reproducibility and/or insufficient

differences among strains are common difficulties seen with

most methods. In addition, interpretive criteria for the vari-

cious methods are undefined.

Among Nocardia species, N. farcinica is most frequently

implicated in infection outbreaks. There are several reports

of strain typing of N. asteroides using various methods, but

it is unclear if results reflect differences in strains or genetic

differences inherent in members of the “N. asteroides com-

plex.” See Table 7 for a summary of methods and organism

targets.

SEROLOGIC METHODS

There have been no recent publications (since 1988) de-

scribing serologic methods for the diagnosis of infections

cau sed by aerobic actinomycetes.

ANTIMICROBIAL SUSCEPTIBILITIES

Susceptibility testing should be performed on all isolates of

Nocardia and other aerobic actinomycetes thought to be of

possible clinical significance. CLSI has recently published

a revised approved standard for susceptibility testing of both

Nocardia species 199

TYPING SYSTEMS

Among the aerobic actinomycetes, reports on various strain

typing methodologies are limited to studies on Rhodococcus

species, Nocardia species, and other aerobic actinomycetes thought to be of

possible clinical significance. CLSI has recently published

a summary of methods and organism

targets.

Nocardia species 199

No-

The spectra of some Nocardia type strains are different from

the spectra of clinical isolates of the same species and that

a species may contain isolates with many different, but

related, spectra. Comparison to all spectra from the same

species may improve the accuracy of the resulting identifica-

tions. It is also important to note that it may be difficult to

accurately identify closely related species (such as mem-

bers of the N. nova complex) using MALDI-TOF (S. An-

tonara, personal communication).

cetes is the lack of spectra for these organisms in the instru-

ment databases. In cases of uncommonly isolated organisms,

users must create their own databases with reference strains

and well-characterized clinical isolates related to the organ-

isms that they wish to identify. It is important to note that

the spectra of some Nocardia type strains are different from

the spectra of clinical isolates of the same species and that

a species may contain isolates with many different, but

related, spectra. Comparison to all spectra from the same

species may improve the accuracy of the resulting identifica-

tions. It is also important to note that it may be difficult to

accurately identify closely related species (such as mem-

bers of the N. nova complex) using MALDI-TOF (S. An-

tonara, personal communication).

*RAPD, randomly amplified polymorphic DNA; PFGE, pulsed-field gel electrophoresis.
only 2% of 138 Nocardia isolates tested over an 11-year period were determined to be sulfonamide resistant (228). In response to the report from the CDC on sulfonamide resistance in the United States, Brown-Elliott et al. reported a retrospective analysis of 552 Nocardia isolates recovered and tested at 6 U.S. laboratories, among which only 2% were resistant to sulfonamides (229). The authors propose that reports of increased resistance may be related to the difficulties in interpretation of sulfonamide broth dilution tests, the lack of a recommended Nocardia species quality control organism, and the lack of proficiency testing programs to ensure accurate interpretation. There are also limited data to indicate the in vivo action of sulfonamides in cases of in vitro resistance. In a recent report, a patient with an arterial-stent-related N. farcinica infection was treated with multiple antibiotics, including trimethoprim-sulfamethoxazole, despite in vitro resistance to this drug. It appeared that the trimethoprim-sulfamethoxazole was useful in controlling the patient's infection (230).

The multisite broth microdilution study published in 2012 noted a significant lack of reproducibility among testing sites for the sulfonamides (223). Of a total of 1,681 replicate sulfonamide MIC results for 5 species (one isolate each of N. brasiliensis, N. cyriacigeorgica, N. farcinica, N. nova, and N. wallacei determined by previous testing to be susceptible to sulfonamides), 14.6% of results indicated resistance to sulfamethoxazole or trimethoprim-sulfamethoxazole. Since criteria for inoculum preparation and assay performance were similar at all testing sites, the authors noted that the most likely explanation for this lack of reproducibility with these drugs is the difficulty of determination of the endpoint, which is defined as the dilution that results in 80% inhibition compared to growth in the control well. Interestingly, only 1.7% of 296 concurrently run disk diffusion tests using the same isolates indicated resistance to sulfamethoxazole. The authors propose that when performing broth microdilution tests for sulfonamides, a disk diffusion test be performed for validation of the MIC result. The inoculated disk diffusion plate may also be useful for checking the inoculum concentration (223). The CLSI document states that isolates showing a discrepancy between the broth microdilution and disk diffusion tests for sulfonamides should be retested or referred to a reference laboratory for testing (62).

The 2012 multicenter study also highlighted additional difficulties that may be encountered in the setup and interpretation of broth microdilution tests for Nocardia (223). Preparation of an adequate inoculum is an important concern; the clumping nature of Nocardia isolates often prevents the preparation of an adequately homogeneous inoculum suspension. The current CLSI document suggests the use of a "pellet pestle" to assist in creating a dense suspension with a minimum of organism clumps (62). In addition, the use of a nephelometer to standardize the inoculum suspension is recommended to provide an appropriately dense inoculum (62). However, even with careful inoculum preparation, resulting colony counts prepared using traditional spread plate techniques may not accurately represent the actual organism concentration in the inoculum, nor do such colony count results correspond to accurate or inaccurate MIC values (223). Because endpoint determination for Nocardia species is more technically challenging than for other organisms, the multisite study manuscript recommends that technical staff become familiar with endpoint determinations as illustrated in the CLSI guidelines, especially for the sulfonamides. Additional recommendations to improve susceptibility testing results include thorough training of technical staff in inoculum and panel preparation, comparison of results with expected results for a particular species (as noted in the current CLSI document), the testing of an appropriate quality control strain (N. nova ATCC BAA-2227 was recommended [223]), and participation in proficiency testing with another laboratory. The multisite study manuscript also recommends referral of any isolate to a reference laboratory if the susceptibility pattern obtained is different from the expected result for that organism (223).

In a study of 51 clinical isolates of Nocardia species and 12 other species of aerobic actinomycetes, Lowman and Aithma compared results from the Etest to results obtained by broth microdilution. Results with the Etest showed only 46.2 to 81.6% agreement within ±1 dilution and 67.5 to 100% categorical agreement with broth microdilution. There were very major errors reported with the Etest for the more rarely isolated species. The authors concluded that the Etest is not an acceptable alternative to broth microdilution for the aerobic actinomycetes and note specific problems with inoculum preparation and reading/interpretation of the test (231).

There is limited information in the literature regarding susceptibility testing of members of the aerobic actinomycetes other than Nocardia. Erol et al. report MIC90 results of testing isolates of Amycolatopsis species from cases of nocardioform placentitis in horses using a commercially available panel (232).

For R. equi, the current CLSI document recommends that a regular Gram-positive panel be inoculated (if such panels include vancomycin and rifampin, critical antimicrobials for this species). Results can be read after 24 h of incubation, and results should be reported as "tentative." Breakpoints for Staphylococcus aureus should be used (62). Liu et al. recently reported susceptibility results for Tsukamurella tyrosovulens, Tsukamurella spumae, and Tsukamurella pulmonis using a short incubation antimicrobial susceptibility testing system and noted that these three species were susceptible to amoxicillin-clavulanic acid, ciprofloxacin, moxifloxacin, and linezolid. T. tyrosovulens and T. spumae were reported as susceptible to sulfamethoxazole, while T. pulmonis was reported as resistant (155). The current CLSI document indicates that susceptibility testing for Tsukamurella species may be read after 48 h of incubation for some species (62).

Moser et al. reported that 13 clinical isolates of Gordonia polypsopraeformans were susceptible to amikacin, amoxicillin-clavulanic acid, ampicillin, ceftriaxone, ciprofloxacin, imipenem, linezolid, and vancomycin using the CLSI-recommended procedure. Eight of the 13 isolates were reported to be resistant to sulfamethoxazole (233).

Drug susceptibility testing of isolates of Segniliparus rugosus may require the use of Middlebrook 7H9 broth, as the use of cation-adjusted Mueller-Hinton broth may provide insufficient growth (234). Using breakpoints recommended for Nocardia species and for rapidly growing mycobacteria (38), Butler et al. (234) indicated that the S. rugosus isolates were susceptible to imipenem, rifabutin, sulfamethoxazole, and trimethoprim-sulfamethoxazole and resistant or intermediate to amikacin, amoxicillin-clavulanate, ceftriaxone, ciprofloxacin, clarithromycin, linezolid, minocycline, and tobramycin.

Isolates in the genera Dietzia tend to be susceptible to a broad range of antimicrobials, and at present, there is no clear evidence that susceptibility can be predicted by species identification (52).
EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

The aerobic actinomycetes are widespread in the environment. Therefore, particularly when an aerobic actinomycete is isolated in culture in small amounts without having been visualized in the direct patient specimen, it may be impossible for the laboratory to determine if the isolate is the result of specimen or laboratory contamination, patient colonization, or actual infection. Some indication of the quantity of the organism present should be given for any isolate of an aerobic actinomycete. Discussion between the clinical and laboratory staff is extremely useful for selection of additional patient specimens and laboratory procedures for determination of the clinical significance of an isolate from a given patient. (See the Clinical Significance section of this chapter for information on species known to cause human disease. Additionally, see Tables 3 through 6 for information on the frequency of isolation of species known to be clinically significant.) Identification of an organism to the genus level may help determine its significance. However, even for accurate genus assignment, molecular methods may need to be employed. In some cases, genus-level identification (if possible) suffices.

When an isolate is reported to the species level, the laboratory should be certain that clinicians are aware of the reliability of the identification method used. Reports should indicate how the isolate was identified. It may be possible to preliminarily identify the more commonly encountered aerobic actinomycetes, particularly Nocardia species, to the species level using phenotypic methods (81, 186), but some are inevitably misidentified by such procedures. Precise identification can be achieved only by gene sequencing; if identification is obtained by other methods, the report should indicate that the identification is presumptive. Susceptibility results should be reported for isolates considered to be clinically significant. For accurate determination of both identification and susceptibility results, referral to a laboratory with expertise in working with these organisms may be necessary.

Whenever a laboratory isolates an aerobic actinomycete for which sequencing indicates that the organism has been rarely isolated, the circumstances surrounding the isolation of the organism should be carefully evaluated to assess its potential clinical significance, and a search of recent literature might be conducted to determine what is already established regarding pathogenicity and antibiotic susceptibility for that species. For such searches, the LPSN and PubMed may be good starting points; care should be taken to consider current nomenclature and taxonomy as stated by the LPSN. The report of a rare or unusual species should be accompanied by a brief summary of whatever is known regarding its clinical significance.

We gratefully acknowledge the assistance of Yvonne R. Shea in the preparation of the colony photographs and for critically reviewing the manuscript.

BACTERIOLOGY

Many species within the genus *Mycobacterium* are prominent pathogens, above all, the members of *Mycobacterium tuberculosis* complex, *Mycobacterium leprae*, and *Mycobacterium ulcerans*. In addition, there are more than 150 species of environmental mycobacteria, called nontuberculous mycobacteria (NTM), which exert various degrees of pathogenicity and virulence.

Tuberculosis is second only to HIV/AIDS as the greatest global killer due to a single infectious agent. Based on the most recent survey data of the World Health Organization (WHO), about one-third of the world’s population has latent tuberculosis, corresponding to approximately 2.4 billion people (1). It was estimated that 8.7 million new cases of tuberculosis occurred and that 1.4 million people died of tuberculosis in 2011. Of particular concern is the increasing extent of estimated multidrug-resistant tuberculosis (MDR-TB) (>300,000 cases; 3.7% of new cases and 20% of previously treated cases) and extensively drug-resistant tuberculosis (XDR-TB) cases, identified to date in 81 countries, as well as the problem of people coinfected with HIV. According to the WHO, the infections of 1.1 million (13%) of the 8.7 million people who have developed tuberculosis worldwide were HIV related, among which 79% were in the African region (1). Reducing the burden of tuberculosis depends largely on how rapidly DOTS (directly observed therapy, short-course) programs can be implemented.

Among the prime obstacles for a successful elimination of the disease are lack of political commitment, shortages of trained staff, and poor laboratory services, together with inadequate patient management. Although the total number of global tuberculosis cases is still increasing in absolute terms as a result of population growth, it has, nevertheless, been observed that the number of incident cases per capita has been falling globally for several years at a rate of 2.2% between 2010 and 2011. Likewise, the tuberculosis mortality rate has decreased 41% since 1990, reflecting the effectiveness of prevention strategies and control measures implemented by health authorities, including the use of more-rapid and efficient laboratory algorithms to detect *M. tuberculosis* and susceptibility testing against antituberculosis drugs. If these common efforts are not jeopardized in the future, it appears that the world is on track to achieve the global target of a 50% reduction of tuberculosis cases by 2015 (1). In this context, the clinical mycobacteriology laboratory plays a pivotal role.

Apart from the members of the *M. tuberculosis* complex, NTM species are increasing in number, and some of them are sources of important diseases in humans (2–6). Thus, rapid and reliable identification of NTM is essential. Overall, the level of service and the choice of methods applied in clinical mycobacteriology laboratories should be determined by the patient population served and by the resources available.

**TAXONOMY AND DESCRIPTION OF THE GENUS**

The genus *Mycobacterium* is the only genus in the family *Mycobacteriaceae* (7) and is related to other mycolic acid-containing genera. The high G+C contents of the DNA of *Mycobacterium* species (61 to 71 mol%, except in *M. leprae* [55%]) are within the range of those of the other mycolic acid-containing genera, *Gordonia* (63 to 69 mol%), *Tsukamurella* (68 to 74 mol%), *Nocardia* (64 to 72 mol%), *Rhodococcus* (63 to 73 mol%), and *Segniliparus* (68 to 72 mol%) (8, 9).

*Mycobacteria* are mainly aerobic, non-spore-forming (except *M. marinum* [10]), nonmotile, slightly curved or straight rods (0.2 to 0.6 μm by 1.0 to 10 μm) that may branch. Colony morphology varies among the species, ranging from smooth to rough and from nonpigmented (nonphotochromogens) to pigmented. Pigmented colonies are regularly or variably yellow, orange, or, rarely, pink, usually due to carotenoid pigments. Some species require light to form pigment (photochromogens), while other species form pigment in either the light or the dark (scotochromogens). Aerial filaments are very rarely formed and never visible without magnification. Filamentous or mycelium-like growth may sometimes occur, but upon slight disturbance, the organism easily fragments into rods or coccoid elements. The cell wall peptidoglycolipid contains meso-diaminopimelic acid, alanine, glutamic acid, glucosamine, muramic acid, arabinose, and galactose. Mycolic acids (whose numbers of carbon atoms range from 70 to 90), together with free lipids (e.g., trehalose-6,6′-dimycolate), provide for a

**doi:10.1128/9781555817381.ch30**
hydrophobic permeability barrier (11). Other important fatty acids are waxes, phospholipids, and mycoserosic and phthienoic acids. Various patterns of cellular fatty acids (whose numbers of carbon atoms range from 10 to 20) are found as well, among which is tuberculostearic (10-R-methylstearic acid), a unique cell component for a number of aerobic actinomycetes (11).

The high content of complex lipids of the cell wall prevents the access of common aniline dyes. Not readily stained by Gram’s method, mycobacteria are stained with special procedures (e.g., Ziehl-Neelsen staining). They are not easily decolorized, even with acid-alcohol, and they are, therefore, acid fast. However, acid fastness can be partly or completely lost at some stage of growth by a proportion of the cells of some species, particularly the rapidly growing ones.

Compared to the growth of other bacteria, the growth of most mycobacterial species is slow, with generation times of up to approximately 20 h (M. ulcerans's is up to 36 h) on commonly used media. A natural division exists between slowly and rapidly growing species of mycobacteria. Slow growers require more than 7 days to produce colonies on solid media from a dilute inoculum under ideal culture conditions. Rapid growers, by definition, require less than 7 days when subcultured on Löwenstein-Jensen (L-J) medium but may also take several weeks to appear in primary cultures from clinical specimens.

Nutritional Requirements and Growth

Most species adapt readily to growth on relatively simple substrates, using ammonia or amino acids as nitrogen sources and glycerol as a carbon source in the presence of mineral salts. A few species (e.g., Mycobacterium haemophilum and Mycobacterium genavense) are fastidious and require supplements such as mycobactin, hemin, or other compounds. To date, M. leprae has not been cultured outside living cells. Growth of mycobacteria is stimulated by carbon dioxide and by fatty acids, which may be provided in the form of egg yolk or oleic acid, even though the latter is toxic in high concentrations (>1%) and has to be neutralized by albumin. Optimum temperatures for growth vary widely among species (from <30 to 45°C).

With the genomes of several mycobacterial species deciphered, functional genomics have provided new insights into their physiological and metabolic regulation and their relation to virulence (12).

Susceptibility to Physical and Chemical Agents

Mycobacteria are able to survive for weeks to months on inanimate objects if protected from sunlight. M. tuberculosis complex organisms, for instance, survive for several months on surfaces or in soil or cow dung, from which other animals may be infected (13). Mycobacteria are not easily killed by freezing or desiccation but can be killed by heat (for Mycobacterium avium, for instance, the time necessary to kill 90% of the cells at 60°C is 4 min, but for Mycobacterium xenopi, it is 33 min) and by ultraviolet (sun)light (NTM, for instance, are 2- to 10-fold more resistant to UV irradiation than Escherichia coli [4]). Mycobacteria are more resistant to acids, alkali, and some chemical disinfectants than most other non-spore-forming bacteria. Quaternary ammonium compounds, hexachlorophene, and chlorhexidine are bacteriostatic at best. Proprietary disinfectants recommended as suitable for use in tuberculosis laboratories are those containing phenols, chlorine, or alcohol (14–16). Other commonly used agents, such as ethylene oxide and formaldehyde vapor, as well as disinfectants, such as 2% alkaline glutaraldehyde, 2% peracetic acid, and stabilized hydrogen peroxide, are effective in killing M. tuberculosis as well. With iodophors, the bactericidal effect depends on the content of available iodine as well as on the presence of organic matter. In their guidelines, the Centers for Disease Control and Prevention (CDC), National Institutes of Health (NIH), suggest intermediate-level disinfectants (reference 15; see also chapter 13).

EPIDEMIOLOGY AND TRANSMISSION

The genus Mycobacterium includes obligate pathogens, opportunistic pathogens, and commensals. Because M. leprae and M. tuberculosis complex organisms are incapable of replication in an inanimate environment, the major ecological niche for them is tissues of humans and warm-blooded animals. M. tuberculosis is carried in airborne particles (droplet nuclei) generated when patients with pulmonary tuberculosis cough. These particles, 1 to 5 μm in size, are kept suspended by normal air currents. Infection occurs when a susceptible person inhales the droplet nuclei. Once in the alveoli, the organisms are engulfed by alveolar macrophages. Usually, the host cell-mediated immune response limits the multiplication and spread of M. tuberculosis. However, some bacilli can remain viable but dormant for many years after initial infection. Patients latently infected with M. tuberculosis are asymptomatic and not infectious but usually have a positive tuberculin skin test (TST) or a positive result with one of the interferon gamma (IFN-γ) release assays (IGRAs). In general, persons with a latent infection have a 10% risk during their lifetime of developing active tuberculosis, whereas patients with HIV infection have a 10 to 15% risk per year of progressing to disease manifestation (17).

In contrast, NTM are free-living mycobacteria usually found in association with watery habitats, such as lakes, rivers, and soil (4). While for some human-pathogenic NTM species, e.g., Mycobacterium haemophilum and Mycobacterium scouleri, the reservoir has not yet been defined (2), for others, such as M. avium complex (MAC) organisms, Mycobacterium chimaera, Mycobacterium genavense, Mycobacterium gordonae, Mycobacterium kansasi, Mycobacterium lentiflavum, Mycobacterium simiae, Mycobacterium xenopi, and some rapidly growing mycobacteria, tap water and/or showerheads have served as reservoirs (18–21). Some NTM species are associated with nosocomial disease and/or pseudo-outbreaks (2). Other well-known sources of positive mycobacterial cultures are bronchoscopes and related devices. Organisms isolated from these pseudo-infections include M. tuberculosis and M. xenopi as well as other NTM. Although not components of the microbiota of humans or animals, NTM may simply be isolated as “bystanders” from the skin, upper respiratory tracts, and intestinal and genital tracts in asymptomatic individuals (3). Due to their ubiquitous nature, the question of their clinical significance is, therefore, important but often difficult to answer (2). The major route of infection of NTM leading to pulmonary disease is via aerosols. Other possible routes of NTM infection from their reservoirs may occur via ingestion of soil or water, inhalation of dusts, and aspiration due to gastric reflux of NTM that entered the stomach via ingestion (4).

CLINICAL SIGNIFICANCE AND DESCRIPTION OF SPECIES

With the advent of molecular techniques for appropriate identification, close to 200 mycobacterial species have now been described, and their number is increasing steadily. This
chapter will focus on the slowly growing mycobacteria only; rapidly growing mycobacteria are described in chapter 32.

**Mycobacterium tuberculosis Complex**

The *M. tuberculosis* complex taxon includes *M. tuberculosis*, *M. bovis*, *M. bovis BCG*, *Mycobacterium africanum*, *Mycobacterium caprae*, *Mycobacterium microti*, *Mycobacterium canetti*, *Mycobacterium pinnipedii*, and the recently described *Mycobacterium mungi* and *Mycobacterium orygis*. Although the members of the *M. tuberculosis* complex are characterized by different phenotypes and mammalian host ranges, they display a very extreme genetic homogeneity, with only approximately 0.01 to 0.03% synonymous nucleotide variation and no significant trace of genetic exchange among them (22–24). Irrespective of this, identification to the species level is not merely an academic exercise but justified for epidemiologic, public health, and therapeutic reasons.

**Mycobacterium tuberculosis**

In the industrialized world, a higher prevalence of tuberculosis occurs among the medically underserved ethnic minorities, the urban poor, homeless persons, prison inmates, alcoholics, intravenous drug users, the elderly in general, foreign-born persons from areas of high prevalence, and contacts of persons with active tuberculosis than among other populations. The greatest known risk factor for progression of latent infection to active tuberculosis is HIV infection. Combined HIV and tuberculosis infections, especially in combination with drug resistance, have caused outbreaks in the past with extremely high mortality rates. In addition, the emergence of XDR-TB has had a dramatic impact on the changing patterns of global tuberculosis (25). Groups with a higher likelihood of progression also include individuals with underlying medical conditions, persons who have been infected within the past 2 years, children ≤4 years old, and persons with fibrotic and/or cancerous lesions on chest radiographs.

Tuberculosis in adults is a slowly progressive process characterized by chronic inflammation and caseation and formation of cavities. These foci may rupture into the bronchi, allowing very large numbers of organisms to spread to other areas of the lungs and to be aerosolized by coughing, hence infecting other persons. Important clinical features of pulmonary tuberculosis are cough, weight loss, night sweat, low-grade fever, dyspnea, and chest pain. Extrapulmonary manifestations of *M. tuberculosis* infection include cervical lymphadenitis, pleuritis, pericarditis, synovitis, meningitis, and infections of the skin, joints, bones, and internal organs (26). Pulmonary disease in AIDS patients often differs in radiologic findings from the ordinary clinical picture of tuberculosis and usually progresses rapidly. In these patients, extrapulmonary manifestation and disseminated disease, sometimes even without the formation of granulomas, are seen more frequently (26).

In culture, colonies of *M. tuberculosis* are off-white and rough on solid medium (Fig. 1). The genome of *M. tuberculosis* (4,411,529 bp) was deciphered more than 15 years ago (27). Studies have shown that modern strains of *M. tuberculosis* have an extremely low level of genetic variation, suggesting that the entire population of *M. tuberculosis* strains resulted from clonal expansion after an evolutionary bottleneck some 35,000 years ago (24, 28). Today’s strains constitute just the visible tip of a much broader progenitor species. Based on very recent molecular data, the *M. tuberculosis* genome appears to be a composite assembly resulting from horizontal gene transfer events predating clonal expansion. The amount of synonymous nucleotide variation in housekeeping genes suggests that tuberculosis bacilli were contemporaneous with early hominids in East Africa and coevolved with their human host much longer than previously thought (24, 29).

**Mycobacterium bovis**

*M. bovis* causes tuberculosis in warm-blooded animals, such as cattle, dogs, cats, pigs, parrots, badgers, deer, camels, some birds of prey, and also primates, including humans. *M. bovis* caused as many as 25% of cases of human tuberculosis in developed countries in the late 19th century; the number of tuberculosis cases caused by *M. bovis* has dropped to 1 to 2% today (30), but this organism still remains an important problem in nonindustrialized nations. Human disease is very similar to that caused by *M. tuberculosis* and is treated accordingly, except that pyrazinamide is ineffective due to the inherent resistance of *M. bovis*. Colonies on egg-based media are small and rounded, with irregular edges and a granular surface; on agar media, colonies are small and flat (7). The genome of *M. bovis* has a size of 4,345,492 bp and a G+C content of 65.6%. The sequence is >99.9% identical to that of *M. tuberculosis*. There are some deletions in the genome which led to a reduced genome size (31).

**Mycobacterium bovis BCG**

In many parts of the world, Bacillus Calmette-Guérin (BCG) is still used for vaccine purposes. Distributed by Calmette in 1924 to laboratories around the world, the strain has been maintained in vitro by serial passaging. Today, there exists a genetically heterogeneous conglomerate of BCG strains (Fig. 2) (32, 33; www.bcgatlas.org) which predominantly conform to the properties described for *M. bovis*, except that they are attenuated in virulence. In rare instances, BCG may, however, disseminate as a complication of intravesical BCG immunostimulation against bladder cancer (34, 35). The 4,374,522-bp genome contains nearly 4,000 protein-coding genes, 58 of which are present in two copies as a result of two independent tandem duplications, DU1 and DU2. Also, mutations in genes encoding σ factors and pleiotropic transcription regulators, like PhoRn and Crp, were uncovered in various BCG strains. Together with gene amplification, these mutations affect gene expression levels, immunogenicity, and possibly protection against tuberculosis, suggesting that early BCG vaccines may even be superior to the later ones, which are more widely used (36). Single nucleotide polymorphism analysis is able to differentiate the *M. bovis* BCG lineage from the virulent *M. bovis* lineage (37).

**Mycobacterium africanum**

*M. africanum*, with a genome size of 4,389,314 bp (G+C content of 65.6%), causes up to half of the cases of human tuberculosis in West Africa. Infections with *M. africanum* display differences from infections with *M. tuberculosis* in patients’ characteristics and immunopathological features (38). The organism has also been reported from other continents, such as the United States, mainly in patients who have lived in Africa (39). Resembling the colonies of *M. tuberculosis*, *M. africanum* has physiological and biochemical properties that position the organism between *M. tuberculosis* and *M. bovis*. Prior to molecular genetics, the definition of *M. africanum* was difficult and its validity questioned by some authors. *M. africanum* strains were classified into two major subgroups on the basis of geographical origin.
and biochemical properties, i.e., *M. africanum* subtype I from West Africa and *M. africanum* subtype II from East Africa. Based on genotypic analyses, subtype II has recently been described as *M. tuberculosis*, thus leaving the West African type as the only *M. africanum* strain (with the two subtypes MAF1 and MAF2 [38, 40]). The species is characterized by the lack of a region of difference (RD9), the presence of RD12, and a specific *gyrB* gene polymorphism (22). These findings are corroborated by most recent genome analyses of *M. africanum*, which reveal a lineage-specific locus and gene erosion common to the *M. tuberculosis* complex (41).

*Mycobacterium caprae*

*M. caprae*, with the former names *M. tuberculosis* subsp. *caprae* (42) and *M. bovis* subsp. *caprae* (43), was originally described as preferring goats to cattle as hosts. *M. caprae* is also seen in sheep, pigs, wild boars, red deers, and foxes (44) and accounted for 31% of human tuberculosis cases, mostly as pulmonary manifestation, in Germany between 1999 and 2001 (43). Easily recognized by its susceptibility to pyrazinamide, *M. caprae* can be added to the list of agents of human tuberculosis contracted from animals. On the basis of mycobacterial interspersed repetitive unit (MIRU) genotyping, it was later demonstrated that *M. caprae* is closely related to the branches of classical *M. bovis*, *M. pinnipedii*, *M. microti*, and ancestral *M. tuberculosis* but separate from modern *M. tuberculosis* (45). With a heterogeneous RD4, *M. caprae* can be differentiated by PCR from *M. bovis*, and the three variants of alpine *M. caprae* isolates can be identified as well (46).

*Mycobacterium microti*

Originally isolated from rodents, such as voles and shrews, *M. microti* also causes naturally acquired tuberculosis in guinea pigs, rabbits, llamas (47, 48), cats (49, 50), meerkats (51), and other warm-blooded animals as well as both immunocompetent and immunosuppressed humans (52, 53, 54). Usually revealing a characteristic “croissant-like” morphology in stained smears (Fig. 3), the organism normally fails to grow in culture. At least the vole type of *M. microti* can easily be recognized upon spacer oligotyping (see chapter 31) since it contains an exceptionally short genomic direct repeat region resulting in identical two-spacer sequence
Mycobacterium canettii was collected by Georges Canetti in 1969. van Mycobacterium canettii living in the United States (60). M. canettii was reported in Africa (59), and in 2009, the first case of meningitis was recognized in a Sudanese refugee (61) of 20 regions where insertion/deletion events have been described. The proposed M. canettii diverged first from the rest of the M. tuberculosis complex. On the basis of variable-number tandem repeat (VNTR) genotyping and analysis of hsp65 gene polymorphisms in 44 strains of M. canettii, Fabre et al. (58) confirmed that M. canettii is the most probable source species of M. tuberculosis complex, rather than just another branch of the taxon. In fact, it is assumed that M. canettii appeared some 2.8 million years ago and may, therefore, be the ancestor of all members of the present-day M. tuberculosis complex (24). Based on sequencing and whole-genome analyses, strains of M. canettii are highly recombinogenic and exhibit early branching, with larger genome sizes, higher rates of genetic variation, and fewer molecular scars than M. tuberculosis and with distinct CRISPR (clustered regularly interspaced short palindromic repeats)-Cas system-associated sequences (62).

Mycobacterium pinnipedii sp. nov.
On the basis of host preference as well as phenotypic and genotypic characteristics, M. pinnipedii sp. nov., another member of the M. tuberculosis complex, was defined by Cousins et al. in 2003 (63). Pinnipedii appear to be the natural host, but the organism is also pathogenic for guinea pigs, rabbits, and possibly cattle. The “seal bacillus” also affects animals in zoological gardens, e.g., camels (Camelus bactrianus) and tapirs (Tapirus indicus) (64). Transmission of M. pinnipedii infection from a tapir to other tapirs (64) and from sea lions to humans was recently demonstrated by the TST and IGRA (65). Infections with M. pinnipedii manifest with granulomatous lesions in lymph nodes, lungs, pleura, and spleen and are able to disseminate.

Novel Proposed Species within the M. tuberculosis Complex
Based on molecular characteristics, two novel taxa of the M. tuberculosis complex have been described. The proposed new species, Mycobacterium mungi, is the causative agent of tuberculosis in the banded mongoose (Mungo mungo) (66), and M. orygi affects larger mammals, such as oryxes, gazelles, antelopes, and waterbucks on the African continent (67–69).

Mycobacterium leprae
In past centuries, leprosy (Hansen’s disease) occurred on a large scale in Europe, in particular in Norway. Today, rigorous control programs in many areas of endemicity, such as southern and Southeast Asia, Africa, and Latin America, have led to a considerable reduction in leprosy burden. Nevertheless, new cases continue to occur in almost all countries where leprosy is endemic, and according to the WHO, high-burden pockets can exist against a low-burden background (70). For 2011, the registered prevalence of leprosy as reported by 105 countries was 219,075, compared to >763,000 in 2001 (70). Currently, there are 18 countries that reported >1,000 new cases. These countries contributed 94% of the new cases detected globally in 2011. With India contributing 58%, Brazil 16%, and Indonesia 9% to all new cases detected, these three countries contributed 83% of the new cases detected globally in 2011. Access to diagnosis and treatment with multidrug therapy (dapsone, rifampin, and clofazimine; available by the WHO free of cost) remain key elements in the strategy to eliminate the disease. With the implementation of the enhanced global strategy from 2011 to 2015, which emphasizes reducing grade 2 disabilities among new cases, it is crucial that leprosy programs focus on underserved populations and remote areas to improve access and coverage, while not neglecting urban centers.

Leprosy is a chronic, granulomatous, and debilitating disease. Its principal manifestations include anesthetic skin lesions and peripheral neuropathy with nerve thickening. Leprosy illustrates a continuous spectrum of disease, from one with very few demonstrable bacilli (tuberculoid leprosy) to a progressive, widespread, and very severe form with massive numbers of organisms due to the absence of cell-mediated immunity (lepromatous leprosy). The majority of leprosy patients show manifestations between these two polar forms and are clinically unstable. Medical complications arise from nerve damage and immune reactions. Shedding from the nose, rather than from skin lesions, is important for transmission, which results most likely from prolonged and intimate contact with a person with multibacillary disease. The natural reservoir for M. leprae is not well established, but naturally occurring infections in the nine-banded armadillo (Dasypus novemcinctus) have been documented in the southern United States, with a prevalence of 0 to 10% in those animals (71).

Together with Mycobacterium tilburgii, M. leprae differs from all other mycobacteria in that it cannot be cultured in vitro. By tradition, the diagnosis of leprosy is essentially a clinical one, based on finding one or more signs of disease which are supported by the presence of acid-fast bacilli (AFB) on slit-skin smears or in skin biopsy specimens. Since leprosy bacilli are much less acid and alcohol fast than M. tuberculosis, 10% sulfuric acid is preferentially used as a decolorizer in place of an acid-alcohol solution (Fite-Faraco stain (72)). In the case of lepromatous disease, nodules and plaques are the preferred sites for biopsies, which reveal numerous AFB. Conversely, in patients with tuberculoid leprosy, the rims of lesions should be biopsied, where usually only a few or no AFB are found. A number of PCR assays have been established to conclusively detect the organism and to characterize M. leprae genotypes (73). A recently developed line probe assay (GenoType LepraeDR; Hain Lifescience, Nehren, Germany) directly detects the
organism and its antibiotic resistance in clinical specimens via detection of mutations in the rpoB gene (conferring resistance to rifampin), the gyrA gene (conferring resistance to ofloxacin), and the folP1 gene (conferring resistance to dapsone [74]). The complete genome of M. leprae is 3,268,203 bp in length, with a G+C content of 57.8%. As in M. bovis, the deletions observed in the genome of M. leprae have lost >1.1 Mb and accumulated >1,100 pseudogenes during reductive evolution (75).

Naturally acquired murine leprosy has been observed in rats, mice, and cats and is caused by Mycobacterium leprae- murium, a species which may be cultured on egg yolk-based media (76). Finally, unique clinicopathologic features of diffuse lepromatous leprosy in humans plus phylogenetic analyses of the 16S rRNA, rpoB, hsp65, rrs, and sigA genes led to the discovery of a new mycobacterial species for which M. lepromatosis has been proposed (77–79).

Nontuberculous Slowly Growing Mycobacteria Frequently Involved in Human Disease

With the increased awareness of NTM disease in humans and the molecular achievements in the diagnosis of these organisms, a large number of prevalence studies have become available (80). The American Thoracic Society (ATS) and the Infectious Diseases Society of America (IDSA) have devised their comprehensive guidelines for the diagnosis, treatment, and prevention of NTM disease in HIV-positive and HIV-negative individuals (2). Although applied widely, the guidelines have recently been challenged by a retrospective analysis of Scandinavian patients from whose respiratory tracts NTM were isolated (81).

Mycobacterium avium Complex

MAC organisms have been isolated from water, soil, plants, animals, indoor water systems, hot tubs, and pools. They are important pathogens of poultry and swine but were not recognized as a cause of human disease until the 1940s. Generally, MAC organisms are of low pathogenicity. Single positive specimens with low numbers of AFB are not infrequently observed in individuals without apparent disease. This complicates the interpretation of culture results, particularly from specimens of the respiratory tract (2, 3).

Before the advent of AIDS, the most common presentation of MAC infection was pulmonary disease, which manifested several different clinical patterns, i.e., tuberculosiss-like infiltrates, nodular bronchiectasis, and solitary nodules, as well as diffuse infiltrates in immunocompromised patients (82). Tuberculosis-like upper lobe fibrocavitary disease due to MAC organisms typically occurs in white men 45 to 60 years of age who are heavy smokers, many of whom abuse alcohol and some of whom have preexisting lung disease. The clinical presentation is similar to that of tuberculosis. In women, nodular bronchiectasis usually occurs in elderly nonsmoking individuals with no predisposing disorders of the lungs or immune system other than associated bronchiectasis (“Lady Windermere syndrome”). These patients usually present with a persistent cough only; the disease tends to have a much slower progression than cavitary disease. Less frequent are thoracic infections in otherwise healthy children (83). In this patient group, MAC organisms are also the leading cause of localized mycobacterial lymphadenitis, which is usually unilateral and involves lymph nodes in the submandibular, submaxillary, or periauricular areas (84). Generalized MAC infections in non-AIDS patients remain extremely rare.

In patients (n = 385) with cystic fibrosis, the overall prevalence of NTM was 8%, with the most prominent species being Mycobacterium abscessus (39%), MAC organisms (21%), and M. gordonae (18%) (85). MAC species affect predominantly adult patients with a mild form of cystic fibrosis, whereas M. abscessus affects younger patients with more severe disease and more frequent intravenous treatment (86).

In conjunction with HIV infection, MAC species have become the most common environmental NTM causing disease in humans. Patients with AIDS may present with disseminated or focal infections, mostly when the CD4 count is below 100 cells/mm$^3$. Bacteremia occurs in nearly all those patients, its magnitude ranging from <1 to $10^2$ CFU/ml. The organisms are found predominantly in circulating monocytes. Almost any organ may be involved, with levels of mycobacteria as high as $10^{10}$ CFU/g of tissue. Focal infections commonly involve the lungs or the gastrointestinal tract and occasionally also the peripheral lymph nodes (87).

MAC organisms are well known for their heterogeneous colony morphology. Glossy, whitish colonies may often occur together with smaller translucent colonies. A third, less frequent, morphology resembles the dry and flat colonies of M. tuberculosis. With age, some MAC strains may develop a yellowish pigment.

MAC organisms are a very heterogeneous group of AFB comprised of, by classical definition, the two taxa M. avium and Mycobacterium intracellulare. Clinically, the former seems to be the more important pathogen in disseminated disease, while the latter is more often seen in respiratory disease. As more-sophisticated molecular tools have become available in laboratories, the taxonomy of the MAC has become increasingly complex. New species within the complex have been proposed and new subspecies discovered. At present, the species M. avium consists of four subspecies, namely, subsp. avium, subsp. silvaticum, subsp. paratuberculosis, and subsp. hominisuis (88). M. avium subsp. paratuberculosis is responsible for paratuberculosis (Johnne’s disease), a chronic inflammation of the gastrointestinal tract that affects mainly livestock and wild ruminants, while in humans, the association of the organism with Crohn’s disease seems to be specific. However, its role in the etiology of the disease remains to be defined (89). Since M. avium subsp. paratuberculosis is one of the slowest-growing mycobacterial species, primary isolation can take several months, and the medium needs special supplements (88). Direct detection of the organism from veterinary and clinical specimens is possible via PCR methods (90).

There are several important differences at the genetic level which distinguish M. avium subsp. hominisuis from M. avium subsp. avium (88). By IS1245-based restriction fragment length polymorphism (RFLP) analysis, M. avium isolates from birds have been identified as M. avium subsp. avium. Since highly variable RFLP patterns were found among all M. avium isolates which belonged to the M. avium subsp. hominisuis, a relation to pet birds in the etiology of lymphadenitis could not be established; i.e., the source of infection may be environmental (91, 92).

There are other taxa very closely related to MAC organisms that could not be assigned to one or the other classical MAC species. For instance, Tortoli et al. (93) proposed to elevate a genetic MAC variant (MAC-A) to the species rank as M. chimæra sp. nov. (see also reference 94). Likewise, the former MAC-X sequence gave rise to the species Mycobacterium colombiense (95, 96), and the scotochromogenic sequent MAC-Q is now considered Mycobacterium vulneris (97). Finally, Ben Salah et al. (98) found clinical MAC isolates which appear to represent three other new
species, *Mycobacterium marseillense*, *Mycobacterium timonense*, and *Mycobacterium bouchedurhonnense*. These new species, together with *Mycobacterium arosense* (99), add to the heterogeneity of MAC members. To date, MAC consists of nine known species, four subspecies of *M. avium* plus certain isolates that are designated “MAC-other” (100).

*Mycobacterium genavense*

*M. genavense* is a slow-growing, fastidious organism (101) that was isolated in 1991 from the blood of an AIDS patient in Geneva, Switzerland, and subsequently in the United States and in several European countries (2, 3, 102). It has been associated with enteritis, genital infections, soft tissue infections, and lymphadenitis in HIV-positive and in HIV-negative immunocompromised individuals. *M. genavense* causes up to 12.8% of all NTM infections in AIDS patients. These infections are similar to those caused by MAC organisms, except that stool specimens are more often smear positive in *M. genavense* infections (103). *M. genavense* is also the most common cause of mycobacterial disease in a variety of pet birds, including parrots and parakeets (104).

*Mycobacterium haemophilum*

*M. haemophilum*, another fastidious mycobacterial organism, was first isolated in 1978 from a subcutaneous lesion in a patient with Hodgkin’s disease (105). Approximately 50% of infections have been in patients with AIDS, with a relatively large number reported from New York City. The other cases have been in other immunosuppressed individuals (105) but also in immunocompetent pediatric patients with localized cervical lymphadenopathy or with a pulmonary nodule. The classical clinical presentation is that of multiple skin nodules in clusters or without a definite pattern, commonly involving the extremities and occasionally associated with abscesses, draining fistulas, cellulitis, endophthalmitis, and osteomyelitis (3, 105).

*Mycobacterium kansasii*

In the United States and many other countries, *M. kansasii* is second to members of the MAC as a cause of NTM lung disease (2, 3). The organism has been cultured from its major reservoir, tap water, in municipalities around the world where clinical disease occurs. It is common in mine workers in both the United Kingdom and South Africa (106), and its infections differ from those due to MAC organisms in that the response to chemotherapy is much better (2).

Chronic pulmonary disease resembling classical tuberculosis is the most common manifestation of *M. kansasii*. Extra-pulmonary infections include cervical lymphadenitis in children, cutaneous and soft tissue infections, tenosynovitis, uveitis, musculoskeletal disease, and, most recently, pericarditis (107). *M. kansasii* rarely disseminates, except in patients with severely impaired cellular immunity (for instance due to organ transplants and AIDS [2]). Connick and Levi (108) reported a unique case of cutaneous *M. kansasii* abscess in an AIDS patient that worsened following initiation of antiretroviral therapy (ART).

*M. kansasii* is a photochromogenic species. Studies of the base sequences of the 16S rRNA gene suggest that, phylogenetically, it is closely related to the slowly growing, nonpigmented species *M. gastri*. Molecular studies have defined up to seven genotypes of *M. kansasii*, with subtypes I and II being the predominant subspecies responsible for human infection (2, 109).

*Mycobacterium malmoense*

The species name *M. malmoense* is derived from the city of Malmö in Sweden, where the first strains were isolated from patients in 1977. Disease due to this organism was later found in other European countries, with an increasing incidence in Scandinavia (2). It remains rare in the United States, Canada, and other areas of the world. However, in these countries, *M. malmoense* infection may be more common than suspected, because it may require 8 to 12 weeks to isolate some strains, which is longer than most laboratories hold mycobacterial cultures.

*M. malmoense* isolates are clinically significant in 70 to 80% of patients. Patients with *M. malmoense* infection are usually adults with chronic difficult-to-treat pulmonary disease (mostly middle-aged men with previously documented pneumoconiosis) or young children with cervical lymphadenitis (2, 3). Septic arthritis of the shoulder (110) and disseminated infections have rarely been reported (111).

*Mycobacterium marinum*

*M. marinum* causes cutaneous infections as a result of trauma to the skin and subsequent exposure to contaminated freshwater fish tanks (fish tank granuloma) or salt water. The disease occurs worldwide. In the United States, it is most common in the southern coastal states. The typical presentation is a single papulonodular lesion confined to one extremity, usually involving the elbow, knee, foot, toe, or finger. The lesion appears 2 to 3 weeks after inoculation, and, with time, may become verrucous or ulcerated (2, 3). A second type resembles cutaneous sporotrichosis, in which the primary inoculation is followed by spread along the lymphatics. More-severe complications include tenosynovitis, arthritis, bursitis, and osteomyelitis. Disseminated infections, including infections in patients with AIDS or persons under systemic steroid therapy, have been rare (2). The *M. marinum* population appears to be genetically structured, i.e., according to host, ecosystem, and tissue tropism in humans. Only certain genotypes appear to be present in humans, and not all of them can produce deep infections, which suggests that the immune system may play a filtering role (112).

*M. marinum* is photochromogenic and requires 28 to 30°C for primary isolation. Ghosh et al. (10) observed spores in old cultures of *M. marinum*, which, upon exposure to fresh medium, germinated into vegetative cells and reappeared again in the stationary phase with endospore formation. With its genome comprising approximately 6,636,827 bp (G+C content, 65.8%), *M. marinum* is genetically very closely related to *M. ulcerans* but also to *M. tuberculosis*, the latter having undergone genome downsizing and external lateral gene transfer to become a specialized pathogen of humans and other mammals (113). Israeli *M. marinum* isolates from humans and fish were compared by direct sequencing of the 16S rRNA and hsp65 genes, restriction mapping, and amplified fragment length polymorphism analysis. Surprisingly, significant molecular differences separated all clinical isolates from the piscine isolates (114).

*Mycobacterium simiae*

First isolated in 1965 from rhesus macaques, more than 400 cases have been reported from a few geographic areas, including the southwestern United States and the Caribbean (2, 115). The environmental niche is assumed to be aquatic. The majority of cases relate to HIV-positive patients, involving primarily the lungs and the reticuloendothelial system. In non-HIV patients, pulmonary manifesta-
tions are common, but lymphadenopathy, skin lesions, genitourinary tract infections, and uveitis also occur (2). In Israeli cystic fibrosis patients, M. simiae was the organism seen most often (40.5%), followed by M. abscessus (31%), and MAC organisms (14.3%) (116). Unless tested for pigment production under the influence of light, it may be misidentified morphologically as M. tuberculosis by an inexperienced observer.

**Mycobacterium szulgai**

M. szulgai was first described as a distinct species in 1972 and is rarely recovered from the environment. Therefore, isolation of this organism is almost always considered clinically significant. Patients are mainly middle-aged men presenting with chronic pulmonary disease indistinguishable from tuberculosis (2). The remaining presentations include rare cases of bursitis, cervical adenitis, tenosynovitis, cutaneous infections, and osteomyelitis (2, 3). Cases of M. szulgai infection in AIDS patients and disseminated disease in an immunocompetent patient have been reported as well. Although M. szulgai is closely related to M. malmoense based on 16S rRNA gene sequences, phenotypic distinction between the two species is easy. M. szulgai is scotochromogenic at 37°C and photochromogenic at 25°C (117).

**Mycobacterium ulcerans**

The frequency of M. ulcerans infection has long been underestimated due to difficulties in isolating the pathogen. Today, it is the third-most-frequent mycobacterial disease in humans after tuberculosis and leprosy. In Africa, the disease is known as Buruli ulcer and in Australia as Bairnsdale ulcer (2, 3, 118, 119). Cases of Buruli ulcer have also become evident in Peru and Japan. Closely associated with tropical wetlands, M. ulcerans most likely proliferates in mud beneath stagnant waters. All ages and both sexes are affected, among them many children under 15 years. Clinical manifestation typically begins as a painless lump under the skin at the site of previous trauma on the lower extremities. After a few weeks, a shallow ulcer develops at the site of the lump. M. ulcerans produces a cytotoxin (mycolactone) with immunomodulating properties that causes necrosis. The type of disease ranges from a localized nodule or ulcer to widespread ulcerative or nonulcerative disease, including osteomyelitis. If untreated, severe limb deformities with contractures and scarring are common. There is growing evidence that M. ulcerans also produces disease in wild animals, such as lizards, possums, koala bears, armadillos, rats, mice, and cattle (120).

Failure to cultivate this organism in the past is due to its fastidious, heat-sensitive nature (optimum temperature, 30°C) as well as to an excessively long generation time (up to 36 h). Isolation from clinical specimens is a slow and difficult process due to many factors (118). Molecular techniques which may provide a more rapid result have been developed (121). Comparative genomic analysis has revealed that M. ulcerans arose from M. marinum by horizontal gene transfer of a virulence plasmid that carries a cluster of genes for mycolactone production, followed by reductive evolution (122, 123).

**Mycobacterium xenopi**

M. xenopi was first isolated in 1957 from skin lesions on an African toad (Xenopus laevis), but it was not recognized as a human pathogen until 1965. In some areas, such as Canada and southeast England, it is second only to MAC organisms as an NTM clinical isolate (2). Together with M. simiae, this organism is the most prevalent species of NTM isolated from respiratory specimens in northern Israel (115). Increased isolation of M. xenopi from clinical specimens may also be due to improved laboratory techniques. Nosocomial infection and pseudoinfection via water storage tanks in hospitals have also been described. Most M. xenopi infections occur in the lungs, usually occurring in male adult patients with underlying lung disease, such as chronic obstructive pulmonary disease or bronchiectasis. Extrapulmonary infections, such as septic arthritis, spondylitis, and disseminated disease, have also been described in immunocompromised individuals (2). Skin and soft tissue manifestations as well as a recent case report of M. xenopi spondylodiscitis in an AIDS patient not only highlight its potential pathogenic role but also point to the uncertainties in therapeutic management. With an optimum growth temperature of 45°C, it seems to frequently occur in hot water systems.

**Nontuberculous Slowly Growing Mycobacteria Rarely Recovered or Rarely Causing Human Disease**

Several species of slowly growing mycobacteria are frequently recovered but are rarely associated with human disease. Some of the case reports of infections attributable to these mycobacteria, especially from the era before the introduction of molecular laboratory techniques, lack sufficient documentation of identification or disease association. Other species are so rarely recovered that most laboratories will never see them.

**Mycobacterium asiaticum**

M. asiaticum was not recognized as a distinct species until 1971. This photochromogenic organism has since very infrequently been isolated from patients with respiratory disease in Australia, the United States, and elsewhere (124). Cases of bursitis and tenosynovitis have been described as well.

**Mycobacterium celatum**

First described in 1993, M. celatum has been isolated from diverse geographic areas (throughout the United States, Finland, and Somalia), mostly from respiratory tract specimens but also from stool and blood. In one series, 32% of the patients from whom M. celatum was isolated were infected with HIV. M. celatum has also been isolated from immunocompetent patients (a child with lymphadenitis and an elderly patient with a fatal pulmonary infection [5]). M. celatum shares phenotypical characteristics with MAC organisms, M. malmoense, and M. shimoidei and can thus be identified only with molecular tests. Within the bacterial chromosome, M. celatum has two copies of the 16S rRNA gene. Several subtypes (1 to 3) have been identified using 16S rRNA gene sequencing or RFLP analysis of the gene encoding the 65-kDa heat shock protein (hsp65).

**Mycobacterium gordonae**

M. gordonae is the most commonly encountered “nonpathogenic” species in clinical mycobacteriology laboratories. This scotochromogenic species is widely distributed in soil and water. A pseudo-outbreak associated with drinking water in a French hospital underlined the necessity for proper maintenance of water supply equipment (125). Convincing evidence that M. gordonae plays a role in disease is difficult to find (2). There are a few reports of peritonitis in patients undergoing continuous ambulatory peritoneal dialysis and in renal transplant patients (126) and a report of disseminated disease in a child with cystic fibrosis (127).
Eckburg et al. (128) have reviewed clinical and chest radiographic findings among persons who are sputum culture positive for *M. gordonae* and concluded that it is a nonpathogenic colonizing organism, even among persons with local or general immune suppression and abnormal chest radiograph findings.

**Mycobacterium scrofulaceum**

The name of this species was derived from scrofula, a historical term used to describe mycobacterial infections of the cervical lymph glands. Until the 1980s, *M. scrofulaceum* was the most common cause of mycobacterial cervical lymphadenitis in children. Since then, it has been replaced primarily by “MAC” (84). Other types of clinical disease are rare. They include pulmonary disease, conjunctivitis, osteomyelitis, meningitis, granulomatous hepatitis, and disseminated disease (2, 3). *M. scrofulaceum* accounted for 14% of the isolates tested in respiratory specimens collected from South African miners (106) and for approximately 2% of the mycobacterial infections in AIDS patients (2).

**Mycobacterium shimoidei**

*M. shimoidei* was first described in 1988 in a Japanese patient with chronic cavitary lung disease. Only a few clinical cases have been reported since, mainly in Japan and Finland. It is a thermophilic organism growing well at 45°C.

**Mycobacterium terrae Complex**

The name of this complex consists of the mycobacteria *M. terrae*, *Mycobacterium nonchromogenicum*, and *Mycobacterium tenuissimum*. Clinical disease due to *M. terrae* is generally limited to tenosynovitis of the hand following local trauma and pulmonary disease (2). *M. nonchromogenicum* is ubiquitous in aquatic environments, and has been the cause of bacteremia in an AIDS patient (2). Molecular analyses of several genes (16S RNA gene, *hsp65*, *tpoB*) have unveiled many previously unreported sequevars within these species but also new species belonging to the complex, such as revealed many previously unreported sequevars within these analyses of several genes (16S RNA gene, *rpoB* (129) accounted for 14% of the isolates tested in respiratory specimens collected from South African miners (106) and for approximately 2% of the mycobacterial infections in AIDS patients (2).

**Newer Species of Nontuberculous Mycobacteria**

As a consequence of more sophisticated molecular technologies applied in the clinical mycobacteriology laboratory, the number of newer species is rapidly increasing (Table 1). However, much less is known about these species, and their clinical relevance remains to be elucidated.

**SAFETY, TRANSPORT, AND COLLECTION OF SPECIMENS**

**Laboratory Safety Procedures**

Nosocomial transmission of *M. tuberculosis* from patients or specimens is of major concern to health care workers and laboratory personnel. Because of the low infective dose of *M. tuberculosis* for humans (50% infective dose [ID₅₀] <10 AFB [acid-fast bacilli]), specimens from suspected or known cases of tuberculosis must be considered potentially infectious and handled with appropriate precautions (15, 16). Risk assessment and the use of appropriate biosafety practices are of prime importance (14, 15). Control of aerosol production and other forms of mycobacterial contamination requires the use of properly functioning biosafety cabinets (BSCs), centrifuges with safety carriers, and meticulous processing techniques (references 16 and 130; see also chapter 12).

In light of the three-times-higher incidence of tuberculosis in laboratory personnel working with *M. tuberculosis* complex than in those not working with these agents, the low infective dose of tubercle bacilli, and the rapid spread by infecting aerosols, the CDC states in their guidelines on biosafety in microbiological and biomedical laboratories (15) that for laboratory personnel working with *M. tuberculosis* complex, biosafety level 2 (BSL 2) practices are not ideal. BSL 2 practices and procedures, containment equipment, and facilities are suggested only for non-aerosol-producing manipulations of clinical specimens, such as preparation of AFB smears. All aerosol-generating activities must be conducted in a class II BSC. Efforts should be made to apply rigorous BSL 3 practices and containment equipment and to provide BSL 3 facilities for laboratories associated with higher risk, namely, those involved in the manipulation of cultures (identification and susceptibility testing) of *M. tuberculosis* complex organisms. Such practices require that laboratory access be restricted, that directional airflow be used to maintain the laboratory under negative pressure, and that workers wear special laboratory clothing and gloves (15, 130). The stringent biosafety measures may, in the future, invite more laboratories to abandon mycobacterial culture if BSL 3 facilities cannot be afforded.

All respiratory protective devices (respirators) used in the workplace should be certified by the National Institute for Occupational Safety and Health (NIOSH) (131). Respirators that contain a NIOSH-certified N-series (not resistant to solids and liquids that contain oil) filter with a 95% efficiency rating (N-95) are appropriate for use. They meet the recommendations from the CDC for selection of respirators for protection against *M. tuberculosis*, as follows: (i) the unloaded filter must filter particles 0.3 μm in size with an efficiency of 95% at flow rates up to 50 liters/min; (ii) the respirator must be qualitatively or quantitatively fit tested to obtain a face-seal leakage rate of no more than 10%; (iii) the respirator must fit different facial sizes and characteristics, which is attained by making the respirators available in at least three sizes; and (iv) it must be checked for face piece fit by the person wearing the respirator each time it is worn, in accordance with the Occupational Safety and Health Administration (OSHA) standards. Surgical masks are not NIOSH-certified respirators and must not be worn to provide respiratory protection.

The decision when and if to use respiratory protective devices in the laboratory should be based on risk assessment. A respirator program should be implemented by the laboratory and include a written protocol describing when respirator use is necessary and the procedures addressing (i) selection of the appropriate respirator, (ii) how to conduct fit testing, and (iii) training of personnel in the use, fit-checking, and storage of the respirator.

All work involving specimens or cultures, such as making smears, inoculating media, adding reagents, opening centrifuge cups, sonication, and setting up molecular tests, must be performed in a BSC. The handling of all specimens suspected of containing mycobacteria (including specimens processed for other microorganisms), with the exception of centrifugation for concentration purposes, must be done within the BSC. Specimens that are to be taken out of the

*MAC, *M. avium* complex; MCRO, relates to groups of unidentified mycobacterial organisms whose GenBank accession numbers have been deposited and which were thereafter described as new species; CSF, cerebrospinal fluid; HPLC, high-performance liquid chromatography; GLC, gas-liquid chromatography; 16S–23S ITS, 16S to 23S internal transcribed spacer sequence.

BSC should be covered before transport. All work surfaces, including benchtops and inside the BSC, should be cleaned with an appropriate disinfectant before and after work. Effective disinfectants include Amphil (Reckitt Benckiser North America, Wayne, NJ) or other phenol-soap mixtures and 0.05% to 0.5% sodium hypochlorite (concentrations vary according to the nature of the contaminated surface). Five percent phenol is no longer recommended as a surface disinfectant due to the documented toxicity of this compound to personnel. Ultraviolet light is a useful adjunct for surface decontamination and may be used to irradiate the work area when it is not in use. Centrifuges should be used with aerosol-free safety containers to carry debris in the event that tubes break. Use of electric incinerators rather than open flames is recommended. The excess inoculum from inoculating loops, wire, or spades may be removed by dipping the tool into a container of 95% ethanol in washed sand prior to insertion in an incinerator. Disposable inoculating loops are recommended, as are syringes with permanently attached needles if needles are required. An autoclave should be available in an easily accessible area and used to decontaminate infectious waste before its removal to disposal areas.

Personnel should be regularly monitored with either the TST or one of the IGRAs annually and more often if a conversion in the laboratory/institution has been documented. Those with a positive TST or positive IGRA should be evaluated for active tuberculosis with a chest radiograph and clinical evaluation. Physical examinations should be obtained when necessary. New converters should be referred to the employee health and the infection control departments for epidemiological evaluation. Laboratories should have written protocols describing procedures for handling laboratory accidents. In case of a laboratory accident with possible formation of aerosols, personnel should hold their breath as much as possible, make sure that biological safety cabinets are on and centrifuges are turned off, and then leave the area to get protection as soon as possible, with the door closed for at least 30 min (the amount of time depends on the type of accident and the amount of risk). Using appropriate respiratory protection devices, personnel can return to the accident area to clean the spill. After such an incident, TST/IGRA-negative personnel should be monitored and retested, preferably using the same method longitudinally. Persons who are pregnant or immunocompromised should be discouraged from working in a mycobacteriology laboratory. (See also “Biosafety and Regulatory Issues” in chapter 12.)

Transportation and Transfer of Biological Agents

Mycobacteria are on the list of infectious agents being regulated for shipping and transfer. Stringent regulations on the transportation of biological agents have been enacted in the United States (for instance, *M. tuberculosis* cultures are no longer accepted by the U.S. Postal Service) as well as in other countries to ensure that the public and workers in the transportation chain are protected from exposure to any infectious agents. Protection is achieved through (i) requirements for rigorous packaging that will withstand rough handling and contain all liquid material within the package without leakage to the outside, (ii) appropriate labeling of the package with the biohazard symbol and other labels to alert the workers in the transportation chain to the hazardous contents of the package, (iii) documentation of the hazardous contents of the package should such information be necessary in an emergency situation, and (iv) training of workers in the transportation chain to familiarize
them with the hazardous contents in order to be able to respond to emergency situations. Details regarding the transport of specimens within and outside a facility have been well described (130).

The reader is referred to the regulatory documents of his/her respective country. For the United States, further information is available in the following documents:

42 CFR, Part 72, Interstate Transportation of Etiologic Agents (257) (this regulation is in revision to harmonize it with other U.S. and international regulations);
49 CFR, Hazardous Materials Regulations, Parts 171 to 180 (258) (applies to the shipment of infectious substances in commercial transportation within the United States);
39 CFR, Part 20, International Postal Service (259) (regarding international mail);
39 CFR, Part 111, General Information on Postal Service (260) (regarding regulations on transporting infectious substances through the U.S. Postal Service [USPS], which are codified in section 346 of publication 52 [261] and section 135 of the International Mail Manual [262]; a copy of the Domestic Mail Manual may be obtained from the U.S. Government Printing Office by phone at 1-202-512-1800 or 1-866-512-1800 or from the USPS website [http://bookstore.gpo.gov/ or http://pe.usps.gov]; Technical Instructions for the Safe Transport of Dangerous Goods by Air published by the International Civil Aviation Organization (ICAO) (264) (these instructions apply to the shipment of infectious substances by air and are recognized in the United States and by most countries worldwide; a copy of these regulations may be obtained from your local OSHA office or at the OSHA website http://www.osha.gov);
49 CFR, Part 1910.1030, Bloodborne Pathogens (263) (these regulations provide minimal packaging and labeling for blood and body fluids when transported within a laboratory or outside it; information may be obtained from your local OSHA office or at the OSHA website http://www.osha.gov);

Dangerous Goods Regulations (DGR), published by the International Air Transport Association (IATA) (265) (these regulations are issued by an airline association, are based on the ICAO Technical Instructions, and are followed by most airline carriers; a copy of these regulations is available by phone at 1-800-716-6326 for the United States and Canada, at 41-22-770-2751 for Europe, Africa, and the Middle East, or from http://www.iata.org/index.htm or http://www.who.int/en/; permits must be obtained for importation and exportation of biological and infectious agents by contacting the Centers for Disease Control and Prevention, Atlanta, GA [www.cdc.gov]).

Collection and Storage of Specimens

General Rules
Many different types of clinical specimens may be collected for mycobacteriological analyses (117, 132). The majority originate from the respiratory tract (sputum, tracheal and bronchial aspirates, bronchoalveolar lavage specimens), but urine, gastric aspirates, tissues, biopsy specimens, and normally sterile body fluids, such as cerebrospinal fluid, pleural aspirates, and pericardial aspirates, are other commonly submitted specimens. Blood and fecal specimens are usually submitted from immunocompromised patients only.

Specimens should always be collected and submitted in sterile, leakproof, disposable, appropriately labeled, laboratory-approved containers without any fixatives. Generally, transport media or preservatives are not necessary owing to the robust nature of mycobacteria. Minute biopsy material (e.g., fine needle aspirates) may be immersed in a small amount of sterile physiological saline. Collection should bypass areas of possible contamination as much as possible, i.e., tap water, since the presence of environmental mycobacteria may result in false-positive smear and/or culture results (133). In general, swabs are not optimal for the recovery of AFB since they provide limited material and the hydrophobicity of the mycobacterial cell envelope often compromises a transfer from swabs onto solid media or into broth media. If transport to the laboratory is delayed more than 1 h, specimens (except blood) should be refrigerated at 4°C. Likewise, upon arrival in the laboratory, specimens should be refrigerated until processed (see chapters 11 and 18 for additional information on specimen collection).

Sputum
Sputum, expectorated or induced, is the principal specimen obtained for the diagnosis of pulmonary tuberculosis. Recent recommendations from the ATS/CDC/IDSA are to collect three sputa at least 8 h apart, one of which should be an early morning specimen, rather than to require collection of sputa over 3 days (130, 134). The number of specimens has, however, been questioned for quite some time. Recent meta-analyses confirmed the low yield of the third specimen in the classical spot-morning-spot strategy (135, 136); the average incremental yield and/or the increase in sensitivity of examining a third specimen ranged between 2% and 5% only. Similarly, Monkongdee et al. (137) and Noeske et al. (138) concluded that a third sputum smear added little to the diagnosis of tuberculosis, even in populations in which the incidence of HIV is high. Pooled sputum specimens are unacceptable for mycobacterial processing because of increased contamination (117). Follow-up cultures should be considered because it is culture (and not a smear) which yields a definite answer as to whether chemotherapy has been effective. Sputum induction increases tuberculosis case detection, and yield was, as demonstrated by a systematic review of the literature (139), generally higher than that with nasopharyngeal aspiration and gastric lavage and compared equally well to that for bronchoalveolar lavage. Children may have difficulties producing sputum. In the age group up to 12 years, a gastric aspirate is usually the specimen of choice for the diagnosis of pulmonary tuberculosis.

Bronchial Aspirates, Bronchoalveolar Lavage Specimens, Fine Needle Aspirates, and Lung Biopsy Specimens
In some patients unable to produce sputum, invasive collection techniques, such as bronchoscopy, may be necessary to diagnose pulmonary tuberculosis or mycobacteriosis. Special care is imperative for cleansing the bronchoscope to avoid cross-contamination with AFB from a preceding patient who underwent bronchoscopy. Also, the bronchoscope should not be in contact with tap water, which may contain environmental mycobacteria. Specimens collected by other invasive techniques, such as fine needle aspiration and open lung biopsy, may be submitted in difficult-to-diagnose cases.
Gastric Lavage Fluids

Aspiration of swallowed sputum from the stomach by gastric lavage may be necessary for infants, young children, and the obtunded. Fasting, early-morning specimens are recommended in order to obtain sputum swallowed during sleep. Samples of 5 to 10 ml, adjusted to neutral pH, should be collected on three consecutive days. If they cannot be processed within 4 h, the laboratory should provide sterile disposable containers with 100 mg of sodium carbonate for collection. Nonneutralized specimens are not acceptable because long-term exposure to acid is detrimental to mycobacteria.

Urine

The first morning specimen should be collected on three consecutive days by the clean catch method (midstream) into a sterile container. The first morning specimen provides the best results because organisms accumulate in the bladder overnight. A minimum of 40 ml of urine is usually required for culture. Twenty-four-hour pooled specimens and small-volume specimens (unless a larger volume is not obtainable) are unacceptable. Catheterization should be used only if a midstream sample cannot be obtained.

Body Fluids

As much body fluid as possible (e.g., cerebrospinal, pleural, peritoneal, pericardial, or synovial [joint] fluid) is aseptically collected by aspiration or during surgical procedures. Bloody specimens may be anticoagulated with sodium polyanethol sulfonate (SPS). Certain body fluids (such as cerebrospinal fluid [CSF] and peritoneal dialysis effluent) may contain very small numbers of mycobacteria. It is advisable to submit larger specimen volumes (e.g., >5 ml for CSF) to increase culture yields and the chance of detecting mycobacterial organisms. Never submit a swab dipped in fluid.

Tissues (Lymph Node, Skin, and Other Biopsy Material), Abscess Contents, Aspirated Pus, and Wounds

Specimens submitted in formalin are unacceptable for smear and culture. As much material as possible should be aspirated aseptically into a sterile container. Tissues must not be immersed in saline or other liquid or wrapped in gauze. For cutaneous ulcers, biopsy material should be collected from the periphery of the lesion. Minute biopsy material may be moistened with a small amount of sterile saline. It is advisable to incubate a second set of cultures at 30°C since one of the organisms with a lower optimum growth temperature (M. haemophilum, M. marinum, M. ulcerans) may be the infectious agent. Swabs are strongly discouraged, unless it is the only specimen available.

Blood

The majority of disseminated mycobacterial infections are due to MAC organisms. Therefore, if such an organism is isolated from blood, it is always associated with clinical disease. If blood has to be transported before inoculation of the medium, SPS, heparin, or citrate may be used as anticoagulants. Blood collected in EDTA or in conventional blood culture bottles and coagulated blood are not acceptable. Direct inoculation of blood onto a solid medium is not recommended either.

For many years, the Isolator system (Wampole Laboratories, Cranbury, NJ) and the radiometric Bactec 13A blood culture bottle (Becton Dickinson Microbiology Systems, Sparks, MD) were the only reliable and recommended systems for mycobacterial blood cultures (140). Since the Bactec 13A medium is no longer available, cultures from blood and bone marrow specimens have to be obtained with alternative media, e.g., the Myco/F Lytic bottles (Becton Dickinson) (140, 141) or the BacT/Alert MB Blood medium (bioMérieux, Marcy-L’Etoile, France) (142).

Stool Specimens

Generally, cultures from feces (>1 g) for mycobacteria are not encouraged, except for patients with AIDS to detect MAC organisms. Past recommendations have been that stool be cultured for mycobacteria only if the direct smear of unprocessed stool is positive for AFB. The sensitivity of the stool smear, however, is only 32 to 34% (143), suggesting that its results should not determine whether a culture for mycobacteria be performed. Screening with smears is, therefore, not an effective way to identify patients at risk for developing disseminated MAC infection.

Inadequate Specimens

Processing of inappropriate clinical specimens for mycobacteria is a waste of both financial and personnel resources. There are quite a few reasons why a specimen should not be accepted (and the clinician should be notified), e.g., (i) too small an amount was submitted; (ii) the “sputum” specimens consist of saliva; (iii) the swabs are dried (a biopsy specimen is preferable); (iv) the sputum or urine is pooled; (v) sample containers are broken; and (vi) the interval between specimen collection and processing is too long (>7 days) (130). Clinical staff must be properly trained to prevent submission of unacceptable specimens.

For additional information regarding the collection and storage of specimens, the reader is referred to a CLSI document (130).

ISOLATION AND STAINING PROCEDURES

Because mycobacteria usually grow slowly and require long incubation times, a variety of microorganisms other than mycobacteria can grow over cultures of specimens obtained from nonsterile sites. Appropriate pretreatment and processing procedures (homogenization, decontamination, concentration), culture media, and conditions of incubation must be selected to facilitate the optimum recovery of mycobacteria (117, 130, 132). In particular, pretreatment of specimens has to be done carefully to eliminate contaminants as much as possible while not seriously affecting the viability of mycobacteria.

Processing of Specimens

Decontamination of a specimen should be attempted only if it is thought to be contaminated. Tissues or body fluids collected aseptically usually do not require pretreatment. If the need to decontaminate a specimen is not clear, the specimen may be refrigerated until routine bacteriologic cultures are checked the next day. It may, however, be easier to initially inoculate a chocolate agar plate to check for sterility overnight before a sample is processed for mycobacteria.

Normally Sterile Specimens

Normally sterile tissue samples may be ground in sterile 0.85% saline or 0.2% bovine albumin and then inoculated directly onto the media. Because body fluids commonly contain only small numbers of mycobacteria, they should be concentrated to maximize the yield of mycobacteria, i.e., centrifuged at ≥3,000 × g for 15 min prior to inoculation.
of the sediment onto media. If the volume of fluid submitted for culture is small and cannot be obtained again, it may be added directly to liquid media.

Contaminated Specimens
The majority of specimens submitted for mycobacterial culture consist of a complex organic matrix contaminated with a variety of organisms. Mucin may trap mycobacterial cells and protect contaminating bacteria from the actions of decontaminating agents. Thus, mycobacteria are recovered optimally from clinical specimens through the use of procedures that reduce or eliminate contaminating bacteria while releasing mycobacteria trapped in mucin and cells. Liquefaction of certain specimens, particularly sputum, is often necessary. Mycobacteria are then concentrated to enhance detection in stained smears and by culture.

Digestion and Decontamination Methods
Sodium hydroxide (NaOH), the most commonly used decontaminant, also serves as a mucolytic agent but must be used cautiously because it is only slightly less harmful to tubercle bacilli than to the contaminating organisms. The stronger the alkali, the higher its temperature during the time that it acts on the specimen, and the longer it is allowed to act, the greater will be the killing action on both contaminants and mycobacteria. Harsh decontamination can kill 20 to 90% of the mycobacteria in a clinical specimen (117, 130, 132). Homogenization should occur by centrifugal swirling, and this swirling should not be vigorous enough to allow material to rise to the cap. After agitation, there should be at least a 15-min delay before opening the tube to allow any fine aerosol droplets formed during the mixing to settle. All such procedures should be carried out in a class II BSC.

Most commonly, a combination liquefaction-decontamination mixture is used. N-Acetyl-L-cysteine (NALC), dithiothreitol, and several enzymes effectively liquefy sputum. These agents have no direct inhibitory effect on bacterial cells; however, their use permits treatment with lower concentrations of NaOH, thereby indirectly improving the recovery of mycobacteria. The appropriate concentration of NaOH is dependent on the observed contamination rate for the individual laboratory. If specimens are heavily contaminated, NaOH may be increased (but cannot exceed 5 to 6%). The most widely used digestion-decontamination method is the NALC–2% NaOH method (117, 130, 132; see also the Appendix). Pretreatment of clinical specimens with sodium dodecyl (lauryl) sulfate (SDS)-NaOH is, in contrast, not suitable for the Mycobacterium Growth Indicator Tube (MGIT) cultivation method (144), since it results in poor recovery of mycobacteria and a delayed mean time to detection of AFB. When C15-carboxypropylbetaine was used, culture and smear sensitivity significantly improved compared to those of the NALC-NaOH procedure. However, the contamination rate was extremely high (20.8%) (145). Pretreatment of sputum from cystic fibrosis patients with chlorhexidine has yielded twice as many NTM-positive cultures as specimens treated with NALC-NaOH. This option is interesting if one takes into account that recovery of NTM is hampered by the presence of Pseudomonas aerugi nosa in the respiratory tracts of 80% of these patients (146).

Addition of cetrimide hydrochloride (CPC) (see the Appendix) to specimens mailed from remote collection stations to a central processing station has yielded a good recovery of M. tuberculosis without overgrowth by contaminating bacteria.

In addition to the use of CPC, the use of sodium carbonate and sodium borate has been recommended for rural areas, allowing M. tuberculosis to remain viable for 5 to 18 days (147). Under field conditions, liquefaction and concentration of sputum for acid-fast staining may also be conducted by treating the specimens with an equal volume of 5% sodium hypochlorite solution (undiluted household bleach) and waiting 15 min before centrifugation (117). Such treated specimens cannot be cultured, however, because the chemical seriously affects the viability of AFB. The major limitation is, therefore, that a second specimen must be collected for culture. The method is very useful, however, for rapid smear preparation and interpretation in laboratories that do not process specimens for culture or that do not have a BSC. Finally, a universal sample processing method utilizing guanidium isothiocyanate did not provide any significant advantage over the standard NALC method in a field study performed in Uganda (148).

Many conventional decontamination protocols used in mycobacteriology interfere with the viability of M. ulcerans. Oxalic acid, NaOH, and, to a lesser extent, mild HCl have a detrimental impact on the viability of M. ulcerans (149). However, treatment with mild hydrochloric acid (final concentration, 0.03 N [149]) or oxalic acid (150) as a decontamination agent provides the best results. A mixture of polymyxin B, amphotericin B, nalidixic acid, trimethoprim, and azlocillin (PANTA) may control secondary contamination.

No one method of digestion and decontamination is ideal for all clinical specimens, all laboratories, and all circumstances. The laboratorian must be aware of the inherent limitations of the various methods used. Even under the best of conditions, all currently available procedures are toxic for mycobacteria to some extent. Thus, the best yield of mycobacteria may be expected to result from the use of the mildest decontamination procedure that sufficiently controls contaminants. Strict adherence to specimen processing is mandatory to ensure the survival of the maximal number of mycobacteria.

Commonly used digestion-decontamination methods are described with step-by-step instructions elsewhere (117, 130, 132) and in the Appendix of this chapter. In general, the specimen is diluted with an equal volume of digestant and allowed to incubate for some time. A neutralizing buffer is added, and the specimen is centrifuged in order to sediment any AFB present. Centrifugation should be carried out at ≥3,000 × g for 15 min to get maximum recovery. The sediment is then inoculated onto the appropriate liquid and solid media.

Whatever method is used, care must be taken to prevent laboratory cross-contamination of patient specimens during processing due to aerosols (130, 151). A single false-positive culture for M. tuberculosis could easily be the basis of a diagnosis of tuberculosis, with profound consequences for the patient, clinical management, epidemiologic investigations, and public health control measures.

Optimizing Decontamination Procedures
While no contamination or very low rates of contamination indicate that the pretreatment conditions were too harsh and eliminated not only bacteria and fungi but also mycobacteria, a contamination rate exceeding 5% of all digested and decontaminated specimens cultured is generally defined as excessive contamination. A high contamination rate suggests either too weak decontamination or incomplete digestion. One or a combination of several of the following measures may be used to help decrease the contamination rate.

---

30. Mycobacterium: General Characteristics ■ 549
1. Cautiously and slightly increase the strength of the alkali treatment. Be aware that >4% NaOH will affect the viability of tubercle bacilli.

2. Use a selective medium (one containing antibiotics) in addition to a none selective primary culture medium to inhibit the growth of bacterial and fungal contaminants. Selective 7H11 agar (Mitchison medium), Mycobactosel agar (BBL Microbiology Systems, Cockeysville, MD), or the Graft modification of L-J medium should be considered. The most useful media for recovering MAC organisms from stool specimens have been Mitchison’s selective 7H11 agar and Mycobactosel L-J medium (152).

3. Make sure that specimens are completely digested; partially digested specimens may not be completely decontaminated. Increase the NALC concentration to digest thick, mucoid specimens.

4. Use an alternative digestion-decontamination procedure for problem specimen types. Respiratory secretions from patients with cystic fibrosis, often overgrown with pseudomonads, can successfully be decontaminated with NALC-NaOH followed by the addition of 5% oxalic acid to the concentrated sediment.

To determine the decontaminating capabilities of each new batch of reagents, the laboratory may wish to inoculate blood agar plates with four to six decontaminated sputum specimens in addition to inoculating mycobacterial media. Numbers of contaminants that grow after 48 h of incubation at 35°C should be minimal to none (117, 130, 132).

**Acid-Fast Stain Procedures**

Smear microscopy, the most rapid and inexpensive way to diagnose tuberculosis, is preferentially done from pretreated and concentrated specimens. In parallel, it is a rapid means of identifying the most contagious patients (153). The predictive value of the AFB smear for M. tuberculosis was 92% for expectorated sputum specimens, 71% for induced sputum specimens, and 71% for bronchoalveolar lavage specimens (154). Current recommendations in the United States, Canada, and Europe support a three-smear approach when screening patients suspected of having an M. tuberculosis infection for isolation purposes. In a large retrospective study involving 3 smears/patient, 89% of patients were identified as being AFB smear positive by the first specimen, 7.8% were identified by the second smear, and 3.2% by further smears. This suggests that a two-smear approach for discontinuation of respiratory isolation precautions may be safe and reduce hospital expenditures (155).

The common Gram stain is not suitable for mycobacteria. The organisms may be Gram invisible, may appear as clear zones or “ghosts,” or may appear as beaded Gram-positive rods, particularly with rapidly growing mycobacteria (156). Special acid-fast staining procedures are necessary to promote the uptake of dyes. Although the exact nature of the acid-fast staining reaction is not completely understood, phenol allows penetration of the stain, which is facilitated by high temperatures, such as those applied, for instance, with Ziehl-Neelsen staining. Mycobacteria are able to form stable complexes with certain aminolane dyes, such as fuchsin. The cell wall mycolic acid residues retain the primary stain even after exposure to acid-alcohol or strong mineral acids. This resistance to decolorization is required for an organism to be termed acid fast. Certain staining protocols include a counterstain to highlight the stained organisms for easier microscopic recognition. A modified Ziehl-Neelsen stain involving cytopsin slides with Triton processing has improved the detection rate of extracellular M. tuberculosis in CSF and also identified intracellular M. tuberculosis in neutrophils, monocytes, and lymphocytes (157).

Alternatively, mycobacteria can be stained by fluorescent dyes (auramine O alone or in combination with rhodamine B). Unlike with carbol fuchsin, auramine O fluorescence is enhanced upon binding to both DNA and RNA. The advantages of fluorescence microscopy over conventional light microscopy outweigh the higher cost for the microscope for the following reasons: (i) there is a much shorter observation time than with Ziehl-Neelsen staining, (ii) there is no requirement to heat the smear, and (iii) the fluorochrome protocol is no more complex than that for carbol fuchsin staining.

Because acid-fast artifacts may be present in a smear, it is necessary to view the cell morphology carefully. AFB are approximately 1 to 10 μm long and typically slender rods, 0.2 to 0.6 μm wide, that may appear curved or bent. Individual bacilli may display heavily stained areas and areas of alternating stain, producing a beaded appearance. Assessing AFB morphology for presumptive identification of mycobacteria or species has to be done with caution and requires the laboratory personnel to have ample training and experience. In liquid medium, M. tuberculosis often exhibits serpentine cording, but cords are also seen with some NTM species, such as MAC organisms, M. gordonae, M. chelonae, M. abscessus, and M. marinum (158, 159). NTM may appear pleomorphic, i.e., as long filaments or coccoid forms, with uniform staining properties. M. kansasii organisms can often be suspected in stained sputum smears by their large size and cross-banding appearance (160). Less than 10% of cells of rapidly growing mycobacteria may be acid fast and may not stain with the fluorochrome stain (161). If the presence of a rapid grower is suspected and the results of acid-fast stains, in particular fluorochrome stains, are negative, it may be worthwhile to stain the smear with carbol fuchsin and to use a weaker decolorizing process. Organisms that are truly acid fast are difficult to overdecolorize. The laboratory must be aware that there are nonmycobacterial organisms with various degrees of acid fastness, such as Rhodococcus species, Nocardia species, and Legionella micdadei, as well as the cysts of Cryptosporidium, Isospora, Cyclospora, and Microsporidium spores. Kinyoun’s cold carbol fuchsin method appears inferior to both the Ziehl-Neelsen and fluorochrome methods (162).

Each slide made from a clinical specimen should be thoroughly examined for the presence of AFB. When a carbol fuchsin-stained smear is read, a minimum of 300 fields should be examined (magnification, ×1,000) before the smear is reported as negative (117, 130, 132). The fluorochrome stain is read at a lower power (×250) than the carbol fuchsin stain; therefore, more material can be examined in a given period. At the lower magnification, a minimum of 30 fields of view should be examined. This requires as little as 90 s. This ease of detection of AFB is of concern because it can make the observer miss fluorescent debris as bacilli. Information about specific staining procedures is given in chapter 19 as well as references 117, 130, and 132.

Low-cost, robust light-emitting diode (LED) microscopes have facilitated the expansion of fluorescence microscopy into low-resource settings (161). This prompted the WHO to recommend in 2010 that LED fluorescence microscopy should replace Ziehl-Neelsen stain microscopy for tuberculosis diagnosis. Fluorescent LED requires a shorter smear reading time (1.5 min per slide) than light microscopy (4
min for Ziehl-Neelsen-stained slides) \( (P < 0.001) \) (164). In a multicountry cross-sectional evaluation, LED fluorescence microscopy and Ziehl-Neelsen smears were compared (three slides for LED fluorescence microscopy versus three Ziehl-Neelsen slides per patient). Sensitivity was 77% for a LED fluorescence microscopy and 70% for Ziehl-Neelsen-stained smears, whereas specificity attained 88.1% and 96.5% for the two methods \( (P < 0.001) \) (165). As documented by a multicenter study analyzing 11,276 slides, the smear positivity rate for LED fluorescence microscopy was 11.2% compared to 8.6% for Ziehl-Neelsen staining (166). Independently of the fluorescence microscope used, it should be noted that auramine-rhodamine-stained slides fade very quickly, and this occurs irrespective of the environment for storage (167).

All smears in which no AFB are seen should be reported as negative. Conversely, when AFB are detected on a smear, the smear should be reported as AFB positive and the staining method should be specified. It is best to confirm positive smears by having them reviewed by another experienced reader. Ideally, all positive fluorochrome-stained smears should be confirmed by a carbol fuchsin-based staining method, e.g., Ziehl-Neelsen staining, and slides stored for future reference (117, 130, 132). The widely accepted practice of confirming positive fluorochrome stains may be challenged in the future. Murray et al. (168) have demonstrated that stain applied to a liquefied (dithiothreitol), concentrated sample and examined before the decontamination process (NaOH) was the most effective method for the detection of AFB.

Information about the quantity of AFB observed on the smear should be provided. The recommended interpretations and reporting of smear results are given in Table 2 (see also reference 130). If only one or two organisms are seen on an entire smear, this should be noted but not reported. Confirmation of this finding should be attempted by preparation of additional smears from the same specimen or, if possible, smears prepared from a new specimen. Observations made with the fluorochrome stains should be converted to a format that equates these observations with those made with a 100× oil immersion objective.

The reliability of smear microscopy is highly dependent not only on the experience of the laboratory personnel but also on the number of AFB present in the specimen. While 10⁶ AFB/ml of specimen usually result in a positive smear, only 60% of the smears are positive if 10⁴ AFB/ml are present (169). The overall sensitivity of the smear has been reported to range from 22 to 80% (153). An important factor influencing sensitivity is the minimum amount of sputum submitted to the laboratory. In a long-term study, the sensitivity of a concentrated smear from >5 ml of sputum was significantly greater than the sensitivity of a smear processed regardless of volume (170). Other factors influencing smear sensitivity include the type of specimens examined, staining techniques, the experience of the reader, the patient population being evaluated, and whether the smear has been done with or without pretreatment (indirect versus direct smear). Respiratory specimens yield the highest smear positivity rate (153). In practice, the fluorochrome stain is more sensitive than the carbol fuchsin stain, even when read at lower magnification, probably because the fluorochrome-stained smears are easier to read.

The specificity of the smear for the detection of mycobacteria is very high. Prolonged or very harsh specimen decontamination and short incubation of cultures may account for smear-negative but culture-positive results. Patients with pulmonary tuberculosis may have positive smears with negative cultures (for 2 to 10 weeks on average) during a course of appropriate treatment.

Cytocentrifugation of sputum has resulted in controversial results concerning the sensitivity of smear microscopy (171, 172). The concentration of sputum by centrifugation after liquefaction with 5% sodium hypochlorite is a possible means of increasing smear sensitivity, in particular in developing countries.

The diagnostic yield of acid-fast stains of body fluids is less than for respiratory specimens because the number of mycobacteria is usually lower. A variety of techniques have been used to concentrate mycobacteria from CSF and other body fluids, but comparative data are lacking. Centrifugation is not an effective way to concentrate mycobacteria in body fluids since mycobacteria have a buoyant density of approximately 1; therefore, many organisms remain in the supernatant.

With each new batch of staining reagents, good laboratory practice includes the preparation of a positive and a negative smear for internal quality assessment (130). Smears containing M. tuberculosis or an NTM (positive control) and a Gram-positive organism, preferably a Nocardia sp. strain which is not totally acid fast (negative control), may be prepared in advance. Cross-contamination of slides during the staining process and the use of water contaminated with NTM during staining procedures are potential sources of false-positive results (133). Staining jars or dishes should not be used. Transfer of AFB in the oil used for microscopy may also occur. Troubleshooting protocols to prevent false-positive and false-negative smear results are available (130).

**Culture**

Culture is more effective than smearing since it can detect as few as 10¹ to 10² viable organisms/ml specimen. Media

*In all cases, one full sweep refers to scanning the full length (2 cm) of a smear 1 cm wide by 2 cm long.
available for the recovery of mycobacteria include nonselective and selective ones (117, 130, 132), the latter containing one or more antibiotics to prevent overgrowth by contaminating bacteria or fungi. Broth media are preferred for a rapid initial isolation of mycobacteria.

**Solid Media**

**Egg-Based Media**

Egg-based media contain whole eggs or egg yolk, potato flour, salts, and glycerol and are solidified by inspissation. These media have a good buffer capacity, a long shelf life (several months, when refrigerated), and support good growth of most mycobacteria. Also, materials in the inoculum or medium toxic to mycobacteria are neutralized. Disadvantages of these media include variations from batch to batch depending on the quality of the eggs used, difficulties in discerning colonies from debris, and the inability to achieve accurate and consistent drug concentrations for susceptibility testing. When egg-based media become contaminated, they may liquefy.

Of the egg-based media, L-J medium is most commonly used in clinical laboratories. The concentration of malachite green in standard acid-fast media (e.g., L-J) was selected to maximize the growth of mycobacteria while inhibiting other microorganisms. In general, it recovers M. tuberculosis well but is not as reliable for the recovery of other species. M. bovis, for instance, grows less well on L-J medium, but growth is stimulated if glycerol is replaced by pyruvate. In contrast to most members of the M. tuberculosis complex, M. bovis is able to grow in a reduced-O₂ atmosphere. M. genavense fails to grow on L-J medium. Good recovery of M. ulcerans is obtained on L-J medium with glycerol (150, 173). Pettragnani medium contains about twice as much malachite green as does L-J medium and is most commonly used for recovery of mycobacteria from heavily contaminated specimens. American Trudeau Society medium contains a lower concentration of malachite green than L-J medium and is, therefore, more easily overgrown by contaminants, but the growth of mycobacteria is less inhibited, resulting in earlier growth of larger colonies.

**Agar-Based Media**

Compared to egg-containing media, agar-based media are chemically better defined. They do not readily support the growth of contaminants; however, the plates are expensive to prepare and their shelf life is relatively short (1 month in the refrigerator). Care should be exercised in the preparation, incubation, and storage of the media, because excessive heat or light exposure may result in deterioration and in the release of formaldehyde, which is toxic to mycobacteria. Agar-based media are transparent and provide a ready means of detecting the early growth of microscopic colonies easily distinguished from inoculum debris. Colonies may be observed in 10 to 12 days, in contrast to 18 to 24 days with egg-based media. Microscopic examination can be performed by simply turning over the plate and examining it by focusing on the agar surface through the bottom of the plate at ×10 to ×100 magnification. This may provide both earlier detection of growth than unaided visual examination and presumptive identification of the species of mycobacteria present. The use of thinly poured 7H11 agar plates (10 by 90 mm; Remel, Lenexa, KS) facilitates this process, as microcolonies are visible after 11 days (174). Agar-based media can also be used for susceptibility testing (175). In the quest for more-rapid and affordable growth techniques, microcolony-based culture methods have been developed. However, as shown by a recent systematic review, there is sufficient evidence neither for the feasibility and costs of implementation of these tests for growth detection and drug susceptibility testing nor for the impact on patient outcomes (176).

Middlebrook medium contains 2% glycerol, which enhances the growth of MAC organisms. Nonantibiotic supplements may be helpful for the recovery of other mycobacteria and in special situations. Addition of 0.2% pyruvic acid is recommended if M. bovis is suspected, and 0.25% l-asparagine or 0.1% potassium aspartate added to 7H10 agar maximizes the production of niacin. Addition of 0.1% enzymatic hydrolysate of casein to the Middlebrook 7H11 formulation (the only difference from 7H10) improves the recovery ofisoniazid-resistant strains of M. tuberculosis. M. genavense fails to grow on 7H11 agar as well. However, Middlebrook 7H11 agar supplemented with mycobactin J (Allied Monitor, Fayette, MO) supports the growth of M. genavense, as do microaerophilic conditions, the radiometric Bactec 7H12 pyrazinamide test medium (101), or addition of blood and charcoal to acidified Middlebrook agar (177).

**Selective Media**

The addition of antimicrobial agents may be helpful in eliminating the growth of contaminating organisms. If a selective medium is used for a particular specimen, it should not be used alone but in conjunction with a nonselective agar- or egg-based medium. Egg-based selective media include L-J Graft medium with penicillin and nalidixic acid and Mycobactosel L-J medium with cycloheximide, lincomycin, and nalidixic acid. Mitchison selective 7H11 medium and its modifications contain carbenicillin (especially useful for inhibiting pseudomonads), polymyxin B, trimethoprim lactate, and amphotericin B.

**Heme-Containing Medium for the Growth of M. haemophilum**

M. haemophilum will grow on egg- or agar-based media only if they are supplemented with hemin, hemoglobin, or ferric ammonium citrate (105). Thus, clinical specimens should be inoculated either on chocolate agar or on media with supplements (e.g., Middlebrook 7H10 agar with hemolyzed sheep erythrocytes, hemin, or a factor X disk, or on L-J medium containing 1% ferric ammonium citrate) to enhance the recovery of this organism. Broth media should be similarly supplemented. M. haemophilum can be isolated from the MGIT (178), whereas the MB/BacT Alert 3D system is less optimal for this organism (179). As a whole, M. haemophilum infections may be underrecognized because of its predilection for a low incubation temperature (30°C) and its unique nutritional requirements.

**Liquid Media**

Broth media may be used for both primary isolation and subculturing of mycobacteria. Cultures based on liquid media yield significantly more rapid results than solid-medium-based cultures. Also, isolation rates for mycobacteria are higher. Middlebrook 7H9 and Dubos Tween-albumin broths are commonly used for subculturing stock strains of mycobacteria and preparing the inoculum for drug susceptibility tests and other in vitro tests. 7H9 broth is used as the basal medium for several biochemical tests. Tween 80 can be added to liquid media and acts as a surfactant that allows the dispersal of clumps of mycobacteria, resulting in a more homogeneous growth. At present, the commercially available culture systems marketed for the isolation of mycobacteria range from simple
tubes, such as the MGIT (Becton, Dickinson Microbiology Systems), to the fully automated systems (e.g., Bactec MGIT 960 [Becton, Dickinson], ESP culture system II and VersaTREK culture system II [Trek Diagnostic Systems, Cleveland, OH], and MB/BacT Alert 3D system [bioMérieux]). These nonradiometric techniques have been tested in various studies against solid media and the radiometric Bactec 460 technique, which has long been considered the gold standard but has been discontinued by the manufacturer.

**Mycobacterium Growth Indicator Tube (MGIT)**

The MGIT (Becton Dickinson Microbiology Systems) contains a modified Middlebrook 7H9 broth in conjunction with a fluorescence quenching-based oxygen sensor (silicon rubber impregnated with a ruthenium pentahydrate) to detect growth of mycobacteria. The large amount of oxygen initially present in the medium quenches the fluorescence of the sensor. Growth of mycobacteria or other microorganisms in the broth depletes the oxygen, and the indicator fluoresces brightly when the tubes are illuminated with UV light at 365 nm. For the manual version, a Wood's lamp or a transilluminator can be used as the UV light source, while in the automated Bactec MGIT 960 system (see below), tubes are continuously monitored by the instrument. Prior to use, the 7H9 broth is supplemented with oleic acid-albumin-dextrose to promote the growth of mycobacteria and with polymyxin B, amphotericin B, nalidixic acid, trimethoprim, and azlocillin (PANTA) to suppress the growth of contaminants.

Overall, the sensitivity and time to growth detection of the MGIT system are similar to those of the Bactec 460TB system and have been superior to solid media in clinical evaluations (180). However, contamination rates for the MGIT system are slightly higher than for the Bactec 460TB system, probably owing to the enrichments added to the MGIT broth that enhance the growth of both mycobacteria and nonmycobacterial organisms.

The principal advantages of the manual MGIT system over the Bactec 460TB system include reduced opportunity for cross-contamination of cultures, no need for needle inoculation, no radioisotopes, and no need for special instrumentation other than a UV light source. Its limitations include higher contamination rates, masking of fluorescence by blood or grossly bloody specimens, and lack of compatibility with some methods of detection and decontamination of specimens (144).

**Automated, Continuously Monitoring Systems**

Several automated, continuously monitoring systems have been developed for the growth and detection of mycobacteria, e.g., the Bactec MGIT 960 (Becton Dickinson), the VersaTREK culture system (VersaTREK Diagnostic Systems), and the MB/BacT Alert 3D (bioMérieux). All have in common that they are no longer based on the use of radioisotopes. The MGIT system uses a fluorescence quenching-based oxygen sensor (ruthenium pentahydrate) to detect growth. The technology used in the VersaTREK culture system is based on the detection in a sealed bottle of pressure changes in the headspace above the broth medium that result from gas production or consumption due to the growth of microorganisms. The MB/BacT Alert 3D system employs a colorimetric carbon dioxide sensor in each bottle to detect the growth of mycobacteria. Each of the systems includes a broth similar to 7H9 broth supplemented with a variety of growth factors and antimicrobial agents. All three systems are FDA cleared for the isolation of mycobacteria; the VersaTREK culture system and the Bactec MGIT 960 system are also cleared for drug susceptibility testing of M. tuberculosis complex organisms to various extents, though.

These systems have similar levels of performance and operational characteristics. In clinical evaluations, recovery rates were similar to those of the Bactec 460TB system and superior to those of conventional solid media (Bactec MGIT 960 [181]; VersaTREK culture system [formerly the ESP culture system II] [182]). In a meta-analysis of 10 published studies encompassing 1,381 strains from 14,745 clinical specimens, the Bactec MGIT 960 and Bactec 460TB systems revealed sensitivities/specificities in detecting mycobacteria of 81.5%/99.6% and 85.8%/99.9%, respectively. Combined with solid media, the sensitivities of the two systems increased to 87.7 and 89.7%, respectively (183). For some systems, time to detection of mycobacteria is similar to those of the old radiometric Bactec 460TB technique. Parrish et al. (184) demonstrated for the Bactec MGIT 960 system a shorter time to detection (13.5 versus 25.2 days) and a greater sensitivity (100% versus 66.6%) for the recovery of members of the M. tuberculosis complex than the MB/BacT/Alert system. For blood specimens, the Bactec/Alert MB system, the manual Myco/F Lytic medium, and the Isolator 10 lysis-centrifugation system detected M. tuberculosis in 16.4 days, 20.0 days, and 23.8 days, respectively (185).

Throughout the literature, contamination rates are reported to have been higher with these new systems than with the Bactec 460TB system. However, all of them share advantages over the radiometric broth system in having no potential for cross-contamination by the instrument, being less labor-intensive, having continuous monitoring, using no radioisotopes, addressing safety more appropriately, and offering electronic data management. Since these systems monitor continuously, bottles are incubated in the instruments for their entire life in the laboratory. As a consequence, these systems are both instrument and space intensive. Some automated systems also lack the versatility of the Bactec 460TB system in that inoculation of blood is not possible, and therefore, additional instruments, e.g., the Bactec 9050 apparatus with Bactec Myco/F Lytic medium, have to be used for this purpose; alternatively, the bottles can be put into the standard Bactec 9240 or FX instrument. The same holds for the incubation of cultures harboring mycobacteria with a lower optimum temperature, such as M. chelonae, M. haemophilum, M. marinum, or M. ulcerans. Susceptibility testing applications for the primary and second-line antituberculosis drugs are available for the Bactec MGIT 960 system and VersaTREK system (formerly ESP culture system II [175]; see chapter 76).

Whenever one works with automated continuously monitoring systems, mycobacterial growth can go undetected. As demonstrated by Pen et al. (186), 1,323 (13%) of 10,263 tested specimens were culture positive for mycobacteria, but approximately 1% of instrument-negative MGIT cultures contained mycobacterial growth when tubes had been inspected visually for clumps before the tubes were discarded after 8 weeks.

**Medium Selection**

Medium selection for the isolation of mycobacteria and culture reading schedules are usually based on personal preferences and/or laboratory tradition. Both should be optimized for the most rapid detection of positive cultures and identification of mycobacterial isolates. The variety of media and methods available today is sufficient to permit laboratories to develop an algorithm that is optimal for their patient
population and administrative needs. Workload, financial resources, and, in particular, the limited amounts of processed sediments are, however, restraining factors in working with too many different types of media. Thus, cultivation of mycobacteria always involves a compromise.

Today, it is generally accepted that the use of a liquid medium in combination with at least one solid medium is essential for good laboratory practice in the isolation of mycobacteria (130). Addition of a solid medium is advantageous for those strains which occasionally do not grow in liquid medium, aids in the detection of mixed mycobacterial infections, and can serve as a backup for broth, which has a higher contamination rate. All positive cultures, even if identified directly from the broth, must be subcultured to solid media to detect mixed cultures and to correlate direct identification results with colony morphology. The nonradiometric growth systems cannot serve as stand-alone culture systems for mycobacteria for the reasons stated above.

Detection of colonies on solid medium certainly offers several advantages over detection of growth in broth, because colonial morphology can provide clues to identification and facilitate the selection of confirmatory tests. However, smears from broth-based systems can sometimes provide microscopic clues, such as cord formation (see above), although the reliability for presumptive identification of M. tuberculosis should be applied with caution since the phenomenon is also observed with some NTM species (158, 159, 160).

Incubation

Temperature

The optimum incubation temperature for most cultures is 35 to 37°C. Exceptions to this include cultures obtained from skin and soft tissue suspected of containing M. marinum, M. ulcerans, M. chelonae, or M. haemophilum, which have lower optimum temperatures. For such specimens, a second set of media has to be inoculated and incubated at 25 to 33°C. Lower temperatures increase detection time. The newer automated liquid-medium-based culture systems do not offer the possibility of incubating at temperatures lower than 36 ± 1°C.

Atmosphere

Five percent to 10% CO₂ in air stimulates the growth of mycobacteria in primary isolation cultures using conventional media. Middlebrook agar requires a CO₂ atmosphere to ensure growth, while it is necessary to incubate egg media under CO₂ for only the first 7 to 10 days after inoculation, i.e., during the log phase of growth. Subsequently, L-J cultures can be removed to ambient-air incubators if space is limited. In the absence of CO₂ incubators, plates may be incubated in commercially available bags with CO₂-generating tablets. Candle extinction jars are unacceptable for use in mycobacteriology laboratories because the oxygen tension is less than that required for the growth of mycobacteria. Broth systems usually do not require incubation at increased CO₂ concentrations.

Time

Mycobacterial cultures on solid and in liquid media are generally held for 6 to 8 weeks before being discarded as negative. Specimens with positive smears that are culture negative should be held for an additional 4 weeks. The same should be done for culture-negative specimens that were positive for mycobacteria by one of the nucleic acid-based amplification assays or for cases for which there is a persisting suspicion of tuberculosis. Plates should be incubated with the medium side down until the entire inoculum has been absorbed. Once this has happened, media should be incubated inverted in CO₂-permeable polyethylene bags or sealed with CO₂-permeable shrink-seal bands to prevent them from drying up during the incubation period. Tubed media should be incubated in a slanted position with the screw caps loose for at least a week until the inoculum has been absorbed; they can then be incubated upright if space is at a premium. Caps on the tubes should be tightened at 2 to 3 weeks to prevent desiccation of the media. Specimens from skin lesions should be incubated for 8 to 12 weeks if M. ulcerans is suspected.

Reading Schedule

Since many mycobacteria are slowly growing organisms, cultures can be examined less frequently than routine bacteriologic cultures. All solid media should be examined within 3 to 5 days after inoculation to permit early detection of rapidly growing mycobacteria and to enable prompt removal of contaminated cultures. Young cultures (up to 4 weeks of age) should be examined twice a week, whereas older cultures could be examined at weekly intervals. Use of a hand lens for opaque media and a microscope for agar media will facilitate early detection of microcolonies.

The manual MGIT may be inspected for growth daily for the first 1 to 2 weeks. Afterwards, it should be inspected twice weekly or weekly for growth.

When using one of the nonradiometric continuously monitoring systems, laboratory personnel are automatically alerted by the instrument if a specimen turns positive. Irrespective of the system used, the acid fastness of the organism has to be confirmed by smear staining. Also, it is highly advisable to subculture the broth on a sheep blood or chocolate agar plate to rule out contaminants. Once growth of AFB is detected, susceptibility testing can be performed, always according to the instructions specified by the manufacturers.

Reporting

Traditionally, solid culture media are being kept for up to 8 weeks. Even though liquid media detect mycobacteria much earlier, most incubation protocols still require a minimum of 6 weeks (130). A large multicenter evaluation involving >1,500 positive cultures (among them, 466 M. tuberculosis isolates) stressed that laboratories using MGIT may issue reports of no growth of M. tuberculosis as early as at 4 weeks (187). This was confirmed by Pfyffer and Wittwer (188); 58.3% of all mycobacteria were detected within 14 days, 37.5% were detected within 21 days, and 4.2% were detected within 28 days if a combination of solid media (L-J/Middlebrook) and liquid medium (Bactec MGIT 960) were utilized. In this context, 50% of species in the M. tuberculosis complex were detected within 14 days, and 50% were detected within 21 days. As much as 70% of NTM appeared within 14 days, 20% were detected within 21 days, and 10% were detected within 28 days.

Storage of Positive Cultures

Positive cultures may be kept at room temperature for several weeks. If subcultured, they may be saved at room temperature for several months. Solid cultures have to be sealed to avoid dehydration of the medium. The CLSI (130) recommends that cultures that may be needed for possible follow-up in the future be frozen at −70°C (a minimum of 1 year is recommended) or cryopreserved as suggested by Shu et al. (189).
IMMUNODIAGNOSTIC TESTS FOR TUBERCULOSIS

Historically, the first immunodiagnostic test was the TST. The shortcomings of this test are well known and include the inability to distinguish active tuberculosis disease from past sensitization by BCG, unknown predictive values, and cross-reaction with NTM.

Over time, much effort has been devoted to the development of serological tests for the diagnosis of tuberculosis, but no test has found widespread clinical use. The sensitivity and specificity of serological tests with crude antigen preparations are too low for clinical application.

In contrast, the two commercially available whole-blood IGRAs have become a more promising, though not perfect, tool to detect tuberculosis infection, in particular, if TST remains equivocal. Both tests are FDA approved but not for testing individuals under the age of 17, individuals with immunedepression due to AIDS, persons taking immunosuppressive drugs (e.g., anti-tumor necrosis factor or corticosteroids), or transplant recipients. Two test systems, the T-Spot.TB (Oxford Immunotec, Oxford/United Kingdom) and the QuantiFERON gold in-tube (QFNG-IT; Cellestis, Victoria/Australia) tests, are not affected by BCG vaccination, do not cross-react with the majority of NTM, and are less prone to variability and subjectivity associated with placing and reading of the TST. Also, individuals to be tested have to see a doctor or health care personnel only once. As shown by a recent systematic review of studies performed in high-, middle-, and low-income countries, the higher per-test cost of IGRAs may be compensated for by low postscreening costs (medical attention, chest X rays, chemoprevention), given the higher specificity of the IGRAs than that of conventional TST (190).

In particular, there was strong evidence of the cost-effectiveness of the IGRAs in screening risk groups, such as immigrants from high-incidence countries, close contacts, and health care workers. Disagreement between QFNG-IT and TST results as well as the high reversion rate with QFNG-IT, however, raised concerns about the effectiveness of QFNG-IT as a sole screening test for health care workers (191).

Although both tests measure T cell IFN-γ responses to two or three M. tuberculosis-specific antigens (ESAT-6, CFP-10, TB 7.7) over a 16- to 24-h incubation period, they are based on different technologies. The T-SPOT.TB assay is based on the enzyme-linked immunosorbent spot (ELISPOT) methodology and requires the isolation and incubation of peripheral blood mononuclear cells (PBMC) and the standardization of 250,000 PBMC in each of its test wells. The assay requires, overall, two working days and may be more laborious than the QFNG-IT. Nevertheless, the use of a standardized number of washed PBMC may represent another advantage. In contrast, the QFNG-IT assay has technical advantages over the T-SPOT.TB assay, since the stimulation of a T cell IFN-γ response in whole blood is performed in tubes precoated with the M. tuberculosis antigens. Also, the enzyme-linked immunosorbent assay (ELISA) is simple to perform and requires one working day. Since background noise may occur, a "nil" control is required to adjust for this background, as well as for heterophile antibody effects and nonspecific IFN-γ in blood samples. The reproducibility of QFNG-IT assay results in duplicate tests is excellent (192).

It is important to stress that neither of these new tests distinguishes between latent and active infection. To date, there are several guidelines available, among them the one for the United States (193). A large number of publications focus on the performance characteristics of each test compared to TST. As a whole, IGRAs are better correlated with the intensity of tuberculosis exposure than the TST (194).

There are several systematic reviews and meta-analyses which document the performance characteristics of the two types of IGRAs in both immunocompetent and immunocompromised patients. In a head-to-head comparison of the QFNG-IT and the T-SPOT.TB assays, Pai et al. (195) concluded that the QFNG-IT test has a specificity of 99% (T-SPOT.TB test, 96%) among non-BCG-vaccinated participants and a specificity of 96% (T-SPOT.TB test, 93%) among BCG-vaccinated participants, while Higuchi et al. (196) reported equal specificities for the two assays. For latent tuberculosis, specificity varied between 98 and 100%.

In immunocompetent adults, the negative predictive values for progression to tuberculosis within 2 years were 97.8% for the T-SPOT.TB assay and 99.8% for the QFNG-IT assay (197). In contrast, it is well understood that IGRAs have limited accuracy in diagnosing active tuberculosis, as evidenced by a meta-analysis of 894 studies (198). This also holds true for HIV-positive individuals (199). Also, QFNG-IT results do not offer much value for treatment monitoring of tuberculosis disease (200).

Diel et al. (201) compared both IGRAs in TST-positive persons recently exposed to pulmonary tuberculosis cases. In that study, factors independently influencing the risk of M. tuberculosis infection and their interactions with each other were evaluated by multivariate analysis. There were five variables which significantly predicted a positive IGRA result, i.e., age, AFB positivity of the source case, cough, cumulative exposure time, and foreign origin of the patient. There was excellent agreement between the two assays (93.9%, kappα = 0.85), with QFNG-IT finding 30.2% of contacts positive and T-SPOT.TB finding 28.7% of them. Again, the IGRAs were more accurate indicators of the presence of latent tuberculosis than the TST (201).

In HIV-positive asymptomatic individuals (n = 286), both the QFNG-IT and T-SPOT.TB assays were more sensitive than the TST (20.0% and 25.2%, respectively, compared with 12.8% for the TST) but seemed, as a whole, to be less sensitive than in immunocompetent patients (202). The value of TST and serial QFNG-IT tests in patients with rheumatic diseases during long-term treatment with tumor necrosis factor blockers has not been defined to date (203).

The performance of IGRAs in children is less understood. Without having the inconveniences and complications associated with the TST, IGRAs are acceptable substitutes for it. The sensitivity and specificity of IGRAs are, however, not significantly higher than the values observed for the TST (204). In children with latent tuberculosis, the agreement between the QFNG-IT and T-SPOT.TB assays was very good (92%), with moderate agreement between the TST and the QFNG-IT assay (77%) and the TST and the T-SPOT.TB assay (75%) (205). Available data suggest that the TST and IGRAs have similar levels of accuracy for the detection of tuberculosis infection or the diagnosis of disease in children (206).

Since the experience with IGRAs is still limited, longitudinal studies are needed to define their predictive values, especially in children and high-risk populations (207). A large meta-analysis has pointed out very clearly present-day limitations of IGRAs, such as with their performance in children, in immunocompromised persons, and in the elderly (208). Other problems concern altered performance characteristics of the assays in conjunction with ethnicity.
(209), specifically with the phenomena of conversions, reversions, and nonspecific variations in serial testing (210–212). Assessment of within-subject IGRA variability is important in establishing thresholds for conversions and reversions. With the QFNG-IT assay, Detjen et al. (192) observed considerable intrapersonal variability in serial analyses within 3 days. Van Zyl-Smit et al. (213) concluded from their study that a 3-spot or 80% IFN-γ response variation on either side of the baseline values explains 95% of the short-term variability and may be useful for interpreting conversions, reversions, and values close to the cutoff point. Therefore, these authors have proposed a borderline or uninterpretable result on either side of the baseline values explains 95% of the short-term variability and may be useful for interpreting conversions, reversions, and values close to the cutoff point. Basically, the problem of indeterminate results occurs with both IFN-γ release assays. In HIV-infected individuals, the T-SPOT.TB assay provided more indeterminate results than the QFNG-IT test (8 versus 1/256, P < 0.01) (202), similar to what has been confirmed by others (14% versus 1.8% (214). If preanalytical errors can be excluded, indeterminate results appear to be dependent on the number of CD4 cells, inasmuch as patients with a CD4 count of ≤200 cells/ml were significantly more likely to have an indeterminate result (202, 214). In children <4 years of age, indeterminate results were more often seen using the QFNG-IT than the T-SPOT.TB assay (215). After the T-SPOT.TB assay was performed, when indeterminate results were obtained with the QFNG-IT test, 65% of the 40 patients yielded a valid result (216). In addition, age, race/ethnicity, and sex were also associated with indeterminate QFNG-IT results (217).

There is a growing number of studies pointing to the need for standardizing IGRA preanalytical practices. Herrera et al. (218), for instance, have demonstrated that a delay in incubation of up to 12 h (which is well within the manufacturer’s maximum delay of 16 h) increased the number of indeterminate QFNG-IT results. Six- and 12-h delays resulted in rates of positive-to-negative reversion (from immediate-incubation results) of 19% and 22%, respectively (219).

The optimal strategy for the diagnosis of latent tuberculosis infection is controversial. Adoption of a two-step strategy (TST followed by an IGRA) may be limited by TST-mediated boosting of subsequent IGRA responses. Van Zyl-Smit et al. (213) have demonstrated that it appears safe to perform a QFNG-IT or T-SPOT.TB assay within 3 days of performing the TST.

From the present state of knowledge, it is obvious that the applications of the IGRA for tuberculosis infection in different high-risk groups have to be tailored. Also, caution has to be exerted in their current use in immunosuppressed patients.

CROSS-CONTAMINATION

With the advent of molecular techniques designed for molecular epidemiology, cross-contamination linked either to laboratory procedures or, more rarely, to contaminated bronchoscopes can easily be proven. False-positive results may be generated at any step between specimen collection and reading of cultures (130, 220). Laboratory personnel should be alerted for a possible laboratory error if (i) the culture result is not compatible with the clinical picture, (ii) there is a late-appearing cluster of cultures which have scanty growth (<10 colonies on solid medium) or a significant delay in recovering mycobacteria from a liquid system, (iii) there is a large number of isolates of a particular species that is usually rare in the laboratory or of an organism that is normally considered an environmental contaminant, or (iv) there is only one positive culture from multiple specimens submitted from a single patient. Practices which can lead to false-positive culture results are numerous and include inadequate sterilization of instruments or equipment (such as bronchoscopes), use of contaminated water for specimen collection or for laboratory procedures, transfer of organisms from one specimen to another through direct contact or via common reagents or equipment, mix-up of testing samples or lids of specimen containers, failure to take precautions which minimize the production of aerosols, etc. Laboratory aspects of cross-contamination are addressed in more detail in the following section.

QUALITY ASSURANCE

General Aspects

Quality control (QC) is vital for monitoring a laboratory’s effectiveness in detecting and isolating mycobacteria. This includes standard components of laboratory quality assurance, such as personnel competency, procedure manuals, external proficiency testing, and QC of media, tests, and reagents (see chapters 18 and 19). Laboratories performing mycobacterial testing should follow QC recommendations in the scientific literature and in ad hoc publications (130, 132, 175). The Clinical Laboratory Improvement Amendments (CLIA) have reported that applications of a principal sanction against laboratories for a proficiency test violation were rare during a 14-year period of study (221).

The Public Health Service introduced the “levels of service concept” for mycobacteriology laboratories in 1967. In this scheme, laboratories define the level of service which best fits the needs of the patient population that they serve, the experience of their personnel, their laboratory facilities, and the number of specimens that they receive, always keeping the biosafety risk in mind. Levels of service were promulgated by the CDC, the ATS, and the College of American Pathologists (CAP) and are based on workload, personal experience, and cost-effectiveness (222). Personnel working in a clinical mycobacteriology laboratory must have proper training and certification in the specific functions that they perform. In the United States, all laboratories performing mycobacteriology testing must be enrolled in an external proficiency test program approved by federal and state regulatory agencies. Level I laboratories (acid-fast smear) must prepare at least 15 specimens per week, and level II laboratories (smear, culture, identification, and susceptibility testing of M. tuberculosis complex organisms) must process at least 15 specimens per week. Level III laboratories perform all the activities of a level II lab and, in addition, identify all NTM (performing susceptibility testing, where applicable).

Multiple test parameters are monitored by adherence to the quality assurance guidelines described in the recent CLSI standard documents (130, 175). Acceptable results derived from testing quality control reference strains do not guarantee accurate results with all clinical isolates. If inconsistent results are seen with clinical isolates (220), the test should be repeated in an attempt to ensure accuracy. Each laboratory should put its own policies into effect regarding the verification of atypical test results.

Laboratories must maintain a collection of well-characterized mycobacterial strains that are used for QC of test
systems. These controls may be obtained from the American Type Culture Collection (ATCC) and proficiency testing programs. Frequent use of stock cultures can be maintained on L-J slants or in 7H9 broth at 37°C or room temperature if subcultured monthly. Cultures on L-J slants may be held for up to 1 year if stored at 4°C. Such maintenance is not recommended for strains with drug resistance. Freezing of organisms suspended in water, saline, or 7H9 broth and storage at −70°C ± 10°C is the best option for long-term maintenance of stock cultures (130).

**QC of Smear, Culture, and Molecular Tests**

Apart from submitting to external QC tests, laboratories should make every possible effort to perform internal QC tests, e.g., with each new lot of medium commercially obtained or prepared in-house. Detailed procedures for monitoring the many different working steps in a clinical mycobacteriology laboratory are outlined in references 130 and 132.

Ideally, positive-control slides should be prepared from a concentrated sputum sample obtained from a patient with active tuberculosis. In practice, many laboratories use suspensions of stock cultures or seeded negative sputa as positive controls for acid-fast staining procedures. Control slides are also commercially available (BBL AFB QC slides; Becton, Dickinson Diagnostic Systems, Sparks, MD). An increase in the percentage of smear-positive but culture-negative specimens of >2% that cannot be attributed to a response to mycobacterial therapy or the presence of AFB in the negative controls suggests that water or reagents used in the pretreatment or staining procedures were contaminated with NTM. *M. gordonae* or *M. terrae* complex are most often involved.

AFB may also be carried over from one slide to another if slides are not set properly apart from each other during the staining process. AFB may also be found in the oil used with the immersion lens after a positive slide is examined. The sensitivity of the AFB smear is directly related to the relative centrifugal force (RCF) (g force) attained during centrifugation. Thus, laboratories should calculate the RCF of their centrifuge and periodically monitor and document that they are reaching sufficient RCF by checking the revolutions per minute with a tachometer (117).

Laboratories should also monitor contamination rates (percentage of specimens producing contaminating growth on culture media) for decontaminated specimens. Contamination rates of 3 to 5% are generally considered acceptable. Rates below 3% usually indicate that the decontamination procedure is too harsh and that the procedure needs to be modified to minimize the lethal effect on mycobacteria. Contamination rates above 5% often indicate a too-weak decontamination, which could compromise mycobacterial cultures due to overgrowth of contaminants. It should be emphasized that the widespread use of liquid media increases the generation of aerosols; as a consequence, the risk of contamination between samples also increases. Laboratories that handle large numbers of isolates of MAC, *M. abscessus*, or specimens from patients with cavitary tuberculosis will probably have much higher contamination rates due to the high incidence of colonization of the sputum with Gram-negative bacteria, especially *Pseudomonas aeruginosa*.

Culturing mycobacteria is naturally prone to errors because of the multiple steps involved in processing cultures, the viability of mycobacteria for long periods in a laboratory environment, and the large number of mycobacteria present in some specimens (151). False-positive cultures may result from mislabeling, specimen switching during handling, specimen carryover (including proficiency testing specimens), contaminated reagents, or cross-contamination between culture tubes or vials (130, 151). Inclusion of a positive control (e.g., a suspension of *M. tuberculosis*) in the processing of patient specimens is discouraged due to the risk of cross-contamination. Standardized laboratory procedures that minimize the potential for errors leading to false-positive cultures should be followed, and mechanisms should be in place to rapidly recognize their occurrence. Transfers or inoculation of cultures must be accomplished by using individual transfer pipettes, single-delivery diluent tubes, or disposable labware. The order in which specimens are processed and media are inoculated should be recorded. A negative-control specimen following processing of patient specimens with the same digestion or decontamination solution can be used for detecting possible specimen contamination of the solutions. Alternatively, processing solutions may be cultured directly. Laboratories should prospectively track positivity rates. The significance of an isolate may be determined by reviewing the order in which specimens were handled for all manipulations (e.g., initial processing, liquid-medium readings, subculturing), the direct-smear results, the time to positivity, and the clinical history. Since the introduction of molecular fingerprinting of *M. tuberculosis* strains, false-positive cultures have been demonstrated to occur more frequently than previously assumed. False-positive cultures were identified in a number of studies that evaluated >100 patients, with a median false-positivity rate of 3.1%. Remarkably, of the 236 patients with false-positive cultures, 67% were treated and underwent unnecessary hospitalization (151). The deleterious impact of these undesirable events may be minimized if the evidence of false positivity is established in a timely manner and a rapid molecular method of fingerprinting is available. Single positive cultures of *M. tuberculosis* strains grown from AFB smear-negative specimens in the absence of clinical signs of tuberculosis should be analyzed by a PCR-derived typing technique to rule out laboratory contamination (130). Strains with identical fingerprints isolated within a 1-week period from different patients should be considered probably false positive.

The CDC and others (130) have recommended that AFB smear results be available and that positive results be reported within 24 h of specimen receipt. The time required for identification and susceptibility testing of *M. tuberculosis* should average 14 to 21 days and 15 to 30 days from the time of specimen receipt, respectively (223).

Nucleic acid amplification (NAA)-based assays require several levels of controls (e.g., to detect amplification inhibition as well as contamination between specimens), in addition to positive or negative controls (224). When used as approved by the FDA, NAA tests for *M. tuberculosis* diagnosis do not replace any previously recommended tests (225). Laboratories that test patient specimens by using laboratory-developed methods or commercially available NAA assays for nonapproved or off-label indications and that report their results must validate the assays and establish their performance characteristics prior to diagnostic use. Approved guidelines for molecular diagnostic methods in clinical microbiology are available from the CLSI; in these documents, the development, validation/verification, quality assurance, and routine use of NAA assays are addressed in detail (224). However, basing the identification of *M. tuberculosis* on a sole positive laboratory-developed test result is not recommended because the results of such assays vary considerably.

Potential probes and/or primers must be selected for sensitivity by using multiple clinical and reference strains of the target organism. Additionally, specificity must be evaluated by testing for cross-hybridization with other organisms which may be present in patient samples (224).
Testing to assess amplification should include positive and negative controls and controls for detection of the presence of inhibitors, such as endogenous nucleic acid. Other QC measures include those referring to assays of restriction enzymes, reagents, inspection of equipment, and laboratory design (i.e., separate areas for processing, amplification, and detection steps) (224). Excellent proficiency testing schemes to assess laboratory performance of nucleic acid amplification tests are currently available in both the United States and Europe.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Adequate funding and focused training are critical in maintaining state-of-the-art mycobacteriology laboratories (130, 175, 224). Laboratories play a pivotal role in the diagnosis and control of tuberculosis, and every effort should be made to implement sensitive and rapid methods for the detection, identification, and susceptibility testing of MAC organisms as well as other mycobacterial species. Specifically, these include the use of (i) fluorochrome stain for mycobacteria in smears, (ii) a broth-based or microcolony method for culture, and (iii) rapid identification methods (e.g., molecular assays).

The 24-h turnaround time for AFB smear results presents a challenge for most laboratories. The daily processing of specimens required to meet this goal adds considerable expense to the laboratory budget.

NAA assays offer the promise of same-day detection and identification of M. tuberculosis. Implementation of these new technologies presents several new challenges. Although the performance characteristics of many of these assays are quite good for smear-positive respiratory specimens, limited information exists on the use of these tests for the diagnosis of paucibacillary pulmonary or extrapulmonary disease. The new technologies have been shown to supplement rather than replace culture. Culture will still be required to obtain organisms for susceptibility testing and detect mycobacteria other than M. tuberculosis.

The significance of the isolation of NTM may be difficult to assess since many species are opportunistic pathogens, and the reader is referred to the criteria suggested by the ATS for their evaluation (2). In addition, accurate identification of NTM will prevent rarely encountered pathogens from being mistaken for nonpathogenic species.

Thus, accurate and timely reporting of the results of AFB microscopy, molecular tests, culture, identification, and drug susceptibility tests is essential to the effective management of individual patients and to the appropriate implementation of public health and infection control measures (130).

APPENDIX

Commonly Used Digestion-Decontamination Methods (117, 130, 132)

NALC-NaOH Method

Reagents

**Digestant.** For each 100 ml, combine 50 ml of sterile 0.1 M (2.94%) trisodium citrate with 50 ml of 4% NaOH. The NaOH and citrate mixtures can be mixed, sterilized, and stored for future use. To this solution, add 0.5 g of powdered NALC just before use. Use within 24 h of addition of the NALC because the mucolytic action of NALC is inactivated upon exposure to air.

**Phosphate buffer.** The buffer is 0.067 M and pH 6.8. Mix 50 ml of solution A (0.067 M Na₂HPO₄, 9.47 g of anhydrous Na₃HPO₄ in 1 liter of distilled water) and 50 ml of solution B (0.067 M KH₂PO₄, 9.07 g of KH₂PO₄ in 1 liter of distilled water). If the final buffer requires pH adjustment, add solution A to raise the pH or solution B to lower it.

NALC-NaOH (optional). Use sterile 0.2% bovine serum albumin (BSA) fraction V (pH 6.8).

**Procedure**

1. Transfer up to 10 ml of specimen to a sterile, graduated, 50-ml plastic centrifuge tube labeled with appropriate identification. The tube should have a leakproof, aerosol-free screw cap. Add an equal volume of the NALC-NaOH solution. The final concentration of NaOH in the tube is 1%.

2. Tighten the cap completely. Invert the tube so that the NALC-NaOH solution contacts all the inside surfaces of the tube and cap, and then mix the contents for approximately 20 s on a vortex mixer. If liquefaction is not complete during this time, agitate the solution at intervals during the following decontamination period.

3. Allow the mixture to stand for 15 min at room temperature, with occasional gentle shaking by hand. Avoid movement that causes aeration of the specimen. A small pinch of crystalline NALC may be added to viscous specimens for better liquefaction. Specimens should remain in contact with the decontaminating agent for only 15 min, since overprocessing results in reduced recovery of mycobacteria. If more-active deactivation is needed, slightly increase the concentration of NaOH.

4. Add phosphate buffer (pH 6.8) up to the 50-ml mark on the tube.

5. Centrifuge the solution for at least 15 min at ≥3,000 × g.

6. Decant the supernatant fluid into a splashproof discard container containing a suitable disinfectant. Do not touch the lip of the tube to the discard container. Wipe the lip of each tube with disinfectant-soaked gauze (separate piece for each tube) to absorb drips, and recap.

7. Using a separate sterile pipette for each tube, add to the sediment 1 to 2 ml of sterile, 0.2% BSA fraction V (pH 6.8). Stir 1 to 2 ml of phosphate buffer (pH 6.8), and resuspend the sediment in the pipette or by shaking the tube gently by hand. BSA may have a buffering and detoxifying effect on the sediment and increases the adhesion of the specimen to solid media. However, BSA may lengthen detection times (as, for instance, in the Bactec 460TB system).

8. Inoculate the specimens onto appropriate solid culture media and into broth media. Use a separate disposable capillary pipette for each specimen to deliver 3 drops to solid medium.

9. Prepare a smear for acid-fast staining. Use a sterile disposable pipette to place 1 drop of the sediment onto a clean, properly labeled microscope slide covering an area approximately 1 by 2 cm. Place the smears on an electric slide warmer at 65 to 75°C for 2 h to dry and fix them. Alternatively, air dry the smears and fix them by passing the slide three or four times through the blue cone of a flame (heat fixing does not always kill mycobacteria, and the slides are potentially infectious).

10. Refrigerate (4°C) the remaining sediment for later use if needed (e.g., for direct susceptibility testing or further treatment if the specimen is contaminated, etc.).

The NALC-NaOH method can be used to process gastric lavage specimens, tissues, stool, urine, and other body fluids. For neutralized gastric lavage specimens and other body fluids (≥10 ml), centrifuge at ≥3,000 × g for 30 min in sterile screw-cap 50-ml centrifuge tubes, decant the supernatants, resuspend the sediments in 2 to 5 ml of sterile distilled water, and proceed as for sputum. If a gastric lavage specimen is mucopulent, add 50 mg of NALC powder per 50 ml of lavage fluid and vortex before centrifugation. Tissue that is not collected aseptically can be ground, placed in a tube, homogenized by vortexing, and processed as for sputum. For stool specimens, place approximately 1 g of a formed specimen or 1 to 5 ml of a liquid specimen in a total volume of 10 ml of 7H9 broth, sterile water, or sterile saline; vortex vigorously for 30 s, and then allow large particles to settle to the bottom of the tube for 15 min. Remove 7 to 8 ml of supernatant, place it into a 50-ml centrifuge tube, and process as for sputum.
Sodium Hydroxide Method

**Reagents**

- **Digestant.** NaOH solution (2 to 4%). Sterilize by autoclaving.
  - 2 N HCl. Dilute 33 ml of concentrated HCl to 200 ml with water. Sterilize by autoclaving.
- **Phenol red indicator.** Combine 20 ml of phenol red solution (0.4% in 4% NaOH) and 85 ml of concentrated HCl with distilled water to make 1,000 ml.
- **Phosphate buffer.** The buffer is 0.067 M and pH 6.8. See the NALC-NaOH procedure for buffer preparation.

**Procedure**

Follow the steps described for the NALC-NaOH method, substituting 2% NaOH for the NALC-alkali digestant.

1. Transfer a maximum volume of 10 ml of specimen to a sterile 50-ml screw-cap plastic centrifuge tube. Add an equal volume of NaOH.
2. With the cap tightened, invert the tube and then agitate the mixture vigorously for 15 min on a mechanical mixer or vortex vigorously and let stand for exactly 15 min. If it is necessary to reduce excessive contamination, the NaOH concentration can be increased to 3 or 4%
3. Add phosphate buffer (pH 6.8) up to the 50-ml mark on the tube. Recap the tube, and swirl by hand to mix well.
4. Centrifuge the specimen at ≥3,000 × g for 15 min, decant the supernatant, and add a few drops of phenol red indicator to the sediment. Neutralize the sediment with HCl. Thoroughly mix the contents of the tube thoroughly. Stop acid addition when the solution is persistently yellow.
5. Resuspend the sediment in 1 to 2 ml of phosphate buffer or sterile 0.1% BSA fraction V.
6. Inoculate the resuspended sediment to appropriate culture media, and prepare a smear.

Zephiran-Trisodium Phosphate Method

**Principle**

This system can be used when the laboratory cannot monitor the exposure time to the decontaminating agent, since the timing of this digestion-decontamination process is not critical. Benzalkonium chloride (Zephiran), a quaternary ammonium compound, together with trisodium phosphate selectively destroys many contaminants with little activity on tubercle bacilli. Zephiran is bacteriostatic to mycobacteria, and so the digested, centrifuged sediment must be neutralized with buffer before being inoculated onto agar medium. The phospholipids of egg medium neutralize for this quaternary compound.

**Reagents**

- **Zephiran-trisodium phosphate digestant.** Dissolve 1 kg of trisodium phosphate (Na₃PO₄·12H₂O) in 4 liters of hot distilled water. Add 7.5 ml of Zephiran concentrate (17% benzalkonium chloride [Winthrop Laboratories, New York, NY]), and mix. Store at room temperature.
- **Neutralizing buffer.** Neutralizing buffer has a pH of 6.6. Add 37.5 ml of 0.067 M disodium phosphate to 62.5 ml of 0.067 M monobasic phosphate (for preparation of buffer solutions, see the NALC-NaOH procedure).

**Procedure**

1. Transfer a maximum volume of 10 ml of specimen to a sterile, 50-ml screw-cap plastic centrifuge tube. Add an equal volume of the Zephiran-trisodium phosphate digestant.
2. Tighten the cap, invert the tube, and then agitate the mixture vigorously for 30 min on a mechanical shaker. Permit the material to stand, without shaking, for an additional 20 to 30 min at room temperature.
3. Centrifuge the specimen at ≥3,000 × g for 15 min, decant the supernatant, and add 20 ml of neutralizing buffer. Vortex for 30 s to thoroughly suspend the sediment in the buffer (the neutralizing buffer serves to inactivate traces of Zephiran in the sediment, which is critical if inoculation of an agar-based medium is intended).
4. Centrifuge the specimen again for 15 min.
5. Decant the supernatant, retaining some fluid to resuspend the sediment.
6. Inoculate egg-based medium, and make a smear. The phospholipids of egg medium provide neutralization for this quaternary compound.

Oxalic Acid Method

**Principle**

The oxalic acid method is superior to alkali methods for processing specimens consistently contaminated with Pseudomonas species and certain other contaminants. Specimens processed by this method may be used with the Bactec 460TB system. It can also be used to decontaminate a previously processed sediment when cultures are contaminated with Pseudomonas and other non-glucose-fermenting Gram-negative bacilli.

**Reagents**

- **5% oxalic acid**
  - Physiological saline (0.85%) 4% NaOH
  - Phenol red indicator or pH paper

**Procedure**

1. Add an equal volume of 5% oxalic acid to 10 ml, or less, of specimen in a 50-ml centrifuge tube (1/1, vol/vol).
2. Vortex the solution, and then allow it to stand at room temperature for 30 min with occasional shaking.
3. Add sterile saline to the 50-ml mark on the centrifuge tube. Recap the tube, and invert it several times to mix the contents.
4. Centrifuge for 15 min at ≥3,000 × g, decant the supernatant fluid, and add a few drops of phenol red indicator to the sediment. Alternatively, use pH paper.
5. Neutralize with 4% NaOH.
6. Resuspend the sediment, inoculate it to media, and make a smear.

CPC Method

**Principle**

Cetylpyridinium chloride (CPC), a quaternary ammonium compound, is used to decontaminate specimens, while sodium chloride effects liquefaction. CPC is bacteriostatic for mycobacteria inoculated onto agar-based media. This effect is not neutralized in the digestion process, and thus sediments from specimens treated with CPC should be inoculated only on egg-based media. This method is incompatible with the Bactec 460TB system.

This method is a means of digesting and decontaminating specimens in transit (>24 h). Mycobacteria remain viable for 8 days in the solution.

**Reagents**

- **CPC digestant-decontaminant.** Dissolve 10 g of CPC and 20 g of NaCl in 1,000 ml of distilled water. The solution is self-sterilizing and remains stable if protected from light, extreme heat, and evaporation. Dissolve with gentle heat any crystals that might form in the working solution. Other reagents used in processing include sterile water and sterile saline or 0.2% sterile BSA fraction V.

**Procedure**

1. Collect 10 ml or less of sputum in a 50-ml screw-cap centrifuge tube.
2. Inside a BSC, add an equal volume of CPC-NaCl, cap securely, and shake by hand until the specimen liquefies.
3. Package the specimen appropriately as specified by current postal regulations, and send it to a processing laboratory.
4. Upon receipt in the processing laboratory (allow at least 24 h for digestion/decontamination to be completed), dilute the digested/decontaminated specimen to the 50-ml mark with sterile distilled water and recap securely. Invert the tube several times to mix the contents.
5. Centrifuge at ≥3,000 × g for 15 min, decant the supernatant fluid, and suspend the sediment in 1 to 2 ml of sterile water, saline, or 0.2% BSA fraction V.
6. Inoculate the resuspended sediment onto egg medium, and make a smear.

Sulfuric Acid Method

Principle
The sulfuric acid method may be useful for urine and other body fluids that yield contaminated cultures when processed by one of the alkaline digestants.

Reagents
- 4% sulfuric acid
- 4% sodium hydroxide
- Sterile distilled water
- Phenol red indicator

Procedure
1. Centrifuge the entire specimen for 30 min at ≥3,000 × g. This may require several tubes.
2. Decant the supernatant fluids; pool the sediments if several tubes were used for a single specimen.
3. Add an equal volume of 4% sulfuric acid to the sediment.
4. Vortex and let stand for 15 min at room temperature.
5. Fill the tube to the 50-ml mark with sterile water.
6. Centrifuge at ≥3,000 × g for 15 min and decant the supernatant.
7. Add 1 drop of the phenol red indicator and neutralize with 4% NaOH until a persistent pale pink color forms.
8. Inoculate the media and make a smear.

This chapter represents a transition from previous chapters that detailed the general characteristics and phenotypic methods of identification of slowly growing mycobacteria. Although phenotypic characterization remains important, molecular techniques are increasingly employed as the gold standard for definitive identification to the species level.

As Tortoli noted in 2003, mycobacterial taxonomy can be divided into two major periods defined by methods used for identification to the species level (1). The first period, characterized by utilization of phenotypic studies, lasted from the late 1880s to the end of the 1980s. The second major era, characterized by a shift to genotypic studies, began during the last decade of the 20th century and has continued to the present time.

The Mycobacterium tuberculosis complex (MTBC) remains the most important group within the genus Mycobacterium from a global and clinical perspective. The MTBC currently includes not only the most significant human mycobacterial pathogens, M. tuberculosis, M. bovis, and M. bovis bacillus Calmette-Guérin (BCG), but also the less frequently encountered pathogens M. caprae, M. microti, M. africanum, M. canetti (the smooth variant of M. tuberculosis), and M. pinnipedii. Further discussion regarding the MTBC can be found in chapter 30 in this Manual.

Of the more than 150 currently validated species of nontuberculous mycobacteria (NTM), approximately 80 are slowly growing species (Table 1). The most clinically significant and/or most frequently encountered slowly growing NTM species include Mycobacterium avium, M. intracellulare, M. kansasi, M. marinum, M. xenopi, M. malmoense, and M. ulcerans. M. gordonae, although rarely a pathogen, occurs frequently in human samples, usually as a consequence of contamination from tap water (Table 2). Like the rapidly growing mycobacterial (RGM) species (see chapter 32 in this Manual), the majority of species of the slowly growing NTM have been described since the early 1990s with the advent of molecular technology. From 2007 to mid-2013, approximately 25 new species were described, including M. eatopæaeum, M. koreense, M. longobardanum, M. minnesotense, M. parakoreense, M. sherrisi, M. shinjukuense, and M. yongonense (2–23).

EPIDEMIOLOGY AND TRANSMISSION

Unlike M. tuberculosis, for which humans are the definitive host, most species of NTM are widely distributed in the environment, and the occurrence of NTM disease is attributed to a combination of host factors, such as age, body weight, the presence of chronic lung diseases (such as cystic fibrosis, bronchiectasis, or chronic obstructive pulmonary disease), alterations of chest structure, and other conditions, along with exposure. Organisms can be found in samples of soil and water, including both natural and treated water sources. For example, M. kansasi, M. xenopi, and M. simiae are regularly recovered from municipal water and only rarely from other environmental sources.

Furthermore, unlike MTBC, there has been no evidence of animal-to-human (except M. marinum from fish/fish tanks) or human-to-human transmission with slowly growing NTM. Human disease due to NTM is assumed to be acquired from environmental sources either directly by inhaling organisms in aerosols or traumatic implantation or indirectly by ingesting contaminated food or water. The source of infection may not always be detected for NTM (24).

Incidence rates of NTM disease are only estimates since, unlike tuberculosis (TB), NTM disease is noncommunicable from human to human, and therefore numbers of infections are not required to be reported to public health agencies. One publication from 2007 reported that the isolation prevalence of all NTM species (excluding M. gordonae) in pulmonary disease in Ontario, Canada, increased from 9.1/100,000 in 1997 to 14.1/100,000 by 2003, with a mean annual increase of 8.4%. Similar increases were noted for individual species. These findings indicate a significant rise in pulmonary disease caused by NTM in Canada (25). Increasing numbers of NTM isolates were also reported for several European countries (26).

Although the data are scarce, NTM disease prevalence is believed to be increasing in the United States as well (24). Nationwide studies by the Centers for Disease Control and Prevention (CDC) have revealed that NTMs

made up one-third of mycobacterial isolates reported in the 1980s (prevalence of 1.8/100,000) and that by the early 1990s they accounted for up to two-thirds of mycobacterial isolates (27–29). A more recent study correlating clinical and microbiologic data of Oregon residents who had at least one NTM isolate between 2005 and 2006, using the American Thoracic Society (ATS) and Infectious Diseases Society of America (IDSA) criteria for defining NTM infection, revealed a prevalence of 8.6 per 100,000 in the general population and 20.4 per 100,000 for individuals ≥50 years of age (30).

The most common infections with NTM are pulmonary diseases, but skin and soft tissue, lymphatic, and disseminated infections also occur. Disseminated infections most often occur in the setting of advanced HIV disease, but non-HIV-infected patients can also be affected. Although regional variations in species isolation have been shown, Mycobacterium avium complex (MAC) strains are the most commonly isolated, pathogenic, slowly growing NTM, but numerous other NTM species also cause disease. In the United States, M. kansasii is the second most frequently recovered pathogenic species (24).

**CLINICAL SIGNIFICANCE**

Because of the presence of multiple species of NTM in the environment and their opportunistic pathogenic nature, the determination of the clinical significance of the isolation of these species is based upon multiple factors, including the clinical setting, host-specific factors, the species, the pathogenic potential of the organism, the number of positive cultures, the source of the culture isolate, and quantitation of the organisms detected by smear and culture (24). For example, although the incidence of a specific NTM such as M. gordonae in cultures is high, the pathogenicity of this species is very low, in contrast to that of species such as MAC and M. kansasii (31).

In contrast to NTM, the isolation of MTBC is always an important finding in a clinical laboratory. The finding of this complex has vital epidemiologic and public health consequences. Further details on clinical significance of the MTBC may be found in chapter 30 in this Manual.

**DIRECT EXAMINATION**

**Microscopy**

One of the first, easiest, and least expensive means of detecting the presence of mycobacteria in clinical samples has been microscopic examination. Special acid-fast stains, along with the use of bright-field and fluorescence microscopy, are needed for staining of the organisms since the routine Gram stain is not optimal for staining mycobacteria. Further discussion of the specific techniques can be found in chapter 30 of this Manual.

**Antigen Detection**

Antigen detection is generally not performed for direct detection of mycobacteria in diagnostic laboratories. However, more recently antigen detection assays that detect liporabi-

\(^{\text{a}}\)Clinical relevance in pulmonary specimens must be proven according to the ATS guidelines.

\(^{\text{b}}\)AccuProbe test is positive for MAC- and for M. intracellulare-specific probes but negative for M. avium-specific probe.

\(^{\text{c}}\)AccuProbe test is positive for MAC-specific probe but negative for M. avium- and for M. intracellulare-specific probes.

\(^{\text{d}}\)No data available for AccuProbe tests.

\(^{\text{e}}\)Sequence data exist for only a fragment of the gene.

\(^{\text{f}}\)Different reports with inconsistent data.

\(^{\text{g}}\)See reference 204. The test method differed from the current strip method.

\(^{\text{h}}\)Abbreviations: Neg, negative; Pos, positive; ND, not determined; Var, varies.
Nornomann (LAM), a major lipopolysaccharide component of the cell wall of M. tuberculosis, have shown promise and have been commercially developed into an enzyme-linked immunosorbent assay (ELISA) (Clearview TB ELISA; Alere Inc., Waltham, MA) and point-of-care lateral flow assays (Determine TB; Alere) (32). A recent meta-analysis of commercially available urinary LAM assays in patients with microbiologically confirmed pulmonary tuberculosis revealed that the sensitivity ranged from 13 to 93% while specificity ranged from 87 to 99% (33). Although the sensitivity of the assay is not optimal for screening all populations, the highest sensitivities were found among HIV-positive patients and increased with advanced immunosuppression (CD4+ T-cell counts, <100 cells/μl) (33).

Nucleic Acid Detection

Early detection of disease caused by members of the MTBC is essential for initiating the appropriate therapy and controlling the transmission of tuberculosis. Direct nucleic acid amplification (NAA) techniques for the detection of MTBC nucleic acids from patient specimens are increasingly being used (34–42). These tests can provide results in as little as 2 hours. In addition to laboratory-developed PCR assays, several commercially available tests are available (Table 3). Two tests have been FDA approved or FDA cleared for the detection of MTBC from smear-positive and smear-negative respiratory specimens, the Amplified Mycobacterium tuberculosis direct (AMTD) test (Hologic GenProbe, San Diego, CA) and the Xpert MTB/RIF test (Cepheid, Sunnyvale, CA) (43). In addition, the Xpert MTB/RIF test is also FDA cleared for the detection of mutations associated with rifampin resistance. For nonrespiratory specimens, no FDA-cleared test is available.

As with all NAA tests, quality control for MTBC nucleic acid amplification tests should include the use of inhibition controls in each specimen to increase the potential for false negative results, unless the laboratory has collected sufficient data to demonstrate that inhibition is negligible in the specimen type being analyzed. In order to prevent cross-contamination with amplicon, a strict unidirectional workflow must be followed, equipment must be dedicated to its respective area, and an effective cleaning procedure must be performed. The use of closed amplification systems has the advantage that tubes containing amplified products do not need to be reopened, and thus the risk of cross-contamination with amplicon is reduced. When NAA tests are being implemented, performance characteristics, such as sensitivity and specificity, need to be established for the laboratory by use of well-known samples. Laboratory proficiency should be examined regularly by comparing NAA test results with microbiological and clinical data and through participation in proficiency testing events sponsored by various regulatory agencies (e.g., the CDC and the College of American Pathologists [CAP]).

In response to the increasing demand for MTBC NAA testing and in recognition of the importance of prompt laboratory results in tuberculosis diagnosis and control, updated guidelines for the use of nucleic acid amplification tests in the diagnosis of tuberculosis were released by the Centers for Disease Control and Prevention in 2013 (44). The recommendations state that NAA testing should be performed on at least one respiratory specimen from each patient with signs and symptoms of pulmonary tuberculosis for whom a diagnosis of tuberculosis is being considered but has not yet been established and for whom the test result would alter case management or infection control activities. However, culture remains the reference standard for laboratory confirmation of tuberculosis and is required for drug susceptibility testing and genotyping.

Several reviews and meta-analyses have evaluated the literature on the diagnostic accuracy of NAA for the direct detection and identification of MTBC from respiratory specimens (35–40, 42, 45–47). A high degree of variability was noted across various studies. Sensitivity values ranged from 36 to 100% (38) or 27 to 100% (42), while specificity ranged from 54 to 100% (38) or 91 to 100% (42). The highest sensitivity and specificity were achieved when smear-positive specimens were analyzed, with smear-negative specimens generally providing lower sensitivity for detection of MTBC. Thus, a positive NAA test result combined with a high clinical probability provides a rapid diagnosis of tuberculosis. In contrast, a patient can be presumed to be infected with an NTM if a negative NAA result (with inhibitors excluded) was obtained from

*Amplified Mycobacterium tuberculosis Direct Test (AMTD) received FDA approval and Xpert MTB/RIF test received FDA clearance for smear-positive respiratory specimens and smear-negative respiratory specimens from patients suspected of having tuberculosis.
a smear-positive specimen. A negative NAA test result, especially from a smear-negative specimen, does not rule out MTBC infection.

For the AMTD test, sensitivity was reported to be 90 to 100% for smear-positive specimens and 63.6 to 100% for smear-negative specimens (42). Specificity is excellent. The most significant drawback of the AMTD test is the use of an open amplification system, which increases the potential for cross-contamination between specimens. In addition, the test is labor intensive and technically complex to perform.

The Xpert MTB/RIF assay is an automated, cartridge-based technique that identifies M. tuberculosis complex and rifampin resistance simultaneously in primary patient respiratory samples using a molecular beacon-based real-time PCR assay. The assay is simple and robust, allowing it to ratory samples using a molecular beacon-based real-time PCR assay. The assay is simple and robust, allowing it to

The Xpert MTB/RIF assay has a sensitivity of >90% in smear-positive respiratory samples and >70% in smear-negative respiratory samples (49, 50). The World Health Organization (WHO) recommends employing the Xpert MTB/RIF as the initial diagnostic test in individuals suspected of having multiple-drug-resistant (MDR) or HIV-associated tuberculosis, particularly in areas of high prevalence (51). In low-incidence countries, samples with high suspicion of MDR (e.g., origin of the patient from Eastern Europe or sub-Saharan Africa; HIV infection; history of tuberculosis) should be considered for referral to a reference laboratory for performance of the Xpert MTB/RIF. Some false rifampin resistance has been reported for the Xpert MTB/RIF assay particularly when used in low-prevalence settings, so confirmation of the NAA result for RIF with conventional drug susceptibility testing is required (52, 53). The Xpert MTB/RIF assay complements, but does not replace, culture or antimicrobial susceptibility testing.

In general, commercially available tests are preferred over laboratory-developed assays because of the standardized protocols and improved quality control. A meta-analysis for the use of in-house NAA tests reported a highly heterogeneous estimate of diagnostic accuracy (range of sensitivity, 9.4 to 100%; range of specificity, 5.6 to 100%) (37). Laboratory-developed tests (LDTs) must be rigorously verified against culture and/or the FDA-approved/cleared tests prior to use. LDTs do offer advantages such as the ability to verify and test a wider variety of specimen sources than the approved/cleared tests, and they are often less costly.

IMMUNODIAGNOSTIC TESTS

Several immunodiagnostic tests are available for the detection of latent infection with MTBC. The tuberculin skin test (TST) has been available for nearly a century and continues to be widely used today. Since 2001, two gamma interferon release assays (IGRAs; QuantiFERON Gold In-Tube from Cellestis/Qiagen, Gaithersburg, MD, and T-SPOT.TB from Oxford Immunotec, Oxford, United Kingdom) have been introduced as an alternative to the TST. The IGRAs provide a number of advantages over the TST, the most notable of which is the lack of a positive response in persons vaccinated with the M. bovis BCG vaccine. Additional information on the two commercially available IGRAs can be found in chapter 30 of this Manual.

IDENTIFICATION

The rapid detection and identification of M. tuberculosis complex have been the most important tasks of a clinical mycobacteriology laboratory. However, within the last 30 years, the number of currently validated NTM species has increased from approximately 30 to more than 150 species. This development has been paralleled by an increasing incidence of infections due to NTM. Thus, clinical mycobacteriology laboratories today also encounter the challenge of providing accurate identification of NTM species. The use of molecular techniques has dramatically accelerated the diagnostic process. MTBC bacilli can be detected rapidly in clinical specimens by NAA tests. DNA probes for the confirmation of MTBC and a few NTM species (M. avium complex, M. gordonae, and M. kansasi) grown on culture media have been available for many years. Historically, species identification has relied, with few exceptions, on the analysis of a series of phenotypic tests for which performance was restricted mostly to specialized laboratories. These tests require a sufficient amount of bacterial cells and several weeks of incubation. It is now recognized that most mycobacterial species cannot be reliably identified by biochemical and other phenotypic tests. Some species may exhibit convergent characteristics, and strains of one species may show variability in certain features. In addition, many new species have not been studied in detail. The most reliable methods for identification of all mycobacterial species today involve molecular analyses of selected genes. These techniques have the additional advantage that they can be performed from liquid culture media, which in general enable more-rapid growth and a more sensitive detection of mycobacteria than solid culture media. Mixed cultures with NTM are not rare, and thus there is a danger of working with cultures in broth only. Thus, all results obtained by molecular methods should be confirmed, even after the reporting of the results, by some important phenotypic characteristics, such as growth rate, colony morphology, and pigmentation (Table 2). Nevertheless, it needs to be stressed that phenotypic tests (e.g., biochemical analyses) are not sufficient for the definitive identification of NTM at the species level.

The Clinical and Laboratory Standards Institute (CLSI) recognizes that not all laboratories have the necessary funds or instrumentation to provide molecular testing in mycobacteriology. Laboratories that have access only to probe technology and that have the appropriate safety equipment (e.g., a class II biological safety [BSL-2] cabinet) can utilize the probes on isolates to rule out MTBC, M. avium complex, M. gordonae, and M. kansasi. If molecular identification techniques are not available, laboratories should refer the other NTM isolates to a reference laboratory with DNA sequencing capabilities for accurate identification (54).

Phenotypic Methods

Current guidelines recommend at least two different media for the culture of mycobacteria. While liquid media (usually Middlebrook 7H9 or 7H11) allow for rapid detection of mycobacterial growth, phenotypic evaluation requires that mycobacteria be grown on solid egg- or agar-based culture media. The rapid growth and subsequent molecular identification of mycobacteria in liquid broth are generally sufficient for definitive species identification, although as discussed above, care must be taken to ensure that the broth culture contains a single organism and is not a mixed culture. Phenotypic analysis alone, including growth characteristics and biochemical properties, are not sufficiently specific to substitute for molecular identification. Therefore, the major application of phenotype-based analyses is to provide orientation for the subsequent diagnostic steps and complement
or confirm molecular identification, which may not always be unambiguous.

The key methods for the phenotypic classification of mycobacteria are the growth rate, optimal growth temperature, morphology, and pigmentation. Biochemical tests have been largely discontinued, and their application in the routine mycobacteriology laboratory has become obsolete.

Growth Rate
Growth rate is an obvious property that can be observed, and mycobacterial growth rate is dependent on temperature, the initial bacterial inoculum, and the species. The estimation of growth rate is most reliably performed on solid medium, even though protocols using standardized growth curves have been developed for growth in liquid culture medium (the Bectec MGIT system from Becton Dickinson and Company, Franklin Lakes, NJ; or the VersaTREK system from Thermo Scientific/Trek Diagnostic Systems, Oakwood Village, OH). To perform a standardized growth test in the routine laboratory, defined suspensions of mycobacteria (e.g., 0.5 McFarland standard) are inoculated on solid media and incubated at 30 ± 1°C and 36 ± 1°C. Cultures are observed for growth at 5 to 7 days and weekly thereafter. Mycobacteria can thus be classified into the slowly and rapidly growing species. RGM are able to form mature colonies within 7 days of incubation, whereas slowly growing species require a longer incubation time for colony formation.

Temperature
*Mycobacterium* species differ in the ability to grow at certain temperatures. For determination of the preferred growth temperature, solid culture media are inoculated with defined suspensions of mycobacteria (e.g., 0.5 McFarland standard) and incubated at various temperatures. For slowly growing species, the minimum set of temperatures for incubation comprises 30 ± 1°C and 36 ± 1°C. Most slowly growing mycobacterial species grow well at 35 to 37°C, but others, including *M. marinum*, grow better at a lower temperature (30°C), especially on primary isolation. Therefore, samples from skin or lymph nodes and other tissue specimens from the body periphery should routinely be incubated both at 30 ± 1°C and at 36 ± 1°C. Additional media incubated at 22 to 25°C and 42°C may be necessary for optimal growth of some species, such as *M. haemophilum* (28 to 32°C), *M. xenopi* (42°C), *M. conspicuum* (22 to 31°C), and *M. stomatopae* (32°C). Cultures to determine temperature requirements of known RGM can be read within 1 week, while slowly growing mycobacteria require a longer period of incubation.

Colony Morphology
Colony morphology is a phenotypic property of mycobacteria that can easily be determined. Morphologic characteristics such as size and colony description (flat, raised, etc.) should be noted, but the most discriminative and relevant property is the smooth or rough growth form of the colonies. *M. tuberculosis* usually grows in rough, nonpigmented colonies on Löwenstein-Jensen slants (Fig. 1) as well as on agar-based media. In contrast, *M. bovis* grows in flat, smooth, nonpigmented colonies. The colony morphology may vary when different formulations of solid media are used. Slowly growing NTM species may also exhibit either rough or smooth variants or both types, but colony morphology is not a reliable parameter for the discrimination of NTM. Recent studies have suggested that smooth/rough colony morphology among the RGM may be related to pathogenicity, with rough colony morphology representing the invasive phenotype.

Pigmentation and Photoreactivity
Pigmentation of mycobacteria has been used for primary classification into nonchromogenic and chromogenic species (Runyon classification system, named for Ernest Runyon, a pioneer taxonomist in mycobacteriology). Species of the MTBC do not produce pigment, while NTM species can be chromogenic (scoto- or photochromogenic) or nonchromogenic. Chromogenic NTM species produce pigment that can range from light yellow and yellow to orange or even rose-colored. Within the pigmented mycobacteria, the photochromogens are nonpigmented in the dark and produce pigmentation only after exposure to light (Fig. 2). Since pigment production is an oxygen-dependent reaction, primary cultures of these species may remain nonpigmented even when exposed to light if the caps are tightly closed. Loosening of the caps, done in a biological safety cabinet, helps promote the color change. The scotochromogens produce pigment when grown in the dark or when exposed to light (Fig. 3). The color may intensify with the increasing age of the culture. The nonchromogenic species do not produce pigmentation when grown either in the dark or after exposure to light. The color of nonchromogenic colonies may remain off-white, buff, or pale yellow and does not intensify when exposed to light (Fig. 4). This separation, however, is no longer performed in most laboratories.

Niacin Accumulation
Some *Mycobacterium* species cannot use nicotinic acid, although they produce it in their biosynthetic pathways. Consequently, nicotinic acid is excreted into the medium and can be detected. Paper strip format tests (BD Diagnostics,
Sparks, MD) to detect niacin or isoniazid are commercially available, are easy to perform, and avoid the use of hazardous reagents. Better results can be obtained with the isoniazid test strips than with the niacin test strips. The detection of niacin is one of the key phenotypic tests for the identification of *M. tuberculosis*, even though molecular techniques have replaced this test in most laboratories. Within the NTM, *M. simiae* can also be positive in the niacin test. *M. tuberculosis* strain H37 and *M. avium* can be used as positive and negative controls, respectively.

**FIGURE 3**  *M. gordonae* grown on 7H10 Middlebrook agar for 10 days. Colonies are yellow and smooth (scotochromogenic). doi:10.1128/9781555817381.ch31.f3

Nitrate Reduction
Several mycobacterial species produce nitrate reductase, which reduces nitrate to nitrite. This ability is assessed by the formation of diazonium salt, which becomes visible through the production of a red water-soluble dye (55). As for the measurement of niacin production, a paper strip assay has proved to be reliable and efficient for the identification of nitrate reduction (BD Diagnostics). The confirmation of the presence of a nitrate reductase is another key phenotypic property for the identification of *M. tuberculosis*. *M. tuberculosis* strain H37 and *M. avium* can be used as positive and negative controls, respectively.

**FIGURE 4**  *M. celatum* grown on 7H10 Middlebrook agar for 10 days. Colonies are small, colorless, and smooth (nonchromogenic). doi:10.1128/9781555817381.ch31.f4

Identification of Species of MTBC Using Phenotypic Markers
If a strain is identified as a member of the MTBC using the AccuProbe test (Hologic GenProbe, San Diego, CA) or another molecular method, further differentiation of the species between *M. tuberculosis*, *M. bovis*, and *M. bovis* BCG can be performed reliably using simultaneous evaluation of several phenotypic markers (Table 4). Species identification is considered acceptable if all test results are unambiguous and all controls give correct results. However, molecular techniques should always be given priority over conventional phenotypic methods to achieve unambiguous and definitive results for species identification. Furthermore, other members of the MTBC, including *M. africanum*, *M. microti*, *M. pinnipedii*, and *M. canetti* can be identified only by molecular tests. Sufficient information on phenotypic properties is not available for these rarely isolated members of the MTBC.

Identification of NTM Species Using Phenotypic Markers
As previously emphasized, species identification of NTM is not feasible using phenotypic tests alone. The number of
species continues to grow, which highlights the lack of distinctive phenotypic properties. In general, only molecular tests provide a reliable identification. However, as previously stated, all results obtained by molecular methods should be consistent with established key phenotypic characteristics (Table 2). As an example, M. chelonae is an RGM with a preferred temperature of 30 ± 2°C. Incubating media inoculated with M. chelonae at higher temperatures may result in delayed growth, which might erroneously suggest a slowly growing NTM rather than a rapidly growing NTM.

**Mycolic Acid Analysis**

The various compositions of the cell wall mycolic acids of different species of mycobacteria were used for diagnostic purposes for many years (56–58). Use of high-performance liquid chromatography (HPLC) analysis of the mycolic acid pattern for identification of Mycobacterium species has largely been replaced by other methods (e.g., sequencing, mass spectrometry) that provide improved species discrimination.

### GENOTYPIC IDENTIFICATION OF NONTUBERCULOUS MYCOBACTERIAL SPECIES

#### Complete Genome Sequences

Complete genomic sequences have been established for >40 mycobacterial species to date. Detailed information on all genome projects either completed or still in progress can be obtained at [http://www.ncbi.nlm.nih.gov/sites/entrez?Db=genomeprj&Cmd=Search&TermToSearch=taxid176](http://www.ncbi.nlm.nih.gov/sites/entrez?Db=genomeprj&Cmd=Search&TermToSearch=taxid176).

#### Single Gene or 16S-23S rRNA Spacer Region Analyses

Partial sequence analysis of selected genes or sequencing of the 16S-23S rRNA internal transcribed spacer region (ITS) is the most practical method for identification of mycobacterial species. Sequence variability among species, but homogeneity within species, is the basic prerequisite for this application. For several genes (16S rRNA, hsp65, and rpoB), specific regions within the gene that work well for species identification have been identified (34, 41, 59–66). The most important target for identification of slowly growing mycobacteria is the 16S rRNA gene.

### 16S rRNA Gene

For routine identification of mycobacteria, sequence analysis of the complete 16S rRNA gene (approximately 1,500 bp) is not practical and also usually not necessary. The information content of a sequence stretch of approximately 500 bp located at the 5′ end of the gene is sufficient for identification of most species and is the only sequencing kit currently commercially available. Specific primers for amplification and sequencing of the mycobacterial 16S rRNA gene (Table 5) have been described and validated (61, 67–74).

Primer 264 and 247 target genus-specific sequence regions and can be used for the detection of mycobacteria even in the presence of contaminating bacteria. Furthermore, the 285 and B9 primers can be used for the sequencing reaction. Either of these can be combined with any of the reverse

*F, forward; R, reverse.*
primers. Both forward primers are located upstream of hypervariable regions A and B, which enable the species-specific identification of most mycobacterial species (61). A few slowly growing species have identical hypervariable regions A and B or an identical complete 16S rRNA gene sequence. These include (i) M. marinum and M. ulcerans and (ii) M. kansasii (sequence variants I and IV) and M. gastri. For accurate identification of these species, sequence analysis of other genes or regions (e.g., ITS, hsp65, and rpoB) is required. All members of the MTBC have identical 16S rRNA gene sequences and thus cannot be discriminated by this technique. In addition, some species have minor intraspecies 16S rRNA gene sequence variants that differ in a few base pairs (e.g., M. gordonae, M. kansasii, and M. lentiflavum (75–77)).

23S rRNA Gene
The 23S rRNA gene is also known to contain conserved and variable sequence regions that enable the specific amplification and species identification of mycobacteria (78, 79). Variable regions can also be found in the 3′ region. The disadvantage of this target is the length of the gene (3,100 bp), which is not readily analyzed for most of the Mycobacterium species since amplification and sequencing must be performed with multiple sets of primers (79).

ITS 1 Region
Another target is the internal transcribed spacer sequence, which separates the 16S and 23S rRNA genes in the operon and is denominated ITS 1. The sequence of this fragment comprises only 200 to 330 bp and thus can easily be analyzed. Several sets of primers that enable the amplification and sequencing of the complete fragment have been published (Table 5) (76, 80, 81). Primers Sp1 and Sp2 allow the genus-specific amplification of the region. Since they target the start site of the ITS, they are not optimal for analysis of the whole ITS 1 sequence. Primers ITS 1 and ITS 2 are located in the 16S and 23S rRNA gene regions, respectively. Using these primers, the entire ITS can be amplified and sequenced. However, they are not genus specific and cannot be used when cultures of mycobacteria are contaminated with other bacteria.

For the ITS 1 sequence, a high variability that could be used for species identification has been shown (80–84). However, for some species, mainly for rapidly growing species but also for some slowly growing species (M. simiae and M. xenopi), two or more sequence variants have been observed. As with the 16S rRNA gene sequence, M. marinum and M. ulcerans have identical ITS 1 sequences and thus cannot be differentiated by this analysis.

hsp65 Gene
One of the first genetic targets used for the differentiation of mycobacteria is an approximately 440-bp fragment of hsp65, which codes for the 65-kDa heat shock protein and is also known as the groEL2 gene (64). The amplification of this fragment, followed by a restriction enzyme digestion using the restriction enzymes BstEII and HaeIII and by analysis of the obtained digestion products using agarose gel electrophoresis, provides restriction fragment length polymorphism (RFLP) patterns that are specific for most clinically significant species (Table 5) (85, 86). An algorithm for the differentiation of the most clinically important species showing the apparent molecular sizes of the fragments has been devised. This PCR-restriction enzyme analysis technique has been used widely, since this is a simple and rapid method with no need for more-sophisticated sequencing techniques. However, technical difficulties, such as small size differences between the fragments or the incidence of similar or identical restriction patterns for some species of closely related mycobacteria and, in particular, new species of mycobacteria, are problems encountered with this method. With the greater availability and decreasing cost of sequencing, sequence analysis of this hsp65 gene fragment has been increasingly used instead of the PCR-restriction enzyme analysis (63, 87).

Advantages of sequencing hsp65 rather than the 16S rRNA gene are especially evident in the identification of closely related species, as hsp65 is much less conserved than the 16S rRNA gene. hsp65 sequencing allows for differentiation of M. marinum from M. ulcerans, M. gastri from M. kansasii, and, with some restrictions, M. avium subsp. avium from M. avium subsp. hominisuis.

rpoB Gene
The rpoB gene encodes the β subunit of the bacterial RNA polymerase. For M. tuberculosis, mutations in an 81-bp region of rpoB (rifampin resistance-determining region) are known to confer resistance to rifampin. For NTM species, sequence variability within rpoB can be used for species identification (34, 60, 88). Several different sequence fragments of the approximately 3,600-bp gene have been used for amplification and sequence determination. Kim et al. (60) amplified a fragment comprising 306 bp at positions 1362 to 1668 (referred to as region 2/3), whereas Lee et al. (88) targeted a 360-bp sequence at positions 902 to 1261 (referred to as region 1/2) (34). In contrast, Adékambi et al. (34) chose a fragment more distant (region 5) and analyzed an approximately 760-bp fragment at positions 2573 to 3337 (Table 5). In the studies of Kim et al. (60) and Lee et al. (88), type strains of many slowly growing mycobacteria were included, whereas detailed analyses using region 3 (34) have been performed mainly for rapidly growing mycobacteria. Extensive investigations using clinical isolates of slowly growing mycobacteria are not available for any part of the rpoB gene to date.

Use of Sequence Databases
For identification of mycobacteria by sequencing analysis, public databases are frequently used, which can present challenges. Public databases contain sequences from strains that are not validly published as species, sequences from strains identified as known species but having divergent sequences, and many sequences from uncultured bacteria that are not further characterized. Furthermore, old sequences that are fragmentary or faulty are still included in the public databases (89).

Thus, the evaluation of the search result has to be done carefully. For example, in the case of an uncommon species, cross-checking of the valid description as a species can easily be performed by using the List of Prokaryotic Names with Standing in Nomenclature (http://www.bacterio.net). When obtaining several correct results deriving from different species, it may help to check the database entries if the sequences have been obtained from type strains.

The International Nucleotide Sequence Database Collaboration database (INSDC; http://www.insdc.org/) can be used for the analysis of the sequences derived from the different genes as detailed above. There are some curated databases and analysis tools that have been constructed for the analysis of the 16S rRNA gene sequences, such as the commercially available tools SmartGene IDNS (SmartGene, Lausanne, Switzerland), RipSeq (Isentio, Sunnyvale, CA), and the MicroSeq microbial identification system (Applied Biosystems, Foster City, CA) or two tools with free access, the Ribosomal
Database Project (RDP; http://rdp.cme.msu.edu/) and the RIDOM (Ribosomal Differentiation of Medical Microorganisms) database (http://www3.ridom.de/tdna/). The advantage of these databases is the quality control of the entries, ensuring that most of the difficulties associated with public databases will not be encountered. For the commercial Web-based databases, the user also has the option to update the system as needed. However, these curated databases can lag behind the updates of the INSDC database and may not include sequence variants of species.

**Pyrosequencing**

Pyrosequencing differs from Sanger sequencing in that it relies on the detection of pyrophosphate release on nucleotide incorporation rather than chain termination with deoxynucleotides. Identification of mycobacteria by pyrosequencing relies on a 20- to 30-bp region within the hypervariable region A of the 16S rRNA gene (90–92). A study evaluating pyrosequencing for the analysis of AFB isolates was performed by Bao et al. in comparison to pyro- typic analysis and Sanger sequencing. Pyrosequencing was capable of identifying 114 (98%) of the 117 AFB isolates and correctly identified most of the slowly growing mycobacteria to the species level (92). Of the mycobacteria tested, it was not able to identify M. scrofulaceum and M. simiae to the species level. Similar to Sanger sequencing of the 16S rRNA gene, pyrosequencing has the same limitation for identification of some of the closely related organisms, as discussed in “Single Gene or 16S-23S rRNA Spacer Region Analyses” above.

Pyrosequencing has the advantage of being a rapid, simple, and inexpensive molecular method for identification of Mycobacterium species. Additional sequencing may be required to differentiate some species due to the short sequence length generated by this technique (91, 93).

**GENOTYPIC IDENTIFICATION OF SPECIES OF THE MTBC**

Within the MTBC, the most prevalent species is M. tuberculosis (93 to 97%), followed in frequency by M. bovis and M. bovis BCG. Identification of M. bovis is of clinical relevance because of the inherent resistance of this species to pyrazinamide, one of the first-line agents for treatment of TB. Strains that are monoresistant to pyrazinamide should be analyzed by molecular techniques. These strains can be M. bovis, M. bovis BCG, or, although rare, monoresistant M. tuberculosis strains. Moreover, M. bovis BCG is used for treatment of bladder cancer, and thus correct identification of M. bovis BCG isolated from patients treated for bladder cancer is necessary to enable a correct decision for treatment of a patient. The identification of the other species is mainly of epidemiological importance and may be an indication of the source of the infection.

**gyrB Gene Sequencing**

The gyrB gene encodes the B subunit of DNA gyrase (topoisomerase II), an enzyme essential for bacterial replication. In 2000, Kasai et al. (94) showed single nucleotide polymorphisms (SNPs) in an approximately 1.2-kbp fragment of the gyrB gene which were specific for some species of the MTBC (Table 5). More-detailed analyses confirmed these results and determined that they could be extended to most members of the MTBC (95).

**RD/Spoligotyping**

Although all members of the MTBC are characterized by a high genetic similarity, several sequence polymorphisms that can be used for species identification have been discovered. Comparative genomic analysis has shown that members of the MTBC have evolved from a common ancestor through sequential DNA deletions with precise genomic deletions (96). These areas in the genome are exploited for the identification of the members of the MTBC and are referred to as regions of difference (RD). The presence or absence of these deletions can be analyzed by PCR assays (97). Spoligotyping, a technique applied primarily for strain typing, identifies most species within the MTBC. However, with this technique, M. bovis BCG cannot be discriminated from M. bovis.

**Line Probes Specific for MTBC**

A commercially available assay (GenoType MTBC; Hain Lifescience, Nehren, Germany) based on line probe technology enables the identification of species within the MTBC (98–101). The test can be performed from solid or liquid media, with a total test time of 4 to 6 hours. The assay is based on an MTBC-specific 23S rRNA gene fragment, gyrB DNA sequence polymorphisms, and the RD1 deletion of M. bovis BCG. Specific oligonucleotides targeting the polymorphisms are immobilized on membrane strips. Amplicons derived from a multiplex PCR react with these probes during hybridization. Species can be identified according to the interpretation table provided with the kit. The inclusion of an MTBC-specific 23S rRNA gene fragment confirms the presence of MTBC in order to rule out possible cross-reactivity. Specific patterns can be obtained for M. tuberculosis/M. canetti, M. africamum/M. pinnipedii, M. microti, M. caprae, M. bovis, and M. bovis BCG. M. tuberculosis and M. canetti as well as M. africamum and M. pinnipedii share identical gyrB sequences, and thus they can be identified by specific patterns, but they cannot be differentiated from each other.

The specificity of this test was 100% when strains from culture collections or clinical isolates were compared (99–101). With strains from culture collections, all species, with the exception of an M. canetti strain (identified as M. tuberculosis), were correctly identified (101). Additionally, 100% of the clinical strains studied were correctly identified (99–101). No false-positive results were obtained with several NTM strains (101).

**Real-Time PCR Assays**

Laboratory-developed, multiplex real-time PCR assays have been described for the rapid identification of MTBC members to the species level from both culture and clinical specimens. The presence or absence of regions of difference (RD) allows identification to the species level of the MTBC using real-time PCR analysis (96, 102).

**Other Molecular Tests for NTM and MTBC**

Sequence analysis of target genes for the identification of mycobacteria may not be practical for routine clinical laboratories. Commercially available assays that are based on liquid- or solid-phase hybridization have been shown to be easily implemented into a routine workflow. They are intended for the detection of some of the most important Mycobacterium species and can be performed from both solid and liquid media.

**AccuProbe Culture Identification Tests**

The AccuProbe test was the first commercial molecular assay for the identification of selected mycobacterial species from positive culture media. Probes are available for the identification of MTBC, M. avium, M. intracellulare, MAC,
M. gordonae, and M. kansasii. All probes are FDA cleared and commercially available. Species identification is based on the hybridization of specific DNA probes to rRNA of the bacteria. Briefly, by heat treatment and sonication, nucleic acids, including the target 16S rRNA, are released from the mycobacteria. A specific DNA probe hybridizes with the target rRNA. Finally, the DNA-rRNA hybrid molecule can be detected by chemiluminescence. The results are obtained within 2 hours. The utility of these tests has been proven in many studies and by usage in many laboratories worldwide (76, 103–107). Specificities of the tests are usually reported to be 100%, or sometimes lower (96%), for MAC. Sensitivity values vary with the test used: 100% for M. gordonae, 95.2% for MAC, and 97.4 to 100% for M. kansasii (76, 103, 104, 107). It has also been shown that MTBC organisms can reliably be identified in the presence of M. avium (105). However, there are also some disadvantages of these tests. The probes are limited to a few, although important, mycobacterial species, necessitating the performance of additional tests for identification of species for which there are no probes. The need to perform individual tests for each target species renders the tests expensive and, if not performed in parallel, also time-consuming. False-positive results for MAC probes have been reported, but they can be prevented if a higher cutoff value (80,000 relative light units instead of the 30,000 relative light units recommended in the technical insert) is used (108). Studies have also shown cross-reactions with the M. intracellulare probe and several slowly growing mycobacterial species (M. arosiense, M. chimaera, M. nebraskense, and M. saskatchewanense) (109). Similarly, cross-hybridizations have been documented with the MAC probe and M. nebraskense, M. palustre, M. saskatchewanense, and M. paraaffinicum. Cross-reactivity has been seen with the MTBC probe and M. celatum (110) and M. holsaticum (109), although this cross-reactivity can be avoided when the selection step of the procedure is performed for 10 min, according to the manufacturer’s instructions (111).

### Line Probe Assays

Alternatively, techniques based on the application of PCR plus reverse-hybridization-designed DNA strip assays (line probe assays), have been developed. Briefly, the target sequences are amplified by PCR using biotinylated primers. The amplified PCR products are allowed to hybridize to immobilized, membrane-bound probes covering the species-specific sequence fragment, followed by an enzyme-mediated color reaction. The banding patterns can be analyzed by eye by comparing the patterns on an interpretation chart. The identification of the species relies on specific banding patterns (Fig. 5).

Three tests for the identification of several mycobacterial species are commercially available but are not yet FDA cleared. The INNO-LiPA Mycobacteria v2 assay (Innogenetics, Ghent, Belgium) is based on the nucleotide differences in the 16S-23S rRNA gene spacer region and can detect the following slowly growing Mycobacterium species: MTBC, M. kansasi, M. xenopi, M. gordonae, M. genavense, M. simiae, M. marinum, M. ulcerans, M. celatum, M. avium/M. intracellulare/M. scrofulaceum complex, M. avium, M. intracellulare, M. scrofulaceum, M. malmoense, and M. haemophilum.

The GenoType Mycobacterium CM/AS test (Hain Lifescience, Nehren, Germany), is based on the detection of species-specific sequences in the 23S rRNA gene. It is composed of two different strips (strip CM is for common mycobacteria, and strip AS is for additional species) and can identify the following slowly growing mycobacteria: with
M. intracellularare probe cross-hybridizes with several slowly growing mycobacterial species, including M. arosiense, M. chimaera, M. colombiense, M. mantienui, and M. saskatchewanense. Two infrequently encountered NTM species, M. raydrence and the nonvalidated species “M. similans,” were incorrectly assigned to the MTBC by the GenoType assay (109). Similarly, the INNO LiPa MAIS assay cross-reacts with M. arosiense, M. heidelbergense, M. mantienui, M. nebraskense, M. parascrofulaceum, and M. paraffinicum (109).

Importantly, neither of the line probe systems has been reported to misidentify members of the MTBC as an NTM (109). All results obtained with line probe tests should be confirmed by key established phenotypic characteristics, such as growth rate, colony morphology, and pigmentation.

A third line probe assay was recently described, the Speed-oligo Mycobacteria (Vircel, Granada, Spain), and is based on targeting both 16S rRNA and 16S-23S rRNA regions. The assay can identify 19 mycobacterial species, including MTBC (M. tuberculosis, M. bovis, M. microti, M. africanum, M. catrae) and 10 additional NTMs (M. avium, M. gordonae, M. interjectum, M. intracellularare, M. kansasi, M. marinum, M. marinum/M. scrofulaceum, and M. xenopi). The Speed-oligo Mycobacteria system has a limited spectrum of species identification compared to the other assays and identifies many of the mycobacterial species to the complex or group. It can be performed on isolates from solid or liquid media within 3 hours. The only clinically relevant misidentification reported in the limited studies published to date was the misidentification of M. marinum as M. kansasi (119, 120). The Speed-oligo Mycobacteria system has also been evaluated for use directly from respiratory specimens and demonstrated an overall sensitivity of 76% (93% from smear-positive and 56% from smear-negative specimens) and specificity of 99%. The study concluded that the assay is an easy and fast alternative for detecting mycobacteria and differentiating between MTBC and NTM, especially from smear-positive specimens (121).

Multiplex Real-Time PCR Assays

There are a handful of reports in the literature on the use of multiplex real-time PCR with probe-based detection for the identification of MTBC and NTM isolates (122) or for the differentiation of members of the MTBC (123, 124). More recently, multiplex real-time PCR coupled with high-resolution melting curve analysis has been reported for the detection of mutations in MTBC isolates associated with resistance to first- and second-line antitubercular agents (125, 126). A commercial multiplex real-time PCR assay (Seegene, Seoul, South Korea) uses a proprietary technology that enables simultaneous screening and detection of multiple targets using a single fluorescent channel. This technology has been used for discrimination between NTM and MTBC directly from clinical specimens using the AnyplexTM MTB/NTM assay. In addition, the Seegene Anyplex II MTB/MDR/XDR detects MTB, MDR-TB, and extensively drug-resistant (XDR) TB in a single real-time PCR from clinical specimens. Although the Seegene assays are not U.S. FDA cleared, they have received CE certification. Studies demonstrating the clinical utility of the Seegene multiple PCR assays for detection of Mycobacterium species are yet to be performed.

M. leprae PCR

As M. leprae is a nonculturable organism, PCR techniques have been developed and applied for its detection from a variety of specimen sources, such as slit-skinc smears, blood, nasal cavity, biopsy specimens, and urine (127–132). Molecular targets for detection of M. leprae PCR have included protein antigens of 18 kDa, 36 kDa (known as the proline-rich antigen [pra1]), and 65 and 85 kDa (the 16S rRNA gene and repetitive sequences) (127, 128, 130, 132–136). Many studies have shown that PCR methods are specific and more sensitive than conventional methods (split skin smears, histopathology, and serologies) for the diagnosis of M. leprae (127, 128, 130, 132–137).

Mass Spectrometry

Matrix-assisted laser desorption ionization–time-of-flight mass spectrometry (MALDI-TOF MS) is revolutionizing the identification of microorganisms and has been recently applied to the identification of mycobacteria. MALDI-TOF MS analysis of mycobacteria involves several steps including inactivation, extraction, and analysis. Several different methods have been described for the inactivation and extraction of mycobacterial cells. Since there are additional safety concerns when dealing with acid-fast bacillus (AFB)-positive cultures, these methods differ from the extraction methods described for other bacteria and fungi. All inactivation and extraction steps should be performed within a BSL-3 facility using the appropriate personal protective equipment (PPE). MALDI-TOF analyses of both whole-cell (138) and purified protein extraction (139–141) methods have been described. Inactivation of mycobacterial cells is usually achieved either by ethanol or by heat treatment and dissociation/lysis of cells by mechanical lysis using either a micropestle or bead beating techniques. Extraction is performed by adding formic acid and acetonitrile to the inactivated mycobacterial cells (139, 141). Following inactivation and extraction, an aliquot is spotted onto a solid target support plate and overlaid with a chemical matrix (for example, alpha-cyano-4-hydroxy-cinnamic acid). The sample plate is loaded into the instrument, and mycobacterial proteins are ionized using a laser. The ionized proteins then move through the time of flight chamber and are separated based on the mass-to-charge ratio of the ions, such that the lighter proteins hit the detector first, followed by the heavier proteins. A mass spectrum is produced as the ions collide with the ion detector and serves as a “fingerprint” for identification of the mycobacterial species. Currently, there are two commercial MALDI-TOF platforms available for microbial identification, the Vitek MS (bioMerieux, Durham, NC) and the Biotyper system (Bruker Daltonics, Billerica, MA) (138–141). Databases supplied with both instruments contain entries for MTBC and many NTMs, including those most commonly encountered in the clinical laboratory. MALDI-TOF MS databases continue to improve in terms of species coverage and the depth of strain diversity, but more esoteric species may be underrepresented and may need to be added by the end user or may await future database updates by the manufacturers.

Recent studies have demonstrated the ability of MALDI-TOF MS to serve as a rapid and accurate means for the identification of mycobacteria from both solid and liquid media (138–141). Saleeb et al. (142) reported some of the earliest use of MALDI-TOF MS with the identification of 104 mycobacterial isolates comprising 17 species. Since this early report, others have also demonstrated that MALDI-TOF MS can unambiguously identify the most commonly encountered species of mycobacteria (143). However, species of the MTBC cannot be differentiated and the closely related M. chimaera and M. intracellularare are not separated, according to recent studies (138, 144).

A potential pitfall of the identification by MALDI-TOF MS in comparison to molecular sequencing methods is the
requirement for a moderate amount of growth present on solid media rather than the scant growth required for sequencing. Not surprisingly, this problem is most evident when dealing with the slowly growing mycobacteria (141). In such circumstances, sequencing may provide a more rapid turnaround time (TAT; i.e., 12 to 24 h) for identification than MALDI-TOF analysis.

Although the costs of MALDI-TOF MS instrumentation are not insignificant, studies have shown that this technique has minimal associated reagent costs, requires minimal technologist time, can be utilized for a wide variety of microorganisms, and provides a reduction in TAT for organism identification, leading to an overall reduction in costs (145).

A second MS method is a novel technology coupling PCR amplification and electrospray ionization mass spectrometry (ESI-MS) to identify M. tuberculosis complex, MTBC resistance determinants, and NTM from culture within ~6 hours. This system measures the mass/charge ratio of PCR amplicons generated from several loci, focusing on conserved, species-specific regions and resistance determinants, to identify base compositions comparative to a database of mycobacteria and resistance determinants. Using the base composition as unique molecular signatures (“fingerprints”), the PLEX-ID system (Abbott Molecular, Des Plaines, IL) is able to identify the organism as an MTBC or NTM and provide resistance markers if an MTBC is identified (146, 147). A recent study demonstrated the ability of the MDR-TB assay on the PLEX-ID to appropriately identify all MTBC and all slowly growing NTMs tested from both broth (MGIT tubes) and solid media using database version NFDU.415.455.349. In comparison to the proportion method, the sensitivity and specificity for the detection of MTBC drug resistance using the MDR-TB assay were 100% and 92.3% for rifampin, 100% and 93.8% for isoniazid, 91.0% and 94.4% for ethambutol, and 100% and 100% for fluoroquinolones, respectively (148). Further studies need to be performed to determine if the MDR-TB assay is capable of detecting AFB directly from clinical specimens.

High instrument costs of the PCR ESI-MS system may hamper the implementation of this technology into small clinical microbiology laboratories, and therefore this technology may be limited to use in reference laboratories or state public health laboratories.

**TYPING SYSTEMS**

Historically, the first strain typing method for M. avium was serotyping based on seroagglutination procedures. Combined use of serotyping and species-specific DNA probes has shown that the organisms previously named serovars 1 through 6 and 8 through 11 are M. avium and that serovars 7, 12 through 17, 19, 20, and 25 are M. intracellulare. Finally, multilocus enzyme electrophoresis has been shown to provide a wider range of polymorphisms than serotyping (149). Serotyping, for both MAC and other mycobacteria, has been replaced by molecular strain typing.

**Genotyping of M. tuberculosis Strains**

The genotyping of M. tuberculosis isolates contributes to the knowledge and control of TB by indication of epidemiological links between patients, discrimination between exogenous reinfections and endogenous reactivations, outbreak detection, and the recognition of laboratory cross-contaminations. The CDC has initiated a laboratory program to provide genotyping services for TB control programs to public health laboratories. Further information may be obtained from their website at http://www.cdc.gov/tb/programs/default.htm.

The introduction of the IS6110-RFLP technique marked a milestone in determining the molecular epidemiology of M. tuberculosis and has been the reference standard for many years. More recently, several alternative PCR-based techniques, which are less time-consuming and in part more discriminative than the classical IS6110-based technique, have been developed.

**IS6110 RFLP Typing**

IS6110 is an insertion sequence that is present in variable numbers (0 to >20 [150]) and has been inserted at various positions in the genomes of MTBC isolates. IS6110-based RFLP analysis is performed using an internationally standardized protocol that facilitates comparison of patterns generated by different laboratories (151). High-quality DNA is isolated from mature culture isolates and subjected to restriction enzyme digestion. The DNA fragments are electrophoretically separated, transferred to a membrane, and hybridized with an IS6110 probe. The resulting patterns are compared to an internal size standard. For large-scale comparisons, the patterns should be digitalized by scanning in order for them to be stored in a database. Using computer analysis, the results from separate runs can be compared to detect identical patterns.

The IS6110 fingerprint patterns are highly discriminatory, but only for patterns with seven or more bands. The complete analysis is laborious and time-consuming if the time to obtain sufficient growth on solid media and the multiple technical steps are considered. Furthermore, the analysis of the complex banding patterns requires sophisticated pattern-matching computer software.

**Spoligotyping**

Spoligotyping (an abbreviation for spacer oligonucleotide typing) is a PCR-based technique that targets the variability in the direct repeat (DR) locus of M. tuberculosis. The DR region that is present in all MTBC strains consists of multiple DRs of a conserved 36-bp sequence separated by nonrepetitive unique spacer sequences. Of these, 43 spacer sequences identified in the genomes of M. tuberculosis and M. bovis BCG are used for the spoligotyping assay (152). The spacer segments are amplified by PCR using primers that target the DR sequence. Amplified DNA fragments are hybridized to a membrane with 43 covalently bound oligonucleotides complementary to the 43 spacers.

There are several advantages of spoligotyping compared to IS6110 RFLP analysis. Since the technique is PCR based, a small amount of DNA is sufficient for analysis. Thus, spoligotyping can be performed from scantily grown solid as well as liquid cultures, enabling a more rapid turnaround time. The technique is less laborious and more rapid than the classical IS6110 RFLP method. Additionally, the format of the result can easily be transferred into a binary code that can be handled in common computer programs, rendering large-scale comparisons less difficult than the classical method. Unfortunately, spoligotyping is less discriminatory than IS6110 RFLP typing and not sufficient for population-based studies. It can be used for M. tuberculosis strains with few IS6110 copies or for M. bovis isolates that also have few IS6110 copies. This technique is useful for the analysis of assumed laboratory cross-contaminations, as the results can be obtained rapidly.

**MIRU-VNTR Typing**

Genotyping may be performed based on the variable numbers of tandem repeats (VNTR) of different classes of genetic elements named mycobacterial interspersed repetitive units.
Previous studies have detailed the method of PFGE related strains. This clumping may also result in different amounts with standardization may result from cell clumping of rough ledge of the species genome. For RFLP typing, some genetic information is necessary for RFLP typing using specific molecular markers (162, 165). For PFGE and AFLPA, no genetic information is necessary – field gel electrophoresis (PFGE) (159 163), amplified fragment length polymorphism analysis (AFLPA) (164), or pulsed-field gel electrophoresis (PFGE) (159). Different approaches have been used for strain comparisons and genotyping of Slowly Growing NTM isolates (158).

Multilocus Sequence Typing
Multilocus sequence typing (MLST) directly measures the DNA sequence variations in a set of housekeeping genes in M. tuberculosis and characterizes strains by their unique allelic profiles. MLST involves PCR amplification of 7 housekeeping genes (gyrA, gyrB, katG, parA, recA, rpoB, and sodA) followed by DNA sequencing (158). A recent study comparing MLST to MIRU-VNTR and spoligotyping was performed to evaluate the discriminatory power between the three methods to assess the genetic diversity of M. tuberculosis. Of the three methods, MIRU-VNTR showed the highest discriminatory power followed by spoligotyping followed by MLST. The authors of the study conclude that the combination of MIRU-VNTR and spoligotyping provides the greatest level of discriminatory power and therefore is the most useful genotyping tool to be applied to M. tuberculosis isolates (158).

Genotyping of Slowly Growing NTM
Different approaches have been used for strain comparisons of NTM. Whole-genome analyses have included pulsed-field gel electrophoresis (PFGE) (159–163), amplified fragment length polymorphism analysis (AFLPA) (164), or RFLP typing using specific molecular markers (162, 165). For PFGE and AFLPA, no genetic information is necessary and the procedures can be performed without further knowledge of the species genome. For RFLP typing, some genetic information, such as the presence of specific IS elements, is a prerequisite.

Pulsed-Field Gel Electrophoresis
PFGE has been a useful technique for strain typing of the slowly growing NTM. This technique requires an actively growing culture and 3 to 4 weeks for completion. Problems with standardization may result from cell clumping of rough strains. This clumping may also result in different amounts of DNA even from different batches of the same strain, causing problematic uneven (light and overloaded) lanes. Previous studies have detailed the method of PFGE related to clinical and epidemiological studies of M. kansasii, M. szulgai, and MAC (166–171). Recently, PFGE has been applied to study macrolide-susceptible and -resistant isolates and multiple cultures of patients with nodular MAC disease and bronchiectasis (166).

Multilocus Sequence Typing
Another approach for NTM typing is analysis of multiple genes with a high sequence variation, like hsp65 or ITS. However, available sequences have not provided the level of variability needed for epidemiological analyses. With the progress of whole-genome analysis and the possibility of large-sequence determination, however, multilocus sequence typing is likely to prove increasingly useful for typing of NTM.

Repetitive-Unit Sequence-Based PCR
Repetitive-unit sequence-based PCR (rep-PCR) has been used for outbreak control of several slowly growing mycobacterial species, including M. simiae, M. gordonae, M. terrae, M. tuberculosis, and M. avium (172–174). The method is commercially available through the DiversiLab System (bioMérieux, Durham, NC). Although the technology is proprietary, the company offers a Web-based library of rep-PCR sequences that can be searched for matches. Few studies have compared rep-PCR results to those obtained with PFGE.

Variable-Number Tandem Repeat
MIRU-VNTRs were initially applied to typing of M. avium subsp. paratuberculosis (MAP) strains but now have been expanded to other members of the MAC (175–177). Although the VNTR loci are usually species specific, the low cost, reproducibility, smaller volume of DNA requirement, and speed of the VNTR technique suggest that it could be a substitute method for PFGE strain comparison with MAC (178).

IS1245/IS900
The most extensive investigations for typing of NTM strains have been undertaken for M. avium. RFLP analysis based on the insertion sequence IS1245, which is restricted to subspecies of M. avium, has been used for genotyping. Standardization of this technique was proposed in 1998 (179), but this technology never became widespread. However, Mijs et al (180) used this method as one tool for distinguishing M. avium subsp. avium strains obtained from bird specimens from swine- and human-derived strains, for which they proposed the name “M. avium subsp. hominisuis.” RFLP analysis based on the insertion sequence IS900 can be used for genotyping of MAP.

The availability of the complete genome sequences of the “M. avium subsp. hominisuis” strain 104 and the MAP strain K-10 allowed the search for divergent regions that can be used for standardization of other techniques for genotyping (165). Based on the genomic sequence data, large-sequence polymorphisms, which were analyzed for their variability among different M. avium strains, could be identified. By the use of multilocus sequence typing, many genes that contain multiple sequence variations can now be analyzed in parallel (181).

ANTIMICROBIAL SUSCEPTIBILITY TESTING
Antimicrobial susceptibility testing (AST) of clinically relevant mycobacteria is crucial for the control of infections
caused by many species of mycobacteria and should be performed for all species, for which CLSI guidelines are available (182). Procedures are technically demanding and require rigid safety precautions, especially when liquid cultures are involved. When handling positive cultures with a high concentration of bacilli, cross-contamination is another critical issue. Therefore, antimicrobial susceptibility testing should be performed only by experienced personnel.

**Nontuberculous Slowly Growing Mycobacteria**

AST of the NTM requires skill and knowledge of the individual species characteristics. Therefore, the CLSI has advised laboratories that infrequently encounter NTM to refer those isolates to a qualified reference laboratory. Laboratories that elect to perform in-house NTM AST should carefully validate their results and monitor their proficiency regularly, as required by specific accrediting agencies, such as the College of American Pathologists (182).

Generally, broth micro- or macrodilution techniques in serial 2-fold concentrations are recommended. Testing is most efficiently performed in 96-well microtiter panels. Breakpoints for some species of slowly growing mycobacteria have been proposed for the following antimicrobials: rifampin, rifabutin, amikacin, ethambutol, ciprofloxacin, moxifloxacin, minocycline, doxycycline, clarithromycin, trimethoprim-sulfamethoxazole, and linezolid (182).

The CLSI recommendation specifies testing for slowly growing species, including *M. kansasii*, MAC, and *M. marinum*. The CLSI and the statement of the American Thoracic Society and the Infectious Diseases Society of America have recommended that only rifampin and clarithromycin results be reported for *M. kansasii* unless the isolate is rifampin resistant; if so, all of the previously listed antimicrobials should be tested (24, 182).

For isolates of *M. marinum*, experts in mycobacterial susceptibility testing concur that AST is unnecessary in most cases due to the narrow range of MICs for this species. In cases of intolerance to agents typically effective for the treatment of infections due to *M. marinum* (i.e., clarithromycin, rifampin, and ethambutol), antimicrobial testing of the previously listed agents should be performed (182).

For MAC, because previous studies have shown that no correlation exists between MICs and the clinical response of the patient to agents other than clarithromycin, testing of only clarithromycin is recommended. However, a recent study of patients with MAC has shown a correlation of amikacin MICs to clinical response and amikacin breakpoints have been proposed to the CLSI (183). Interpretive criteria are also provided for moxifloxacin and linezolid, but no clinical correlation studies have been performed to date (182).

Other species of slowly growing NTM have insufficient data to make specific recommendations for testing, and therefore the CLSI recommends that testing of these NTM should follow the guidelines for testing rifampin-resistant *M. kansasii*.

Fastidious species that require iron- or hemin-containing media for growth, such as *M. haemophilum*, may be tested using an alternative agar disk elution method with commercial antimicrobial disks in molten agar. The CLSI has recommended testing of antimicrobials, including rifampin, clarithromycin, amikacin, ciprofloxacin, trimethoprim-sulfamethoxazole, linezolid, and doxycycline or minocycline (182).

Specific details and discussion of the AST procedures can be found in chapter 76 of this Manual.

### M. tuberculosis Complex

Currently, methods for testing MTBC are based on the method of proportion, which relies on a clinical definition of drug resistance. Susceptibility testing of MTBC may be performed in agar-based (agar proportion method) or broth-based (commercial) systems. Agar proportion methods may be performed using either commercially prepared or in-house media.

Both the agar proportion and newer liquid detection systems define resistance as growth of >1% of an inoculum of bacterial cells in the presence of a “critical” concentration of the drug. By convention, the critical concentration corresponds to the lowest concentration of drug that inhibits 95% of “wild-type strains” of MTBC that have never been exposed to the antimicrobials without simultaneously inhibiting strains of MTBC from patients who do not respond to treatment and that are considered resistant. The critical concentration is thus the standard concentration by which susceptibility and resistance are established.

A newer method for MTBC susceptibility testing uses a 96-well microtiter panel containing 12 lyophilized first- and second-line antmycobacterial agents. In contrast to the more common agar proportion methods, the MycoTB panel (Thermo Scientific/TREK Diagnostics, Oakwood Village, OH) tests a range of concentration of each antimycobacterial providing a MIC that is consistent with AST formats for other bacterial organisms. Two studies comparing the Sensititre MycoTB panel have demonstrated 94 to 100% categorical agreement with the reference agar proportion method. The Sensititre MycoTB panel appears to be a more rapid (10 to 14 days versus 21 days), quantitative, and efficient method than the gold standard agar proportion method (184, 185). An additional advantage to the Sensititre MycoTB panel is the availability of second-line susceptibility results in the case of a resistant strain. The disadvantage is the absence of pyrazinamide in the panel, which would require testing by another method. Another disadvantage is potential safety concerns associated with working in microtiter plates with possible drug-resistant strains.

Generally, the first isolate of MTBC cultures from each patient should be tested, and susceptibility testing should be repeated if the patient fails to respond to therapy or if the cultures remain positive at 2 to 3 months. Primary susceptibility testing includes a battery of antimicrobials, including isoniazid at two concentrations (critical and higher concentrations), rifampin, ethambutol, and pyrazinamide. When an isolate is resistant to rifampin or any two of the other primary drugs, a secondary panel including a higher concentration of streptomycin and additionally capreomycin, ethionamide, amikacin, p-aminosalicylic acid, rifabutin, cycloserine, linezolid, moxifloxacin, and levofloxacin should be tested (182).

Direct susceptibility testing of smear-positive samples from patients known to have or suspected of having M. tuberculosis involves inoculation of drug-containing medium with a directly processed sample (i.e., concentrated after decontamination and digestion). Indirect susceptibility testing may be performed using cultures already growing either in liquid or in solid medium. This method is usually used on smear-negative samples or if the direct test results are invalid due to contamination, insufficient numbers of colonies in the drug-free quadrants, or insufficient growth after 3 weeks of incubation. Details on both methods of susceptibility testing can be found in chapter 76. Standardized agar proportion methods are not considered rapid methods. Therefore, the addition of a commercial liquid susceptibility system with shorter incubation is strongly recommended for
patient testing. It is imperative, however, that any commercial system be validated to produce results that correlate with the standard susceptibility agar proportion methods. As with any other laboratory test, adequate and consistent quality control and proficiency testing should be performed to ensure accurate and consistent results (182).

Molecular detection of drug resistance markers in MTBC generally makes use of laboratory-developed PCR or sequencing methods that target well-characterized genes (katG, rpoB, pncA, gyrB, etc.) that have mutations associated with resistance to first- and second-line agents (186). These LDTs have been used for detection of resistance markers from culture isolates and, in some instances, directly from respiratory specimens. In addition, the commercially available Xpert TB/RIF assay (Cepheid), discussed earlier in this chapter, provides information about rifampin resistance directly from respiratory specimens. The CDC offers a service for the rapid molecular detection of drug resistance in MTBC using sequencing methods from culture isolates or NAA test-positive sediments. Targets associated with resistance to both first- and second-line agents are interrogated with reported sensitivities of 97.1% for rpoB, 85.4% for katG, 84.6% for pncA, 78.6% for embB, 81.6% for gyrA, and 90.8% for MDR TB (187).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Implementation of sensitive and rapid methods for the detection, identification, and susceptibility testing of MTBC and NTM is of paramount importance to the diagnosis and control of TB and NTM disease. The use of the fluorochrome stain for mycobacterial smears, a broth-based culture system, and the use of DNA probes or sequence analysis for identification along with direct susceptibility testing of smear-positive specimens are optimal for supporting the critical decisions required for optimal patient care. As emphasized in this chapter, phenotypic testing of the slowly growing mycobacterial species has limited use and for other mycobacteria (i.e., rapidly growing mycobacteria) should be applied only in conjunction with molecular assays. Laboratory work should be organized to prioritize timely and accurate identification of MTBC and susceptibility testing of clinically significant isolates.

In order to optimize rapid detection, identification, and AST for the shortest turnaround times, the U.S. Association of Public Health Laboratories has recommended that the Fast Track Referral Model System be implemented. This network system helps to ensure that quality state-of-the-art technology is used, results are reported in a timely manner, and the tracking and fingerprinting of isolates of MTBC occur efficiently for optimal exchange of information between medical centers and the public health sector (54).

CLSI guidelines recommend reporting results within 24 hours for acid-fast bacterium smears and interim reports if growth is seen on inoculated solid medium or when a positive signal is detected on liquid medium. A confirmatory report should be issued once growth is evident, and an identification of either NTM or MTBC should be reported. Moreover, reporting should be done as soon as species level identification is available for NTM and, finally, when susceptibility testing is completed (usually within 7 to 14 days for NTM with broth systems). Additionally, for MTBC, identification from culture results should be reported within an average of 14 days, and a complete culture report with susceptibility results should be reported within an average of 4 to 6 weeks. The use of liquid medium rapid detection systems along with solid medium is critical in order to meet these guidelines (24, 54, 182).

In an effort to develop a more consistent and practical method of reporting identifications performed by molecular techniques, the CLSI (54) has published interpretive criteria for the identification of mycobacterial species by DNA target sequencing, including consensus cutoff values for percent identity. The document states that mycobacteria with 100% 16S rRNA partial (500-bp) gene sequence identity for genus and species may be definitively reported with both genus and species. However, for those isolates whose identity is 99.0% to 99.9%, the recommendation is to report as “Mycobacterium most closely related to [the species given]”. However, if the identity to a recognized species is ≥95 to 98.9%, the results should state that the isolate cannot be definitively identified by 16S rRNA gene sequencing; identification should be given as “most closely related to Mycobacterium sp.”

Microheterogeneity within an NTM species (i.e., 1 to 5 bases in the 16S rRNA gene are different from the sequence of a known reference strain) has been described for several slowly growing species, including M. gordonae, M. bohemicum, M. kansasi, M. celatum, and M. lentiflavum. In general, members of the genus Mycobacterium are closely related to each other in their 16S rRNA gene sequences and may differ by only a few bases or not at all. In the absence of strong phenotypic differences, definitive NTM identification may be difficult, if not impossible. Turenne et al. advocate that the individual strain ambiguities should be examined carefully using optimum quality sequence databases for comparison, and even then, results may remain inconclusive without resorting to sequencing of alternate targets (89).

As has been discussed, 16S rRNA partial gene sequencing is not useful for separation of some species, including the species within the MTBC. Thus, with MTBC, reporting results of only the 16S rRNA gene sequence should state “Mycobacterium tuberculosis complex.” When species level identification is necessary, alternate targets, such as gyrB, may provide species differentiation, except for MTB and M. canetti.

Among the slowly growing NTM, several species are not identifiable with 16S rRNA gene sequencing alone. For example, M. kansasi and M. gastri share sequence identity in their complete 16S rRNA genes, and thus alternate gene targets or determination of photochromogenicity and/or growth rates are required to provide species resolution. Alternate gene targets that may help in cases where sequencing of the 16S rRNA gene is not adequate include the ITS 1 region, hsp65, gyrB, rpoB, recA, and dnaA genes. Specific numerical cutoff values such as are recommended for the 16S rRNA gene are not yet recommended for these genes.

The more accurate characterization of new species by molecular technology and the enhancement of clinical data with standardized AST results continue to advance our knowledge of the MTBC, NTM, and disease caused by these species. Proper interpretation and reporting of species identification, even by molecular methods, should be checked against fundamentally established phenotypic characteristics, such as growth rate, colony morphology, and pigmentation. Determination of temperature requirements also may be useful for select isolates.

Finally, appropriate AST of clinically significant species is vital to recognize and effectively treat multiple-drug-resistant mycobacterial species, including multidrug-resistant and extensively drug-resistant MTBC strains, as well as NTM such as M. simiae, MAC, rifampin-resistant M. kansasi, and other clinically significant drug-resistant species.

31. Characteristics of Slowly Growing Mycobacteria

31. Characteristics of Slowly Growing Mycobacteria

**Mycobacterium: Clinical and Laboratory Characteristics of Rapidly Growing Mycobacteria**

BARBARA A. BROWN-ELLIOTT AND RICHARD J. WALLACE, JR.

**TAXONOMY AND DESCRIPTION OF THE AGENTS**

The rapidly growing mycobacteria (RGM) are generally defined as nontuberculous species that grow on laboratory media within 7 days (1). RGM contain long-chain fatty acids, known as mycolic acids, that can be quantitated using chromatographic techniques, such as high-performance liquid chromatography (HPLC). Prior to the molecular era, HPLC was used for identification of species of the RGM in most major reference laboratories. However, this method has been replaced in most laboratories by more definitive molecular identification methods for more accurate species identification (2).

Currently, there are more than 140 species of nontuberculous mycobacteria (NTM), among which approximately 70 are species of RGM. More than half of the RGM species have been described since the early 1990s. Since 2010, only three new validated species, *Mycobacterium litorale*, *M. bacteremium*, and *M. iranicum*, have been added to the list (3–5). Although the species *M. algericum* was described as an RGM, only microcolonies were evident at 1 week. Moreover, this organism is most closely related to the slowly growing mycobacteria of the *M. terrae* complex and thus, by definition, should not be considered an RGM (6). Additionally, most recently, the species *M. abscessus* was subdivided into two subspecies. The former species *M. abscessus* is now designated *M. abscessus* subsp. *abscessus*, and two previously described species, *M. massiliense* and *M. bolletii*, have been combined and proposed to form another subspecies of *M. abscessus*, *M. abscessus* subsp. *bolletii* (7, 8). The latter designation is controversial since the recent discovery that no functional erm gene is present in isolates previously named *M. massiliense*, in contrast to the case for isolates previously called *M. bolletii*, with a functional erm gene conferring inducible macrolide resistance. Moreover, the 2012 descriptions of the genomic sequences of *M. abscessus* subsp. *bolletii* (previously *M. bolletii*) and *M. abscessus* subsp. *massiliense* (previously *M. massiliense*) may help to resolve some of the questions surrounding the species and provide information to better discriminate between the subspecies (9, 10). Interestingly, Choi et al. noted two RNA gene operons in the species, which is a distinctly different finding from previous reports of a single rRNA gene operon in *M. abscessus* (11, 12). Moreover, recent studies showed that *M. abscessus* subsp. *massiliense* is composed of several different genotypes, which are also related to colony morphology (13). Thus, for ease of reading in this chapter, we use the terminology “*M. abscessus* subsp. *massiliense*” to refer to the former species *M. massiliense*.

Two newly described species, *M. bacteremium* and “*M. franklinii*,” were described in 2011, although the latter species has not yet been validated (4, 14). The second recently validated species, *M. litorale*, was described from soil samples in China in 2012 but has not been recovered from clinical samples (3). A third newly described species, *M. iranicum*, has been reported as a pathogen in the United States, Europe, and Asia and has been isolated from respiratory, wound, and cerebrospinal fluid cultures (5).

There are currently six major groups or complexes of RGM, based on pigmentation and genetic relatedness (Table 1). The first group of nonpigmented pathogenic species includes 10 species, some of which once belonged to the *M. fortuitum* group (Table 1) (1, 15–19).

The second group of nonpigmented RGM is the *M. chelonae/M. abscessus* group listed in Table 1 (1, 7, 20–23). A previously described species, *M. salmoniphilum*, has been revived and also considered to be related to this group. Although this species has been recovered from disseminated disease of salmon and trout, it has not been recovered from humans (24). “*M. franklinii*,” the currently nonvalidated species, has been described for multiple patients with sinus-pulmonary disease, primarily from the northeastern United States (14). Six isolates from extrapulmonary sources have also been described. The organism is closely related to the *M. chelonae/M. abscessus* group.

A third nonpigmented group, the *M. macagenicum* group, currently includes three species, as noted in Table 1 (1, 20, 25).

The fourth group, the *M. smegmatis* group, is currently composed of the two late-pigmented species, i.e., *M. smegmatis* (formerly known as *M. smegmatis sensu stricto*) and *M. goodii* (1, 16, 26).

The fifth group of RGM includes the early-pigmented species, which traditionally have been difficult to identify by conventional (phenotypic) laboratory methods. The only proven pathogens in this group are *M. neoaurum* and *M. bacteremium* (Table 1), which have been associated with mycobacteremia in patients with catheter infections, and *M. iranicum*, which has been recovered from five respiratory
samples, a hand wound, and two cerebrospinal fluid samples (4, 5, 27). Several newly described early-pigmented species, including M. canariense, M. cosmeticum, and M. monacense, are also clinically significant (28–30). There are a number of previously listed environmental (nonpathogenic) species as well (1, 17, 28, 31–33).

Current studies based on DNA sequence analysis suggest the presence of a sixth, nonpigmented pathogenic group, composed of M. mageritense and M. wolinskyi (2, 21, 22).

The introduction of the new species noted above within the RGM emphasizes the importance of molecular identification to the species level and questions the meaningfulness of the current “group” classifications, especially for the M. fortuitum group. However, because previous data (prior to the reliance on genetic testing) and publications use this “group” nomenclature, these designations are retained in this chapter for ease of discussion (1). As more information is obtained using advanced molecular technology and more laboratories adopt this newer methodology, the group designations may become even more obsolete.

**CLINICAL SIGNIFICANCE**

The RGM are opportunistic pathogens that produce disease in a variety of clinical settings. The three major clinically important species of RGM, responsible for approximately 80% of mycobacterial disease in humans, are the M. fortuitum group (including M. porcinum), M. chelonae, and M. abscessus (19, 34, 35). Other potentially pathogenic and clinically significant RGM species are included in Table 2 (1, 2, 15–17, 20–24, 26, 28, 30, 32, 33, 36–39). RGM are presumed to be common in the environment and have been identified most often in tap water when associated with outbreaks of catheter sepsis in bone marrow transplants, wound infections, and associated pseudo-outbreaks of disease (1, 35). The specific reservoir for M. abscessus chronic lung infections has yet to be identified.

**Community-Acquired Skin and Soft Tissue Infections**

The most common infection seen with the RGM is a post-traumatic-wound infection. The patients are generally healthy, and drug-induced immune suppression shows a minimal increase in risk for this type of infection. The M. fortuitum group accounts for approximately 60% of cases of localized cutaneous infections, but any of the more than 30 pathogenic RGM species listed in Table 2 can cause disease (1, 15, 33, 40, 41).

Traumatic wound infections, especially open fractures, often involve species within the former Mycobacterium fortuitum third-biovariant complex (i.e., M. porcinum, and M. houstonense) (Table 1) (1, 40). More than 75% of the infections reported in a series of 85 isolates of the M. fortuitum third biovariant from the United States and the Queensland, Australia, state laboratory were associated with skin, soft tissue, or bone infections (1). The majority of infections occurred 4 to 6 weeks following puncture wounds or open fractures. Metal puncture wounds (48%) and injuries from motor vehicle accidents (26%) were the most common antecedent injuries, and approximately 40% of the injury sites involved the foot or leg. Stepping on a nail was the most frequently related scenario. None of the isolates in this series were studied by molecular techniques that would identify them as one of the species within the former M. fortuitum third-biovariant complex. A 2011 report of an outbreak from 2003 until 2010 in a large university medical center in Texas, involving M. porcinum, included not only multiple respiratory isolates but also environmental water and ice isolates, along with clinical isolates from localized abscesses (spinal and paraspinal sites, finger, neck, and breast), peritoneal fluid, blood, and/or Port-a-Cath sites (35).

Sporadic cases of localized wound infections following medical or surgical procedures, including needle injections, can occur with M. chelonae but are less common than those with M. fortuitum.

In late 2011 and early 2012, an outbreak of 19 cases of M. chelonae associated with tattoo ink were reported in New York (42). This was the largest documented outbreak of this type involving M. chelonae. The clinical picture of post-traumatic-wound infection ranges from localized cellulitis or abscesses to osteomyelitis (1). A 2006 report from a major U.S. clinical referral center for patients from Minnesota, Wisconsin, Iowa, and South Dakota characterized 63 HIV-negative patients with RGM infections involving M. abscessus or M. chelonae (71%) or involving the M. fortuitum group (29%). Moreover, patients with M. chelonae or M. abscessus usually had multiple (disseminated) cutaneous

(Continued on next page)
lesions, in contrast to those with single (localized) lesions due to M. fortuitum. Most patients with M. fortuitum had undergone a prior surgical procedure or had experienced a penetrating trauma at the infected site. Patients with M. chelonae or M. abscessus were older and more likely to be on some type of immunosuppressive agent (43). Localized or disseminated infections with M. chelonae most frequently occur in patients receiving long-term corticosteroids and/or chemotherapy, organ transplant recipients, and patients with rheumatoid arthritis or other autoimmune disorders or suppressive therapy (43). Immune suppression in diseases such as AIDS has not been a significant risk factor for development of localized or disseminated M. chelonae infections (1, 43).

Starting in 2000, an outbreak of furunculosis on the lower extremities, caused by M. fortuitum, was described for lower extremities, caused by M. fortuitum infections (1, 43).

Occasionally, members of group 6 (M. mageritense, and M. smegmatis sensu stricto), and members of group 4 (M. smegmatis group, including M. smegmatis sensu stricto, and M. goodii) (49) have been reported from infections following traumatic injury and surgical or medical procedures, such as cardiac surgery, breast reduction surgery, and facelift plastic surgery. Cellulitis and localized abscess are the most common manifestations (1, 26, 34).

**Disseminated Cutaneous Disease**

For unknown reasons, disseminated cutaneous disease is rare for all taxonomic groups other than the M. abscessus/M. chelonae group, even in immunocompromised patients, including those with AIDS (1, 34, 50).

In contrast, disseminated cutaneous disease due to both M. abscessus and M. chelonae is much more common. It typically presents as multiple chronic painful red nodules, usually involving the lower extremities (1, 34). These lesions then drain spontaneously, with the drainage usually being acid-fast bacillus smear positive. With disease due

†Formerly M. abscessus.
∥Formerly M. massilense and M. bolletii (the taxonomic change is currently controversial).
*“M. franklinii” is currently a nonvalidated species.
*“M. houstonense” is currently a nonvalidated species.
‖Grows at 30°C and slowly growing mycobacterium at 35°C.
*Determined by DNA strain typing.
§Grows on or degrades a variety of organic substrates.
®Pathogenic for fish.
ND, no data available.
to M. chelonea, almost all patients are immunosuppressed, usually from low-dose corticosteroid therapy. Although the disease is presumably a consequence of hematogenous spread, bacteremia is rarely identified. A portal of entry for the infection is rarely evident (1, 34). In a series of 100 clinical isolates from skin and soft tissue, we reported that 53% were from patients with disseminated cutaneous infections (1).

Disseminated cutaneous disease due to M. abscessus occurs less frequently but is serious (1). Like disseminated M. chelonea disease, most cases occur in chronically immunosuppressed patients receiving corticosteroids, and the disease has no apparent portal of entry. Also like the case with M. chelonea, patients with disseminated cutaneous infection due to M. abscessus rarely have detectable bacteremia and/or endocarditis but usually present with multiple draining cutaneous nodules, usually in the lower extremities (1, 34).

A rare type of disseminated infection due to RGM in immunocompetent hosts presenting with lymphadenopathy was recently described for patients from Thailand (51).

### Bone and Joint Infections

The RGM may also cause bone and joint infections. Like bacterial disease, osteomyelitis may follow open bone fractures, puncture wounds, and hematogenous spread from another source. The most common scenario is an open fracture of the femur, often followed by orthopedic surgical procedures. The most frequent pathogen recovered in this setting is the M. fortuitum group, including the newly described species M. houstonense, M. boenickei, and M. setense (1, 15, 17, 52, 53). The two newly described species in the M. smegmatis group, M. goodii and M. wolinskyi, have also been associated with osteomyelitis (1, 26). Bone involvement secondary to a puncture wound is likely the second major cause of osteomyelitis. Infections most commonly involve the M. fortuitum group (1). M. fortuitum infections in prosthetic knees and joints have also been reported (52). Vertebral osteomyelitis has also been described (54, 55).

### Pulmonary Infections

#### Chronic Lung Infection and Bronchiectasis

As with disseminated cutaneous disease, chronic lung disease is rare among RGM groups, except for the M. chelonea/M. abscessus group (55). Chronic lung infections with RGM, most often in nonsmoking older women with associated bronchiectasis, are sometimes associated with the M. avium complex (MAC) as well. M. abscessus is the causative agent in >80% of cases of pulmonary disease due to RGM (34).

Similarities exist between patients with MAC and those with M. abscessus, such that a common pathogenicity or host susceptibility factor may be involved (34). Multiple cultures of M. abscessus from respiratory samples are usually associated with significant pulmonary disease.

#### Cystic Fibrosis

M. abscessus subsp. abscessus and M. abscessus subsp. massiliense have been isolated with increasing frequency from the respiratory tracts of patients with cystic fibrosis (CF) (1, 57–62). A 2012 study concluded that CF patients with M. abscessus were younger and had more severe disease and more frequent intravenous antimicrobial treatment (62). M. abscessus is the second most common species of nontuberculous mycobacteria recovered from CF patients (after the MAC), and it may be the most common species associated with clinical disease in this setting (59). Patients with CF also have bronchiectasis, in addition to chronic, recurrent airway and parenchymal infections that may be the primary risk factors for susceptibility to NTM disease (58, 59). Bronchiectasis, an almost universal factor in M. abscessus infection, appears to be less predominant in patients with M. abscessus subsp. massiliense infection (63). Recent studies have indicated that because of a nonfunctional erm gene in this species, patients with the former M. abscessus subsp. massiliense are successfully treated with macrolides more often than patients with M. abscessus subsp. abscessus (80% success rate, in contrast to 25% success for patients with M. abscessus subsp. abscessus) (63, 64).

At present, there is no explanation for the apparently varying geographic distribution of M. abscessus subsp. massiliense strains in the general population with respiratory disease. Recent data showed a much higher prevalence (55%) among 150 patients studied in South Korea than in other populations, such as only 28% of 40 patients at the National Institutes of Health in the United States, 21% of 39 isolates in the Netherlands, 22% of 50 patients with CF in France, and 26% of 102 patients in Japan (63).

#### Chronic Aspiration Syndrome

M. fortuitum has been reported as a pathogen in half of the cases of chronic aspiration disease secondary to underlying gastroesophageal disorders, such as achalasia (1, 34). Pulmonary disease with M. fortuitum in the absence of these disorders is rare. Pulmonary disease with M. chelonea and M. smegmatis has been described in only a few cases, including lipoid pneumonia.

### Miscellaneous Lung Disease

A rare case of pulmonary disease with M. mageritense was recently described for a patient with a compromised immune system (1, 34, 56). However, the previously discussed recent outbreak of M. porciun described the first reported cases of clinically significant pulmonary disease associated with this species, a member of the M. fortuitum group (35).

#### Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis among metal grinders working with contaminated metalworking fluids in industrial plants has been associated with a newly described species of RGM, M. immunogenenum (1, 34, 65). Multiple pseudo-outbreaks associated with this species have been reported, resulting from contaminated automated bronchoscope cleaning machines and metalworking fluids. This species is able to grow and remain viable in degraded metalworking fluid and is resistant to the routine biocides used for disinfection of metalworking fluids (1, 65). However, as yet, this species has not been reported from open lung biopsy specimens from these patients.

### Central Nervous System Disease

Central nervous system disease involving the RGM is rare, but morbidity and mortality are high. Most of the reported cases have been associated with M. fortuitum (1, 66, 67).

#### Corneal Infections (Keratitis)

The number of RGM recovered from ocular infections has been increasing over the last 20 years. A retrospective review of cases of NTM keratitis from 1982 to 1997 at an eye institute in Florida showed that 19 of 24 cases were due to RGM (68). A recent study which identified 113 ophthalmic isolates by molecular methods showed that the most common RGM were M. chelonea (45%), M. abscessus (42%), and the M. fortuitum group (8%) (69).
Since the early 1990s, other descriptions of epidemic and sporadic ocular infections associated with the RGM have been published, including postkeratoplasty infections and infections following laser in situ keratomileusis (LASIK) surgery (1, 69).

Otitis Media
The most common NTM ear disease is chronic otitis media due to M. abscessus. In a 1988 outbreak of 17 cases of otitis media in two ear-nose-throat clinics, patients presented with chronic ear drainage with a perforated tympanic membrane and a prior tympanostomy tube (1). In another series, 20 of 21 cases of sporadic chronic otitis media (some with associated mastoiditis) were due to M. abscessus infection following ear tube placement. Approximately one-half of the isolates from these cases were aminoglycoside resistant, resulting from the long-term use of aminoglycoside ear drops (1). Sporadic cases of this disease continue to be seen. The key to the disease appears to be the presence of the foreign body (tympanostomy tube).

Recently, otitis media and otomastoiditis caused by M. abscessus subsp. massiliense were described for middle-aged adults with underlying otologic disease. These patients were treated successfully with clarithromycin-containing regimens for up to 9 months (70).

Health Care-Associated Infections
Health care-associated disease with RGM has been reported most commonly with M. fortuitum, M. chelonae, M. abscessus, and M. mucogenicum, although any species may be involved. Most infections occur following contamination with tap water (1, 40, 71, 72). Types of infections include postsurgical wound infections, catheter sepsis, infections following hemodialysis, postinjection abscesses, vaccine-related outbreaks, and otitis media following tympanostomy tube replacement (1, 73, 74). These have been seen as both sporadic cases and localized outbreaks. Recent outbreaks have involved cosmetic procedures, such as liposuction, liposculpture, acupuncture, and mesotherapy, a procedure comprising multiple subcutaneous injections of pharmaceutical or homeopathic medications for cosmetic purposes (41, 73–80).

In addition to true outbreaks of infection, numerous health care-associated pseudo-outbreaks have been described. Contaminated or malfunctioning bronchoscopes, automated endoscope cleaning machines, and contaminated laboratory reagents and ice have been implicated (1, 73, 81–83).

Catheter-Associated Infections
Central catheter-associated infections are the most common health care-associated infections due to the RGM (1, 39, 85). They are the most common cause of RGM bacteremia, but the disease may also present as local wound drainage as part of an exit site or tunnel infection (1, 85). Other types of catheters can also become infected, including peritoneal catheters, ventriculoperitoneal shunts, and shunts for hemodialysis (1). The most common species are M. mucogenicum, M. fortuitum, M. abscessus, and the newly described species M. bacteremicum. An outbreak of M. phocacium and M. mucogenicum was described for five patients with central venous catheters in an oncology unit in a Texas hospital (86). This outbreak represents the first report of clinical isolates of M. phocacium in a hospital in the United States.

Surgical Wound Infections
Surgical wound infections due to RGM are a well-recognized clinical entity. In the 1970s and 1980s, these were most commonly associated with augmentation mammoplasty and coronary artery bypass surgery, and multiple disease outbreaks occurred (1, 87). Infections following these types of surgery are now less common, although a cluster of 12 cases of post-augmentation mammoplasty surgical site infections due to M. fortuitum and M. porcinum was reported between 2002 and 2004 in Brazil (87). More often, however, these types of infections have been replaced by infections following other types of cosmetic surgeries, such as liposuction, and other types of prosthetic surgeries, such as knee replacements.

In a 1989 report (15), approximately 80% of RGM wound isolates related to cardiac surgery were from seven southern coastal states, including Texas, Louisiana, Georgia, Maryland, Alabama, Florida, and South Carolina. A second report, published in the same year, showed that 92% of 37 identified cases of surgical wound infection following augmentation mammoplasty were also from patients in southern coastal states, with the majority located in Texas, Florida, and North Carolina, suggesting that the disease risk was highest in the southeastern United States (1).

Recovery of both subspecies of M. abscessus has been reported from outbreaks of infections associated with laparoscopic surgeries and cosmetic surgeries in Brazil, the Dominican Republic, and Korea (76, 78). These and other recent reports suggest that although few studies have identified these newer subspecies in invasive infections, they have been misclassified in previous studies (88).

Prosthetic Device Infections
Infections following insertion of prosthetic devices, including prosthetic heart valves, artificial knees and hips, lens implants, and metal rods inserted into the vertebrae to stabilize bones following fractures, have also been described (1, 52). Again, M. fortuitum is the most common pathogen, but any of the pathogenic RGM, including the M. smegmatis group, can be associated with this type of infection (1).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS
Details of standard methods are included in chapter 30. Transport of species is accomplished by using leakproof containers and proper safety protocols. Specimens for detection of RGM should be delivered to the laboratory in a timely manner following appropriate shipping and handling regulations for shipping biological or infectious materials (89).

Disinfectants
The RGM are generally resistant to the activity of biocides, such as organomercurials, chlorine, 2% formaldehyde, and alkaline glutaraldehyde, all of which are commonly used disinfectants (1). A report of the contamination of benzalkonium chloride, a widely used antiseptic compound, with M. abscessus and of a resulting outbreak of this species in several patients following steroid injections after skin disinfection emphasizes the limitations of disinfectants against the RGM (90).

DIRECT EXAMINATION
Microscopy
The use of mycobacterial smears is a rapid and reasonably sensitive step in the diagnosis of RGM disease. Gram stains of colonies showing faintly staining, "ghost-like" beaded
Gram-positive bacilli are often helpful in establishing a diagnosis of mycobacteriosis. Ziehl-Neelsen or Kinyoun staining may also be useful. However, the use of smears alone is not sufficient for species identification. A large study found that NTM, including RGM, are likely to be detected by fluorochrome staining of specimens, especially those from patients at low risk for AIDS in areas where lung disease is endemic (89, 91). Further details of the staining procedures are found in chapter 30.

**Nucleic Acid Detection**

Currently, there are no commercial nucleic acid detection systems available for direct detection of NTM. An indirect method could be identifying an acid-fast bacillus smear-positive sample that is negative by a nucleic acid amplification test specific for Mycobacterium tuberculosis, but this does not prove the presence of RGM compared to the slowly growing NTM.

**ISOLATION PROCEDURES**

Primary isolation of RGM optimally requires culture at 28 to 30°C rather than 35°C, especially for recovery of M. chelonae and M. immunogenum (1). Direct examination and isolation procedures are detailed in chapter 30.

Recovery of RGM from routine blood culture systems does not appear to be problematic. However, no large comparative studies of commercial systems have been performed to date.

**IDENTIFICATION**

**Biochemical Testing**

As previously stated, the RGM are defined as NTM that grow within 7 days (most species grow within 3 to 4 days) (1). Until the advent of more modern molecular techniques, traditional laboratory identification of the RGM was based primarily upon growth rate, pigmentation, colonial morphology, and a select battery of biochemical tests (1). These standard tests included tests of arylsulfatase production, tolerance to 5% NaCl, nitrate reductase activity, and iron uptake. All members of the M. fortuitum group and M. chelonae/M. abscessus group exhibit a strongly positive arylsulfatase reaction at 3 days. The M. smegmatis group (M. smegmatis and M. goodii) and M. wolinskyi have similar growth rates but do not exhibit arylsulfatase activity at 3 days (1, 26). Approximately 95% of the isolates of M. smegmatis (sensu stricto) and 80% of M. goodii isolates develop a late (7 to 10 days) yellow-orange pigmentation (1, 26).

The current proposal for the clinical laboratory is that biochemical testing of the RGM should be replaced by molecular methods. Moreover, biochemical testing should be performed only when describing a new species as part of a polyphasic identification algorithm.

**Supplemental Biochemical Testing: Carbohydrate Utilization**

The supplementation of standard biochemical tests with carbohydrate utilization has allowed more complete and accurate laboratory identification of established species and discrimination of some (but not all) new species (1). Identification to the species level and susceptibility testing (see chapter 76) should be performed on isolates of RGM considered to be clinically significant.

However, as previously stated, molecular testing is the only definitive means of identifying the RGM species, and laboratories should proceed cautiously in identifying these species by biochemical testing alone (92, 93).

**Antimicrobial Susceptibility Tests for Taxonomic Identification**

As discussed above, other adjunctive nonmolecular tests, including antimicrobial susceptibility tests, have also been utilized for identification of the RGM (1, 93). They are less commonly used currently, with the advent of molecular techniques, but can provide species confirmation in conjunction with molecular results. As a screening tool, isolates of the M. fortuitum group and the M. chelonae/M. abscessus group can be differentiated by the use of a polymyxin B (300 IU) disk diffusion method. Generally, isolates of the M. fortuitum group exhibit a partial or clear zone of inhibition (≥10 mm) around the polymyxin disk, whereas isolates of the M. chelonae/M. abscessus group show no zone of inhibition (1).

Moreover, M. chelonae and M. abscessus also have different antimicrobial susceptibility patterns. One major difference between the two species is resistance to cefoxitin. By agar disk diffusion, M. chelonae shows complete resistance to cefoxitin, with no partial or complete zones of inhibition, in contrast to the partial or complete zones seen with M. abscessus. Isolates of M. chelonae generally have cefoxitin MICs of ≥256 μg/ml, whereas the modal MIC for isolates of M. abscessus is 32 to 64 μg/ml (1). Furthermore, recent studies have shown that isolates of M. abscessus subsp. abscessus, but not M. chelonae or M. abscessus subsp. massiliense, have an inducible erm gene similar to the gene in M. fortuitum, which conveys macrolide resistance (94, 95).

Isolates of M. abscessus also have lower amikacin MICs and are resistant to tobramycin, whereas tobramycin is more active than amikacin with M. chelonae. Additionally, isolates of M. chelonae are more susceptible in vitro to some of the newer antibiotics, including linezolid and moxifloxacin, than are isolates of M. abscessus (92).

**HPLC Identification**

HPLC analysis of the mycobacterial cell wall mycolic acid content is routinely used in large reference or state health department laboratories to identify slowly growing isolates of NTM, but it has been problematic with RGM (1, 96). HPLC can be helpful for placing RGM isolates into groups or complexes, but it is not specific enough to identify most species with a high degree of accuracy.

**Molecular Identification Methods**

**Nucleic Acid Probes**

The INNO-LiPA multiplex probe assay (Innogenetics, Ghent, Belgium) is based on the principle of reverse hybridization (97). Although the assay has not received U.S. Food and Drug Administration clearance, it can identify both rapidly and slowly growing mycobacterial species. Biotinylated DNA obtained by PCR amplification of the 16S-23S internal transcribed spacer (ITS2) is hybridized with specific oligonucleotide probes immobilized as parallel lines on membrane strips. The main advantage of this system is that a large variety of species may be identified by a single assay, without the need to select an appropriate probe. One limitation of the assay is the cross-reactivity that may be detected with species of the M. fortuitum group and several species, such as M. thermoresistibile, M. agri, and M. alvei, that are rarely found in clinical samples (1, 97). Additionally, it
failed to differentiate isolates of closely related species, such as M. chelonae and M. abscessus (98). Since the original studies with the INNO-LiPA assay, however, the system has been improved to include additional probes for the M. fortuitum-peregrinum complex and M. smegmatis.

A similar commercial PCR method which targets the 23S rRNA gene, the GenoType Mycobacterium assay (Hain Lifescience, GmbH, Nehren, Germany), provides probes for simultaneous identification of M. chelonae and specific probes for M. peregrinum, M. fortuitum, and M. phlei. These two systems are widely used in Europe for NTM identification (99, 100).

Sequence Analysis
Nucleic acid sequence analysis has been performed for the identification of mycobacteria for several years. This identification tool has been useful for the discrimination of most of the newly described species of RGM (38, 101–103).

Partial 16S rRNA Gene Sequence Analysis
Generally, the identification of mycobacteria, including RGM, focuses on two main hypervariable domains, known as region A and region B, located at the 3′ end of the 16S rRNA gene. These regions correspond to Escherichia coli positions 129 to 267 and 430 to 500, respectively. Hypervariable region A, especially, contains most of the species-specific sequence variations (so-called “signature sequences”) in mycobacterial species, and sequencing of this region allows taxonomic identification of most mycobacteria, including many species of RGM (2, 38).

A commercial gene sequencing system, the MicroSeq 500 16S rDNA bacterial sequencing kit (Life Technologies, Foster City, CA), analyzes the first 500-bp sequence and compares the sequence with those in a commercially prepared database. The use of this commercial system alone cannot differentiate some major species of RGM, such as M. chelonae and M. abscessus, which require sequencing of other regions or other genes for identification (101, 103). For this reason, clinical laboratories have supplemented the commercial database with additional sequences from their own or other libraries, such as RIDOM (Würzburg, Germany) or GenBank.

In contrast to the case with 16S rRNA gene sequencing, the commercially available partial 16S rRNA gene sequencing system (MicroSeq ‘first 500 bp’) has a number of large gaps for identification of RGM. For example, isolates of two major RGM pathogens, M. chelonae and M. abscessus, require sequencing of sites outside the first 500 bp, as they are identical in this region but differ at other 16S rRNA gene sites (in the 3′ region) (38, 101, 102). To ensure accurate identification, at least 300 bp of quality sequence should be compared between the reference and query sequences and should cover at least one region of the gene where variations are to be expected. Therefore, most clinical laboratories currently sequence between 450 and 480 bp in order to provide an adequate sequence (104).

In general, members of the genus Mycobacterium are closely related to each other, and closely related species may differ by only a few base pairs, or none at all. For example, M. goodii, which is difficult to distinguish from M. smegmatis phenotypically, except by susceptibility pattern, has only a four-base difference in the entire 16S rRNA gene (26).

A quality-controlled database is indispensable for the evaluation and accurate identification of unknown strains (103). The laboratorian should also recognize that sequence analysis is an important component in a polyphasic approach to the identification of unknown strains. While in some instances molecular analysis-based identifications without conventional testing may be adequate, more often there are cases in which the broader picture must be reviewed. Some investigators suggest that key phenotypic tests, including colonial morphology, pigmentation, and growth rate, are necessary, especially for the differentiation of closely related species (103).

The lack of consensus on standard reporting criteria or a cutoff value has been a major obstacle in interpretation of sequence data (103, 104). Reporting criteria, such as (i) distinct species, (ii) “related” to a species, and (iii) “most closely related to” a species, depending upon the amount of sequence difference between the unknown isolate and the 16S rRNA gene database entries (40), have been recommended but not validated (38, 103).

The 2008 CLSI MM18-A (104) document recommends guidelines for 16S rRNA gene sequencing in order to identify Mycobacterium spp. in a consistent, practical manner. For sequences with 100% sequence probability, the definite genus and species may be assigned. However, for sequence probabilities of 99.0 to 99.9%, the document recommends reporting “genus, most closely related to species,” and for isolates with sequence probabilities of 98.9 to 99.0%, laboratories should consider reporting “unable to definitively identify by 16S rRNA gene sequencing, most closely related to Mycobacterium sp.” (104). We agree that although 100% identity is mandatory for signature sequences, one or a few mismatches at other positions may be acceptable for identification to the species level (104).

Sequencing remains a complex and often cost-prohibitive expense for a routine clinical laboratory, which also may not have an adequate volume of isolates to warrant sequencing. Therefore, the consensus opinion is that not all laboratories should attempt to incorporate sequencing into their laboratory routine. Moreover, requests for sequencing should instead be sent to a qualified reference laboratory with skill and experience in the method (103, 104).

Sequencing of the hsp65 Gene
Although the 65-kDa heat shock protein gene (hsp65) is highly conserved among genera of mycobacteria, it exhibits more interspecies and intraspecies polymorphisms than those in the 16S rRNA gene sequence (105–107). This variability can be advantageous for the development of other strategies for the identification of genetically related species of RGM (106, 107). Most sequencing or restriction fragment length polymorphism analyses have utilized a 441-bp sequence identified by Telenti et al. (107), often referred to as the Telenti fragment.

Studies based on DNA sequencing have demonstrated interspecies allelic diversity within the RGM. Detailed studies of several RGM species, including M. peregrinum, M. porcinum, M. senegalense, M. chelonae, and M. abscessus, have shown 4 to 6 sequence variants (sequevars) per species that differ by 4 to 6 nucleotides within the 441-bp Telenti fragment (107, 108).

Additionally, unlike 16S rRNA gene sequencing, the hsp65 sequencing method is able to differentiate isolates of M. abscessus from those of M. chelonae (they differ by almost 30 bp in the 441-bp hsp65 sequence, compared to only 4 bp in the entire 1,500-bp 16S rRNA gene sequence) (108). In contrast to the case with 16S rRNA gene sequences, with sequencing of the hsp65 gene, even RGM species with a high degree of 16S rRNA gene similarity, such as M. fortuitum, M. septicum, M. peregrinum, M. houstonense, and M. senegalense, can be discriminated as distinct species.
Like the case for other sequencing methods, one limitation of sequencing the hsp65 gene is that few or no sequences of newer RGM species are available in databases, and detailed sequencing of older species (i.e., multiple strains) has not been done, such that only one sequence per species is generally available. Thus, development of a comprehensive database and in-house validation are essential (2, 103, 108).

**rpoB Sequence Analysis**

Initial studies using rpoB (the gene encoding the β-subunit of RNA polymerase) sequencing for description of species were based upon partial rpoB gene sequence analysis, comprising only about 20% of the entire gene length. Other investigators have suggested that species identification of a variety of RGM species is possible using a 340- to 360-bp region, but extensive variation may require development of more species-specific probes (20–22, 109–111).

The utility of rpoB was recently emphasized in a study comparing the phylogenetic relationships among 19 RGM species, including the major pathogens in this group, by comparing rpoB to several different sequence targets, including the 16S rRNA gene, hsp65, sodA, and recA. All 19 species showed good discrimination with rpoB (22, 112).

Not only has the rpoB sequence been useful for the identification of established species, but it has also helped to enable the discrimination of species that cannot be differentially by the 16S rRNA gene or the hsp65 sequence alone. Newly described species that are usually differentiated by rpoB sequencing include *M. abscessus* subsp. massiliense, *M. phocaicum*, and *M. aubagnensis* (20, 21, 23). However, recent studies have shown that multilocus sequencing is necessary to identify *M. abscessus* subsp. massiliense (7, 8, 115).

**Sequence Analysis of Other Gene Targets**

Other molecular targets for taxonomic identification, including the 32-kDa protein gene, the superoxide dismutase gene (sodA), the 16S-23S rRNA ITS, dnaJ, secA1, and recA, have been suggested for mycobacterial identification utilizing either PCR-restriction fragment length analysis (PRA) or direct sequencing (22, 51, 113–115). However, preliminary data suggest that these gene sequences are more variable than hsp65, and, to date, they have been utilized less commonly for the laboratory identification of the species of RGM (22, 113, 114).

Moreover, a major limitation of all sequence-based testing is the lack of sufficient databases (21, 103). Additionally, a multigenic approach for taxonomic evaluation of species has been suggested widely by investigators and was recently proposed by an ad hoc committee for the reevaluation of the species definition in bacteriology (116).

Recent studies by Kim et al. used erm(41) gene sequences to differentiate *M. abscessus* subsp. massiliense from *M. abscessus* subsp. abscessus and *M. abscessus* subsp. bolletii (117). The results of species identification using erm(41) were concordant with those of multilocus sequence analysis including rpoB, hsp65, sodA, and the 16S-23S ITS (117). However, Blauwendraat et al. reported that sequencing of sodA provides little value in species differentiation (98).

**Multilocus Sequence Analysis**

Recent studies have shown the inaccuracy of single-target sequencing for differentiation of species within the *M. abscessus* complex (i.e., *M. abscessus* subsp. *abscessus*, the former species *M. massiliense*, and the former species *M. bolletii*) (118). The previous strategy, using *rpoB* sequencing for identification of species within the *M. abscessus* complex, appears to be unacceptable due to the composite genetic structure, which suggests that genetic exchanges among members of the group led to legitimate recombination events among homologous housekeeping genes in a large number of isolates of the *M. abscessus* complex studied thus far (114, 118, 119).

These studies also emphasize the need for multiple-gene sequencing in the definition of species (118). A 2011 study by Macheras et al. suggested the use of eight housekeeping gene sequences (4,071 bp), including argH, cya, gfpK, gnd, murC, pgm, pta, and parH (120). Their work also brings into question the previous criteria for differentiation of species based on >3% *rpoB* sequence divergence between two RGM species (36, 120). Furthermore, their work substantiates a later study by Leao and colleagues asserting that *M. massiliense* and *M. bolletii* are not different species (7, 8).

**PCR-Restriction Enzyme Analysis**

PRA of hsp65 has become a valuable tool for the identification of RGM. With the whole-sequencing PRA method used on hsp65, minor differences (sequences) within the species rarely involve a restriction site, so most species have only one PRA pattern. Currently, the 441-bp Telenti fragment of hsp65 remains the most useful sequence for PRA identification of RGM, although it has not been evaluated extensively with the pigmented RGM and with the newer species and subspecies of RGM, such as *M. phocaicum*, *M. aubagnensis*, *M. abscessus* subsp. *massiliense*, and others (1, 107, 108). However, use of another restriction enzyme (SmII) in addition to the BstEI and HaeIII enzymes may enable differentiation of *M. abscessus* subsp. *massiliense* from the former species *M. bolletii* and *M. abscessus* (R. J. Wallace, unpublished data). Additionally, the correlation of rough/smooth colony morphology of *M. abscessus* subsp. *massiliense* has been demonstrated by hsp65 PRA with Hinfl (13).

The advantages of PRA are that the method of identification does not rely upon growth rate and nutritional requirements, the equipment is relatively inexpensive, and the results for a large number of mycobacterial species can be generated rapidly. The disadvantages are that it requires knowledge of PCR and is a relatively complex procedure that requires extensive in-house validation, since there are no available commercial systems. Furthermore, the method is not approved by the U.S. Food and Drug Administration. However, as with all sequence-based methods of identification, its utility is limited by the availability of an updated public database.

Algorithms for identification of mycobacterial species, including RGM, by PCR-restriction fragment length polymorphism analysis of the hsp65 gene have been proposed (89, 106, 107). Figure 1 shows a PRA gel of the most commonly encountered RGM in the clinical laboratory.

**Variable-Number-Tandem-Repeat (VNTR) Analysis**

Recently, Choi and colleagues demonstrated identification to the species level of 85 isolates of the *M. abscessus* complex (M. *abscessus* subsp. *abscessus*, M. *abscessus* subsp. *massiliense*, and M. *abscessus* subsp. *bolletii*), using VNTR11 and VNTR23 as targets (121). The assay was also able to differentiate the *M. abscessus* complex from other mycobacterial species, including *M. fortuitum* and *M. chelonae*. Complete agreement of identification was noted among the 85 strains. VNTR11 showed a polymorphism of two to four copies (179 to 278 bp) in *M. abscessus* but only one copy in
The sequence, located in variable region II according to the numbering of Adékambi et al. (20), at positions 1105 to 1219 (including primer sequences), successfully identified 99/100 isolates of M. abscessus and M. chelonae (125).

Matrix-Assisted Laser Desorption Ionization—Time of Flight Mass Spectrometry

Matrix-assisted laser desorption ionization—time of flight mass spectrometry (MALDI-TOF MS) technology was recently demonstrated to be a reliable and rapid (approximately 90 min to identification of most RGM species) technological advance for the identification of NTM, including the RGM. The current method produces unique spectral fingerprints based on extracted proteins. Moreover, MALDI-TOF MS provides a less expensive and less labor-intensive procedural alternative to gene sequencing for identification of the RGM (126, 127). In a recent study by Lotz and colleagues, the investigators were able to differentiate several clinically relevant species of RGM, including M. impariense/M. chelonae/M. abscessus subsp. abscessus, but not M. abscessus subsp. abscessus, from M. abscessus subsp. bolletii or M. abscessus subsp. massilense (128). Additionally, 6/8 isolates of M. fortuitum, 8/8 isolates of M. mucogenicum, and 6/7 isolates of M. peregrinium were also correctly identified in liquid media, compared to 25/26 isolates of M. chelonae, 25/26 isolates of M. fortuitum, 13/16 isolates of M. peregrinium, and 19/20 isolates of M. mucogenicum correctly identified from solid media (128). Overall identification for both slowly and rapidly growing mycobacterial species was 97% (128).

The original studies using MALDI-TOF MS began in 2004, using more complex strategies, with whole cells for mycobacterial identification, than the protein extract methods available at present. In early studies, Hettick et al. tested eight strains of RGM (M. fortuitum) and were able to illustrate a high degree of reproducibility between culture strains (129, 130). Additionally, Wallace and colleagues tested 22 isolates of RGM and showed that the clustering of strains by MALDI-TOF MS was comparable to that by PRA and genetic sequencing (18). In 2006, Pignone et al. used root mean square values for the comparison of different mycobacterial profiles of 14 strains of RGM (5 M. fortuitum group, 3 M. mucogenicum, 3 M. abscessus, and 3 M. chelonae strains) (131). These investigators showed reproducible identification, with unique mass spectral profiles of all 14 strains of the RGM, extending the work of the previous studies by Hettick et al. (129, 131). Although Lefmann et al. identified 24 clinical and 12 type strains of mycobacteria (including 9 strains of the M. tuberculosis complex) by using MALDI-TOF MS, they only tested two clinical and two type strains of RGM, and their strategy entailed initial PCR and transcription-RNase cleavage steps, unlike the systems currently being evaluated (132).

Today’s MALDI-TOF MS systems are more easily incorporated into the routine workflow of the laboratory and provide rapid and accurate identification of many strains of mycobacteria, as shown by Saleeb and colleagues (126). Currently, the two predominant commercial MALDI-TOF MS systems are the Bruker Biotyper (Bruker Daltonics, Billerica, MA) and bioMerieux Vitek MS (bioMerieux, Durham, NC) systems. The current systems also contain a spectral database and identification algorithms for the detection of conserved and microbe-specific peak patterns in whole-cell mass spectra (127). The most time-consuming portion of the current method for identification of mycobacteria is the inactivation and extraction procedure (126). Although MALDI-TOF MS is able to identify multiple species of
RGM, the method is still inadequate to distinguish closely related RGM species, including M. abscessus subsp. abscessus versus M. abscessus subsp. massiliense, and M. mucogenicum versus M. phocaicum (126). Just as for genetic sequencing methods, the importance of an extensive database for MALDI-TOF MS cannot be overemphasized. Most users are currently supplementing the available commercial databases with their own in-house-developed databases to allow species-level differentiation of a greater number of species of NTM (126).

Future applications suggested for MALDI-TOF MS include refinement of the databases, possible typing of organisms, detection of the absence or presence of specific proteins associated with virulence and antimicrobial resistance, and development of methods for direct detection and identification from clinical samples (127).

**TYPING SYSTEMS**

**Pulsed-Field Gel Electrophoresis**
Pulsed-field gel electrophoresis (PFGE) is the most widely used method for molecular strain typing of the RGM. Although PFGE has never been standardized for RGM, most investigator groups (concur that small (2 or 3 bands) differences between isolates indicate that the isolates are closely related; differences of 4 to 6 bands indicate that the strains are possibly related, and differences of ≥ 7 bands indicate that the isolates are genetically different (16, 82, 84, 133). Because unrelated strains of most RGM contain highly diverse PFGE patterns, this technique has been useful in epidemiological investigations. With the addition of thiourea as a modification of the original method, it is now possible to obtain reliable results by PFGE for all species of RGM, including isolates previously affected by DNA degradation (134, 135). Recent studies have shown that DNA smear patterns of previous isolates are correlated with the presence of *dnd*, a DNA degradation gene (136).

**Random Amplified Polymorphic DNA PCR**
In the random amplified polymorphic DNA PCR (RAPD-PCR) method, using one arbitrary primer and low-stringency conditions, the primer hybridizes to both strands of template DNA where it is matched or partially matched, resulting in strain-specific heterogeneous DNA products. Zhang and colleagues applied the RAPD-PCR or arbitrarily primed PCR analysis method to compare strains of *M. abscessus* (134). They were able to confirm several previous observations about prior nosocomial RGM outbreaks, including a 1988 epidemic of otitis media due to aminoglycoside-resistant *M. abscessus* in children with prior tympanostomy tubes, as well as a cardiac surgery outbreak (1, 134).

**VNTR Analysis**
The development of strain typing methods using VNTR would be valuable for helping to explain differences between isolates from chronic new infections and relapse infections. Blauwendraat and colleagues also indicated that the method would show whether or not cross-infection occurs and, moreover, enable prospective studies of strains of the *M. abscessus* complex correlated with clinical outcomes (98). Recently, Wong et al. (137) described a VNTR typing assay (MavA) using 18 tandem repeats in the *M. abscessus* genomic sequence, which was found to be superior to multilocus sequencing, with 100% typeability, 100% locus stability, and 100% reproducibility.

**Repetitive-Sequence-Based PCR**
A commercial system, DiversiLab system (bioMerieux, Durham, NC), is available for strain typing of organisms, including mycobacteria, by using repetitive elements interspersed throughout the genome. The system electrophoretically separates repetitive-sequence-based PCR (rep-PCR) amplicons on microfluidic chips to provide computer-generated readouts. The discriminative power has been reported to equal or exceed that of standard restriction fragment length polymorphism analysis for some species of mycobacteria, with a smaller sample size than that for standard PFGE, and in a much shorter time frame (114, 138). Limitations of the system include the lack of an extensive established database and the cost of the system.

**Enterobacterial Repetitive Intergenic Consensus PCR (ERIC PCR)**
Enterobacterial repetitive consensus sequences are repetitive elements distributed along the bacterial chromosome, at intergenic regions of polycistronic operons or flanking open reading frames. The method was recently evaluated with isolates of the *M. abscessus*/*M. chelonae* complex and with isolates of *M. fortuitum* (87, 139). Typing of isolates by ERIC PCR works in mycobacteria as a RAPD PCR because the presence of ERIC repeats has never been demonstrated in available *Mycobacterium* genomes, and amplification with appropriate ERIC primers can occur in the absence of genuine ERIC sequences (139). In a study of outbreak strains of *M. abscessus* in Brazil, ERIC PCR showed higher discriminatory power than PFGE for typing of strains which had shown smear patterns with PFGE using thiourea (139), although this method was not as discriminatory when testing isolates of *M. fortuitum* (87, 139).

**SEROLOGIC TESTS**
Serologic classification of mycobacteria has been attempted starting in 1925 with *M. avium* complex. However, serotyping has not been suitable for routine species identification of mycobacteria including the RGM and early studies served to emphasize the complexity of the antigenic composition of mycobacteria with many antigens shared by more than one species (140).

**ANTIMICROBIAL SUSCEPTIBILITIES**
Several different methods have been used for susceptibility testing of RGM for clinical purposes. These methods include agar disk diffusion, broth microdilution, agar disk elution, and E-test. Each method has proved useful but none of the methods were well standardized until 2003 with the publication of the Clinical and Laboratory Standards Institute (CLSI) guidelines (141). In the M24A document, the CLSI recommended broth microdilution as the reference method for susceptibility testing of the RGM (142). Nine antimicrobials including amikacin, cefoxitin, ciprofloxacin, clarithromycin, doxycycline, linezolid, imipenem, sulfamethoxazole and tobramycin have been recommended for testing and breakpoints have been established for these agents. A recent tentitive CLSI guideline revision to include additional agents such as moxifloxacin, meropenem, minocycline, and trimethoprim-sulfamethoxazole has also been published (142).

Additionally, a change of the imipenem intermediate breakpoint from 8 μg/mL to 8–16 μg/mL has enabled reporting of this drug with isolates of *M. abscessus* and *M. chelonae* which was not previously recommended (142).
BACTERIOLOGY

Briefly for the broth microdilution method, drug dilutions are prepared using serial 2-fold dilutions of cation-adjusted Mueller-Hinton broth. Suspensions of organisms are prepared to match a 0.5 McFarland turbidity standard. The suspensions are then diluted to a concentration of approximately \(10^6\) CFU/ml. From that suspension, 100 µl is delivered into the wells of a 16-well microtiter plate with a final concentration of approximately \(10^4\) CFU/well (142). MICs are optimally read after incubation at 30°C for 3 days.

Several specific recommendations about test results have also been made. Tobramycin should only be reported for isolates of \(M.\) chelonae. Any RGM isolate with an amikacin MIC of \(\geq 64\) µg/ml should be retested and/or sent to a reference laboratory in order to confirm resistance (although mutational resistance involving the 16S rRNA gene does occur). Also, if any isolate of the \(M.\) fortuitum group has an imipenem MIC >8 µg/ml, this should also be repeated with careful attention paid to inoculum density and a maximum incubation time of 3 days because of the instability of imipenem over time.

A caveat that is the MICs of sulfamethoxazole and trimethoprim-sulfamethoxazole are read using 80% inhibition growth as the susceptibility endpoint not 100% inhibition as is used for the other antimicrobials. Overinoculation of the MIC panels is often most obvious with sulfonamides. An inexperienced laboratorian may interpret the sulfonamide MIC as resistant when in reality the inoculum was too heavy. Rarely isolates of the \(M.\) fortuitum group are resistant to sulfonamides. If an isolate in this group is found resistant, a repeat test with lower inoculum is warranted (142).

The recent finding of the presence of a functional \(erm\) gene that induces macrolide resistance in many isolates of the \(M.\) fortuitum group, and \(M.\) abscessus subsp. abscessus but not \(M.\) chelonae or \(M.\) abscessus subsp. massiliense also has made changes to the manner in which clarithromycin reporting should be done (94, 95). A major revision to the CLSI document has been added to recommend an initial 3-day reading of MICs followed by a final reading at 14 days (unless the isolate becomes resistant before that time) to detect a functional \(erm\) gene in RGM isolates (142). The significance of the finding of these genes has not yet been assessed in clinical trials. However, a recent landmark study in Korea among 64 patients with \(M.\) abscessus subsp. abscessus and 81 patients with \(M.\) abscessus subsp. massiliense lung disease showed that approximately 80% of the patients with \(M.\) abscessus subsp. massiliense could be successfully treated with a macrolide containing multidrug regimen in contrast to only about 20% of the patients with \(M.\) abscessus subsp. abscessus (64). The investigators suggested that inducible resistance to clarithromycin could explain the decreased efficacy of clarithromycin containing antibiotic regimens against \(M.\) abscessus lung disease (64).

A 2012 study by Choi and colleagues has also shown other susceptibility differences between \(M.\) abscessus subsp. massiliense (143). These investigators observed evidence of \(\text{in vitro, ex vitro, and in vivo} \)activity of moxifloxacin and two macrolides, clarithromycin and azithromycin, against \(M.\) abscessus and \(M.\) abscessus subsp. massiliense (143). When moxifloxacin was combined with a macrolide against \(M.\) abscessus, antagonism (defined as fractional inhibitory concentration (FIC) >2) was observed in 65.4% (7/26) strains with clarithromycin and 46.2% (12/26) with azithromycin in vitro. Similar results were seen in macrophage cultures and a murine model. In contrast, however, either indifferent (FIC 0.5 and <2) or synergistic (FIC \(\leq 0.5\)) effects of the same combinations were seen in strains of \(M.\) abscessus subsp. massiliense. These findings may help to further explain the differences in efficacy of macrolide-moxifloxacin treatment regimens against \(M.\) abscessus and \(M.\) abscessus subsp. massiliense (144). Further details of the antimicrobial susceptibility method and guidance for patient therapy may be found in chapter 76.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Dramatic taxonomic changes largely attributed to the advent of molecular testing, have occurred over the past 10 to 20 years. Multiple new species have been introduced and some former subspecies have attained species status. Of the more than 70 valid species of RGM currently described, almost half have been described within the past 10 years.

The recommended species identification methods are evolving, with declining interest and efficiency of phenotypic testing including HPLC and increasing availability and accuracy of molecular methods. Phenotypic tests have limited utility (e.g., citrate utilization to separate \(M.\) chelonae from \(M.\) abscessus), and as \(M.\) fortuitum, which is rarely considered a pathogen except in the setting of achalasia or lipoid pneumonia, may also be recovered from respiratory samples. The pathogenic potential of the RGM is generally related to clinical findings (unexplained fever, dimorphic inflammatory lesions, etc.), immune status of the patient, number of positive cultures, quantity of organisms in the sample recovery from smear positive samples, and sources of the recovered species. Some established and newly described species have been identified from environmental samples but as yet not identified as human or animal pathogens (89). These factors emphasize the necessity to perform species level identification and susceptibility testing on clinically significant isolates of RGM. Furthermore, isolates recovered from a single sample are less likely to be significant than those from multiple samples.

When species identification of a clinically significant isolate is not available (i.e., susceptibility may be finalized prior to identification of species), MICs should be reported for antimicrobials as recommended by the CLSI. An identification such as “Rapidly growing Mycobacterium sp,” may be acceptable until identification has been performed. However, the report should include a caveat that tobramycin is reported only for \(M.\) chelonae (142).

When MIC results are reported, an interpretation of MIC values (i.e., “susceptible,” “intermediate,” or “resis-
tant”) should be given for each antimicrobial for which there are recommended breakpoints (142). For agents such as tigecycline where no breakpoints have been recommended, an MIC value with a notation that “no CLSI breakpoints have been established for this species” should accompany the report. Moreover, because of the documented lack of efficacy for the use of first-line tuberculosis drugs (i.e., ethambutol, rifampin, isoniazid), laboratories should not report MICs for these agents against RGM (92).

Furthermore, for cultures that remain positive for the same species after 6 months of appropriate antimicrobial therapy, confirmation of species identification by molecular methods and repeat antimicrobial susceptibility testing is warranted (142).

Although recent advances in antimicrobial therapies including the new macrolides, fluoroquinolones, oxazolidinones and tigecycline have enhanced the therapeutic options and the prognosis for RGM disease, there is still a compelling need for the development of more efficient, effective, and safe oral antimicrobials for treatment. For example, M. abscessus subsp. abscessus lung disease is generally considered incurable with the currently available antimicrobials. Susceptibility testing of the RGM is necessary in order to select optimal antimicrobial therapy and to monitor the development of mutational drug resistance which may occur with the prolonged therapy required for RGM disease.

REFERENCES

This chapter describes the approaches used to identify Gram-negative rods, with emphasis on the greater difficulty in identifying non-glucose-fermenting organisms. We present a scheme to identify these organisms centered around three enzymatic activities, i.e., oxidase, trypsin (benzyl-arginine aryiamidase or benzyl-arginine aminopeptidase), and pyrrolidonyl aminopeptidase. These enzymatic reactions are fast and easy to interpret, and they are stable markers in almost all taxa discussed; i.e., there are few species for which these tests yield variable intraspecies results.

Before presenting the identification scheme, several issues of terminology and methodology need to be addressed. First, the use of only the substrate name to designate a biochemical test is imprecise and can lead to confusion. We suggest referring to the specific activity of the biochemical test. For example, we use “gelatin hydrolysis” or “gelatinase” instead of “gelatin” to indicate that the test demonstrates the degradation of and not the production of gelatin.

The term “production” is used when a specific metabolic product is sought, as in the case of indole, which is produced as a degradation product of tryptophan. The term “hydrolysis” is used when it is the disappearance of the substrate (and not the appearance of a degradation product) which is being demonstrated. For instance, tyrosine is present as a granulous deposit in agar, and a clearance zone is observed around the colonies or streak when tyrosine is hydrolyzed.

Although all biochemical tests rely on the presence of enzymes, the term “enzymatic activity” is used for tests in which a bacterial suspension is added to a substrate and the enzymatic activity is read without the need for bacterial growth. Enzymatic activity is detected by (i) a chromogenic shift of the substrate, e.g., by the degradation of colorless o-nitrophenyl-β-D-galactopyranoside (ONPG) by β-galactosidase, which results in liberation of o-nitrophenol, a yellow compound; (ii) by the color change of a pH indicator added to the suspension, e.g., phenol red for assessing tributyrate esterase activity; or (iii) by another indicator of enzymatic activity that causes a color change by interacting with the enzymatic product (e.g., Griess reagents turn red after interacting with nitrite [nitrate reductase activity], Kováč’s reagents turn red after interacting with indole [indole production], or cinnamaldehyde turns orange to pink after interacting with free β-naphthylamine [aminopeptidase activity]).

This chapter also uses precise terminology for the terms “utilization,” “oxidation,” and “glycolysis.” “Utilization” is not a precise term to address either assimilation or the usage of any substrate being metabolized, and therefore we avoid using it. “Oxidizer” is often used to describe saccharolytic nonfermenters as opposed to asaccharolytic nonfermenters. However, in strict biochemical terminology, it refers to oxidative phosphorylation as opposed to fermentation as an alternative route after glycolysis. In this chapter, we do not use the term “oxidation” to mean “saccharolysis,” but we specifically use the term “acidification of carbohydrates” or “saccharolysis.” In addition, we avoid the use of “glycolysis” for “saccharolysis,” because “glycolysis” may be interpreted as referring to the acidification of glucose only or can be understood as the biochemical metabolic cycle preceding fermentation or respiration.

TEST METHODS WITH EMPHASIS ON GRAM-NEGATIVE NONFERMENTERS

Careful attention to testing methods is critical when describing their application to nonfermenters. Slight variations of reagents or incubation conditions can cause numerous misidentifications and have caused erroneous descriptions of new species. Also, although several media and biochemical tests are used for the identification of fermenting Enterobacteriaceae, these are not necessarily optimal when testing nonfermenters. Nonfermenters require good aeration because of their strict respiratory metabolism, most often with atmospheric oxygen as the terminal electron acceptor. The growth of most nonfermenters in liquid media is moderate or weak due to the intrinsically poor aeration of liquid media. Therefore, a small inoculum such as that used for Enterobacteriaceae is not appropriate. Instead, liquid media should be inoculated with a turbid suspension of nonfermenters. Whenever bacterial growth is not required, as with testing enzymatic activity, it is preferable to use a heavy suspension of bacterial cells in an aqueous solution of the substrate rather than to inoculate a liquid medium. Further detailed remarks can be found below where the different biochemicals used for identification are described.

*This chapter contains information presented in chapter 31 by Georges Wauters and Mario Vaneechoutte in the 10th edition of this Manual.
Below we briefly describe some specific tests or modifications used in the identification algorithms of this chapter and of chapter 44 and highlight protocols that should be followed when these tests are performed and their results are interpreted, with an emphasis on their application to nonfermenters. The descriptions of the other tests discussed in this chapter can be found in chapter 19.

**Assimilation or Utilization of Organic Compounds as the Sole Carbon Source for Growth**

Different approaches exist to determine the capacities of strains to assimilate, i.e., utilize organic compounds as the sole carbon source for growth. Microbial ID/Characterization (Biolog, Hayward, CA) and API NE and API 32GN (BioMérieux, Marnes-la-Coquette, France) are commercial systems that score growth by assessing the optical density of the minimal broths to which the organic compound has been added. Another method to assess the assimilation of an organic compound as the sole carbon source is to observe the alkalization of a minimal medium to which the sole carbon source and a pH indicator have been added. Therefore, the term “alkalization” is frequently used as synonymous to the term “assimilation,” although “assimilation” may be preferred as a more general term (see below). Simons’ citrate agar base medium is frequently used, with bromothymol blue as the pH indicator (yellow at pH 6.0, green at pH 6.9, and blue at pH 7.6). Citrate as the sole carbon source can be replaced by any compound to be tested (1). For most substrates, the medium is also alkalized as a result of the production of hydroxyl radicals and CO$_2$ by the metabolism of the sole carbon source added. Because CO$_2$ can escape, the remaining radicals alkalize the medium. Therefore, it is essential that the tubes be incubated with a loose lid to allow the carbon dioxide to escape. Alkalization facilitates the interpretation, but as stated above, growth without alkalization can occur with some substrates and should be interpreted as assimilation positive, as well.

In this chapter, we limit the description of assimilation assays for the identification of nonfermenters to assays for acetamide and acetate, used solely as additional characteristics to differentiate between some species. However, as described in chapter 44, Acinetobacter identification has been based largely on assimilation tests by supplementing the basal mineral medium of Cruze et al. (2) with a 0.1% (wt/vol) concentration of the carbon source. We refer the reader to that chapter for basal medium composition, inoculation, and interpretation.

**Acid Production from Carbohydrates or Sugars: Saccharolysis**

The term “acid production” may refer to acidification of a carbohydrate by fermenters as well as by nonfermenters. For diagnostic purposes, while there is no need to differentiate between these modes of acid production (fermentation or oxidation), it is important to distinguish acidification from assimilation. Assimilation is tested on minimal media lacking all carbon sources except the one tested for utilization, whereas more-complex media (peptone-rich media) aimed at supporting the optimal growth of the organism tested are used to assess the acidification of the single carbohydrate substrate added.

Except with the strong acid producers *Pseudomonas aeruginosa* and *Acinetobacter* spp. and some rare species, like those of the genus *Asaia*, acid production by nonfermenters is usually much weaker than acid production by fermenters. Nonfermenters acidify only as a result of their general metabolic activity; this usually leads to weaker acidification than fermentation, which produces strong acids like lactic acid. Nonfermenters acidify only under well-aerated incubation conditions. Therefore, the conditions to assess this weaker acidification by nonfermenters should be optimized to avoid false-negative results. API kits, like API 20 E (Enterobacteriaceae), API 20 NE (non-Enterobacteriaceae), and API ID 32 GN (Gram negatives), are not suited to detect the acidification of carbohydrates by nonfermenters. API 20 NE and API ID 32 GN only score assimilation, which, as already stated above, is sometimes confused with acidification. Two examples are presented to emphasize this point. The results of carbohydrate acidification for *Chryseobacterium caeni* N4T, obtained by Kämpfer et al. (3), were substantially different from the original description of this species (4). Quan et al. (4) described *C. caeni* as an asaccharolytic species, whereas Kämpfer et al. (3) found the type strain of this species to be one of the most saccharolytic strains among the members of the *Chryseobacterium* genus, rapidly acidifying glucose, maltose, sucrose, trehalose, and L-arabinose. This contradiction may be explained by the fact that Quan et al. (4) used the API 20 E, API 20 NE, and API 32 GN galleries to assess the acidification of carbohydrates. Another example comes from the description of *Ralstonia insidiosa* (5), which mentions that no acid is produced from glucose, sucrose, or lactose when the organism is tested with RapID NF Plus (Remel) and API 20 NE (BioMérieux), whereas this species clearly acidifies glucose, L-arabinose, D-xylene, and maltose (6).

Because acid production from carbohydrates by nonfermenting Gram-negative rods results in a weaker pH change than that caused by fermentation, the medium and incubation conditions should be optimized to detect the weak acid production. This can be achieved by (i) heavy inoculation; (ii) good aeration; (iii) using media with only small amounts of peptones, because nonfermenters’ aerobic metabolism promotes alkalization and neutralizes the (weak) acidification; and (iv) using media with an appropriate pH indicator.

The oxidation/fermentation medium, with its low peptone content of 0.1%, as originally described by Hugh and Leifson (7), is widely used for this purpose, but acidification of carbohydrates by nonfermenters is better demonstrated on slanted solid media. Ammonium salt agar (ASA) has been recommended (8), but better results can be obtained with low-peptone phenol red (LPPR) agar, as originally described for testing the acidification of ethylene glycol (9). The slant is heavily inoculated, and the medium is incubated for up to 7 days. LPPR agar is more sensitive to acidification of a substrate than ASA, because it is not buffered and because phenol red shifts color to yellow already at pH 6.8, whereas ASA is buffered and the indicator used, i.e., bromocresol purple, shifts only when the pH has dropped to as low as 5.2.

Acid production from the sugar alcohol ethylene glycol, best tested on LPPR agar with 2% ethylene glycol (9), is interesting for the identification of nonfermenters, because it is independent of acid production from sugars. This method is helpful in identifying species that acidify ethylene glycol but not sugars, such as *Alcaligenes faecalis*, *Oligella* spp., and *Kersteria gyiorum*. Conversely, species like *Burkholderia* spp. and *Ralstonia pickettii* acidify sugars but not ethylene glycol.

**Arginine Dihydrolase**

Arginine dihydrolase activity by nonfermenters can best be tested by dense inoculation (McFarland standard, 4 to 5) in Moeller broth with 1% arginine. After inoculation, the broth is overlaid with paraffin oil. Alkalization, caused
by the production of ammonia, is detected by the pH indicators. A positive result is indicated by a purple color, which can be read after 4 h to up to 2 days. These enzymatic reactions can proceed in the absence of oxygen and therefore are not hampered by the presence of paraffin, which is needed to prevent false-positive alkalization of the broth due to aerobic metabolic pathways, like peptone metabolism. This is a problem especially when prolonged incubation is needed, as is the case with some *Haemophilus* strains.

**Esulin Hydrolysis**

Esulin hydrolysis by nonfermenters is preferably tested on esulin agar without bile, because bile can inhibit some nonfermenters, such as *Moraxella* spp. Broad streak inoculation should be applied. Strains positive for esulin hydrolysis cause a blackening of the agar after overnight incubation.

**Flagellum Stains**

The detection of flagella is very useful for the identification of some groups of nonfermenters that are otherwise biochemically very similar. Since flagellum staining and microscopy require additional efforts, we limit their use to those species that cannot be differentiated by other methods. There are several types of flagellation. The genera *Achromobacter*, *Alcaligenes*, *Bordetella*, and *Cupriavidus*, including *Cupriavidus gilardii* (originally described as polar [10]), have peritrichous flagella (9). *Ochrobactrum* and *Rhizobium* spp. also exhibit peritrichous flagella, but they frequently have only one or two lateral flagella. *Pseudomonas aeruginosa*, *Pseudomonas stutzeri*, *Pseudomonas alcaligenes*, *Pseudomonas pseudoalcaligenes*, *Pseudomonas oryzihabitans*, the genera *Brevundimonas* and *Shewanella*, *Ralstonia pickettii*, and *Pseudomonas paucimobilis* have polar monotrichous flagellation. In the last two species, the flagella are rarely detected. *Pseudomonas putida*, *Pseudomonas fluorescens*, *Pseudomonas luteola*, the *Burkholderia cepacia* group, and *Stenotrophomonas maltophilia* have polar multitrichous flagella, and the genera *Comamonas*, *Delftia*, and *Herbaspirillum* have bipolar multitrichrous tufts.

We have found that flagella are best stained as follows (adapted from the work of Kodaka et al. [11]). Ten volumes of solution A [10 ml of 5% phenol, 2 g of tannic acid, and 10 ml of KAl(SO$_4$)$_2$·12H$_2$O (saturated solution)] are mixed with 1 volume of solution B (12 g of crystal violet in 100 ml of 96% ethanol). The mixture is allowed to stand first for 2 to 3 days, without filtration, centrifugation, or shaking. This stain can be used for up to 1 year when stored at room temperature. Staining is carried out by making a suspension with a density of <0.5 McFarland standard from fresh colonies on tryptic soy agar (TSA) in a mixture of 50% ethanol and 70% tap water, briefly heating a coverslip (24 by 60 mm) (not a microscopic slide) by holding it in a flame, and adding a small drop (5 μl) of the suspension. This drop spreads spontaneously and is allowed to dry. The staining solution is added for 1 to 4 min (longer for longer-stored staining solution), and the coverslip is rinsed with tap water and allowed to dry in an incubator. Pritt glue is applied to the coverslip for better adherence, and the coverslip is then placed onto a slide, with the colored face upward. It is observed under a ×100 magnification.

**Flexirubin Pigment Production**

Flexirubin pigment production can be assessed for yellow-pigmented colonies of the *Flavobacteriaceae*. A small mass of bacterial cells is collected with a loop and deposited in a drop of a 20% KOH solution on a slide; a red color indicates the presence of flexirubin pigments (8). *Sphingomonas paucimobilis* produces yellow colonies, but not flexirubin, whereas most *Myroides* strains produce weakly yellow colonies and are always flexirubin positive.

**Gelatin Hydrolysis**

Gelatin hydrolysis is best assessed by means of the plate method. Incubate the plate (nutrient agar plus 0.4% gelatin) with a spot or a streak and incubate until luxuriant growth is obtained. When the isolate is gelatin hydrolysis positive, visual clearing of the agar is usually obvious. If it is not, add an HgCl$_2$ solution (12 g of HgCl$_2$, 16 ml of HCl [35%], and 80 ml of distilled water [dH$_2$O]) and observe the clearing. The use of HgCl$_2$ solution is generally avoided because of its high toxicity.

**Growth at 41°C**

Growth at 41°C should be tested by adding 1 drop of a small inoculum (e.g., as for swabbing susceptibility testing plates) in broth tubes incubated in a warm water bath, with a precision of ±0.1°C. Care should be taken that the broth is still completely clear, i.e., not turbid at all, after inoculation. Use of 1.5 to 2 ml of tryptic soy broth (TSB) with a maximal air surface (e.g., in tubes of 16 mm) instead of 5 ml is preferred for better aeration and optimal growth of nonfermenters. The test is read as positive when growth, observed as the presence of any turbidity, occurs. The use of a positive-control tube at 37°C is recommended to exclude the possibility that negativity for growth at 41°C is caused by a general loss of viability.

**H$_2$S Production or Sulfite Reductase Activity**

H$_2$S production or sulfite reductase activity is best tested on Kliger's iron agar (KIA), containing thiосulfate and Fe salt. The H$_2$S produced from thiosulfate by sulfite reductase will react with the Fe salt to produce FeS, a strong black precipitate which for clinically relevant nonfermenters is observed only for *Shewanella* species. Lead acetate paper, held over the medium to detect evaporating H$_2$S fumes, is not very useful. This method detects the weak production of H$_2$S from the amino acids methionine and cysteine. This reaction is widely observed among *Enterobacteriaceae* and is therefore not very discriminative. (Note that when this reaction is present with nonfermenters, the observed result is usually weak and can yield variable or false-negative results.) Amino acid-derived H$_2$S production is too weak to be detected on KIA.

**Indole Production**

Indole production can be detected by different methods. The broth growth method includes inoculation of a broth culture, e.g., heart infusion broth, incubation for 48 h, extraction with xylene, and addition of Ehrlich's reagent (see chapter 19). However, as is the case for the spot indole test (see chapter 19), the broth growth method is not advisable for nonfermenters, because it may lack sensitivity and may be difficult to interpret, yielding a false-negative result for indole production. For example, *Flavobacterium mizutaii*, which is clearly positive for indole production, was described as negative (12), because indole production was assessed using the broth growth method. Similarly, *Elizabethkingia meningoseptica* is mentioned as only 50% indole production positive (13), but using the heavy-suspension method, we have never encountered an *E. meningoseptica* isolate that was negative for indole production. In general, most members of
the genera Chryseobacterium, Elizabethkingia, and Empedobacter are indole positive, but this reaction is sometimes weak and difficult to demonstrate by conventional broth methods. Therefore, we recommend a simple, rapid, growth-independent method for demonstration of indole production. A heavy suspension (4 to 5 McFarland standard) is prepared in a 0.3% tryptophan solution in dH₂O. After 3 to 4 h of incubation, indole is detected by adding Kovac’s reagent (for its composition, see chapter 19). This method allows detection of all indole-producing nonfermenting Gram-negative rods within a short time.

**Motility**

Motility can easily be determined by microscopic observation of a wet-mount preparation of a young colony from an agar plate. Motility can be studied by inoculation of sulfide-indole motility (SIM) medium, described in chapter 19. Another culture method, circumventing the need for microscopy, uses inoculation of a large inoculum of a fresh culture in soft agar (0.3% agar), preferably in a small petri dish (5-cm diameter); this provides better aeration than tubes, reducing the potential for false-negative results. For some species, such as *Sphingomonas*, motility can best be demonstrated after incubation of cultures at room temperature, instead of the usual 30 to 35°C for other nonfermenters.

**NaCl Requirement**

Most commercially available basic media (like TS1) already contain NaCl and should not be used to assess the requirement for NaCl. It is best to use well-aerated tubes with peptone water, i.e., an aqueous solution of 1% tryptone or Casitone, without NaCl rather than peptone water to which 1% NaCl has been added. Because one is testing the ability of an organism to grow under these conditions, a small inoculum should be used to allow facile detection of turbidity. Also, care should be taken that the inoculum is prepared from a suspension in dH₂O or 1% peptone water without NaCl. The halotolerance of isolates can be studied using peptone water containing increasing concentrations of NaCl, up to 12%.

**Nitrite and Nitrate Reductase Activities**

Nitrite and nitrate reductase activities can be determined together in nitrate broth (see chapter 19), but for nonfermenters, they are best determined by heavy inoculation of separate nitrate and nitrite broths, in which (after incubation) the presence of nitrite is detected by the addition of Griess reagents and, eventually, of zinc dust.

Nitrate can be reduced to nitrite by nitrate reductase, and nitrite can be reduced by nitrite reductase to either nitrogen gas (N₂) or ammonium for assimilation into amino compounds. Some species reduce only nitrate, others reduce both nitrate and nitrite, and a few may reduce nitrite without reducing nitrate.

Nitrate reduction to nitrite by nitrate reductase is best detected in 0.5 or 1 ml of 0.1% KNO₃ broth (for prolonged incubation) or aqueous solution (4 h), using a turbid inoculum (McFarland standard of 4 to 5). The organism is positive for nitrate reductase activity when the addition of Griess reagents (solution A first and then solution B) results in a pink color within 2 min, indicating the presence of nitrite, i.e., the reduction of nitrate to nitrite.

Nitrite reductase activity can be tested by adding a very heavy inoculum (McFarland standard of 8 to 10) to a small volume, e.g., 0.5 or 1 ml, of nitrite broth (0.001% NaNO₂ in 1% peptone). The organism is positive for nitrite reductase activity when, after 4 to 24 h of incubation, the addition of Griess’ reagents results in a colorless solution, indicating the absence of nitrite, i.e., the reduction of nitrite to N₂, or ammonium.

In summary, certainly for nonfermenters, it may be advisable to use separate nitrate and nitrite broths, to eventually add a Durham tube to the nitrite broth (instead of to the nitrate broth, as is usually done), and to add zinc dust to the nitrate broth (the last only for strains for which both nitrate and nitrite broths remain colorless after the addition of the Griess reagents). Interpretation can be done according to Table 1 in chapter 19 of the previous edition of this Manual (17).

**Pyrolidonyl Aminopeptidase (Pyrolidonyl Arylamidase) Activity**

Pyrolidonyl aminopeptidase (pyrolidonyl arylamidase) activity has been shown to be very helpful in the identification of nonfermenters (14, 15) and is a central characteristic, together with oxidase and trypsin, in the identification scheme proposed here. The test is described in chapter 19.

**Starch Hydrolysis**

Starch hydrolysis is tested by inoculation onto Mueller-Hinton agar (MHA), which contains starch. Flooding with iodine solution (low) yields a purple-blue color in the presence of starch. Starch hydrolysis is read as a non-purple-stained zone around the streak.

**Susceptibility to Colistin**

Susceptibility to colistin can be tested on common agars, using 10-μg colistin disks. For diagnostic purposes, any zone of inhibition is interpreted as susceptible.

**Susceptibility to Desferrioxamine**

Susceptibility to desferrioxamine, an Fe chelator, can be tested on MHA (or on TSA for strains growing poorly on MHA) by using paper disks loaded with 250 μg of desferrioxamine or by using commercially available Rosco tablets (15). Media should not contain blood, because this provides large amounts of bioavailable Fe, which, in turn, causes false-positive resistance results. Any inhibition zone is interpreted as susceptible.

**Susceptibility to Vancomycin**

Susceptibility to vancomycin is tested by disk diffusion, using 30-μg vancomycin disks. Some Gram-negative organisms are vancomycin susceptible, and this can be used as a rapid and distinctive identification tool.

**Trypsin or Benzyl-Arginine Arylamidase Activity**

Trypsin or benzyl-arginine arylamidase activity is very discriminative for nonfermenters, since the strains of almost all taxa exhibit an all-or-nothing positive result, providing a test with high discriminatory value. Therefore, this test can act as a first step in identification. Testing for trypsin activity is described in chapter 19, but the procedure is also easily performed by adding a trypsin tablet (Rosco) to a dense bacterial suspension in 0.5 ml of dH₂O, the results of which can be read within 4 h of incubation by the addition of cinnamaldehyde [see “Pyrolidonyl Aminopeptidase (Pyrolidonyl Arylamidase) Activity” above] (15).

**IDENTIFICATION SCHEME AND IDENTIFICATION TABLES**

Below, we outline a proposal for rapid and simplified biochemical testing, with emphasis on the identification of
TABLE 1  Dichotomous identification algorithm for Gram-negative bacteria with poor or no growth on SBA

1a. Growth on SBA p → 2
1b. Growth on SBA n → 3
2a. Cells are tiny coccobacilli → 3
2b. Cells are diplococci or coccobacilli → Neisseria, except Neisseria gonorrhoeae (chapter 34), Moraxella (chapter 44)
2c. Cells are fusiform rods → Capnocytophaga (chapter 35)
2d. Cells are rods → 4
3a. Urease p → Brucella spp. (chapter 47)
3b. Urease n → 4
4a. Oxidase n → Francisella (chapter 46)
4b. Oxidase p → 5
5a. Hydrogen sulfide production on KIA p → Francisella philomiragia (chapter 46)
5b. Hydrogen sulfide production on KIA n → Bordetella spp. (chapter 45)
6a. Colony color pink → Asaia, Azospirillum, Methylobacterium, Roseomonas (chapter 44)
6b. Colony color other → 7
7a. Cauliflower-like colonies → Bartonella (chapter 48)
7b. Other colonies → 8
8a. Ornithine decarboxylase p, acidification of glucose n → Eikenella (chapter 35)
8b. Ornithine decarboxylase n, acidification of glucose p → 9
9a. Acidification of lactose p → 10
9b. Acidification of lactose n → 11
10a. Acidification of xylose p, sucrose n → Dysgonomonas (chapter 35)
10b. Acidification of xylose n, sucrose p → Aggregatibacter aphrophilus (chapter 35)
11a. Acidification of sucrose p → 12
11b. Acidification of sucrose n → 13
12a. Alkaline phosphatase p → Suttonella (chapter 35)
12b. Alkaline phosphatase n → Cardiobacterium (chapter 35)
13a. Catalase p → Aggregatibacter actinomycetemcomitans (chapter 35)
13b. Catalase n → Simonsiella (chapter 35)
14a. Regan-Lowe agar or Bordet-Gengou agar required for growth → Bordetella pertussis (chapter 45)
14b. Chocolate agar required for growth → 15
14c. Buffered charcoal yeast extract agar required for growth → 18
14d. Brain heart infusion agar with serum required for growth → 19
15. Chocolate agar required for growth
16a. Cells are diplococci or coccobacilli → Neisseria gonorrhoeae (chapter 35)
16b. Cells are bacilli → 16
17a. Requirement for hemin (X) and/or adenine dinucleotide (V) p → Haemophilus (chapter 36)
17b. Requirement for hemin (X) and/or adenine dinucleotide (V) n → Francisella (chapter 46)
18a. Cells are long rods → Legionella (chapter 49)
18b. Cells are regular rods → Francisella (chapter 46)
19a. Cells are pleomorphic, bent filamentous rods → Streptobacillus (chapter 35)
19b. Cells are small rods → Bartonella, Afipia (chapter 48)

*a, positive; p*, weakly positive; n, negative; → [number], go to number indicated further on in the table; SBA, 5% sheep blood agar; KIA, Kliger’s iron agar.

Chapter numbers in parentheses indicate the chapters in which the organism(s) is described further in this Manual.

Gram-negative nonfermenters. Most nonfermenting Gram-negative bacteria of clinical relevance have an optimal growth temperature between 30 and 37°C and grow on simple media, such as TSA, MHA, and sheep blood agar (SBA). A few species, however, may grow better below 30°C (e.g., Methylobacterium), and some Moraxella species are more fastidious and require SBA at 37°C for optimal growth.

The scheme below makes it possible in most cases to record the following characteristics within 3 days, starting with KIA: growth on TSA, MHA, and/or SBA; oxidase; hydrogen sulfide production; fermentation of lactose and glucose; colony pigmentation; motility; susceptibility to colistin, desferrioxamine, and vancomycin; alkaline phosphatase; benzyl-arginine aminopeptidase (trypsin); pyrrolidonyl aminopeptidase; urease; β-galactosidase; indole production; nitrate reductase; nitrite reductase; lysine decarboxylase; arginine dihydrolase; and acidification of glucose, mannitol, xylose, and ethylene glycol. The reagents used can be prepared once each year and stored at 4°C.

For the sake of manageability, Advenella incenata (see chapter 45) and the species of the genus Pandoraea (see chapter 43) have not been included in this simplified scheme for aerobically growing Gram-negative bacteria. The extreme variability of the phenotypic characteristics within these species and the biochemical inactivity of some Pandoraea species would have rendered the scheme proposed here impractical. However, these species are listed below (see Table 5), and information on their characteristics has been filled out as completely as possible.

Gram-negative bacteria can be identified using the scheme below. It should be mentioned that Acinetobacter...
cells can stain Gram variable; sometimes one of two cells in a pair of diplococci is Gram negative and the other is Gram positive. Also, some phylogenetically Gram-positive bacteria may stain Gram negative, e.g., *Lactobacillus* *iners* and *Gardnerella* *vaginalis* (16). These have not been included in the scheme below. The scheme begins with observation of growth on SBA and takes advantage of observed pigment production.

Table 1 lists the organisms that are very fastidious and grow poorly or not at all on SBA. Species like *Acinetobacter parus* or most *Moraxella* spp. also grow poorly or slowly, but clearly visible colonies are formed after 48 h at 37°C; these are described below (see Table 4). The organisms that grow on SBA and that exhibit pink or purple colonies are included in Table 2. For those species that grow well on SBA and do not form pink or purple colonies, proceed according to the steps outlined below.

Day 1. Stab inoculate a KIA tube. Incubate overnight at 30 to 37°C.

Day 2. Interpret the KIA results (differentiate between fermenters and nonfermenters) as follows. If both the butt of the tube and the slant are yellow, the culture is positive for the fermentation of both lactose and glucose. Refer to Table 3 (glucose-fermenting Gram-negative organisms). If only the butt is yellow, the organism is negative for lactose and positive for glucose fermentation. Refer to Table 3. If there is no yellow color, the organism is negative for both lactose and glucose fermentation; i.e., the organism is a nonfermenter. Proceed with the testing outlined for day 3 below.

53a. Esculin hydrolysis n → *Brevundimonas diminuta*, partim pyrrolidonyl aminopeptidase n (80%) (chapter 43)
53b. Esculin hydrolysis p → 54
54a. Desferrioxamine R, vancomycin S → *Sphingomonas* spp., partim pyrrolidonyl aminopeptidase n (75%) (chapter 44)
54b. Desferrioxamine S, vancomycin R → *Brevundimonas vesicularis* (chapter 43)
55a. Nitrate reductase n → 56
55b. Nitrate reductase p → 58
56a. Desferrioxamine S, nitrite reductase p, arginine dihydrolase n, acidification of glucose n, of xylose n → *Alcaligenes faecalis*, partim trypsin p (30%) (chapter 45)
56b. Desferrioxamine R, nitrite reductase n, arginine dihydrolase p, acidification of glucose p, of xylose p → 57
57a. Gelatinase p → *Pseudomonas fluorescens*, partim pyoverdin production n (5%), partim pyrrolidonyl aminopeptidase n (40%), partim nitrate reductase n (80%) (chapter 42)
57b. Gelatinase n → *Pseudomonas putida*, partim pyoverdin production n (5%) (chapter 42)
58a. Starch hydrolysis p, cauliflower-like and often yellowish colonies → *Pseudomonas stutzeri* (chapter 42)
59a. Nitrite reductase p → 60
59b. Nitrite reductase n → 62
60a. Growth at 41°C n → *Pseudomonas fluorescens*, partim pyoverdin production n (5%), partim pyrrolidonyl aminopeptidase n (40%), partim nitrate reductase p (20%), partim nitrite reductase p (5%) (chapter 42)
60b. Growth at 41°C p → 61
61a. Gelatinase n, acidification of mannitol n, often yellowish → *P. mendocina* (chapter 42)
61b. Gelatinase p (80%), acidification of mannitol p (70%) → *P. aeruginosa*, partim pyoverdin production n (35%), partim pyrrolidonyl aminopeptidase n (5%), partim nitrate reductase p (5%), partim nitrite reductase p (95%) (chapter 42)
62a. Acidification of glucose p → 63
62b. Acidification of glucose n → 64
63a. Growth at 41°C p → *P. aeruginosa*, partim pyoverdin production n (35%), partim pyrrolidonyl aminopeptidase n (5%), partim nitrite reductase n (5%), or *P. pseudoalcaligenes*, partim acidification of glucose p (10%) (chapter 42)
63b. Growth at 41°C n → *Pseudomonas fluorescens*, partim pyoverdin production n (5%), partim pyrrolidonyl aminopeptidase n (40%), partim nitrate reductase p (20%), partim nitrite reductase n (95%) (chapter 42)
64a. Acidification of fructose p* → *P. pseudoalcaligenes*, partim acidification of glucose n (90%) (chapter 42)
64b. Acidification of fructose n → *P. alcaligenes* (chapter 42)
65a. Pyrrolidonyl aminopeptidase p → 66
65b. Pyrrolidonyl aminopeptidase n → 87
66a. Fastidious, small colonies on SBA, plump coccobacilli → *Moraxella atlantae* (chapter 44)
66b. Good growth → 68
67a. Desferrioxamine S → 68
67b. Desferrioxamine R → 69
68a. Urease p(p), nitrite reductase p, acidification of glucose p, of xylose p, colistin R → *Ralstonia pickettii* (chapter 43)
68b. Urease n, nitrite reductase n, acidification of carbohydrates n, colistin S → *Comamonas terrigena* (chapter 43)
69a. Lysine decarboxylase p → *Burkholderia cepacia*, partim pyrrolidonyl aminopeptidase p (50%) (chapter 43)
69b. Lysine decarboxylase n → 70
70a. β-Galactosidase p → *Herbaspirillum* spp. (chapter 55)
70b. β-Galactosidase n → 71
71a. Motility n → *Bordetella petrii* (chapter 45)
71b. Motility p → 72
72a. Nitrate reductase p → 73
72b. Nitrate reductase n → 81
73. Urease p(p), arginine dihydrolase p(p) → 74
73b. Urease n, arginine dihydrolase n → 75
74a. Gelatinase p → *Achromobacter acidovorans* (chapter 43)
74b. Gelatinase n → *Achromobacter delafeldii* (chapter 43)
75a. Colistin R → 76
75b. Colistin S → 77
76a. Acidification of mannitol p, of xylose n → *Delftia acidovorans* (chapter 43) (in addition, assimilation of acetamide p ↔ *Comamonas testosteroni* [chapter 43])
76b. Acidification of mannitol n, of xylose p → *Achromobacter xylosoxidans* (chapter 45)
77a. Nitrite reductase p → 78
77b. Nitrite reductase n → 79

Hydrogen sulfide production-negative, indole production-negative, oxidase-positive, Gram-negative nonfermenters; trypsin negative, pyrrolidonyl aminopeptidase positive

TABLE 4

Dichotomous identification algorithm for aerobically growing Gram-negative nonfermenters (strict aerobes)

(Continued)

78a. Acidification of glucose (p) → Acidovorax temperans (chapter 43)
78b. Acidification of glucose n → Achromobacter dextrithrix (chapter 45)
79a. Alkaline phosphatase p* → Cupriavidus gilardii, partim pyrrolidonyl aminopeptidase p (15%), partim nitratreductase p (50%) (chapter 43)
79b. Alkaline phosphatase n → 80
80a. Flagellation polar or bipolar → Comamonas testosteroni (chapter 43) (in addition, assimilation [alkalinization] of acetamide n ↔ Delftia acidovorans)
80b. Flagellation peritrichous → Achromobacter piechaudii (chapter 45)
81a. Acidification of glucose p, of xylose p → 82
81b. Acidification of glucose n, of xylose n → 84
82a. Acidification of mannitol n → Ralstonia insidiosa (chapter 43)
82b. Acidification of mannitol p → 83
83a. Acidification of ethylene glycol n, growth at 41°C p → Acidovorax wautersii (chapter 43)
83b. Acidification of ethylene glycol p, growth at 41°C n → Ralstonia mannitolilysitica (chapter 43)
84a. Urease p → Cupriavidus pauculus (chapter 43)
84b. Urease n → 85
85a. Alkaline phosphatase p* → Cupriavidus gilardii, partim pyrrolidonyl aminopeptidase p (15%), partim nitrate reductase n (50%) (chapter 43)
85b. Alkaline phosphatase n → 86
86a. Acidification of ethylene glycol p, growth at 41°C p → Bordetella hinzii (chapter 45)
86b. Acidification of ethylene glycol n, growth at 41°C n → Cupriavidus respiraculi (chapter 43)
87a. Acidification of glucose p → 88
87b. Acidification of glucose n → 94
88a. Colistin R → 89
88b. Colistin S → 91
89a. Acidification of ethylene glycol p → Burkholderia pseudomallei (chapter 43)
89b. Acidification of ethylene glycol n → 90
90a. Acidification of sucrose n, desferrioxamine S → Burkholderia multivorans, partim desferrioxamine S (85%) (chapter 43)
90b. Acidification of sucrose p (90%), desferrioxamine R → B. cenocepacia, partim PAP n (50%) (chapter 41) or Burkholderia multivorans, partim desferrioxamine R (15%) (chapter 43)
91a. Urease p → 92
91b. Urease n → 93
92a. Arginine dihydrolase p → Haematobacter missouriensis (chapter 44)
92b. Arginine dihydrolase n → Paracoccus yeei, mucoid, yellowish colonies, O-shaped coccoid cells (chapter 44)
93a. Nitrate reductase p, nitrite reductase p → Psychrobacter faecalis (chapter 44)
93b. Nitrate reductase p, nitrite reductase n → Wohlfartiimonas chitiniclastica (chapter 44)
94a. Desferrioxamine S → 95
94b. Desferrioxamine R → 101
95a. Urease p → Oligella ureolytica (chapter 44)
95b. Urease n → 96
96a. Motility p → 97
96b. Motility n → 99
97a. Nitrite reductase p → Alcaligenes faecalis, partim trypsin n (70%) (chapter 45)
97b. Nitrite reductase n → 98
98a. Growth at 41°C p → Comamonas kerstersii (chapter 43)
98b. Growth at 41°C n → Comamonas aquatica (chapter 43)
99a. Nitrite reductase p → Oligella urethralis (chapter 44)
99b. Nitrite reductase n → 100
100a. Acidification of ethylene glycol p, tributyrate esterase p → Moraxella osloensis (chapter 44)
100b. Acidification of ethylene glycol n, tributyrate esterase n → Moraxella lincolnsii (chapter 44)
101a. Urease p → 102
101b. Urease n → 105
102a. Motility p → Bordetella bronchiseptica (chapter 45)
102b. Motility n → 103
103a. Arginine dihydrolase p → Haematobacter massiliensis (chapter 44)
103b. Arginine dihydrolase n → 104
104a. Growth on 12% NaCl p, growth at 41°C p → Psychrobacter phenylpyruvicus (chapter 44)
104b. Growth on 12% NaCl n, growth at 41°C n (7% positive) → Psychrobacter sanguinis (chapter 44)
105a. Motility p → Cupriavidus gilardii, partim PAP n (85%) (chapter 43)
105b. Motility n → 106

(Continued on next page)
Day 3. Begin the identification of nonfermenters (non-glucose-fermenting organisms) (Table 4).

Inoculate two TSA plates and incubate them overnight at 30 to 35°C. Two SBA plates can be used (more appropriate for more-fastidious organisms), but pigmentation is sometimes more clear on TSA. Inoculation of TSA (or SBA) is used in order to record pigment production, to obtain dense growth on day 4, and to prepare a dense inoculum to carry out rapid enzymatic tests and to inoculate other media, as described below. Two plates are inoculated to keep one for prolonged testing, if necessary. Proceed to day 4.

Day 4. Record the results of oxidase; perform and record the results of 10 enzymatic tests.

A. Perform and record the oxidase test by picking colonies from TSA with a swab to which a drop of oxidase reagent (promptly) positive; (p), positive after a delay; p

B. To perform the following 10 enzymatic tests, use one of the two TSA plates. As previously mentioned, all of these reactions require a heavy inoculum, that is, a McFarland standard of 0.5, inoculate one MHA plate. Incubate it for 4 to 5 h. A yellow color indicates a positive result.

1. Alkaline phosphatase. Prepare the inoculum in 0.5 ml of dH2O containing one alkaline phosphatase tablet (Rosco). Incubate for 4 to 5 h. A yellow color indicates a positive result.

2. TrpH, i.e., benzyl-arginine amineopeptidase. Prepare a suspension in 0.5 ml of dH2O containing one trypsin tablet (Rosco). Incubate for 4 to 5 h. Add 1 drop of cinnamaldehyde reagent. An orange-to-pink color within 5 min indicates a positive result.

3. Pyrrolidonyl aminopeptidase. Prepare a suspension in 0.5 ml of dH2O containing one pyrrolidonyl aminopeptidase tablet (Rosco). Incubate for 4 to 5 h. Add 1 drop of cinnamaldehyde reagent. An orange-to-pink color, usually within 5 min, indicates a positive result.

4. β-Galactosidase. Prepare a suspension in 0.5 ml of dH2O containing one ONPG tablet (Rosco). Incubate for 4 to 5 h. A yellow color indicates a positive result.

5. Indole production. Prepare a suspension in 0.5 ml of 0.3% tryptophan solution. Incubate for 4 to 5 h. Add 8 to 12 drops of Kovác’s reagent. Indole production is positive when the supernatant turns red.

6. Urease. Prepare a suspension in 1 ml of liquid Christensen urea. Incubate for 4 to 5 h. A pink color indicates a positive result. Monitor the suspension for up to 1 to 2 days if results are still negative after 4 to 5 h and when no final identification has yet been reached.

7. Nitrite reductase. Prepare a suspension to a McFarland standard of 4 to 5 in 1 ml of 0.1% KNO3 broth. Incubate for 4 to 5 h. Take 0.5 ml of the solution and add a drop of Griess reagent A and subsequently 1 drop of Griess reagent B. The test is positive when the suspension immediately turns red, indicating the presence of nitrite. The test may also be positive when the suspension is colorless in cases of strong nitrite reductase activity. When the result is not clear, repeat the test after 24 h with the remaining 0.5 ml of solution.

8. Nitrite reductase. Prepare a suspension to a McFarland standard of 6 to 8 in 1 ml of 0.001% NaNO2 broth. Incubate it for 4 to 5 h. Take 0.5 ml of the solution and add a drop of Griess A reagent and subsequently add a drop of Griess B reagent. The test is positive when the suspension is colorless, indicating the absence of nitrite. When the result is not clear, repeat the test after 24 h with the remaining 0.5 ml of solution.

9. Lysine decarboxylase. Prepare a suspension in 1 ml of Moeller broth plus 1% lysine. Cover the suspension with paraffin oil. Incubate for 4 to 5 h. A purple color of the medium indicates a positive result. Monitor the suspension for up to 1 or 2 days.

10. Arginine dihydrodase. Prepare a suspension in 1 ml of Moeller broth plus 1% arginine. Cover the suspension with paraffin oil. Incubate it for 4 to 5 h. A purple color of the medium indicates a positive result. Monitor the suspension for up to 1 or 2 days, e.g., for some strains of Pseudomonas pseudocaldihaligens or of Haematobacter spp. that are positive after a delay.

Further simplification is possible by preparing a suspension at a McFarland standard of 4 to 5 in 1.5 ml of dH2O and dividing it into three aliquots of 0.5 ml, to which disks for tests 1 to 3 can be added. Also, tests 4 and 5 can be carried out in the same tube by adding the ONPG disk to the tryptophan solution. In that case, after 4 to 5 h of incubation, read the color for β-galactosidase before adding Kovác’s reagent to read the color for indole production.

C. Testing for susceptibility to colistin, desferrioxamine, and vancomycin. Starting from TSA, prepare a suspension at a McFarland standard of 0.5, inoculate one MHA plate.

33. Identification of Aerobic Gram-Negative Bacteria

| Characteristics useful for identification according to the dichotomous Table 4 are listed in boldface type; the distinction between groups in each dichotomy is indicated by roman rather than italic type. Alphanumeric data are percentages of positive isolates. PAP, pyrrolidonyl aminopeptidase; MCA, MacConkey agar; SBA, sheep blood agar; TSA, tryptic soy agar; CB, coccobacilli; DC, diplococci; PY, partly yellow; n, negative; n*, negative, but some isolates of this species are positive for this characteristic (dealt with elsewhere in the table); n/p, most strains are negative; o, data not listed; p, positive; pp, strongly (promptly) positive; p*, positive, but some isolates of this species are negative for this characteristic (dealt with elsewhere in the table); p w, weakly positive; (p), positive after a delay; (p) w, weakly positive after a delay; p/(p), most strains are positive, but some are positive after a delay; p/p w, most strains are positive, but some are weakly positive; R, resistant; R/S, most strains are resistant; S, susceptible; S/R, most strains are susceptible; S [number], percentage of susceptible strains; v, strain dependent. |
plate to obtain confluent growth, and add colistin (10 μg), desferroxamine (250 μg), and vancomycin (30 μg) disks. Incubate overnight at 30 to 37°C. Proceed to the instructions for day 5 (A).

D. MHA is preferred for susceptibility testing, because green pigment due to pyoverdin (fluorescein production) can be scored more easily on this medium. Proceed to the instructions for day 5 (B).

E. Testing for motility. Starting with TSA, stab inoculate underneath the surface of the soft agar (0.5% TSA), preferably in a small (e.g., 5-ml) petri dish. Incubate overnight at 30°C. Proceed to the instructions for day 5 (C).

F. Testing for acidification of carbohydrates. Starting with TSA, inoculate four LPPR agar tubes, one each with 1% glucose, 1% mannitol, 1% xylose, and 2% ethylene glycol, and incubate them for 24 h at 30°C. Proceed to the instructions for day 5 (D).

Day 5. Record susceptibility, green colony pigmentation (pyoverdin production), motility, and acidification of carbohydrates.

A. Record susceptibilities to different antibacterial agents. Any clear zone of inhibition is considered to indicate susceptibility for diagnostic purposes. A complete lack of a zone of inhibition is interpreted as resistance.

B. Record pyoverdin production as the presence of diffusible green pigment on MHA.

C. Record motility. Motility is positive when the culture spreads from the inoculation zone.

D. Record the acidification of glucose, mannitol, xylose, and ethylene glycol. The test is positive when the red color of the medium turns orange to yellow. Extend incubation up to 7 days when necessary.

Prolongation of reading is done when a test is still negative or doubtful and when no final identification (on the basis of the other test results) has yet been reached. When final identification is not reached on the basis of these rapid tests, additional tests should be used (see above, chapter 19, and individual chapters on organism groups). These include flagellum stain, gelatin hydrolysis, esculin hydrolysis, starch hydrolysis, growth on MacConkey agar, acidification of sucrose or of raffinose, tributyrate esterase and Tween 80 esterase, and acetamide assimilation (alkalinization), requirement for NaCl, halotolerance, and growth at 41°C. Selection of these tests depends on the group of species that has been suggested already on the basis of the rapid tests and can be deduced from the dichotomous identification algorithm in Table 4 and/or from Table 5.

Neisseria
JOHANNES ELIAS, MATTHIAS FROSCH, AND ULRICH VOGEL

TAXONOMY
According to the second edition of Bergey’s Manual of Systematic Bacteriology, the genus Neisseria belongs to the family Neisseriaceae of the order Neisseriales (1), which is placed in the class Betaproteobacteria. Since the 1980s, several alterations have been made within the taxonomy and classification of the family Neisseriaceae, due to knowledge gained from molecular analyses. The exclusion and subsequent reassignment of the genera Moraxella, Acinetobacter, and Psychrobacter to the Gammaproteobacteria were first proposed by the use of DNA-rRNA and DNA-DNA hybridization techniques (2) and later confirmed by 16S rRNA gene sequencing (3). Today, the family Neisseriaceae is the only family within the order Neisseriales, and, in addition to the genus Neisseria, contains Eikenella, Kingella, and 32 other genera.

DESCRIPTION OF THE GENUS NEISSERIA
Most members of the genus Neisseria are cocci with a diameter of up to 2 μm, presenting as single bacteria or in pairs. The species Neisseria elongata, N. weaveri, N. bacilliformis, and N. shayegni sp. nov. (4) are notable exceptions that consist of short rods, frequently arranged as diplobacilli or in chains. While Neisseria species are Gram negative, they occasionally show a tendency to withstand decolorization. Capsules (N. meningitidis) and pili (N. meningitidis and N. gonorrhoeae) may be present, but flagella are not formed. N. meningitidis is the only species expressing a polysaccharide capsule, of which 12 different serogroups are distinguishable (5). Strains of several species, such as N. flavescens, N. sicca, and N. subflava, may produce a yellowish pigment. Neisseria spp. grow optimally under aerobic conditions and at temperatures of 35 to 37°C. Nevertheless, isolation of N. gonorrhoeae from body sites with reduced oxygen tensions suggests a capability of anaerobic growth, which was suggested to be due to nitrite respiration (7). Microaerobic growth by denitrification of nitrite via NO has also been shown for N. meningitidis (8). While many species are not nutritionally demanding, the human-pathogenic species N. gonorrhoeae and N. meningitidis are fastidious, showing particular susceptibility to unfavorable environmental factors, such as extreme temperatures, desiccation, and alkaline or acidic conditions. All species are oxidase positive and, with the exception of N. elongata subsp. nitroreducens (9) and some N. bacilliformis strains (10), catalase positive. Neisseria species produce acid from carbohydrates by oxidation, not fermentation. Some species, such as N. elongata and N. cinerea, are asaccharolytic. Most members of the genus are able to reduce nitrite. The natural habitats of the members of this genus are the mucous membranes of animals and humans. The species N. gonorrhoeae and N. meningitidis are exclusively human pathogens. Exotoxins are typically not produced (1). All species classified in the genus Neisseria are naturally competent for DNA uptake and display a high frequency of horizontal gene transfer (11). As a consequence, phylogenetic analyses of this genus based on different genes may yield incongruent results (12). Note that this distortion also applies to 16S rRNA gene sequencing, which has been used to define inter- and intrageneric relationships within the Neisseriaceae and Moraxellaceae (3). Multiple-locus instead of single-locus approaches might therefore be more suitable for the resolution of species of Neisseria (13).

According to Euzéby’s “List of Prokaryotic Names with Standing in Nomenclature” (http://www.bacterio.net/n/neisseria.html), the genus Neisseria presently consists of 28 species.

EPIDEMIOLOGY AND TRANSMISSION
N. gonorrhoeae causes gonorrhea, which is the second most commonly reported notifiable disease in the United States (http://www.cdc.gov/std/stats11/gonorrhea.htm). N. gonorrhoeae is always considered pathogenic, and humans are the only hosts of this bacterium. It is transmitted mainly through sexual practices and infects the mucosal surfaces of the urethra, cervix, rectum, pharynx, and eyes. The risk of infection is greatly influenced by sexual behavior yet can be reduced by the use of condoms (14). Furthermore, the eye can be infected as an intrapartum event during passage of the fetus through the birth canal. The rate of gonorrhea in the United States decreased by 74% from 1975 to 1997, following implementation of the gonorrhea control program in the mid-1970s (http://www.cdc.gov/std/stats11/gonorrhea.htm); it further decreased to the lowest recorded figure, 98.1/100,000, in 2009, and was slightly increased (to 104.2/100,000) in 2011. Rates vary considerably between states, with values below 8/100,000 in Vermont and over 400/100,000 in the District of Columbia. Women have acquired more infections than men since 2002; in 2011, rates in women and men were 108.9/100,000 and 98.7/100,000, respectively. The group with the highest burden of disease is young adults between 20 and 24 years of age. In 2011, the gonorrhea rate remained highest among African Americans
(427.3/100,000), with African American women between 20 and 24 years of age being particularly affected (2,050/100,000). The overall rate in the United Kingdom (32.1/100,000) was lower than that in the United States in 2011 (http://www.gov.uk/phe). While the age distribution is very similar to that in the United States, men have consistently higher rates than women in the United Kingdom. In 2011, both sexes had the highest burden of disease in the age group of 20- to 24-year-olds, with rates of 112.9/100,000 and 192.4/100,000 in women and men, respectively.

N. meningitidis also occurs exclusively in humans and plays dual roles as a commensal and a potentially invasive pathogen. On average, the mucosal surfaces of the oro- and nasopharynges of 10% of the population are colonized by this bacterium (15). Carriage is strongly age dependent, with adolescents and young adults attaining rates of over 30%, in contrast to infants, with carriage rates of a few percent (15). As a consequence of repeated episodes of carriage, the percentage of sera with bactericidal activity against pathogenic strains increases with age. Transmission occurs through large-droplet secretions from the oropharynx and is favored by repeated or close contact. Nevertheless, outbreaks and clusters are rare in developed countries (16). Disease occurs in only a minute proportion of individuals acquiring N. meningitidis and follows a typical age distribution, with infants and adolescents having the highest incidences in developed countries. Apart from genetic host polymorphisms (17), individuals with underlying conditions, such as properdin deficiencies (18), late complement deficiencies (18), and splenic impairment including asplenia (19), are at increased risk for invasive meningococcal disease (IMD). Also, behavioral risk factors, including exposure to smokers (20) and kissing (21), have been described to contribute to acquisition of disease.

IMD is rare in developed countries. In the United States, the incidence for the year 2011 was estimated to be 0.20/100,000 (22), with serogroups B, C, and Y constituting 91% of all cases. Incidences in European countries are variable, with England and Wales reaching a rate of 1.65/100,000, with an 82% dominance of serogroup B, in 2011 (http://www.gov.uk/phe) and Germany reporting a rate of 0.43/100,000, with a 67% proportion of serogroup B, in 2012 (23). In contrast, African countries in the so-called meningitis belt regularly report epidemic waves, mainly caused by serogroup A, with rates soaring to values over 300/100,000 (24).

A number of vaccines have been developed for the prevention of IMD. In 2007, the Advisory Committee on Immunization Practices recommended vaccination of all adolescents (preferably at 11 to 12 years of age) with a quadrivalent polysaccharide-protein conjugate vaccine covering serogroups A, C, W, and Y (25), emphasizing in 2010 the addition of a booster dose at 16 years of age (26). Due to high rates of serogroup C disease in the 1990s and early 2000s, several European countries implemented vaccination campaigns with a conjugate vaccine against serogroup C, which led to a dramatic reduction of disease with this capsule type (27). Poor immunogenicity of the serogroup B capsular polysaccharide, consisting of (2→8)-α-Neu5Ac (a polyisialic acid composed of N-acetylneuraminic acid subunits), and concerns about induction of autoimmunity due to the presence of (2→8)-α-Neu5Ac on normal tissues have thus far precluded the development of glycoconjugate vaccines against serogroup B. Nevertheless, outer membrane vesicle vaccines have been used to combat local epidemics caused by serogroup B, e.g., in New Zealand (28). Also, a recombinant protein-based vaccine with an outer membrane vesicle component targeting serogroup B (29) was recently approved by the European Medicines Agency and the Australian Therapeutic Goods Administration.

**CLINICAL SIGNIFICANCE**

Members of the genus Neisseria have a high affinity for mucosal membranes. A wide variety of species can be isolated from humans, including N. gonorrhoeae, N. cinerea, N. elongata, N. flavescens, N. lactamica, N. meningitidis, N. mucosa, N. polysaccharaea, N. sicca, and N. subflava. Several species are predominantly recovered from animals, such as N. animalis, N. animaloris, N. zoodegmatis (from throats of cats and dogs) (30), N. denitrificans (from throats of guinea pigs), N. dentiae (from dental plaques of domestic cows), N. macacae (from oropharynges of rhesus monkeys), and N. weaveri (from the oral flora of dogs). Similar to N. elongata, the new species N. bacilliformis likely colonizes the oral cavity and respiratory tract of humans (10). Most human Neisseria species are considered normal inhabitants of the upper respiratory tract which cause disease in an opportunistic fashion. Rarely, species of animal origin can cause wound infections in humans after bites (31). N. meningitidis mostly appears as a mere commensal of the human oropharynx yet can cause life-threatening, acute disease in previously healthy individuals. N. gonorrhoeae, however, is always considered a pathogen, even if obvious signs of disease are absent.

Uncomplicated infection by N. gonorrhoeae (gonorrhea) manifests most commonly as acute urethritis in men. The major symptoms are urethral discharge, sometimes associated with dysuria, typically without frequency or urgency. Coinfection of the preputial (Tyson’s), urethral (Littré’s), and bulbo-urethral (Cowper’s) glands is possible. Also, completely asymptomatic infections occur in up to 10% of cases. Most cases of untreated urethritis resolve spontaneously after several weeks. Further localized complications after gonococcal urethritis include acute epididymitis, penile edema, and abscesses of the above-mentioned glands. In women, the endocervix is the primary site of genital infection. Additionally, N. gonorrhoeae may infect the urethra, the rectum, the peri-urethral (Skene’s) glands, and the ducts of the greater vestibular (Bartholin’s) glands. The squamous epithelium of the vagina is typically not infected in sexually mature women. In contrast to infection in men, asymptomatic infection in women is common (32). Also, if symptoms appear, they often cannot clearly be attributed to infection by N. gonorrhoeae, as concurrent infection by Chlamydia trachomatis and Mycoplasma genitalium is common. The main complaints include increased vaginal discharge, dysuria, and intermenstrual bleeding. Ascension of the infection may result in pelvic inflammatory disease, which manifests as various combinations of endometritis, salpingitis, tubo-ovarian abscess, and peritonitis. Acute perihepatitis (Fitz-Hugh-Curtis syndrome) can develop following direct extension of N. gonorrhoeae from the fallopian tube to the liver capsule and the surrounding peritoneum. While over 80% of rectal infections remain asymptomatic, some patients complain of acute proctitis. Pharyngeal infection is acquired by oral sexual exposure and is mostly asymptomatic yet can also cause overt pharyngitis or tonsillitis (33). While probably less transmissible than rectal or urethral gonorrhea, its silent nature and considerable prevalence among men who have sex with men (MSM) render pharyngeal infection a common reservoir for gonorrhea in sexually active MSM. Gonococcal conjunctivitis in adults usually results from autot inoculation or ocu logenital or orogenital exposure. If the
infection is not treated promptly, corneal ulceration may rapidly develop. Conjunctivitis of the newborn (ophthalmia neonatorum) is transmitted during birth and is favored by premature rupture of the membranes and preterm delivery. Historically a common cause of blindness, it can be prevented by administering a 1% aqueous solution of silver nitrate or an antibiotic ointment (usually containing erythromycin) into the conjunctiva after delivery. Disseminated gonococcal infection reflects bacteremic dissemination, possibly generation of immune complexes, and indirect immunological mechanisms. Disseminated gonococcal infection complicates fewer than 1% of mucosal infections (34). It usually manifests as septic arthritis and a characteristic syndrome of polyarthrithis and dermatitis and should be suspected in patients presenting with tenosynovitis, arthritis, and vasculitic skin lesions (35).

IMD commonly presents as meningitis, acute sepsis, or a combination of both. In addition, unusual presentations include transient mild bacteremia, chronic meningococcal sepsis, pneumonia (mainly by serogroup Y), septic arthritis, and endocarditis (36). Symptoms of meningitis vary widely and can include a stiff neck, headache, confusion, and photophobia. Lethality of meningococcal meningitis without sepsis can be as low as 3% (37). Sequelae, such as sensorineural hearing loss, developmental delay, and speech defects, affect a substantial portion of survivors, yet in a smaller proportion than in other forms of acute bacterial meningitis (38). Petechial lesions are telltale signs of meningococcal sepsis, and they can coalesce and become ecchymotic. Nevertheless, nonpurpuric maculopapular rashes, readily confused with viral exanthems, have also been associated with meningococcemia. Meningococcal septic shock can take a fulminant course with a lethality of 30% (39), and plasma concentrations can reach up to $10^9$ meningococci/ml (40), which in turn leads to massive activation of cytokines and vasotoxic anaphylatoxins. Meningococcal shock syndrome is characterized by myocardial depression, vasoplegia, capillary leakage, and disseminated intravascular coagulation (39). Complications of IMD include arthritis, pericarditis, cranial nerve dysfunction, meningococcal pericarditis, and, rarely, cerebral or spinal infarction. In addition, adolescent survivors of IMD have been described as suffering from a series of long-term consequences, including poorer physical and mental health, quality of life, and educational achievement (41). Bacteremia can also manifest without signs of sepsis, in the form of chronic meningococcemia, a condition associated with low-grade relapsing fever, arthritis, and rash (42). Meningococcal pneumonia has been recognized as an infrequent clinical syndrome for more than 100 years (43). Most meningococcal pneumonias are caused by serogroup Y and affect adults disproportionately (44). A preceding viral illness, notably pandemic influenza (45), has been reported to promote its development. N. meningitidis is an uncommon cause of acute bacterial conjunctivitis and can also be the etiologic agent of urethritis in men.

The clinical significance of Neisseria species other than N. gonorrhoeae and N. meningitidis is covered in “Evaluation, Interpretation, and Reporting of Results” at the end of the chapter.

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

*Neisseria gonorrhoeae*

The selection of specimens for culture-based diagnosis of gonorrhea depends on sex, the level of sexual maturity, and the exposed anatomical sites. The anterior portion of the male urethra is sampled by introducing a swab up to 2 cm in a rotatory fashion. Samples from the endocervical canal are obtained by introducing a swab after removal of mucus plugging the cervical orifice. For MSM and women who practice anal intercourse, rectal samples should be taken. Swabs heavily contaminated with feces must be discarded. For symptomatic patients, direct swabbing of lesions under rectoscopic guidance improves culture yields. A pharyngeal swab should be obtained from individuals in high-risk groups, including MSM. Vaginal swabs are inadequate for culture-based diagnosis for sexually mature women yet can be used for prepubescent females. If the hymen is intact, however, the specimen is collected from the vaginal orifice. Dacron (polyethylene terephthalate)- or rayon (viscose)-tipped swabs, e.g., Transwab (Medical Wire, Corsham, United Kingdom), Bactiswab (Remel, Lenexa, KS), or Mini-tip Amies (Copan Innovation, Brescia, Italy), are preferable for culture-based diagnosis of gonorrhea. Calcium alginate swabs should be avoided due to reported toxicity (46). Also, cotton buds and oil-based lubricants can contain unsaturated fatty acids, which inhibit N. gonorrhoeae. Although direct plating maximizes the culture yields of gonococci, this approach is not always practical or possible. In such cases, Amies-based semisolid transport media can be used to transport swabs to the processing laboratory. There are, however, considerable performance differences in commercial Amies-based transport systems after 24 and 48 h that are not uniformly rectifiable by the addition of charcoal (47). Therefore, it is advisable to process swabs transported in these media within 6 h after collection. During the time of transport, media should be kept at room temperature and not refrigerated.

Survival and transport of gonococci for over 24 h can be achieved by culture medium transport systems which allow direct plating of specimens in a clinical environment. These usually consist of a solid medium, onto which swabs are inoculated directly after collection, and a CO$_2$-generating system within a resealable container. A CO$_2$-rich atmosphere is generated by tablets containing citric acid and sodium bicarbonate that are activated after addition of water. Commercially available systems include Biocult-GC (Orion Diagnostica, Espoo, Finland) and JEMBEC GC-Lect agar (Becton, Dickinson and Company, Franklin Lakes, NJ).

Similar to culture samples, specimens for molecular detection of *N. gonorrhoeae* are best sampled by use of rayon- or Dacron-tipped swabs, since calcium alginate was reported to inhibit PCR (48). The inhibitory influence of aluminum shafts is contentious, and preliminary testing in conjunction with the employed molecular kit is advisable. Transport and collection systems specifically designed for molecular detection include the Digene female swab specimen collection kit (Qiagen Inc., Valencia, CA) and the STD swab specimen collection and transport kit (Roche Diagnostics, Basel, Switzerland). Some molecular kits can also be used for urine and vaginal swabs (see “Nucleic Acid Amplification Tests”).

*Neisseria meningitidis*

The types of specimens that can be used for the detection of *N. meningitidis* include blood, cerebrospinal fluid (CSF), nasopharyngeal and oropharyngeal swabs, bronchoalveolar lavage fluid, joint aspirates, urethral and endocervical swabs, petechial aspirates, and biopsies. Pharyngeal swabs used for determination of meningococcal carriage are best taken from the posterior pharyngeal wall through the mouth and
plated directly after sampling (49). Alternatively, swabs may be put into Amies-based transport media and plated, preferably within 5 h after collection. Growth of N. meningitidis and N. gonorrhoeae in commercial blood culture media is adversely affected by the anticoagulant sodium polyanetholesulfonate (50), for which no suitable substitute is currently available. The inhibitory action is reduced by the addition of gelatin at a concentration of 1 g/liter to most commercially available blood culture media.

Laboratory Safety Issues for Handling of Meningococcal Cultures

Rare cases of fatal meningococcal disease have been described for laboratory staff (51). Risk factors for laboratory-acquired infection are exposure to droplets or aerosols containing N. meningitidis (51). Laboratories working with live N. meningitidis isolates should comply with biological safety containment level 2 standards, including the use of class II biological safety cabinets whenever infectious splashes or aerosols may be created, e.g., during mobilization of organisms from culture plates, handling of liquid cultures, and performance of carbohydrate utilization tests, oxidase testing, and slide agglutination tests.

DIRECT EXAMINATION

Microscopy

In cases of urethritis, the direct smear for Gram staining should be prepared with a swab that is different from that used for the collection of a culture specimen. A presumptive diagnosis of gonococcal urethritis in men is made by visualization of polymorphonuclear leukocytes. The sensitivity of microscopic diagnosis for these sites has been highest for urethral slides of men, where it reaches 89% (52). For endocervical smears and rectal smears of MSM, however, it drops to 51% and 54%, respectively (52). The specificity of microscopic diagnosis for these sites has been reported to be over 90%. Microscopy is not useful for the diagnosis of pharyngeal gonorrhea. Nevertheless, microscopic diagnosis is mandatory for normally sterile material.

A Gram stain of CSF is required for all cases of suspected bacterial meningitis sent to the laboratory. Visualization of Gram-negative diplococci is sufficient for the presumptive diagnosis of meningococcal meningitis (Fig. 1). If more than 1 ml of CSF is available, the specimen should be centrifuged at 1,000 × g for 10 min and the pellet used for microscopic examination and culture. Cytocentrifugation also increases the sensitivity of microscopic investigation. On Gram-stained smears, meningococci appear as Gram-negative diplococci both inside and outside polymorphonuclear leukocytes, which are typically abundant in samples from cases of bacterial meningitis. Organisms may tend to resist decolorization.

Antigen Detection

Diagnosis of meningococcal meningitis can be made through the use of commercially available antigen detection kits. These methods are useful if no or only limited access to microscopes is available. They are of questionable clinical usefulness compared with Gram staining (53) and should therefore not be used as a substitute for microscopy. Commercially available latex agglutination tests, which consist of latex particles coated with monoclonal antibodies targeting the capsular polysaccharides of common serogroups, include the Pastorex meningitis test (Alere Inc., Waltham, MA) and the Wellcogen N. meningitidis A, C, Y, and W135 test (Oxoid Ltd., Basingstoke, United Kingdom). These assays have a reasonable sensitivity and specificity (54) yet are useless for the detection of uncommon serogroups (55). In laboratories handling only a small number of cases, the cost of purchasing and storing antigen detection kits outweighs any potential benefits for patient management.

Currently, no commercially available antigen detection kits with adequate sensitivity and specificity exist for the diagnosis of gonococcal infection.

Nucleic Acid Detection

Neisseria gonorrhoeae

Nucleic acid tests permit the rapid and sensitive detection of N. gonorrhoeae from clinical samples without the requirement of bacterial viability. They have been in use since the early 1990s and can be categorized as hybridization assays and nucleic acid amplification tests (NAATs).

Hybridization Assays

The two commercially available hybridization assays include the Digene CT/GC dual ID HC2 (Qiagen Inc., Valencia, CA) and Gen-Probe Pace 2 (P2 assay; Gen-Probe Inc., San Diego, CA) tests, which use RNA probes targeting genomic DNA and DNA probes targeting rRNA, respectively. The detection method for the RNA-DNA hybrids in the HC2 assay involves antibody-mediated recognition of the hybrids and subsequent binding of alkaline phosphatase-conjugated antibodies, which act on a chemiluminescent substrate. Signal amplification results from multiple alkaline phosphatase molecules being attached to a conjugated antibody, several of which bind to a single captured hybrid. In the P2 assay, the DNA probes are labeled with a chemiluminescent substrate, which is quantified after separation of the stable DNA-RNA hybrids from the nonhybridized probe. The sensitivities of hybridization tests are probably higher than that of culture (56, 57). Today, however, hybridization tests have largely been replaced by NAATs (see below).

Nucleic Acid Amplification Tests

Most commercial NAAT assays developed to date are multiplex NAAT assays targeting both N. gonorrhoeae and C. trachomatis. The Roche Amplicor CT/NG assay (Roche Diagnostics, Basel, Switzerland) is a first-generation assay that uses PCR for amplification of the DNA cytosine methyltransferase gene. It has shown cross-reactivity with strains of several commensal Neisseria species, contributing to low positive predictive values (PPV) with urogenital specimens in several studies (58). Additional testing has
been carried out with real-time PCR assays targeting the porA pseudogene (59), gyrA (60), and the 16S rRNA gene (61). Nevertheless, confirmatory tests themselves can introduce shortcomings, as shown for the poorly specific target cppB (encoding cryptic plasmid protein B) (61, 62) and the insufficiently sensitive porA pseudogene (61). The Becton Dickinson ProbeTec SDA assay (Becton, Dickinson and Company, Franklin Lakes, NJ) is a second-generation test that uses strand displacement amplification for the multiplication of DNA. It targets a region within the multicopy pilin gene-inverting protein homologue (63). Due to its limited specificity and cross-reactivity with commensal Neisseria species (64), confirmatory tests using the porA pseudogene (65), cppB (66), and opa (67) have been employed. Additional testing by other NAATs, the Aptima Combo 2 (AC2) and Aptima GC (AG) tests (see below), showed high concordances for cervical and urethral swabs (68) and for male urethral swabs and first-catch urine (69). The AC2 test (Gen-Probe, San Diego, CA) is also a second-generation test, and it uses transcription-mediated amplification for the replication of gonococcal 16S rRNA and a chemiluminescent single-stranded DNA probe for product detection. The AG test represents a confirmatory assay based on the same technology and even uses the same capture probe as the AC2 test, yet it targets a slightly different region of the rRNA subunit. Evaluations regarding the performance of this assay have largely been favorable. Specificity and sensitivity were shown to be higher than those for the Amplicor assay in Australia (70). While a study using the AC2 test with the AG test as a confirmatory assay demonstrated a PPV of 97% among 60,000 female urine and cervical swabs, despite a low prevalence (71), PPV varied between 75% and 100% for urogenital specimens in a multicenter study (69). Specificities of the AC2 test compared with the SDA test were very similar and always over 94% in several studies investigating first-void urine (72), vaginal (73), rectal (74, 75), and pharyngeal (75, 76) specimens. The Abbott RealTime CT/NG assay (Abbott Molecular, Maidenhead, Berkshire, United Kingdom) and the Cobas 4800 CT/NG test (Roche Molecular Systems, Pleasanton, CA) constitute further additions to the arsenal of NAATs, targeting a region in the N. gonorrhoeae opacity (Opa) gene (77) and the direct repeat region DR9 (78), respectively. Studies including several thousand clinical specimens have shown high sensitivities (>96%) and specificities (>99%) for both assays (79, 80). Finally, the Cepheid CT/NG Xpert Rapid PCR test (Cepheid, Sunnyvale, CA), which targets several undisclosed genomic targets, showed a favorable PPV of over 91% in a large population with an overall prevalence of 2.3% (81).

In summary, NAATs provide several advantages over culture-based diagnosis, yet they also have a series of important limitations. The main advantages are their superior sensitivity over culture, as evidenced in numerous clinical studies (74–76, 82), and their less stringent collection and transport conditions. The current list of NAATs with FDA approval includes the Amplicor, Abbott RealTime, AC2, ProbeTec, Cobas 4800 CT/NG, and Xpert tests. Most NAATs are licensed for male urine specimens; further approved specimens differ by test and are listed in Table 1. Importantly, no NAAT is currently cleared for oropharyngeal, rectal, ocular, or pediatric specimens. Major limitations of NAATs include a high cost, carryover contamination, high-quality control requirements, an absence of antibiotic resistance data (58), and varying specificity (83). When challenged on a panel of Neisseria and Moraxella isolates, most tests show specificities between 85.9% and 99.1% (83); this implies that PPV of most presently used NAATs may not reach the recommended value of 90% (84, 85) in settings with low prevalences of around 1% (86). Assays may also be susceptible to inhibition by substances present in patient samples, e.g., in urine (87), and competing amplification in the case of coinfection with C. trachomatis (58). The assay complexity, involving steps such as nucleic acid extraction, amplification, and detection, requires stringent quality control and staff training. Nevertheless, the latest commercial assays, such as the AC2, Abbott RT, and Cobas 4800 CT/NG tests, can be integrated into fully automated molecular testing systems, such as the Panther (Hologic, Bedford, MA), m2000 (Abbott Molecular, Maidenhead, Berkshire, United Kingdom), and Cobas 4800 (Roche Diagnostics, Rotkreuz, Switzerland) systems, respectively. Furthermore, the Xpert test is a cartridge-based point-of-care test with minimal hands-on and turnaround times (81).

*SDA, strand displacement amplification; TMA, transcription-mediated amplification.
**Neisseria meningitidis**

Several in-house methods have been developed to enable culture-independent diagnosis of IMD, and these are especially useful when previous antibiotic treatment or unfavorable transport conditions lead to a negative culture. The DNA targets used for molecular diagnosis include *ctrA* (88), *IS1106* (89), *siaD* (90, 91), *porA* (92), *porB* (93), *fetA* (94), and housekeeping genes used for multilocus sequence typing (MLST). Specifically, *ctrA* was evaluated as a target for real-time detection of meningococcal DNA (95). Apart from facilitating laboratory confirmation of meningococcal disease, the polysialyltransferase gene (*siaD*) can be used for serogrouping (serogroups B, C, W, and Y), while the *porA*, *porB*, *fetA*, and housekeeping genes allow culture-independent typing (16). False-positive results have been reported for *IS1106*, which should therefore not be used as a single target for routine screening (89). Moreover, *ctrA* testing is negative in rare cases of IMD caused by *N. meningitidis* harboring the capsule-null locus (96).

**ISOLATION PROCEDURES**

Cultivation of *N. gonorrhoeae* requires the use of chocolate agar, which supports the growth of many other commensal bacteria. To isolate *N. gonorrhoeae* from mucosal and other nonsterile body sites, several selective media containing a mixture of inhibitory agents have been developed. All of them contain the antibiotics vancomycin and colistin for the suppression of Gram-positive and Gram-negative bacteria, respectively. The prototype medium, developed by Thayer and Martin (97), consists of a chocolate agar base which, in addition to the above antibiotics, contains nystatin for the inhibition of yeasts. The addition of trimethoprim to the modified Thayer-Martin medium and following formulations prevents swarming of *Proteus* species. Martin-Lewis medium contains ansomycin, which has increased activity against *Candida albicans*, instead of nystatin. Further modifications include GC-Lect agar (Becton, Dickinson and Company), which provides additional control against *Campylobacter* species and against vancomycin-resistant Gram-positive contaminants by the addition of lincomycin. Moreover, the reduced vancomycin concentration in GC-Lect agar enhances the recovery of uncommon vancomycin-susceptible *N. gonorrhoeae* strains. In contrast to the media described above, New York City medium is a clear peptone-corn starch agar containing yeast dialysate, citrated horse plasma, and lysed horse erythrocytes. It contains the antibiotics vancomycin, colistin, amphotericin B, and trimethoprim.

Specimens should be inoculated on warmed or room temperature media. Plates should be incubated at 35 to 37°C with 3 to 7% CO₂ in a moist atmosphere after inoculation. This is accomplished in a commercially available CO₂ incubator equipped with a humidifier. A moist, CO₂-rich atmosphere can also be generated with a candle extinction jar, using white, nonscented candles. Cultures should be examined daily for growth and held for a minimum of 72 h.

For culture-based detection of *N. meningitidis* from primarily sterile materials, such as CSF or joint fluid, specimens should be inoculated onto sheep blood agar and chocolate agar. Specimens from mucosal surfaces (e.g., respiratory material) must be inoculated additionally on selective media (see above) which exclude growth of most commensal *Neisseria* spp. Incubation conditions are identical to those for *N. gonorrhoeae*. Nevertheless, in contrast to *N. gonorrhoeae*, *N. meningitidis* tends to grow more readily on solid media and almost invariably grows on blood agar plates. Media must be examined for suspicious growth at 24, 48, and 72 h. After 72 h of no growth, a negative culture result can be issued.

**IDENTIFICATION**

**Presumptive Identification**

**Colonial Morphology**

After 48 h of growth on chocolate agar, colonies of *N. gonorrhoeae* are up to 1 mm in diameter, opaque, grayish white, glistening, and convex. Morphology can vary subject to the presence of pili and opacity proteins. Colonies of *N. gonorrhoeae* expressing pili and opacity proteins are wrinkled and well defined, with a clear edge, while nonpiliated colonies have more diffuse edges and are more glistening. Due to rapid pilus phase variation, colonial morphology can appear heterogeneous after primary inoculation.

Colonies of *N. meningitidis* have smooth entire edges and are about 1 mm in diameter after 18 h of growth on blood agar. They are gray, convex, glistening, and occasionally mucoid. Blood agar beneath the colonies may display a gray-green discoloration.

**Microscopic Morphology**

A Gram stain must be performed on suspected *N. gonorrhoeae* and *N. meningitidis* colonies to confirm the presence of uniform Gram-negative diplococci. Consistent results are obtained with <24-h-old colonies, before autolytic processes appear. Microscopic examination of suspicious colonies growing on selective plates is essential to rule out Gram-negative rods belonging to the genera *Moraxella* (e.g., *Moraxella osloensis*), *Acinetobacter*, and *Klebsiella* occasionally growing on them. While *Acinetobacter* spp. can be indistinguishable from *N. meningitidis* and *N. gonorrhoeae* by Gram staining, they can be discerned by their negative oxidase reaction (see below).

**Oxidase Test**

Performance of the oxidase test is mandatory for colonies suspected to belong to *Neisseria*. Both *N. gonorrhoeae* and *N. meningitidis* give a positive reaction. In the filter paper method, an oxidase reagent (1% dimethyl-p-phenylene-diaminedihydrochloride or tetramethyl-p-phenylene-diaminedihydrochloride) is placed on filter paper, onto which a colony is rubbed with a wooden stick (Nichrome loops may give a false-positive reaction). A fresh isolate should produce a deep purple color within 10 s. Commercial strips (e.g., Microbact oxidase strips [Oxoid, United Kingdom]) are a useful alternative.

**Definitive Identification**

**Carbohydrate Utilization Assays**

*Neisseria* species produce acid from carbohydrates by oxidation, not fermentation. The only carbohydrate used by *N. gonorrhoeae* is glucose, while *N. meningitidis* additionally catabolizes maltose (Table 2). Rarely, however, *N. gonorrhoeae* (98) and *N. meningitidis* (99) fail to acidify carbohydrate-containing media. Also, several acascharyotic species, including *N. cinerea*, *N. flavescens*, and *N. elongata*, do not produce acid at all from sugars. The traditional cystine tryptic agar sugar method has been replaced by rapid carbohydrate utilization tests in most routine laboratories. These tests give results within 4 h and are integrated into commercial kits, including the ApiNH (bioMérieux,
Immunologic Methods for Culture Confirmation

All commercially available tests for the culture confirmation of *N. gonorrhoeae* rely on the recognition of gonococcal protein I (with its IA and IB variants) by a pool of monoclonal antibodies. The Phadebact Monoclonal GC test (Bactus AB, Huddinge, Sweden) is a coagglutination assay employing inactivated *Staphylococcus aureus* cells coated with antibodies bound via their Fc portions to staphylococcal protein A. Cross-reactions with *Moraxella catarrhalis*, *N. cinerea*, and *N. lactamica* have been reported. Nevertheless, more recent studies found the test to be highly sensitive and specific for culture confirmation of *N. gonorrhoeae* (100, 102). The BD GonoGen II test (Becton, Dickinson and Company) is a colorimetric test employing antibodies absorbed to metal sol particles, which give the reagent its raspberry red color. False-positive reactions with *N. lactamica* and *N. meningitidis* have been observed (103). Furthermore, the solubilizing buffer of the GonoGen II kit was described to only insufficiently extract protein I (100), resulting in false-negative reactions for some isolates. However, repeat testing with an extended extraction method led to a high specificity and sensitivity of the test (100). The MicroTrak culture confirmation test (Trinity Biotech, County Wicklow, Ireland) uses fluorescein isothiocyanate-labeled antibodies for confirmation of *N. gonorrhoeae*. Positive specimens are identified by the presence of apple-green fluorescent diplococci under a fluorescence microscope. Among the immunologic methods, the MicroTrak test was appraised as being the most labor-intensive (100). While earlier evaluations pointed to a high specificity yet limited sensitivity (103), false-negative reactions were not observed in a later study (100).

Multitest Identification Systems

Several kits combine carbohydrate utilization tests and direct enzyme detection assays for rapid confirmation of isolates belonging to *Neisseria*. The AptNH system can be used for the identification of *Neisseria*, *Haemophilus*, and *M. catarrhalis* and uses 13 miniaturized tests. In total, the test comprises four sugar utilization tests (assessing glucose, fructose, maltose, and sucrose), eight enzyme substrate tests, and an acidimetric penicillinase test. In contrast, the RapID

NH (Remel, Lenexa, KS) system contains only 2 carbohydrate utilization tests (for glucose and sucrose), 10 enzyme substrate tests, and a resazurin reduction test. The ApNH and RapID NH kits are inoculated with dense bacterial suspensions adjusted to McFarland standards of 4 and 3, respectively. Results are obtained after incubation at 37°C for 2 and 4 h, respectively. The denser bacterial inoculum used in the ApiNH system might explain its slightly higher sensitivity than that of the RapID NH test (100). The automated bacterial identification platform Vitek II (bio-Mérieux) can also be used for identification of Neisseria species. Its NHI card contains 30 biochemical tests. Valenza and colleagues reported misidentification of N. gonorrhoeae as N. cinerea for one isolate, owing to the lack of glucose utilization (99). In another study, all N. gonorrhoeae isolates were identified correctly, yet 6% of them received a low discrimination result (104).

Matrix-Assisted Laser Desorption Ionization–Time of Flight Mass Spectrometry
Matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) mass spectrometry has generated a lot of interest as an emerging technique in the identification of bacterial pathogens. A pioneering study analyzing 29, 13, and 15 strains of N. gonorrhoeae, N. meningitidis, and other Neisseria species, respectively, reported that direct bacterial profiles were sufficiently different to allow species identification of pathogenic Neisseria isolates (105). Further studies assessing the performance of two major mass spectrometer systems confirmed its usefulness for identification of Neisseria species yet included only very few isolates (106, 107). An analysis focusing on Neisseria meningitidis verified the ability of MALDI-TOF mass spectrometry to correctly identify all 100 study strains and additionally categorize them into groups of clonal complexes (108). While these reports are promising, more studies are needed to quantify the method's ability to accurately identify species within the genus Neisseria.

Hybridization Test
The Accuprobe culture identification test (Gen-Probe Inc., San Diego, CA) is a DNA probe assay for N. gonorrhoeae strains isolated from culture. Similar to the AC2 and AG tests, the Accuprobe test targets gonococcal rRNA. After lysis of bacteria, released rRNA is bound by single-stranded DNA probes labeled with a chemiluminescent substrate. Labeled DNA-RNA hybrids are detected in a luminometer. While the test has not been evaluated lately, an older study confirmed its high sensitivity and specificity (109).

DNA Sequencing
Interpretive criteria for identification of bacteria and fungi by use of DNA target sequences have been published by the Clinical and Laboratory Standards Institute (CLSI) (110). Harmsen et al. established a reference database for 16S rRNA gene sequence fragments, including a representative set of Neisseria spp. obtained from reference strain collections (http://rdna.ridom.de/), which in most cases allows the identification of an organism belonging to the genus Neisseria to the species level (3). Nevertheless, sequence diversity between different species of the genus can be as low as 1% by 16S rRNA gene sequencing. A 413-bp fragment of the gene encoding 50S ribosomal protein L6 (rplF) has been shown to provide a higher resolution (111). Also, multilocus approaches, including 7-locus (112) and 52-locus (ribosomal) (13) MLST, are robust methods for species assignment within the genus Neisseria.

TYPING SYSTEMS
Neisseria gonorrhoeae
Methods used for typing of N. gonorrhoeae include opa typing, pulsed-field gel electrophoresis, multiantigen sequence typing, and MLST. While both opa typing and pulsed-field gel electrophoresis are highly discriminatory, they are cumbersome and poorly portable. Multiantigen sequence typing, on the other hand, represents a portable, sequence-based typing method for N. gonorrhoeae, based on sequencing of coding regions of the highly polymorphic antigens Por and TbpB (β subunit of transferrin-binding protein) (113). Moreover, MLST (114) based on the sequence typing of seven housekeeping gene fragments was also shown to be highly discriminatory for N. gonorrhoeae typing (112).

Neisseria meningitidis
N. meningitidis is a highly variable organism, and a vast array of techniques has been developed to describe variants. The simplest method of typing is based on the nature of the polysaccharide capsule. In total, 12 different serogroups can be distinguished, which include A, B, C, E, H, I, K, L, W, X, Y, and Z (5). The nomenclature was recently updated, with serogroups W135 and 29E being renamed W and E, respectively (5). Serogrouping of common serogroups is usually performed by slide agglutination with a set of commercially available sera (supplied by Remel, Lenexa, KS, or Becton, Dickinson and Company, Franklin Lakes, NJ). A further level of differentiation can be achieved by serotyping and serosubtyping, which designate the serological characterization of the outer membrane proteins PorB and PorA, respectively. Today, however, DNA sequence-based typing schemes for hypervariable outer membrane proteins have replaced sero(sub)typing. Protocols are available at http://neisseria.org. Typing targets have been harmonized throughout Europe (115) (Table 3). Protocols for multiple-locus variable-number tandem-repeat analysis have also been developed for meningococci (116). Finally, use of whole-genome sequencing, as employed for the analysis of historical outbreaks (117, 118), is likely to be extended in the coming years.

SEEROLOGIC TESTS
Serologic tests are used for the determination of protection against IMD after vaccination or for seroepidemiologic studies. They do not contribute to the ascertainment of invasive disease, since asymptomatic carriage can also elicit protective (i.e., high) titers. The serum bactericidal assay is a functional assay using an external complement source, such as baby rabbit or human complement, that determines a bactericidal titer. It is currently regarded as the best surrogate test for vaccine protection across all serogroups (119). In addition to the serum bactericidal assay, serum IgG concentrations against serogroups A, C, W, and Y can be determined by enzyme-linked immunosorbent assay (ELISA) or bead assays (120).

ANTIMICROBIAL SUSCEPTIBILITIES
Neisseria gonorrhoeae
The CLSI recommends the use of GC agar containing 1% growth supplement for disk diffusion testing of N. gonorrhoeae (121). Colony suspensions of isolates need to be adjusted to a 0.5 McFarland standard before inoculation onto media. The CLSI further recommends agar dilution for the
measurement of MICs, yet due to their ease of use, gradient test systems (e.g., Etest) represent an acceptable and frequently used surrogate. Treatment and control of gonorrhea are aggravated by the ability of N. gonorrhoeae to mount resistance against a wide range of antibiotics. While penicillin was the treatment of choice up to the 1970s, the emergence and increase of penicillinase (122) and chromosomally mediated penicillin resistance led to the abandonment of penicillin as a treatment option. Similarly, plasmid- and chromosomally mediated resistance against tetracycline resulted in the replacement of this drug by broad-spectrum cephalosporins in the 1980s, and later by the fluoroquinolones. Nevertheless, resistance against fluoroquinolones emerged in Southeast Asia in the 1990s (123) and spread widely to many countries, including the United States (124). Since April 2007, quinolones are no longer recommended to treat gonococcal infections in the United States (124). Since April 2007, quinolones are no longer recommended to treat gonococcal infections in the United States (124).

*PorA, porin A; FetA, ferric enterobactin transport protein A; PorB, porin B; abcZ, putative ABC transporter gene; adk, adenylate kinase gene; aroE, shikimate dehydrogenase gene; fumC, fumarate hydratase gene; gdh, glucose-6-phosphate dehydrogenase gene; pdhC, pyruvate dehydrogenase subunit gene; pgm, phosphoglucomutase gene; penA, gene encoding penicillin binding protein 2.

Neisseria meningitidis

According to the CLSI, testing should be performed by disk diffusion on Mueller-Hinton agar with 5% defibrinated sheep blood or by broth microdilution using cation-adjusted Mueller-Hinton broth with 2.5 to 5.0% lysed horse blood (121). Alternatively, gradient test systems (e.g., Etest) are frequently used. In contrast to N. gonorrhoeae, N. meningitidis is usually penicillin susceptible, and β-lactamase production is rare (132). In many countries, penicillin is still regarded as a treatment of choice for IMD, although reduced susceptibility, resulting from modification of penicillin binding protein 2, has increasingly been recorded in several countries (133, 134). Its molecular basis lies in a combination of five amino acid polymorphisms, at positions 504, 510, 515, 541, and 566 of the penA gene (130). As with cefixime, cutoff MIC values for decreased susceptibility against ceftriaxone differ, with cutoffs of ≥0.5 mg/liter and ≥0.25 mg/liter for GISP and EuroGASP, respectively; nevertheless, the percentage of isolates with a MIC of 0.25 mg/liter was comparably low, i.e., 1.3% of isolates within GISP in 2011 (126), suggesting a true difference between surveillance networks. A further concern is the emergence of resistance against ceftriaxone, due to alterations within the penA gene (130). As with cefixime, ceftriaxone MIC values for decreased susceptibility against ceftriaxone differ, with cutoffs of ≥0.5 mg/liter and ≥0.25 mg/liter for GISP and Euro-GASP, respectively. While neither network recently reported strains meeting its own definition of decreased susceptibility, 0.05% and 0.02% of strains in GISP had MICs of 0.25 mg/liter in 2010 and 2011, respectively.

Due to the above-described developments, several guidelines now list a combination of intramuscular ceftriaxone and oral azithromycin as a first-line treatment regimen (85, 131). Ceftriaxone may be replaced by cefixime if ceftriaxone is not available. As described before, fluoroquinolones may be used for treatment only after antimicrobial susceptibility is documented by culture.
found to have a mosaic structure, suggesting multiple events of interspecies horizontal DNA transfer originating from commensal Neisseria species (135). Moreover, MICs of cefotaxime were reported to be higher in penicillin-intermediate strains (136). The CLSI defines cefotaxime nonsusceptibility as having a MIC of >0.12 mg/liter, yet it does not provide a threshold for resistance (121). While cefotaxime nonsusceptibility is rare globally, disquietingly high MICs of up to 8 mg/liter were reported from a sample of 8 nonsusceptible strains in India (137). Nevertheless, spread to other countries has not taken place, and the mechanism of nonsusceptibility has not been verified. Rifampin and ciprofloxacin are used for chemophylaxis in close contacts of patients. Rifampin-resistant strains have MICs of >2 mg/liter and result from point mutations in the RNA polymerase β subunit (rpoB) gene (138). Despite this one-step mechanism, the rate of resistance is very low (139). Resistance against ciprofloxacin emerged in the United States in 2007 (140) and is associated with a point mutation at position 91 of the gene encoding subunit A of DNA gyrase (gyrA). While the rate of resistant isolates is low in the United States (140) and Europe, an alarmingly large proportion (65% of isolates) was reported in an outbreak of IMD in India (141). The CLSI defines ciprofloxacin resistance as having a MIC of ≥0.12 mg/liter or a zone diameter of ≤32 mm, using the 5-µg ciprofloxacin disk diffusion method (121). Azithromycin is used for mucosal eradication in patient contacts in areas with high rates of ciprofloxacin resistance (140). Due to the lack of resistant strains (143), “susceptibility-only” criteria were issued by the CLSI, according to which strains with azithromycin MICs of ≤2 mg/liter are considered susceptible (121).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Neisseria gonorrhoeae

Due to the imperfect specificity of many diagnostic methods used for identification of N. gonorrhoeae, results have to be interpreted in the context of local disease prevalence, which considerably influences the test’s PPV. This particularly applies to NAATs, which, due to varying specificities, cannot be recommended uniformly for use in low-prevalence settings. If medicolegal ramifications are likely to result from a positive test, as is the case, e.g., in victims of sexual assault, special scrutiny has to be applied to all laboratory procedures involved in the issuing of a positive result.

In low-prevalence settings, special protocols should be in place to ensure confirmation of results. This is also important for specimens from children and adolescents and for the documentation of sexual abuse. In such cases, suspected N. gonorrhoeae should be confirmed by at least two different methods, including (i) multitest identification systems, (ii) immunologic methods, (iii) DNA probe culture confirmation, (iv) sequencing of the 16S rRNA gene, or (v) MALDI-TOF mass spectrometry. Additionally, strains and DNA need to be conserved.

In settings of high prevalence, such as in laboratories serving genitourinary medicine clinics, tests giving a “yes-no answer” may be preferable over systems identifying the exact species. In these settings, two levels of confidence may be attached to the laboratory report. A presumptive diagnosis of gonorrhea may be issued if either of the following two criteria is met: (i) microscopic visualization of typical Gram-negative diplococci on examination of a smear of male urethral exudate or endocervical secretions; and (ii) growth of oxidase-positive bacteria from the male urethra or endocervix on selective media, with a colonial morphology and microscopic appearance (Gram-negative diplococci) suggestive of N. gonorrhoeae. A definitive diagnosis requires (i) isolation of oxidase-positive Gram-negative diplococci from sites of exposure (e.g., urethra, endocervix, throat, or rectum) by culture on selective media and (ii) confirmation by biochemical or molecular methods.

The choice of approach is often determined by the workload and prevalence of gonorrhea in the service area of the laboratory. Laboratories that rarely encounter N. gonorrhoeae should prefer kits which give a full identification to the species level.

Neisseria meningitidis

N. meningitidis is always considered a pathogen when isolated from usually sterile body fluids, such as blood or CSF. Also, if it is isolated from the urethra, cervix, or conjunctiva, a pathogenic role is likely. In such cases, N. meningitidis should always be reported and the strain be forwarded to a reference laboratory. Many national guidelines consider meningococcal conjunctivitis an indication for chemophylaxis of the patient and close contacts, due to a high immediate risk of invasive disease (144, 145). Detection of N. meningitidis from bronchoalveolar lavage fluid or sputum has to be interpreted in liaison with the clinician, as it does not automatically imply a pathogenic role. Growth from oropharyngeal or nasopharyngeal specimens usually reflects asymptomatic carriage and may be omitted from laboratory reports, as it readily leads to confusion regarding the pathogenic significance. Eradication of asymptomatic carriers should not be recommended. Similarly, typing of meningococcal carriage isolates should not routinely be performed. Furthermore, obtaining nasopharyngeal swabs to detect meningococci from close contacts of a patient with invasive disease should not be done on a routine basis, as this may reveal the presence of unrelated strains and delay the decision regarding whom should be offered chemoprophylaxis.

Other Neisseria Species

Neisseria animalis

N. animalis strains are Gram-negative cocoid rods that may constitute currently underrecognized agents of dog bite infections (31). N. animalis is a commensal of the oral cavity of cats and dogs and was formerly named CDC group EF-4a. N. animalis produces yellowish white, convex, opaque, shiny, smooth, and hemolytic colonies on blood agar (146). In contrast to most other Neisseria species, these strains grow on MacConkey agar. As a distinctive characteristic, N. animalis is arginine dihydrolase positive. Isolates have been described as being ampicillin susceptible (31). Further characteristics are detailed in Table 2.

Neisseria bacilliformis

Like N. elongata, N. weaveri, and N. shayeghani sp. nov., N. bacilliformis organisms are rods, not cocci. On blood agar, colonies are smooth and glistening and have sizes of up to 1 mm after 24 h (10). The colors of colonies range from light gray to buff (Fig. 2). Catalase reaction and reduction of nitrate are variable, and strains are asaccharolytic (10). Strains are associated with the human respiratory tract and
have occasionally been recovered as causative agents of endocarditis (10, 147).

**Neisseria cinerea**

As the species name suggests, colonies of *N. cinerea* have an ash-gray color, and they are up to 1.5 mm in diameter. Isolates are asaccharolytic; i.e., they do not acidify carbohydrate-containing media. Due to their carbohydrate utilization profile, *N. cinerea* strains can be confused with glucose-negative *N. gonorrhoeae* (99). Furthermore, growth on selective media is occasionally possible despite colistin susceptibility (148). *N. cinerea* colonizes the oropharynges of over 24% of adults (149). Furthermore, it has been attributed a role in ocular infections in infants (150).

**Neisseria elongata**

*N. elongata* forms grayish white, semiopaque colonies, which have a diameter of up to 3 mm after 48 h of incubation. In contrast to the majority of species within *Neisseria*, *N. elongata* organisms are short rods of ca. 0.5 μm in diameter. The species consists of three subspecies: *N. elongata* subsp. *elongata*, *N. elongata* subsp. *glycolytica*, and *N. elongata* subsp. *nitroreducens* (Table 2). As an exception within the genus *Neisseria*, *N. elongata* subsp. *nitroreducens* is catalase negative. Like other *Neisseria* species, *N. elongata* mainly appears as a colonizer of the human oropharynx. Nevertheless, several cases of endocarditis caused by *N. elongata* have been published (151).

**Neisseria flavescens**

*N. flavescens* produces smooth and opaque yellow colonies. *N. flavescens* does not generate acid from sugars yet produces polysaccharide from sucrose, which can be detected by pouring an iodine-containing solution (e.g., Lugol’s solution) over colonies growing on brain heart infusion agar with sucrose. The iodine test is positive if colonies develop a deep blue color, indicating the presence of a starch-like polysaccharide. *N. flavescens* colonizes the oropharynx of humans and only rarely causes disease, such as endocarditis (152). Recent genomic analyses suggest that this species should be relabeled a variant of *N. subflava* (13).

**Neisseria lactamica**

*N. lactamica* is readily confused with *N. meningitidis*, since it is morphologically similar and may grow on selective media. Nevertheless, it acidifies lactose in addition to glucose and maltose and is γ-glutamyl-aminopeptidase negative. *N. lactamica* is a commensal of the upper respiratory tract in infants and children. In contrast to the case for *N. meningitidis*, colonization of the oropharynx with *N. lactamica* begins as soon as 2 weeks after birth (153). It is rarely pathogenic, although exceptional cases of meningitis and septicemia have been described. *N. lactamica* usually displays reduced susceptibility to penicillin.

**Neisseria mucosa**

*N. mucosa* typically grows in large, adherent, mucoid colonies, which are mostly nonpigmented. In carbohydrate utilization tests, strains of this species are glucose, maltose, fructose, and sucrose positive. *N. mucosa* is usually an apathogenic commensal in the nasopharynx of humans. However, it has been associated with infective endocarditis (154) and with bacteremia in a neutropenic patient (155). Due to variable susceptibility to penicillin, the choice of antibiotic treatment must be supported by susceptibility testing.

**Neisseria polysacchararea**

Strains of *N. polysacchararea* present as small, grayish yellow, translucent colonies. Similar to *N. meningitidis*, they acidify glucose and maltose but not fructose or lactose. In addition, they may grow on selective media. In contrast to *N. meningitidis*, however, the iodine test is positive, indicating the production of polysaccharide from sucrose (similar to the case for *N. flavescens*). This species colonizes the nasopharynx of children and has so far not been associated with disease.

**Neisseria sicca**

The colonies formed by *N. sicca* are large (≤3 mm), dry, wrinkled, and grayish white, although some strains may produce a yellowish pigment. Its carbohydrate utilization profile is indistinguishable from that of *N. mucosa*, but it does not reduce nitrate. This bacterium is a common oropharyngeal commensal in humans. Nevertheless, it can appear as an opportunistic pathogen. *N. sicca* has been implicated, e.g., as the causative agent of endocarditis (156). Recent genomic analyses suggest that *N. sicca* and *N. macacae* should be categorized as variants of *N. mucosa* (13).

**Neisseria subflava**

*N. subflava* appears as smooth, variably transparent colonies with a yellowish pigment. This species contains the previous species *N. subflava*, *N. perflava*, and *N. flava* (1). Strains of *N. subflava* acidify glucose and maltose. In addition, *N. subflava* bv. *subflava* and *N. subflava* bv. *flava* produce acid from fructose, while *N. subflava* bv. *perflava* acidifies sucrose and produces polysaccharide from sucrose. *N. subflava* is a common commensal of the human oropharynx but has occasionally been associated with invasive diseases, such as meningitis, endocarditis, and bacteremia (157). Similar to the case for *N. lactamica*, reduced susceptibilities to penicillin, and also cefixime and ciprofloxacin, have been reported (158).

**Neisseria weaveri**

Colonies of *N. weaveri* are of variable size (1 to 2 mm), smooth, flat, and slightly glistening (1). They have entire edges and are grayish. Like most species of the genus *Neisseria*, *N. weaveri* is strongly catalase and oxidase positive. Like *N. bacilliformis* and *N. elongata*, *N. weaveri* organisms are
Neisseria zoodegmatis
Similar to N. animaloris, N. zoodegmatis is a Gram-negative cocccoid rod (30) and was formerly named CDC group EF-4b. Its habitat (30), colony morphology, growth on MacConkey agar (146), and clinical significance (31) are identical to those of N. animaloris. Nevertheless, in contrast to N. animaloris, N. zoodegmatis is arginine dihydrolase negative (146).

Aggregatibacter, Capnocytophaga, Eikenella, Kingella, Pasteurella, and Other Fastidious or Rarely Encountered Gram-Negative Rods*

REINHARD ZBINDEN

The bacterial genera covered in this chapter are taxonomically diverse and belong to the families Cardiobacteriaceae, Flavobacteriaceae, Leptotrichiaceae, Neisseriaceae, Pasteurellaceae, and Porphyromonadaceae, but common traits justify their discussion as a group. They are isolated infrequently and constitute part of those Gram-negative genera that stand apart from the Aeromonadaceae, Enterobacteriaceae, Vibrionaceae, and Rickettsiales. With the exception of Chromobacterium and some Pasteurella species, for aerobic growth they require supplemented media, on which they often grow slowly (48 h at 35 to 37°C), and fail to grow on enteric media. A 5 to 10% CO₂ atmosphere may be necessary for growth initiation and improves growth on subculture. With the exception of Chromobacterium, they do not possess flagella but may show gliding or twitching motility, resulting in limited spreading of colonies and pitting of the agar surface.

The identification of these genera is difficult by conventional phenotypic methods. Commercially available systems (1–5) allow identification of the frequently encountered human isolates. If accurate identification of uncommon isolates is of concern, then molecular methods, e.g., 16S rRNA gene analysis, are necessary (6). The application of matrix-assisted laser desorption ionization–time-of-flight mass spectrometry (MALDI-TOF MS) shows promising results (7, 8). Molecular methods and MALDI-TOF MS are both discussed in this chapter. The patterns of the cellular fatty acids are no longer integrated in the tables; these data can be found in chapter 33 of the 10th edition of this Manual. This chapter discusses only species that can be isolated from humans.

TAXONOMY AND DESCRIPTION OF THE AGENTS

The taxonomy of the family Pasteurellaceae has undergone important changes (9; http://www.icsp.org/subcommittee/pasteurellaceae/taxa.html); the family consists of >80 named species distributed in 17 genera, of which 4 are known to contain human pathogens: Actinobacillus, Aggregatibacter, Haemophilus, and Pasteurella. Minimal standards for the description of genera, species, and subspecies of the Pasteurellaceae have been proposed and might create further changes (10). Aggregatibacter spp., formerly named Haemophilus (11), are included in this chapter. The genus Haemophilus, as presently constituted, is described in chapter 36. Neisseria spp. with rod forms, i.e., Neisseria elongata subsp. glycotoxica and subsp. nitroreducens, Neisseria weaveri, and CDC group EF-4a, renamed Neisseria animaloris (12), are described in chapter 34 but are included in a differentiation table in this chapter (see Table 4).

Actinobacillus

The genus Actinobacillus in the family Pasteurellaceae consists of facultatively anaerobic, nonmotile, Gram-negative rods and comprises animal (A. equuli, A. lignieresii, and A. suis) and exclusively human (A. hominis and A. ureae) species but no longer includes Actinobacillus actinomycetemcomitans (11). The G+C content of the DNA of Actinobacillus spp. is between 40 and 43 mol% (13).

Aggregatibacter

Multilocus sequence analysis of A. actinomycetemcomitans, Haemophilus aphrophilus, Haemophilus paraphrophilus, and Haemophilus segnis (11) had suggested that these bacteria represented a monophyletic group. In addition, DNA-DNA relatedness between H. aphrophilus and H. paraphrophilus was 77%, and DNA from H. aphrophilus was able to transform H. paraphrophilus to have an NAD-independent phenotype (11). It was, therefore, proposed to transfer A. actinomycetemcomitans, H. aphrophilus, H. paraphrophilus, and H. segnis into a new genus, Aggregatibacter in the family Pasteurellaceae, with the species Aggregatibacter aphrophilus comprising the former H. aphrophilus and H. paraphrophilus, i.e., including V factor-dependent and -independent isolates (11). The G+C content of the DNA of Aggregatibacter spp. is 42 to 44 mol% (13).

Capnocytophaga

The Capnocytophaga genus in the family Flavobacteriaceae at present consists of nine species (C. canimorsus, C. cynodegmi, C. ochracea, C. gingivalis, C. sputigena, C. haemolytica, C. granulosa, C. leadbetteri, and genospecies AHN8471) of

*This chapter contains information presented by Reinhard Zbinden and Alexander von Graevenitz in chapter 33 of the 10th edition of this Manual.

doi:10.1128/9781555817381.ch35

652
facultatively anaerobic, nonmotile, Gram-negative rods, but with gliding motility (14). The G+C content of the DNA of this genus is 34 to 44 mol% (15).

**Cardiobacterium**
The *Cardiobacterium* genus in the family *Cardiobacteriaceae* consists of facultatively anaerobic, nonmotile, Gram-negative rods, with the species *C. hominis* and *C. valvarum* (16). The G+C content of the DNA of these species is 59 to 60 mol% (17).

**Chromobacterium**
The *Chromobacterium* genus in the family *Neisseriaceae* (18) contains several facultatively anaerobic, motile species, of which *C. violaceum* is at present at the only agent of human disease. Its DNA content is between 65 and 68 mol% (18). *C. haemolyticum*, isolated from a sputum culture, is so far represented by one strain only (19) and is not covered here.

**Dysgonomonas**
The genus *Dysgonomonas* in the family *Porphyromonadaceae* consists of facultatively anaerobic, nonmotile, Gram-negative rods (20). Four species have been described: *D. capnocytophagoides* and *D. gadei* (21), *D. mossii* (22), and *D. hofstadii* (23). The G+C content of the DNA is ~38 mol% (20).

**Eikenella**
The genus *Eikenella* in the family *Neisseriaceae* (18) consists of facultatively anaerobic, nonmotile, Gram-negative rods. Thus far, only one species, *E. corrodens*, has been recognized. The G+C content of the DNA of *Eikenella* is between 56 and 58 mol% (18).

**Kingella**
The genus *Kingella* in the family *Neisseriaceae* consists of the facultatively anaerobic, nonmotile species *K. kingae*, *K. denitrificans*, *K. oralis*, and *K. potus* (18, 24). The G+C content of the DNA of these species is between 47 and 58 mol% (18).

**Pasteurella**
The taxonomy of the genus *Pasteurella* in the family *Pasteurellaceae* has been in flux for some time (10, 13; http://www.bacterio.net). *P. multocida* can be separated into the subspecies *multocida*, *septica*, and *gallicida*; *P. canis*, *P. dagmatis*, and *P. stomatis* are other species isolated from humans. In spite of the genotypically homogeneity of *P. multocida* isolates, phenotypically diverse lineages have been observed, e.g., sucrose-negative variants from infections that were made by large cats (25). The G+C content of the DNA of *Pasteurella* species is between 38 and 46 mol% (13). New genera or reclassifications may be necessary for species discussed below that are preceded by "(P.)" or "(Pasteurella)" (26).

**Simonsiella**
The genus *Simonsiella* in the family *Neisseriaceae* consists of several obligately aerobic species that may show gliding motility (18). The only species isolated from humans is *S. muelleri*. This genus has a G+C content in its DNA of 40 to 50 mol% (18).

**Streptobacillus**
The *Streptobacillus* genus in the family *Leptotrichiaceae* (27) consists of one facultatively anaerobic, nonmotile species, *S. moniliformis*, with a G+C content in its DNA of 24 to 26 mol% (27). See chapter 54 for the genus *Leptotrichia* of the family *Leptotrichiaceae*.

**Suttonella**
The *Suttonella* genus in the family *Cardiobacteriaceae* (17) consists of facultatively anaerobic, nonmotile, Gram-negative rods and so far contains only one species, *S. indolgenes* (formerly *Kingella indologenes*) (http://www.bacterio.net). The G+C content of its DNA is 49 mol% (17).

**EPIDEMIOLOGY AND TRANSMISSION**
Most bacteria in this group are part of the microbiota of the nasopharynx and/or the oral cavity of animals and/or humans and are parasitic, with the only environmental genus being *Chromobacterium*. Transmission from animals occurs by contact (e.g., bites and licking of wounds), from humans to humans by droplets (e.g., directly with *Kingella* spp. or by paraphernalia or human bites with *E. corrodens*). They may cause infections anywhere in the human body. Risk factors exist for certain types of septicaemia (e.g., liver cirrhosis for *P. multocida*, neutropenia for oxidase-negative *Capnocytophaga* spp., and chronic granulomatous disease for *C. violaceum*). Endogenous infections occur as well, e.g., HACEK (*Haemophilus* spp., *Aggregatibacter* spp., *Cardiobacterium* spp., *E. corrodens*, and *Kingella* spp.) endocarditis (28).

The habit of the HACEK group, e.g., *Haemophilus* spp. and *Aggregatibacter* spp., is the human oral cavity, including dental plaque; infections are endogenous (11, 29). The normal habitat of *Cardiobacterium* spp. is the human oral cavity and nasopharynx but possibly also the gastrointestinal and urogenital tracts (17, 28). Infections are endogenous. The natural habitat of *E. corrodens* is the oral cavities and possibly the gastrointestinal tracts of humans and some mammals, from which it can be transmitted via saliva (bites, syringes) to other individuals (30–32). Endogenous infections prevail, however. The natural habitat of *Kingella* spp. is the upper respiratory tract and oral mucosa of humans and possibly other primates. *K. kingae* colonizes the throat but not the nasopharynx of many children aged 6 months to 4 years (33). Ribotyping and pulsed-field gel electrophoresis have shown that *K. kingae* can be transmitted via respiratory droplets (34), although most infections are endogenous. *K. oralis* has been isolated from the human mouth (18). *S. indolgenes* is not an official constituent of HACEK but is well known as an agent of endocarditis (35). However, its natural habitat is not known (17).

A. *lignieresii* (primary habitat in the oral cavities of sheep and cattle), *A. equuli* (in the oral cavities of horses and pigs), and *A. suis* (in the oral cavities of pigs) can be transmitted to humans by animal contact (29). Exclusively human are *A. hominis* and *A. ureae*, whose normal habitat is unknown (29, 36).

The oxidase- and catalase-negative species *C. ochracea*, *C. gingivalis*, *C. spautigena*, *C. haemolytica*, and *C. granulosa*, as well as the recently described *C. leadbetteri* and genospecies AHN8471, are normal but not prominent members of the human oral microbiota (14). The first three have been isolated from adults with periodontal disease but also from periodontitis-free adults; the other four have been isolated from supragingival and subgingival plaque in children and adults (14). Infections are endogenous. The oxidase- and catalase-positive species *C. canimorsus* and *C. cynodegmi* reside in the oral cavities of healthy dogs (25% of dogs have *C. canimorsus* as determined by culture and 85 to 100% of
dogs have it as determined by PCR) and cats (15%, as determined by culture) (37). Chromobacterium inhabits soil and water in tropical and subtropical climates between latitudes of 35°N and 35°S (South Africa, Southeast Asia, Australia, southeastern United States, and, rarely, South America) (38, 39). The portal of entry is usually the skin, but oral intake has also been reported (40).

Most D. capnocytophagoides strains have been isolated from stools of immunocompromised patients, and a few strains have been isolated from other sources (41). The natural habitats of this and the other Dysgonononas spp. are unknown (22, 23).

Pasteurella spp. are widespread in healthy and diseased wild and domestic animals, including rodents, dogs, and cats, inhabiting the nasopharynx and gingiva (13). Human isolates are transmitted predominantly from animals by contact (bites or licking or scratching of wounds). Of the “related” species, (Pasteurella) aerogenes occurs primarily in pigs (42), (Pasteurella) caballi in pigs and equines (42, 43), and (Pasteurella) pneumotropica in rodents and dogs (44); the natural habitat of (Pasteurella) bettyae is uncertain.

The natural habitat of S. muelleri is the oral cavity of humans. In healthy human populations, the incidence of Simonsiella spp. is in the range of 30 to 40%. Children possibly have a higher incidence than adults. In dogs and cats, Simonsiella spp. are common and abundant (18).

S. moniliformis occurs naturally in the upper respiratory tract of up to 100% of wild and laboratory rats and other rodents (mice, gerbils, squirrels, ferrets, and weasels) and occasionally of dogs and cats preying on rodents. Transmission to humans occurs either from bites of those animals (rat bite fever) or from consumption of contaminated food or water (Haverhill fever) (45).

**CLINICAL SIGNIFICANCE**

*Actinobacillus* spp.

A. lignieresii causes actinobacillosis, a granulomatous disease in cattle and sheep in which, similar to actinomycosis, sulfur granules form in tissues (46). A few human soft tissue infections after a cow or sheep bite or other contacts have been reported (42). A. equuli and A. suis have caused a variety of diseases in horses and pigs; human infections are generally due to horse or pig bites or contact (42). Both species have also been isolated, albeit rarely, from the human upper respiratory tract (13, 47). A. ureae is most often a commensal in the human respiratory tract, particularly in patients with lower respiratory tract disease (13), but has also been found as an agent of meningitis following trauma or surgery (48) and of other infections in immunocompromised patients (49). A. hominis has also been isolated from such patients but has occurred as a commensal as well, albeit rarely (36). Virulence factors belong to the pore-forming protein toxins of the RTX family; RTX toxins have repeats in the structural toxin peptide and exhibit a cytotoxic and often also a hemolytic activity. They are particularly widespread in species of the family Pasteurellaceae (50).

*Aggregatibacter* spp.

A. actinomycetemcomitans is one of the major agents of juvenile and adult periodontitis (51) and may occur together with Actinomyces spp. in actinomycotic sulfur granules (11). Furthermore, it may cause HACEK endocarditis (28), soft tissue infections, and other infections (52). In a large, multinational cohort study, HACEK organisms were the causes of 1.4% of all cases of endocarditis (53). HACEK endocarditis is characterized by a relatively long interval between first symptoms and diagnosis (range, 2 weeks to 6 months), large vegetations on native or artificial valves of the left side, and frequent embolizations. Prognosis is good with appropriate antibiotic treatment (28, 53). Virulence factors are an RTX leukotoxin (50), a cytotoxic distending toxin (54), and the adhesin EmaA (55), as well as fimbrae (56).

A. aphrophilus may cause systemic disease, particularly bone and joint infections, spondylodiscitis, and endocarditis (52, 57, 58).

A. segnis, whose frequency may be underestimated due to apparent misdiagnoses, may cause endocarditis (59). It may be an important cause of bacteremia and sometimes of other infections, e.g., pyelonephritis (60).

*Capnocytophaga* spp.

C. ochracea, C. gingivalis, C. sputigena, C. haemolytica, and C. granulosa have been reported as agents of septicemia and other endogenous infections (endocarditis, endometritis, osteomyelitis, soft tissue infections, peritonitis, ophthalmic lesions, and noma) (30, 47, 61–63) in immunocompetent and immunosuppressed (mainly neutropenic) patients. They are able to suppress neutrophilic chemotaxis and lymphocyte proliferation (64). The association with periodontitis remains unclear (14).

Infections with *C. canimorsus* and *C. cynodegmi* are associated mainly with dog or cat bites or contact. Patients infected with *C. canimorsus* most often present with septicemia and have previously been splenectomized or are alcoholics. In fulminant cases with a poor prognosis, disseminated intravascular coagulation, acute renal failure, respiratory distress syndrome, and shock may develop (65). Hemolytic-uremic syndrome and thrombotic thrombocytopenic purpura are other possible sequelae (66). Meningitis (67, 68), keratitis (65), and endocarditis (69) have been reported as well. *C. cynodegmi* has been isolated more rarely, mainly from localized or systemic infections (70). *C. canimorsus* resists phagocytosis by macrophages and killing by complement and leukocytes; macrophages incubated with the bacterium fail to produce several proinflammatory cytokines (71).

*Cardiobacterium* spp.

Disease caused by both *Cardiobacterium* species is mainly HACEK endocarditis (16, 53); *C. hominis* prosthetic valve endocarditis has been described after upper endoscopy and colonoscopy (72), and on rare occasions, *C. hominis* has been isolated from other body sites (30, 73). Most reported cases of *C. vulvarum* endocarditis are related to periodontal diseases (74). In blood culture-negative cases, the diagnosis has been made by broad-range PCR applied to valve tissue (75).

*Chromobacterium violaceum*

Localized infections usually arise from contaminated wounds, and septicemia with multiple organ abscesses may follow. They are significantly associated with neutrophil dysfunction (glucose-6-phosphate dehydrogenase deficiency, chronic granulomatous disease). Children without these conditions and those with bacteremia show a high fatality rate (38–40). A number of virulence factors other than endotoxin, i.e., adhesins, invasins, and cytolytic proteins, have been described (76).

*Dysgonononas* spp.

Diarrhea was reported to have occurred in 10 of 20 patients with fecal isolates of *C. capnocytophagoides*, whereas routine
stool cultures yielded the organism in 1 to 2.3% of cultures (77). Bacteremia occurs as well (41); one blood isolate was found to be identical by ribotyping to one in the stool of a patient with pancreatic carcinoma (79). D. gadei has been isolated from a human gallbladder (21) and from blood (80), and D. hofstadii has been isolated from a wound (23).

**Eikenella corrodens**

*E. corrodens* is associated with juvenile and adult periodontitis (51) but is also an agent of infections of the upper respiratory tract, pleura and lungs, abdomen, joints, bones, wounds (e.g., from a human bite), and, rarely, other infections, like noma (30). These organisms are often indolent and found mixed with other members of the oropharyngeal microbiota, particularly staphylococci and streptococci. Risk factors are dental manipulations and intravenous drug abuse. Endocarditis is of the HACEK type if monomicrobial, but polymicrobial non-HACEK cases are known (28). *E. corrodens* can trigger a cascade of events that induce inflammation in periodontal tissue (82).

**Kingella spp.**

Infections with *K. kingae* show a predilection for bones and joints of previously healthy children <4 years of age (33). The use of culture and broad-range and *K. kingae*-specific real-time PCR shows it to be the most common cause of osteoarthritic infection in this age group (83). Septic arthritis, discitis, and osteomyelitis of the lower extremities as well as occult bacteremia are conspicuous. Stomatitis and/or upper respiratory infections may precede systemic disease, suggesting entry through a damaged mucosa (33). In adults, systemic infections occur in immunocompromised individuals (84) or may present as HACEK endocarditis (28, 53). Virulence factors are an RTX toxin (85) and type IV pili (86).

*K. denitrificans* has been reported as an agent of endocarditis (28, 53). *K. oralis* has been isolated from patients with periodontitis, but its relationship to the disease is unclear. *K. potus* has caused a wound infection following a kinkajou bite (24).

**Pasteurella spp.**

Human isolates of *P. multocida* are mostly found in wound or soft tissue infections. Less frequent are colonization or infection of the respiratory tract and (by hematogenous or contiguous route) systemic disease, such as meningitis, dialysis-associated peritonitis, endocarditis, osteomyelitis, urinary tract infection, and septicemia, with cirrhosis of the liver being a particular risk factor (87–90). The subspecies most frequently encountered is subspp. *multocida*, which is also more frequent in respiratory infections and bacteremias than subspp. *septica*, which is most often associated with wound infections and central nervous system infections (42, 88). Infected cat bite wounds contain pasteurellae significantly more often than infected dog bite wounds, reflecting a higher oropharyngeal colonization rate in cats than in dogs (88). In the respiratory tract, colonization may eventually lead to sinusitis or bronchitis as well as pneumonia and empyema, the latter two mostly in patients with prior respiratory disease (87). Virulence factors are capsules (five serotypes, of which A and D account for most human isolates), lipopolysaccharide (88), sialidases, hyaluronidase, surface adhesins, iron acquisition proteins (91), and the *P. multocida* toxin (PMT) (92). The PMT has many properties that mark it as a potential carcinogen; the PMT is a highly potent mitogen and has been demonstrated to block apoptosis (92).

Cases of human infection with *P. canis* (from dogs), *P. dagmatis*, and *P. stomatis* (from dogs or cats) are infrequent (88, 93, 94); however, *P. canis* is the most common species isolated from infected dog bite wounds (42). *P. dagmatis* has been reported in systemic infections such as pneumonias, peritonitis, septicemia, and endocarditis; furthermore, *P. dagmatis* can cause exacerbation of bronchectasis symptoms in chronic obstructive pulmonary disease patients (93). A prosthetic valve endocarditis caused by a *P. dagmatis*-like isolate originating from a patient's cat was recently described (95). In some cases of pasteurellosis, animal contact could not be established (96). Double infections with two Pasteurella spp. have also been observed (93).

Of the “related” species, (P.) *aerogenes* has caused wound infections from pig and hamster bites (42, 97), (P.) *betyae* has been found in infections of newborns and in infections of the male and female genital tracts (98), and (P.) *caballi* has been isolated from horse bites (42); (P.) *pneumotropica* is a rare agent of systemic infection in humans (44). Reported cases of human infection with *Aeubacterium gallinarum, Bibersteinia trehalosi, Gallibacterium anatis*, and *Mannheimia haemolytica*, all formerly in the genus Pasteurella, remain doubtful when stricter identification criteria are employed (99) or require confirmation (100).

**Simonsiella spp.**

S. *muelleri* has not been found associated with disease. *Simonsiella* can be encountered in exfoliative cytology specimens of the upper gastrointestinal tract, erosions of the oral mucosa, and the respiratory tract and should not be confused with a truly pathogenic organism (101).

**Streptobacillus moniliformis**

Rat bite fever is a systemic illness beginning with fever and chills, followed by migratory, sometimes even suppurative, polyarthritis and a maculopapular rash on the extremities. Rare complications include endocarditis, myo- or pericarditis, pneumonia, septicemia, and abscess formation (45, 102, 103).

**Suttonella indologenes**

Human isolates of *S. indologenes* have been very rare; they have been isolated from ocular sources (47) and a blood culture in a case of endocarditis (35).

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

Collection and transport of specimens should follow the guidelines described in chapter 18; the low viability of many species makes the use of transport media, e.g., eSwab (Copan Diagnostics Inc., Murrieta, CA), whenever indicated, mandatory. Cultures of most bacteria described in this chapter can be stored at room temperature for 1 to 2 weeks. However, for some other very fastidious bacteria, e.g., *C. canimorsus*, subcultures must be performed frequently. For keeping strains in a culture collection, the isolates should be frozen in a cryoprotective solution, e.g., skim milk, at −70°C.

**DIRECT EXAMINATION**

Direct microscopy of specimens or of positive blood cultures supported by clinical information may identify the
corresponding bacteria; e.g., the typical morphology of spindle-shaped cells in the Gram stain and the anamnestic history of a dog bite allow the presumptive identification of \( C. \) canimorsus. In a few instances of blood culture-negative cases, microscopy of the seeded valve and/or broad-range 16S rRNA gene sequence PCR of the valve or emboli have allowed the diagnosis of endocarditis (75). When the question arises as to whether an isolate is a Gram-negative coccus or coccobacillus, a penicillin disk can be added to the agar plate after streaking with the isolate. After incubation, the Gram stain from growth around the disk shows coccolid forms in the case of typical \( Neisseria \) spp.; otherwise it shows long rods (104).

**Actinobacillus** spp. are medium-sized, Gram-negative, rod-shaped or coccoid bacteria with a tendency to bipolar staining. Their arrangement is single, in pairs, and, rarely, in short chains.

**Aggregatibacter** spp. are coccoid to rod-shaped, Gram-negative bacteria, occasionally exhibiting filamentous forms. A commercial PCR-based hybridization method for the detection of \( A. \) actinomycetemcomitans and other periodontal pathogenic bacteria, e.g., \( E. \) corrodens and \( Capnocytophaga \) spp., has been described (105).

**Capnocytophaga** spp. are mainly fusiform, medium-to-long cells with tapered ends (Fig. 1a). \( L. \) baccalis is a long, fusiform, Gram-negative rod but with one tapered and one square end (Fig. 1b). Differentiation is supported by biochemical reactions; furthermore, lactic acid is the major fermentation end product of \( L. \) baccalis, and succinic acid is the major fermentation end product of \( Capnocytophaga \) spp. (47). \( C. \) canimorsus can also be detected by broad-range PCR (68).

**Cardiobacterium** spp. are pleomorphic on blood agar. \( C. \) hominis stains irregularly and appears as straight, Gram-negative rods in short chains, pairs, or rosettes, sometimes with bulbous ends; occasionally, filaments are formed. On chocolate agar, this morphology is less distinct than on blood agar. In a few instances, broad-range PCR of valve or emboli have led to the diagnosis (75).

**C. violaceum** is a medium-sized, Gram-negative rod or coccus that is motile by one polar flagellum and one to four lateral flagella (18). A PCR technique for its detection has been developed (106).

**Dysgonomonas** spp. are small, Gram-negative rods or cocci similar to \( Moraxella \) spp. (Fig. 1c) (20). In contrast to coccoid \( Neisseria \) spp., these two genera show long rods in the Gram stain from growth around the penicillin disk (104).

**E. corrodens** is a slender, straight, small, Gram-negative rod with rounded ends (Fig. 1d). A specific PCR is also commercially available (105).

**Kingella** spp. are short, Gram-negative rods with square ends that lie together in pairs or clusters (Fig. 1e). They tend to decolorize unevenly on Gram stains. A broad-range PCR has detected \( K. \) kingae-specific sequences in culture-negative osteoarticular specimens (83).

**Pasteurella** spp. are small, Gram-negative rods or cocci that occur singly, in pairs, or in short chains. Bipolar staining is frequent. “Related” species are more rod-like. A PCR technique for their detection is mainly applied in the veterinary field (107).

**Simonsiella** spp. are Gram-negative, crescent-shaped rods (0.5 to 1.0 \( \mu \)m long) arranged in multicellular filaments (10 to 50 \( \mu \)m by 2 to 8 \( \mu \)m) and segmented into groups of mostly eight cells, resulting in a caterpillar-like appearance. The long axis of each cell is perpendicular to the long axis of the filament. Incomplete decolorization on Gram stains is common.

**S. moniliformis** is a Gram-negative rod with a variable morphology. Depending on age and culture conditions, cells may appear as straight, small to medium-size rods or as 100- to 150-\( \mu \)m-long tangled chains and filaments with bulbar swellings (Fig. 1f). In culture-negative cases, broad-range PCR of fluids has been employed (108). A PCR assay that uses primers designed on the basis of 16S rRNA gene sequence data has been described; the PCR product treated with the restriction enzyme BfaI generates three fragments specific for \( S. \) moniliformis (109).

**S. indologenes** is a plump, irregularly staining, Gram-negative rod; occasionally, pairs, chains, or rosettes are formed.

### ISOLATION PROCEDURES

For culture of members of this group, the use of blood or chocolate agar and, wherever normal microbiota and specific bacteria are suspected, of selective media is mandatory. Most of them are facultatively anaerobic and do not grow on MacConkey agar. HACEK members do not need more than 5 days of incubation in modern blood culture systems (110).

**Actinobacillus** spp. and **Aggregatibacter** spp. require enriched media, and they grow better in a 5 to 10% \( CO_2 \) atmosphere. Some \( A. \) aphrophilus (formerly \( H. \) paraphrophilus) strains and \( A. \) segnis require \( V \) factor; none requires hemin. Selective media for \( A. \) actinomycetemcomitans have employed bacitracin and vancomycin (111).

Primary isolation of \( Capnocytophaga \) spp. requires 5 to 10% \( CO_2 \) and enriched media; the composition of the blood agar base influences the ability to grow (112). For detection in mixed cultures, selective media containing bacitracin, polymyxin B, vancomycin, and trimethoprim have been used (113), as have Thayer-Martin and Martin-Lewis agars (15). \( C. \) canimorsus has most often been isolated from blood cultures. However, it may not be detected by commonly used automated blood culture systems; therefore, clinicians should inform the laboratory about risk factors for \( C. \) canimorsus infection so that subcultures on enriched media can be performed in a blind manner (112).

**Cardiobacterium** spp. mostly require 5 to 10% \( CO_2 \) and increased humidity for initial growth on blood agar. **Cardiobacterium** spp. have most often been isolated from blood.

**C. violaceum** grows on routine media, even on most enteric ones, at 30 to 35°C, its optimal temperature (18).

**Dysgonomonas** spp. grow slowly on blood agar in \( CO_2 \)-enriched atmosphere (20). A selective medium containing cefoperazone, vancomycin, and amphotericin B has been used for stool cultures (78).

With a few exceptions, **E. corrodens** strains require hemin for growth unless 5 to 10% \( CO_2 \) is present (18). **E. corrodens** grows well on commercial Columbia agar (112).

Recovery of \( K. \) kingae from body fluids and pus can be difficult because these specimens seem to be inhibitory. For isolation from mixed cultures, media containing clindamycin or vancomycin as well as Thayer-Martin agar have been recommended (18). The use of various blood culture media has significantly improved the detection rate (33).

In contrast to some **Haemophilus** spp., **Pasteurella** spp. are hemin and \( CO_2 \) independent and will, therefore, grow on media without blood. “Related” species may even grow on enteric media (13).

**S. Muelleri** grows aerobically on blood agar. There are no enrichment procedures for **Simonsiella**, but an isolation
FIGURE 1  (a) Capnocytophaga ochracea. Gram stain of a 48-h culture grown on sheep blood agar (Institute of Medical Microbiology, University of Zurich, Zurich, Switzerland). (b) Leptotrichia buccalis. Gram stain of a 48-h culture grown on sheep blood agar (Institute of Medical Microbiology, University of Zurich). (c) Dysgonomonas capnocytophagoides. Gram stain of a 48-h culture grown on sheep blood agar (Institute of Medical Microbiology, University of Zurich). doi:10.1128/9781555817381.ch35.f1
method with tryptic soy broth without dextrose agar has been described (18). S. moniliformis is best isolated from blood, joint fluid, or abscess material. For culture, media enriched with sheep, horse, or rabbit blood (15%) seems to be optimal, serum, or ascitic fluid and a 5 to 10% CO₂ atmosphere at 37°C are required. Sodium polyanethol sulfonate in blood culture media is inhibitory (45). S. indolgenes grows slowly on blood agar. Aerobic growth is enhanced by high humidity and CO₂, which makes the organism appear to be facultatively anaerobic (17).

IDENTIFICATION

Phenotypic identification of fastidious Gram-negative rods presents several challenges. Triple sugar iron or Kligler’s agar may not support the growth of fastidious genera (e.g., Eikenella). Media should be rich in peptones (e.g., cystine Trypticase agar); serum (except rabbit serum) should not be used, because it may split maltose. The inoculum should be large (cell paste or agar blocks). Unsupplemented media used in blood culture and formation from carbohydrates may yield false-negative reactions. Gas formation from carbohydrates is scant or absent in most species. Indole may have to be extracted with xylene. Furthermore, phenotypic characteristics used for identification are subject to variation and dependent on individual interpretation and expertise. Correct identification to the species level often requires multiple substrates that may not be available to routine laboratories (60, 99) and may not even be provided by automated systems (4). However, the VITEK 2 Neisseria-Haemophilus identification card (VITEK 2 ID-NH card; BioMérieux, Marcy l’Etoile, France) allows for the identification of most bacteria of the HACEK group (2, 4). Pasteurella spp. are not in the database of the VITEK 2 ID-NH card, but they are in the database of the identification card for Gram-negative bacilli (VITEK 2 ID-GNB card; BioMérieux) (1). See chapter 33 for the dichotomous identification algorithms for Gram-negative bacteria. Determination of key reactions may be used for a rapid presumptive identification, e.g., with Api NH (BioMérieux) (114). A positive ornithine decarboxylase reaction and missing sugar acidification in the cystine Trypticase agar are typical for E. corrodens (104); a blood culture isolate with a positive indole reaction and a negative catalase reaction is diagnostic for C. hominis; P. multocida has a typical pattern of acidification of sugars and a positive indole reaction, and together with a history of cat bite the diagnosis is feasible.

The application of newer identification methods like MALDI-TOF MS shows promising results regarding the identification of HACEK group members (7, 8). The inclusion of the species in the databases of the two MALDI-TOF MS systems, i.e., VITEK MS (BioMérieux) and Bruker MALDI Biotyper (Bruker Daltonik GmbH, Bremen, Germany), is mentioned below. Accurate identification of fastidious Gram-negative rods isolated from normally sterile body sites is important for initiation of appropriate patient management. In view of the phenotypic closeness of the species, molecular methods (e.g., 16S RNA gene or rpoB gene sequencing) seem optimal for the identification to the species level of Actinobacillus, Aggregatibacter, Capnoctophaga, and Pasteurella spp. (6, 9, 44, 60, 100). Furthermore, molecular methods can identify new species in association with clinical entities.

Colonies of Actinobacillus spp. are ~2 mm in diameter after 24 h of growth at 37°C, smooth or rough, viscous, and often adherent to the agar. Smooth colonies are dome shaped and have a bluish hue when viewed by transmitted light. Biochemical reactions are listed in Table 1. Some Actinobacillus spp. are included in both MALDI-TOF MS databases. A. urea is included in the VITEK 2 ID-NH card database. A. actinomyceutemcomitans colonies initially show a central dot and a slightly irregular edge and, on further incubation, develop a star-like configuration resembling “crossed cigars” and pit the agar. After several subcultures, this rough morphology may give way to smooth and opaque, nonpitting colonies, reflecting loss of fimbriae. In liquid media, the bacterium forms granules that adhere to the sides and to the bottom of the tube. Colonies of other Aggregatibacter spp. are granular or smooth, grayish white to yellowish, and opaque; without CO₂, there is pleomorphism, with small and large colonies. For species identification, a battery of tests (requirements for V and X factors, biochemical tests, colonial morphology [Table 1]) is necessary to avoid confusion with Haemophilus spp. Aggregatibacter spp. have negative reactions for production of indole, ornithine decarboxylase, and urease and are not dependent on X factor; Haemophilus spp. are at least positive for one of those three reactions or cannot synthesize heme components from δ-aminolevulinic acid. Automated systems may present difficulties in identifying these bacteria to the species level (4, 59, 60, 99). A. segnis is identified by PCR (59, 60). Aggregatibacter spp. mentioned in Table 1 are included in both MALDI-TOF MS databases as well as in the VITEK 2 ID-NH card database.

Colonies of Capnoctophaga spp. on blood agar are very small after 24 h at 37°C and reach 2 to 4 mm in diameter after 2 to 4 days; they are convex or flat and often slightly yellow when scraped off agar, show regular or spreading edges with gliding motility, and adhere to the agar surface (15). Phenotypic differentiation of species in the oxidase-negative group may be inconclusive due to the similarity of many biochemical reactions (Table 2) and the lack of suitable substrates even in automated systems (4). This has frequently given rise to identification as “Capnoctophaga spp.” 16S rRNA gene sequencing is at present the most adequate diagnostic tool (6, 14, 115). All Capnoctophaga spp. mentioned in Table 2 are included in the database of the Bruker MALDI Biotyper, and some of these species are in the database of the VITEK MS system. The VITEK 2 ID-NH card database includes Capnoctophaga spp. at the genus level.

Colonies of Cardobacterium spp. attain a diameter of ~1 mm after 48 h at 37°C on blood agar; they are circular, smooth, and opaque, and they may pit the agar. Biochemical test reactions are recorded in Table 3. Differences between the two species are minimal and concern indole production in some strains, mannitol fermentation, and quantitative composition of cellular fatty acids (16). Some automated systems may misidentify C. vulvani (114). Both species are included in the database of the Bruker MALDI Biotyper. The VITEK 2 ID-NH card database includes Cardobacterium spp. at the genus level.

Colonies of C. violaceum measure 1 to 2 mm in diameter after 24 h of growth, are round and smooth, have an almond-like smell, and may be beta-hemolytic. Most strains produce a violet pigment called violacein, which is soluble in ethanol but not in water. Identification is easy if this pigment is produced, although the positive oxidase reaction will be detected only by a modified technique (116). Biochemical reactions are listed in Table 3. This species may even grow on most enteric media. Nonpigmented strains may be confused with Aeromonas spp. but are lysine, maltose, and manitol negative. C. violaceum is included in both MALDI-

\(^a\)Data are from references 14, 21, 23, 47, and 104. +, ≥90% of strains positive; –, ≥90% of strains negative; ND, no data; ONPG, ortho-nitrophenyl-β-D-galactopyranoside; v, variable. All species are negative for urease and ornithine decarboxylase and form acid from glucose (sometimes only with addition of serum). \(^b\)The isolates of D. gadei were catalase and indole positive (21, 80). D. mossii and D. hofstadii (one strain) differ in a few reactions in the Api Rapid ID32A system (23).

*aData are from references 16, 24, 47, 74, and 104. +, ≥90% of strains positive; -, ≥90% of strains negative; G, gas; LD, lysine decarboxylase; ND, no data; TMA, Thayer-Martin agar; v, variable; w, weak. All species are negative for urease and acid production from lactose and rhamnose.

*bSome strains form small amounts of gas.

*cWeakly positive reactions may be observed in oxidation-fermentation media.

produces propionic and succinic acid) (47) are of help if 16S rRNA gene sequencing is not available (21, 23, 47). Dysgonomonas spp. are not yet in the MALDI-TOF MS databases nor in the VITEK 2 card databases.

Colonies of E. corrodens are 1 to 2 mm in diameter after 48 h of growth, show clear centers that are often surrounded by spreading growth, may pit the agar, and assume a slightly yellow hue after several days. In liquid media, granules are produced. Typical isolates fail to form acid from carbohydrates in nonsupplemented media and are ornithine decarboxylase and nitrate reduction test positive; lysine decarboxylase activity is variable (Table 3). E. corrodens grows poorly or not at all on triple sugar iron or Kligler’s agar. E. corrodens is well identified by the VITEK 2 ID-NH card and by MALDI-TOF MS (4, 7).

Kingella colonies on blood agar in 5 to 10% CO₂ (which enhances growth) are 1 to 2 mm in diameter after 48 h of growth. One type is smooth with a central papilla, and the other spreads and pits the medium. Only K. kingae shows a small but distinct zone of hemolysis on blood agar. Colonies have a short viability and have to be subcultured frequently. Biochemical test results are listed in Table 3. In addition to microscopic and colonial morphology, the tests serve to separate kingellae from rod-shaped members of the genus Neisseria (Table 4), with which they may be confused in automated systems (4). Since K. denitrificans may grow on Thayer-Martin or Martin-Lewis agar (18), it may be misidentified as Neisseria gonorrohoea unless the catalase reaction, negative for Kingella, is performed. Kingella spp. are in both MALDI-TOF MS databases as well as in the VITEK 2 ID-NH card database.

Colonies of Pasteurella spp. are 1 to 2 mm in diameter after 24 h of growth at 37°C and are opaque and grayish. Encapsulated strains tend to be mucoid. A slight greening underneath the colonies may be noted. Indole-positive isolates exhibit a mouse-like odor. Biochemical reactions are listed in Table 5. The oxidase test has to be performed on blood agar; a weak reaction after 30 s is characteristic for many Pasteurella spp. (117). Nutritional fastidious, non-motile strains of Enterobacteriaceae, e.g., Escherichia coli, may be misidentified as Pasteurella unless an oxidase test is performed. In view of the phenotypic closeness of some taxa (25; http://www.bacterio.net), species identification in automated systems may be unsatisfactory (1, 93, 94). 16S rRNA gene sequencing and sodA gene sequencing have provided reliable species identification, the latter with even more discriminatory power (100). All Pasteurella spp. mentioned in Table 5 are included in the database of the Bruker MALDI Biotyper, and some Pasteurella spp. are included in the database of the VITEK MS system. The VITEK 2 ID-GNB card database includes Pasteurella spp.

Colonies of Simonsiella spp. are 1 to 2 mm in diameter after 24 h, may show gliding motility, and produce a pale yellow pigment. S. muelleri is beta-hemolytic. Biochemical tests are listed in Table 3. Simonsiella spp. are not yet in the MALDI-TOF MS databases nor in the databases of the VITEK 2 cards.

S. moniliformis may show wild-type and L-phase colonies in the same culture. The former are 1 to 3 mm in diameter after 48 to 72 h of growth on blood agar and are round and smooth. L-phase colonies grow better on clear media, yielding the “fried egg” appearance, with irregular outlines and coarse lipid globules. In liquid media, growth occurs mainly in the form of “puff balls” at the bottom of the tube. The organism dies quickly unless subcultured (45). It is
biochemically inert; glucose is acidified weakly and in a delayed fashion (Table 2). Fatty acid analysis can confirm the diagnosis, as can 16S rRNA gene sequencing (47, 102, 108). S. moniliformis is included in the database of the Bruker MALDI Biotyper.

Colonies of S. indologenes may spread or pit the agar surface of the blood agar. Biochemical tests are listed in Table 3. S. indologenes is included in both MALDI-TOF MS databases.

**TYPING SYSTEMS AND SEROLOGIC TESTS**

On the basis of surface polysaccharides, six serotypes of A. actinomycetemcomitans can be distinguished, of which a, b, and c are most common. Serotype b is associated with periodontitis, endocarditis, and penicillin resistance; serotype c is associated with periodontal health and extraoral infections (118, 119).

Typing of Capnocytophaga spp. has been done by multilocus enzyme electrophoresis or by restriction fragment length polymorphism analysis (14). Typing of C. violaceum has employed recA PCR-restriction fragment length polymorphism analysis (120). For E. corrodens, typing has been done by arbitrarily primed PCR demonstrating unstable clonality of E. corrodens in the oral cavity (121). For typing of Pasteurella spp., PCR profiling, restriction endonuclease analysis, ribotyping, multilocus sequence typing, and pulsed-field gel electrophoresis have been employed (25, 122).

Detection of antibodies directed against any of the bacteria discussed in this chapter has been tried on a small scale only and does not seem to offer much value.

**ANTIMICROBIAL SUSCEPTIBILITIES**

Approved guidelines for broth microdilution susceptibility testing of the HACEK group and for antimicrobial dilution and disk susceptibility testing of Pasteurella spp. have been published by the Clinical and Laboratory Standards Institute (CLSI) (123) (see chapter 74). β-Lactamase production among members of the HACEK group is well documented, and β-lactamase-producing isolates are ampicillin resistant; some isolates may be resistant to ampicillin due to mechanisms other than β-lactamase production; routine performance of a β-lactamase test is recommended for all HACEK isolates (123). The European Committee on Antimicrobial Susceptibility Testing (EUCAST) has recently published breakpoints for antimicrobial dilution and disk susceptibility testing of P. multocida; for all other species, EUCAST has defined non-species-related pharmacokinetic/pharmacodynamic breakpoints (124).

<sup>a</sup>Data are from references 13, 29, 43, and 47. +, ≥90% of strains positive; –, ≥90% of strains negative; v, variable; w, weak. All species reduce nitrate to nitrite and are negative for arginine dihydrolase and esculin hydrolysis.

<sup>b</sup>The three subspecies, multocida, septica, and gallicida, can be separated on the basis of sorbitol and dulcitol fermentation (+/− in subsp. multocida, −/− in subsp. septica, and +/− in the mostly avian subsp. gallicida); weakly sorbitol-positive strains of subsp. multocida can be recognized by a specific PCR profile (130).

<sup>c</sup>New genera or recategorizations may be necessary for species preceded by "<sup>f</sup>(P.)" (26).
Susceptibility studies of Actinobacillus spp. are extant for a few isolates of the human-pathogenic species that are susceptible to many antimicrobials, including penicillin (36, 49).

Aggregatibacter spp. are susceptible to cephalosporins, tetracyclines, and aminoglycosides (52, 53, 57, 60, 125). Resistance to amoxicillin is not uncommon, but amoxicillin combined with a β-lactamase inhibitor has been effective (125).

Capnocytophaga spp. are usually susceptible to broad-spectrum cephalosporins, carbapenems, clindamycin, macrolides, tetracyclines, and fluoroquinolones but are resistant to aminoglycosides (63). Multidrug-resistant isolates have occasionally been encountered (62).

C. hominis and C. valvarum are susceptible to many antimicrobials, including penicillin (16, 72, 125). β-Lactamase production is rare, and its effect can be neutralized by clavulanic acid (123, 126).

C. violaceum is resistant to many antimicrobials (β-lactams and colistin) but is mostly susceptible to imipenem, fluoroquinolones, gentamicin, tetracyclines, and co-trimoxazole (59).

D. capnocytophagoides strains are susceptible to tetracyclines, clindamycin, macrolides, and co-trimoxazole, whereas they are resistant to cephalosporins, aminoglycosides, and fluoroquinolones but is often resistant to narrow-spectrum cephalosporins, macrolides, and clindamycin (32, 125, 127).

β-Lactamase-positive strains have been reported, but the enzyme was inhibited by β-lactamase inhibitors (123, 127).

Kingella spp. are generally susceptible to β-lactam antibiotics, macrolides, tetracyclines, co-trimoxazole, and quinolones (33, 125). β-Lactamase-positive isolates have been reported to be susceptible to combinations with β-lactam inhibitors (33).

Pasteurella spp. are generally susceptible to penicillin, broad-spectrum cephalosporins, tetracyclines, quinolones, co-trimoxazole, and azithromycin; resistance to erythromycin can occur (128). Rare penicillin-resistant isolates of Pasteurella spp. have been encountered, but their effect can be neutralized by clavulanic acid (123, 129). For isolates of Pasteurella spp. from bite wounds, routine testing is usually not necessary; multiple organisms are often present in these specimens. Empiric therapy directed toward these organisms is generally effective for P. multocida as well (123).

S. muelleri is not yet an established pathogenic bacterium, and susceptibility data are scarce.

S. moniliformis is susceptible to penicillin and tetracyclines, the mainstays of treatment, and to cephalosporins, carbapenems, aztreonam, clindamycin, erythromycin, and tetracycline; it shows intermediate susceptibility to aminoglycosides and fluoroquinolones and is resistant to colistin and co-trimoxazole (45, 103). Patients with S. moniliformis endocarditis require dual therapy with high-dose penicillin G in combination with an aminoglycoside; the use of an aminoglycoside appears to enhance activity against the cell wall-deficient L forms of S. moniliformis (45, 102, 103).

The susceptibility of S. indologenes resembles that of HACEK organisms (35).

# EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Some bacteria of the group are colonizers of the human or animal oral cavity; therefore, the evaluation of their isolation may be difficult. All should be identified to the species level if isolated as pure cultures from normally sterile body sites. Interpretation as infectious agents and results of susceptibility testing should be clearly reported to the physician.

With specimens normally colonized with aerobic and anaerobic bacteria, as well as with specimens from wounds, e.g., bite wounds, the significance of the bacteria discussed in this chapter depends on their predominance and the absence of other potentially pathogenic bacteria. If these conditions are met, identification to the species level is needed for adequate interpretation and reporting as infectious agents and for susceptibility testing. If none of these conditions is present, a repeat culture and close cooperation between the microbiology laboratory and the physician are necessary for interpretation, for identification to the species or genus level, and for susceptibility testing.

Unusual Pathogenic Gram-Negative Aerobic and Facultatively Anaerobic Bacteria, 2nd ed. Williams & Wilkins, Baltimore, MD.

TAXONOMY AND DESCRIPTION OF THE GENUS

Haemophilus spp. are members of the family Pasteurellaceae (1). While the number of Haemophilus species described greatly exceeds the number of human pathogens, eight species affecting humans currently included in this genus are H. influenzae, H. aegyptius, H. ducreyi, H. pittonii, H. paraphrophilus, H. aegyptius, H. paraphrophilus, and H. paraphrophilus. Recently a new taxon, H. sputorum, has been proposed by Norskov-Lauritsen et al. (2) based on a cluster analysis of 300 commensal Haemophilus isolates. Isolates of the proposed taxon H. sputorum did not exhibit β-galactosidase activity and formed a unique cluster closely related to H. paraphrophilus. H. sputorum has been isolated from blood, sputum from cystic fibrosis patients, and sockets of extracted teeth (2). Aggregatibacter aphrophilus, Aggregatibacter paraphrophilus, and Aggregatibacter segnis were formerly included in the genus Haemophilus but have been reclassified into the genus Aggregatibacter (formerly Actinobacillus) based on molecular taxonomy (3). Additionally, A. aphrophilus and A. paraphrophilus have been combined into a single species, A. aphrophilus (3). A description of the characteristics and epidemiology of the newly reclassified A. aphrophilus species group can be found in chapter 35 in this Manual. A comprehensive review of the taxonomy of Haemophilus species has been provided by Kilian (4, 5).

Even given the recent reclassification of species, significant genetic diversity still exists in the Haemophilus genus. The genomes of these species range in size from 1.8 Mb for H. influenzae to 2.8 Mb for H. ducreyi (5). DNA-DNA hybridization studies demonstrate significant heterogeneity between species; studies conducted by Burbach et al. as discussed in reference 5 demonstrate binding ratios between H. influenzae and other species to range from 10% (H. paracuniculus) to 70% (H. aegyptius). H. influenzae is most closely related to H. aegyptius, with 90% homology, but is most distant from H. ducreyi, with only 18% homology. Intraspecies heterogeneity is also significant, ranging from 50 to 100% in H. influenzae and H. parainfluenzae strains (5).

Members of the Haemophilus genus are small, nonmotile, non-spore-forming, non-acid-fast, pleomorphic, Gram-negative bacilli with fastidious growth requirements. Cells in this genus are coccobacilli or short rods. The cell wall resembles those of other Gram-negative bacilli but contains fewer fatty acids than occur in other members of the family Pasteurellaceae (1, 5, 6); the lipopolysaccharide of Haemophilus is structurally different from those of members of the Enterobacteriaceae (1, 5, 6). The fatty acid composition of the cell wall includes n-tetradecanoate (14:0), 3-hydroxy-tetradecanoate (3-OH-14:0), n-hexadecanoate (16:0), and hexadecanoate (16:1) (7). Fimbriae have been observed on the cell walls of certain species of H. influenzae and H. aegyptius (5). The genome of Haemophilus spp. is characterized by a G+C content of 37 to 45% (1, 5, 8).

Haemophilus spp. are facultatively anaerobic, with requirements for X and/or V factors for growth. X factor is protoporphyrin IX, a metabolic intermediate in the hemin biosynthetic pathway (5). V factor is composed of nicotinamide complexed as NAD or NADP. Both factors are present in erythrocytes (“haemophilus” means “blood loving” in Greek). Requirements for these compounds vary based on the species, with H. influenzae, H. aegyptius, and H. haemolyticus requiring both X and V factors for growth, whereas others require only a single factor (Table 1). Optimal growth occurs at 35 to 37°C in the presence of 5 to 7% CO2. All species are CAMP reaction negative and produce alkaline phosphatase (9).

Organisms within the Haemophilus genus typically grow on chocolate agar, producing colonies that are usually smooth, with a flat or convex shape. They are nonpigmented (i.e., buff or light tan) or slightly yellow and are 0.5 to 2.0 mm in diameter. Certain Haemophilus spp. produce beta-hemolysis when grown on sheep blood agar plates (Table 1). Growth in broth can vary between homogeneous and granular.

Species of Haemophilus, other than H. ducreyi, typically ferment a wide range of different biochemical substrates. In particular, fermentation of glucose, sucrose, lactose, mannose, and xylose are useful characteristics in the species identification of organisms in this genus. Production of indole, ornithine decarboxylase, urease, catalase, and β-galactosidase plus the ability to produce beta-hemolysis when grown on blood-containing media are other variable properties of Haemophilus spp. that aid in the species identification of organisms in this genus (Table 1).

Strains of H. influenzae may produce one of six distinct capsular polysaccharides or may be nonencapsulated. Nonencapsulated H. influenzae strains are referred to as nontypeable (NTHi) (10) (Fig. 1). The presence of polysaccharide capsular antigen provides the basis for serotype designations, “a” to “f.” Capsular serotyping is based on the polysaccharide composition of the capsular structure. Depending on the

### EPIDEMIOLOGY AND TRANSMISSION

Haemophilus species can be found as part of the commensal biota of mucous membranes in humans. Colonization of the oral cavity superior to the palatal arches by *H. parainfluenzae* and *H. pittmaniae* is normal (5, 12–15). *H. parahaemolyticus* and *H. haemolyticus* colonization in healthy individuals remains rare, although *H. haemolyticus* has been isolated from subgingival dental plaques (5). Colonization of the cervix with *H. ducreyi* has been documented following sexual intercourse (16, 17).

*H. influenzae* may also be found as part of the commensal bacterial biota of the mucosal surfaces of the upper respiratory tract (URT) of many healthy individuals (16); however, asymptomatic colonization of the URT with encapsulated strains of *H. influenzae* type b (Hib) is rare. Carriage of Hib was reported in only 2 to 5% of healthy children in the prevaccine era and has further decreased (−0.06%) since the introduction of the pediatric Hib conjugate antigen vaccine, Hib, in the 1980s (19). In contrast, NTHi, together with strains of *H. parainfluenzae*, represents a major portion of the cultured bacterial microbiota of the pharynx and nasopharynx of >90% of healthy individuals (13, 20). Clones of NTHi present in the URT differ when asymptomatic carriers are compared to those with infection (20, 21). In asymptotically colonized individuals, the clones vary continuously, with a mean duration of carriage of 1 to 2 months (21). However, during infection, a single clonal group predominates. As a result of widespread use of HIB, the distribution of serotypes causing invasive infection has shifted. A recent report by the U.S. Centers for Disease Control and Prevention (CDC) classified 69.5% of invasive isolates as nontypeable, 2.2% as type a, 3.6% as type b, 0.3% as type c, 0.3% as type d, 5.7% as type e, and 18.3% as type f from 1999 to 2008 (22). Despite the reduction in Hib carriage and the efficacy of the vaccine in preventing invasive infections, the prevalence of invasive *H. influenzae* and Hib remains high among Alaskan Natives and Native Americans (22). Recently, an increase in the incidence of invasive *H. influenzae* infections has been observed in patients aged >65 years (22, 23). MacNeil et al. (22) reported that from 1999 to 2008 the incidence of invasive *H. influenzae* was 4.09 per 100,000 population, with 19.5% of invasive infections occurring in nursing home residents (22).

The incubation period for *H. influenzae* is poorly understood. The presence of a concomitant or preceding viral infection can predispose previously healthy carriers to infection. In these instances, the colonizing bacteria invade the inflamed or damaged mucosa and enter the bloodstream. The antiphagocytic nature of the Hib capsule and the absence of the anticapsular antibody lead to increasing bacterial proliferation (18). When the bacterial concentration exceeds a critical level, it can disseminate to various sites, including the meninges, subcutaneous tissue, joints, pleura, pericardia, and lungs. The presence of antibody, complement, and phagocytic cells determines the clearance of the bacteremia and can influence dissemination (18).

Host defenses include activation of the alternative and classical complement pathways and production of antibodies...

Directed against the polyribosylribitol phosphate (PRP) capsule of Hib. Antibody reactive with the Hib capsule plays a primary role in conferring immunity. Newborns have a low risk of infection because of the presence of maternal antibodies acquired through colostrum. Beginning at about 2 months of age, when maternal antibodies to the PRP capsule begin to wane, infants are at high risk for developing invasive H. influenzae disease. In the absence of maternal antibodies, and even following natural infection, the anti-PRP immune response of infants is diminished (18). Therefore, infants are at risk for repeat infections because prior episodes of infection do not confer immunity. By the age of 5 years, most children have naturally acquired antibodies.

**CLINICAL SIGNIFICANCE**

*H. influenzae*

Invasive infections caused by *H. influenzae*, such as meningitis, epiglottitis, orbital cellulitis, and bacteremia, are usually caused by capsular type b strains and generally fall within biotypes I and II of this species (24). Life-threatening *Haemophilus* infections, however, have fortunately become exceedingly uncommon in developed countries since the development and introduction of the pediatric HIB vaccine (25–27). When infections caused by Hib occur today, it is usually in the setting of an unvaccinated child, although they may also arise in both children and adults as a result of head trauma or cerebrospinal fluid (CSF) leak or following a neurosurgical procedure. Biotype IV strains, at least in the pre-HIB vaccine era, were often found to cause systemic infections in neonates as well as aggressive infections of the genital tract in postpartum women (28, 29).

The vast majority of *H. influenzae* infections today are caused by NTHi (10, 20). This organism is an important cause of acute conjunctivitis, acute otitis media, acute maxillary sinusitis, acute bacterial exacerbation of chronic bronchitis, and pneumonia (18). The organism gains access to the site of infection by direct contiguous spread from its reservoir in the URT. Spread via respiratory secretions, usually on the hands of patients, NTHi can also lead to conjunctival infection. Antecedent viral infections with resultant inflammation of the eustachian tubes and sinus ostia predispose patients to infection of the middle ear cavity and maxillary sinususes, respectively, by compromising egress from and ingress to these closed spaces (30). Establishment of infection in the lungs is facilitated by any condition that diminishes mucociliary clearance of organisms from the respiratory tree (18, 31, 32). Examples include smoking, chronic obstructive pulmonary disease, viral infection, recurrent bacterial infection, and physiological alterations, such as those that occur in individuals with cystic fibrosis.
Persons at risk for systemic NTHi infection, particularly the elderly, also include those with functional or anatomic asplenism, sickle cell disease, complement deficiencies, Hodgkin’s lymphoma, congenital or acquired hypogammaglobulinemia, and T-cell immunodeficiency states (e.g., HIV infection). Rarely is NTHi documented to be a cause of bacteremia; in a recent study, Laupland et al. (33) found the incidence of NTHi bacteremia to be 304 cases per 33,601,000 person-years. This may be due to the relative avirulence of the organism, the inadequacy of conventional blood culture techniques in propagating this fastidious bacterium, or the lack of contemporary studies investigating the epidemiology of invasive H. influenzae infections.

**H. ducreyi**

Chancroid is a sexually transmitted disease caused by H. ducreyi that is usually characterized by the development of a single painful genital ulcer, with associated inguinal lymphadenopathy occurring 2 to 7 days following exposure (34–36). Keratinocytes are likely the first cell type encountered by H. ducreyi upon infection of human skin; thus, the interaction between H. ducreyi and keratinocytes is likely important in establishing infection (37). Chancroid occurs most often in developing countries, including much of Asia, Africa, and Latin America. Epidemics of disease are associated with low socioeconomic status, poor hygiene, prostitution, and drug abuse. Commercial sex workers are also believed to serve as reservoirs for H. ducreyi. After 1987, reported cases of chancroid in the United States declined steadily until 2001. Since then, the number of cases reported has fluctuated from 17 to 55 cases annually. In 2010, only 24 cases were reported to the CDC, with 12 of these cases from Texas (38). Because of difficulties in establishing an etiologic diagnosis of H. ducreyi infection and limited resources in many countries of endemicity, the true incidence of chancroid is unknown. The incidence of H. ducreyi in the United States and other industrialized countries also remains unknown due to poor diagnostic techniques and underreporting, likely making chancroid a more important cause of genital ulcers than is currently reported.

**Other Haemophilus spp.**

*H. parainfluenzae* remains the predominant species colonizing the URT, accounting for fully 75% of the *Haemophilus* biota in the oral cavity and in the pharynx. Interestingly, *H. parainfluenzae* does not routinely colonize the nasal cavity. *H. parainfluenzae* is thought to account for at least some cases of acute otitis media, acute sinusitis, and acute bacterial exacerbation of chronic bronchitis, although its role in these diseases is often inconclusive. Infrequently, it has also been identified as a cause of subacute bacterial endocarditis. As is the case with systemic infections due to NTHi, blood cultures can be falsely negative in patients with *H. parainfluenzae* endocarditis due to the fastidious nature of the pathogen and the potential lysis of the organism in the high concentrations of sodium polyanethol sulfonate present in blood culture bottles (39–41).

*H. aegyptius*, a distinct species of *Haemophilus* that closely resembles biotype III strains of *H. influenzae* and that has been referred to as the Koch-Weeks bacillus, is an important cause of acute purulent conjunctivitis (42). This disease, often called pink-eye, occurs most often in younger children, especially those having extensive contact with other children in closed settings, such as day care centers and grammar school classrooms. It is characterized by the rapid onset of conjunctival inflammation, visual disturbance, ocular pain and pruritus. It often involves both eyes and is highly transmissible.

Brazilian purpuric fever, a condition that occurs most often in South America, is characterized by rapid onset of high fevers, hypotension, diffuse cutaneous hemorrhaging, and abrupt vascular compromise (43). The causative agent is often mistaken to be *H. aegyptius* but is instead an organism that is classified in biogroup III of *H. influenzae* (43, 44). These strains are characterized by the inability to ferment D-xylose, by a particular pattern of their housekeeping genes, by a distinct rRNA restriction pattern, and by resistance to serum bactericidal activity, making them unique among known *H. influenzae* biogroups (5).

*H. haemolyticus* has recently been reported as a cause of invasive disease in the United States, mischaracterized as *H. influenzae* (45). The report by Anderson et al. (45) retrospectively evaluated 161 NTHi isolates collected from 2009 to 2010 and 213 isolates collected from 1991 to 2000 and identified 7 strains associated with bacteremia, septic arthritis, or peritonitis that were mischaracterized as *H. influenzae*. In each instance, strains were poorly hemolytic or nonhemolytic and characterized by phenotypic microbiological identification techniques as *H. influenzae*. The report emphasized the importance of molecular identification techniques in characterizing NTHI strains.

Other *Haemophilus* species have only rarely been implicated as causes of infection in humans, although lower respiratory tract infection, sinusitis, conjunctivitis, bacteremia, meningitis, wound infections, peritonitis, arthritis, osteomyelitis, and brain abscess have been documented in individual case reports or small case series (7, 46).

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

The collection of specimens for the diagnosis of *Haemophilus* infections is predicated on the nature of the infection being evaluated. Details of specimen collection and transport can be found in chapter 18. In patients suspected of having meningitis, blood and CSF cultures should be performed. Middle ear fluid obtained by tympanocentesis is the specimen of choice for patients with otitis media; however, in patients with perforated tympanic membranes and otorrhea, an aseptically collected aspirate of middle ear fluid from the external auditory canal is also satisfactory. In cases of maxillary sinusitis, direct sinus aspirates or middle meatal swab specimens collected under endoscopic guidance should be obtained. Conjunctival swab specimens are required in the evaluation of patients thought to have *Haemophilus* conjunctivitis. In patients suspected of having bronchopulmonary infections due to *Haemophilus* spp., specimens representative of lower respiratory tract secretions should be obtained in such a way as to avoid contamination with oropharyngeal commensal biota. This means that collection of optimal specimens, such as by bronchoalveolar lavage or bronchial washing (less preferable), should be performed to provide optimum specificity when evaluating patients suspected of having *Haemophilus* bronchopulmonary infections. While collection of sputum and tracheal aspirates is less invasive, distinguishing between pathogens and oral biota can be nearly impossible by this means. When bacterial pneumonia is suspected, blood cultures should also be obtained. Importantly, with one exception, nasal, nasopharyngeal, and nasal swab specimens are of no value whatsoever in evaluating patients suspected of having *Haemophilus* infections at any of these respiratory tract sites. The one possible exception is in cystic fibrosis patients experiencing
an exacerbation. In this setting, an induced deep-cough specimen collected on a swab inserted into the posterior pharynx may be rewarding (47). In patients suspected of having Haemophilus infections in normally sterile sites, such as the pleural space, synovium, pericardium, or peritoneum, fluid aspirated aseptically from the site of involvement represents the specimen of choice. Concomitant blood cultures should also be performed.

Finally, specimens for culture of *H. ducreyi* should be collected from the margins of genital lesions with a saline- or broth-moistened swab. The swab should be immediately transported to the laboratory and plated without delay to avoid loss of organism viability. It is imperative that health care providers inform the laboratory of the clinical suspicion of chancroid so that appropriate media for culture of *H. ducreyi* can be employed. If extended transport is required, swab specimens should be plated directly at the time of collection in the patient care area or the specimen swab should be placed in transport medium containing hemin (48). When refrigerated (4°C), the use of Amies transport medium has been demonstrated to maintain the viability of *H. ducreyi* for up to 3 days. Alternatively, specially formulated thioglycollate-hemin-based media containing albumin and glutamine can also be used to preserve organism viability for transport taking >3 days (35, 49). Studies evaluating the viability of *H. ducreyi* using flocked swabs and liquid Amies transport media are limited, and additional studies are needed. While optimal cultivation of *H. ducreyi* is based on collection of ulcer materials, lymph node aspirates, pus, and aspirates from buboes can also be submitted for culture, albeit with less sensitivity than ulcer material. When cultivating *H. ducreyi* from these specimens, laboratories should consider allowing clinicians to directly plate specimens to maintain optimal recovery. Specimens for *H. ducreyi* nucleic acid amplification techniques should be collected using standard collection techniques for nucleic acid amplification from genital specimens, although large-scale studies evaluating specific transport media have not been conducted.

Long-term storage of *Haemophilus* spp. is usually accomplished by lyophilization or freezing of isolates at −60 to −80°C in tryptic soy broth with >10% glycerol or on porous beads (Pro-Lab Diagnostics, Round Rock, TX).

**DIRECT EXAMINATION**

**Microscopy**

On Gram stain, *Haemophilus* spp. appear as small, pleomorphic, Gram-negative coccobacilli with cocoid, cocobacillary, rod-shaped, or filamentous forms (Fig. 2). Because of the pleomorphism of *Haemophilus* spp., careful interpretation of the Gram stain smears must be undertaken to avoid confusion with other Gram-negative bacteria, such as *Neisseria meningitidis*. Underdecolorization of Gram stains may erroneously suggest the presence of *Streptococcus pneumoniae*, *Listeria monocytogenes*, or *Streptococcus agalactiae*.

Gram stain smears of CSF should be prepared and examined and the results reported within 1 h of receipt of the specimen in the laboratory directly to the health care provider who requested the test. With nonturbid specimens, following centrifugation in a cytospin centrifuge at 10,000 × g for 10 min, a concentrated smear is prepared. With visibly turbid specimens, a direct smear should be prepared in addition to the cytospin smear. A Gram stain is performed immediately and examined for the presence of polymorphonuclear leukocytes and bacteria morphologically compatible with *Haemophilus* spp. In rare cases, the CSF Gram stain may reveal many polymorphonuclear leukocytes but no bacteria. When this occurs, prepare another cytospin smear and stain with acridine orange (BD, Sparks, MD; or Remel, Lenexa, KS).

The same approach as that applied to Gram staining CSF should be applied to pleural, peritoneal, synovial, and pericardial fluid specimens. Middle ear fluid specimens and sinus aspirate Gram stains should be prepared directly from the specimen without cytocentrifugation.

Gram stains of lower respiratory tract secretions may be prepared directly from the specimen (e.g., expectorated sputa, endotracheal suction specimens, transbronchial biopsy specimens, bronchial brush biopsy specimens, and thoracotomy specimens) or following cytocentrifugation (e.g., bronchial washes and bronchoalveolar lavage fluid).

Strands of small, Gram-negative bacilli arranged in a railroad track-like manner on a direct Gram stain are highly suggestive of *H. ducreyi*. However, Gram staining of genital specimens for *H. ducreyi* is controversial because most genital ulcers contain a mixed bacterial biota, making Gram stain interpretation difficult. Furthermore, the positive yield of a Gram stain for *H. ducreyi* is low in comparison to that of culture or detection with nucleic acid amplification tests.

**Antigen Detection**

Commercial immunochromatographic techniques are available for the detection of *S. pneumoniae*, *Streptococcus dysgalactiae*, *H. influenzae*, and *N. meningitidis* directly from CSF and other body fluids. While these techniques provide a rapid identification of the pathogen, they lack sensitivity and specificity compared with Gram staining (50). Thus, the use of *H. influenzae* antigen detection is of limited clinical value and is generally discouraged. However, in certain clinical contexts, such as in resource-constrained regions when the prevalence of disease is high and routine culture is unreliable, antigen-based detection methods may prove useful.

**Molecular Techniques**

Nucleic acid amplification assays, most notably assays predicated on PCR, have been developed to detect *H. influenzae* directly in various clinical specimens, including CSF, plasma, serum, and whole blood (27, 51). These techniques can be multiplexed to detect other common bacterial causes of specific infectious disease entities, such as meningitis.
While publications cite variable detection sensitivities of these techniques, specificity is generally excellent (52–54).

Studies have demonstrated that the diagnostic accuracy of chancroid based on clinical presentation and patient history ranges from 33% to 80% (55) and that culture is ~75% sensitive (56, 57), making it an ideal target for molecular techniques. Molecular strategies have been developed to directly detect *H. ducreyi* from clinical specimens. Primers for these assays have been designed to amplify sequences from either the *H. ducreyi* 16S rRNA gene, the *rrs* (16S)-*rrl* (23S) ribosomal intergenic spacer region, an anonymous fragment of cloned *H. ducreyi* DNA, or the *groEL* gene, which encodes the *H. ducreyi* heat shock protein (56). One strategy includes a chloroform extraction followed by a one-tube nested PCR directed to the 16S rRNA gene, with longer outer primers for annealing at a higher temperature and shorter inner primers labeled with biotin and digoxigenin for binding with streptavidin and colorimetric detection (58). Another strategy is to target the *hbdA* gene; a protocol utilizing this target has been described by Chen and Ballard (59). The sensitivity of PCR directly from clinical specimens varied among assays between 83% and 95% compared to culture or clinical diagnosis (56, 58). The adaptations of molecular methods offer superior sensitivity for the diagnosis of chancroid; they are clearly advantageous in areas where the organism is endemic, particularly where testing by culture is difficult or impossible.

In addition to direct detection of *H. ducreyi* from clinical specimens, studies have also applied PCR to direct detection of *H. influenzae* and *H. parainfluenzae* from clinical specimens. In one study by Kuhn et al. (60), the authors evaluated three commercial PCR assays for detection of infectious agents associated with infective endocarditis. This study demonstrated superior performance of PCR compared with culture using both whole blood and valve tissue; the sensitivity of PCR reached 85%, compared with 45% for culture from both whole blood and heart valve tissue. However, while this study resulted in high sensitivity for PCR, the specificity of the PCR was low (40%) due to culture-negative specimens, likely as a result of antimicrobial treatment of patients prior to collection of diagnostic specimens (60). In a second study on meningitis, Wu et al. (61) demonstrated that the sensitivity of real-time PCR and Gram stain was less affected by the presence of antibiotics than culture and Gram stain for detection of *H. influenzae*, *N. meningitidis*, and *S. pneumoniae*. The study further demonstrated that the specificity of PCR and Gram stain exceeded that of culture (95.7, 98.25, and 81.3%, respectively) and resulted in identification of an additional 33 (of 451 total specimens) cases of meningitis that were culture negative (61). Other studies have evaluated molecular methods to detect *Haemophilus* spp. from respiratory specimens (62–64), demonstrating sensitivity of up to 95%, but did not correlate detection of *H. influenzae* with clinical disease.

The use of molecular methods for the identification of other *Haemophilus* spp. directly from clinical samples has proven difficult. The lack of both sensitivity and specificity has been problematic. In clinical specimens, small numbers of organisms may be present, leading to limitations in detection sensitivity. That is especially the case in patients with *Haemophilus* bacteremia (65). To achieve adequate sensitivity, large volumes of blood or CSF must be processed, creating laborious nucleic acid extraction and concentration processes with little clinical relevance. Another complicating factor is related to the influence of antimicrobial therapy. While culture frequently becomes negative following administration of the first appropriate dose of antimicrobials, patients can retain bacterial DNA in their blood or CSF for at least 2 weeks following clearance of the organism, leading to false-positive reactions, often making the interpretation of results challenging.

In certain other specimens, particularly specimens from the respiratory tract, commensal strains of *Haemophilus* spp. are often present, rendering positive results inconclusive. Further, the presence of other commensals or use of antimicrobials prior to screening may result in false-negative reactions, thus contributing to a lack of assay specificity. For these reasons, the use of molecular detection techniques is not currently advocated for the detection of *Haemophilus* spp. directly in clinical specimens until clinically significant thresholds for molecular quantification of organisms from respiratory specimens are achieved.

### ISOLATION PROCEDURES

**Media**

Optimum recovery of *Haemophilus* spp. in culture requires the use of enriched media that support the growth of these fastidious bacteria. Media must contain at least 10 μg/ml of free X and V factors. High concentrations of both the X and the V factor are found in whole blood, most of it sequestered within erythrocytes. X factor is protoporphyrin IX and can be derived from whole blood or can be added to bacteriological media using crystalline hemin; X factor is readily available in standard blood agar. V factor is composed of nicotinamide complexed as NAD or NADP and is also readily available in blood. However, nicotinamide is not readily bioavailable because of its intracellular location and the presence of NAD-glycohydrolase enzymes in blood. For the growth of *Haemophilus* spp. on solid media, either crystalline hemin and NAD must be added to a final concentration of 10 μg/ml, or the blood used in the medium must be heated such that the red cells lyse and release free X factor and V factor into the medium. The latter can be accomplished by adding blood to the basal medium as it cools to 80°C after being autoclaved. This is referred to as “chocolatizing” blood. For optimal growth of *Haemophilus* spp., a concentration of 5% chocolatized sheep blood should be employed (1).

The optimum growth of *Haemophilus* spp., especially of more-fastidious species, such as *H. ducreyi* and *H. aegyptius*, requires, in addition to the X and V factors, supplementation of media with various other growth factors. Two commercially available supplements that supply these growth factor requirements are IsoVitaLeX (BD) and Vitox (Remel). These growth factors contain glucose, cystine, glutamine, adenosine, thiamine, vitamin B(12), guanine, iron, and amino-benzoic acid and provide adequate supplementation for the growth of *H. ducreyi* and *H. aegyptius*. Enriched chocolate agar containing 5% lysed sheep red blood cells and supplemented with 1% IsoVitaLeX or 1% Vitox represents one general-purpose medium that is commonly used in clinical laboratories to effectively propagate *Haemophilus* spp. (Fig. 3). Another medium that reliably supports the growth of *Haemophilus* spp. is Levinthal medium (66). Because of its transparency, Levinthal medium offers the added benefit of permitting the detection of colony iridescence, a property that is frequently associated with encapsulation (Fig. 4) (67, 68). One investigation found that a medium consisting of GC (BD or Remel) agar base, 5% heated sheep red blood cells, and 1% yeast autolysate provided the best growth of all *Haemophilus* spp. other than *H. ducreyi* (69).
A significant challenge in the recovery of *Haemophilus* spp. from respiratory tract specimens is bacterial overgrowth due to the presence of other less fastidious commensal bacteria. Supplementation of media with some combination of bacitracin, vancomycin, and/or clindamycin serves to inhibit overgrowth with commensals, thus permitting the recovery of *Haemophilus* spp. (70). Use of such selective media is particularly relevant to the recovery of *Haemophilus* spp. from respiratory tract specimens from patients with cystic fibrosis, acute exacerbation of chronic bronchitis, conjunctivitis, and epiglottitis (Fig. 5) (71). Several versions of selective *Haemophilus* media are available commercially, including *Haemophilus* isolation agar (Remel) and *Haemophilus* isolation agar with bacitracin (BD). These media contain beef heart infusion agar with casein peptone to supply nutritional requirements, combined with horse blood to supply the X and V factors and to distinguish hemolytic species of *Haemophilus* from those that are not. Bacitracin is added to inhibit normal biota, including *Neisseria* spp.

The use of selective media is also helpful in recovering *H. ducreyi* from genital tract specimens (49). Selective media may include any of the following: GC agar base with 1% IsoVitaleX, 5% fetal bovine serum, 1% hemoglobin, and 3 μg vancomycin; GC agar base with 5% Fildes enrichment, 5% horse blood, and 3 μg vancomycin; 5% fresh rabbit blood agar with 3 μg vancomycin; or Mueller-Hinton agar with 5% chocolatized horse blood, 1% IsoVitaleX, and 3 μg vancomycin (49). Preferably, two different selective media are employed to ensure optimal sensitivity (49).

Growth of *Haemophilus* spp. may also be achieved on 5% sheep blood agar by use of the microsatellite phenomenon, although it is not recommended for routine clinical testing. With the microsatellite test, a single streak line of hemolysin-producing *Staphylococcus* spp. is placed on an agar surface previously inoculated with a specimen suspected of containing *Haemophilus* spp. The hemolysin produced by the *Staphylococcus* species lyses the erythrocytes immediately adjacent to the streak line in the medium, releasing sufficient concentrations of X factor (hemin) and V factor (NAD) into the medium to supply the growth factor requirements of *Haemophilus* spp. *Staphylococcus* also secretes NAD into the medium in proximity to the streak line. Colonies of *Haemophilus* thus appear in a narrow zone adjacent to the staphylococcal streak. This is referred to as "satelliting" growth (Fig. 6). Organisms other than staphylococci can also produce the satellite phenomenon with *Haemophilus*, e.g., enterococci and yeast.

Although *Haemophilus* spp. are not a common cause of bacteremia, special techniques are not necessary for their recovery from blood specimens with modern, continuously monitoring blood culture systems (7, 72). The broth medium used in such systems supports the growth of *Haemophilus* spp. because the blood specimen itself supplies adequate concentrations of both the X and V factors when the erythrocytes present in the specimen lyse as they come into contact with the blood culture broth. However, the common practice of using such systems for the culture of normally sterile body fluids, e.g., synovial, peritoneal, pericardial, and pleural fluid, may be problematic insofar as these specimens may not contain sufficient amounts of blood to supply the necessary levels of the X and V factors to support the growth of *Haemophilus* spp. In situations where *Haemophilus* spp. is strongly suspected in such specimens, blood culture bottles

FIGURE 3 Colony morphologies of type b encapsulated (left) and nonencapsulated (right) strains of *Haemophilus influenzae* when propagated on enriched chocolate agar. doi:10.1128/9781555817381.ch36.f3

FIGURE 4 Colony morphologies of type b encapsulated (left and right) and nonencapsulated (center) strains of *Haemophilus influenzae* when propagated on Levinthal agar. Note the conspicuous iridescence apparent with the encapsulated strain. doi:10.1128/9781555817381.ch36.f4
should be supplemented with at least 10 μg of both sterile hemin and NAD/ml prior to inoculation with clinical specimens. The use of commercial supplements such as Fildes enrichment (BD, Franklin Lakes, NJ) can also be used to aid in the propagation of Haemophilus spp.

Following inoculation, solid media should be incubated at 35 to 37°C in a moist atmosphere and in the presence of 5 to 7% CO₂. Under these conditions, most Haemophilus spp. grow within 24 to 48 h. When specimens for H. ducreyi and H. aegyptius are cultured, incubation may be necessary for up to 5 days to allow sufficient time for the growth of these fastidious organisms. Further, when technologists attempt to propagate H. ducreyi, plates should be incubated at slightly lower temperatures, i.e., 30 to 33°C in 5% CO₂ in a high-moisture environment. Use of lower incubation temperatures will improve the recovery of H. ducreyi in comparison to incubation temperatures of 35 to 37°C.

**Colony Appearance**

Colonies of Haemophilus on suitable solid media, in general, are nonpigmented or slightly yellow and flat to convex, and have a diameter of 0.5 to 2 mm after 48 h of incubation. Certain species of Haemophilus produce beta-hemolysis (Table 1).

Colonies of H. influenzae on chocolate agar are smooth, low, convex, grayish, and translucent. Encapsulated strains often have a mucoid appearance, while nonencapsulated strains produce smaller, buff colonies (Fig. 3). Most strains of H. influenzae produce indole, emitting a strong amine-like odor. Non-indole-producing strains emit a “mousy” odor. Colonies are 1 to 2 mm in diameter and often grow within 24 h. Colonies grown on clear media, such as Levinthal agar, demonstrate iridescence under obliquely transmitted light (67, 68). Iridescence is most conspicuous with young colonies and disappears with age. Iridescent colors may include yellow, red, green, or blue. Iridescence is more apparent with capsular type b strains; nonencapsulated strains typically demonstrate a blue-green color (Fig. 4).

Colonies of H. aegyptius reach a colony size of only ca. 0.5 mm after 48 h of growth. Colonies are low, convex, and translucent, with a smooth, entire surface. On semisolid agar media (which contains ~0.4% agar, compared with 1.5% for solid media), “comet-like” colonies are produced (5, 42).

Colonies of H. parainfluenzae are typically off-white to yellow and, like H. influenzae, 1 to 2 mm in diameter after 24 h of growth. The colony appearance is extremely varied, i.e., flat and smooth, granular with serrated edges, or heaped up and wrinkled. Colonies exhibiting the last morphology may be slk intact across the surface of the agar. The colony morphology of H. parainfluenzae may change as the colonies age.

Colonies of H. haemolyticus are translucent, smooth, and convex and do not form satellites around Staphylococcus. Colonies usually achieve a diameter of 0.5 to 1.5 mm after 24 h, with a clear zone of beta-hemolysis surrounding each colony when the organism is grown on blood agar; H. haemolyticus can lose its ability to cause hemolysis following serial subculture on bacteriological media. The growth properties and colony morphology of H. parahaemolyticus and H. paraphrophaeomyticus are similar to those of H. haemolyticus.

H. ducreyi grows poorly, regardless of the medium used, and frequently 3 to 5 days will pass before growth appears. Colonies growing on chocolate agar are small, flat, gray,
and smooth. Larger colonies may be interspersed among small colonies but have the same morphology. Growth on blood agar is poor, with a slight beta-hemolysis surrounding the colonies. As with *H. parainfluenzae*, older colonies of *H. ducreyi* are cohesive and can be slid across the agar.

**IDENTIFICATION**

The identification and differentiation of *Haemophilus* spp. are achieved through determination of X and V factor requirements for growth; performance of the porphyrin test; assessment of hemolysis; determination of carbohydrate fermentation patterns; and production of indole, ornithine decarboxylase, urease, catalase, and β-galactosidase (Table 1). The pattern of X and V growth factor requirements and the porphyrin test provide sufficient information for the presumptive species identification of selected *Haemophilus* spp. Definitive species identification, however, requires assessment of the other phenotypic characteristics listed above (Table 1). Alternatively, sequencing of the 16s rRNA gene or matrix-assisted laser desorption ionization–time-of-flight mass spectrometry (MALDI-TOF MS) also provide definitive identification of these organisms.

**X and V Factor Growth Requirements**

X and V factor requirements for the growth of *Haemophilus* spp. may be determined by swab inoculation of a suspension of test organism equivalent in turbidity to a 0.5 McFarland standard across the entire surface of a 100-mm petri dish containing tryptic soy agar. Filter paper disks or strips impregnated with X factor, V factor, and the X and V factors (Remel or BD) are then placed on the agar surface, and the plate is incubated for 20 to 24 h at 35°C in an atmosphere of 5 to 7% CO₂. The pattern of satellite growth around individual disks or strips, in the absence of growth elsewhere on the plate, is used to define the growth factor requirements of the test strain (Fig. 7). Tryptic soy agar is the preferred medium for use when the X and V growth factor requirements for *Haemophilus* spp. are determined, as other media may yield erroneous results (73, 74). Alternatively, triplates (Haemophilus ID II; Remel) and quadplates (Haemophilus ID Quad; Remel) can be used to assess X and V growth factor requirements. When performing X and V factor studies, care should be taken to avoid carrying X factor along with the inoculum. This can result in erroneous identification of *H. influenzae* as *H. parainfluenzae*.

All of the X factor-requiring species of *Haemophilus*, most notably *H. influenzae*, lack the enzymes necessary to convert δ-aminolevulinic acid (ALA) into protoporphyrin, a metabolic intermediate in the biosynthesis of X factor (75). Thus, they require that X factor be supplied exogenously in order to support growth. By taking advantage of this observation, a rapid test, known as the porphyrin or ALA test, can be performed to quickly determine if a test organism requires X factor for growth (76). When positive, the porphyrin test indicates that the test organism is X factor independent; when negative, the porphyrin test indicates that the organism requires X factor. Since the vast majority of X factor-requiring *Haemophilus* spp. recovered in the clinical laboratory are *H. influenzae*, when the porphyrin test is performed with a clinical isolate and found to be negative, it can be inferred with a high likelihood that the organism is *H. influenzae*.

The porphyrin test is performed using commercially available ALA disks (Remel) or through preparation of liquid porphyrin medium (76). To prepare liquid porphyrin medium, 2 mM ALA and 0.8 mM MgSO₄ in 0.1 M phosphate buffer (pH 6.9) are aliquoted in glass tubes with 0.5 ml of porphyrin medium in each tube. Tubes can be stored at 4°C for several months or for years at −20°C. Tubes are inoculated with a loopful of freshly grown bacteria and incubated for 4 h at 35°C in ambient air (1). Following incubation, the tubes are examined for brick-red fluorescence with a device, such as a Wood’s lamp, that emits a 360-nm-long-wave UV light (Fig. 8). Tubes with questionable results may be reincubated for up to 24 h. Alternatively, Kovács reagent (0.5 ml) can be added to the liquid porphyrin medium, and the tube can be shaken and observed for a red color in the lower water phase (1). A negative-control tube lacking ALA should also be inoculated when the porphyrin test is performed to rule out false-positive reactions due to the presence of indole. The porphyrin test has been shown in several studies to outperform...
growth factor–based methods for differentiation of H. influenzae from non-H. influenzae species (77).

Conventional Biochemical Tests

The list of biochemicals necessary for the differentiation of Haemophilus species is provided in Table 1. Carbohydrate fermentation is determined in phenol red broth containing 1% carbohydrate supplemented with 10-μg/ml NAD and hemin. Following heavy inoculation, fermentation tubes are incubated at 35°C without CO2 for up to 1 week and examined periodically for a red-to-yellow color, indicating a positive reaction. Usually positive reactions become apparent within 24 h; however, H. aegyptius and A. segnis have been noted to demonstrate weak reactions following a 24-h incubation (1).

Indole production can reliably be determined with most strains of H. influenzae and H. parainfluenzae using a spot indole test (Remel or BD). However, reliable assessment of indole production by other Haemophilus spp. requires use of a solution of 0.1% L-tryptophan in 0.067 M phosphate buffer at pH 6.8. Following inoculation, the suspension is incubated for 4 h at 35°C in ambient air, 0.5 ml of Kovács reagent is added to the tube, and the tube is shaken and examined for the appearance of red color in the upper portion of the tube as an indication of a positive reaction (1, 5) (Fig. 9).

Production of ornithine decarboxylase is determined using ornithine decarboxylase medium (see chapter 19) or Moeller medium. A tube containing either medium is heavily inoculated, incubated for 4 to 24 h at 35°C in ambient air, and examined for a purple coloration as an indication that the organism produces ornithine decarboxylase (1, 5) (Fig. 9). Species of Haemophilus positive for ornithine decarboxylase include several biotypes of H. influenzae and H. parainfluenzae.

As was the case with indole production, in most instances, a spot urease test (Remel or BD) can be used to reliably detect urease production by most strains of H. influenzae and H. parainfluenzae. Determination of urease production with other species requires the use of a urease medium containing 0.1 g KH2PO4, 0.1 g K2HPO4, 0.5 g NaCl, and 0.5 ml phenol red (1:50) dissolved in 100 ml of distilled water. The pH is adjusted to 7.0 with NaOH, and 10.4 ml of a 20% aqueous solution of urea is added. After inoculation, the tube is incubated for 4 h at 35°C in ambient air and examined for a pink-to-red coloration, indicating a positive reaction (1, 5) (Fig. 9).

Commercial Biochemical Identification Systems

Several commercial identification systems have been developed to identify Haemophilus spp. These systems employ a battery of conventional biochemical tests, frequently in a miniaturized form, with results available in shorter time periods than with conventional biochemical tests. The performance characteristics and identification accuracy of these commercial systems are extremely variable (69, 73, 77, 78). The RapID NH system (Remel) contains 11 biochemical reactions in a microwell tray. The reactions used for identification of Haemophilus include the production of urease, indole, ornithine decarboxylase, proline, and γ-glutamyl aminopeptidase; resazurin reduction; glucose and sucrose utilization; nitrate reduction; and phosphate hydrolysis. The kit uses phosphate hydrolysis and nitrate reduction reactions to identify an isolate as belonging to the genus Haemophilus and the remaining reactions to identify the isolate to the species level and to determine the biotype of H. influenzae. Although various results have been reported with the RapID NH system, when used properly, ≥95% of clinical isolates of H. influenzae should be correctly identified (73).

The BBL Crystal Neisseria/Haemophilus ID system (BD) and API NH kit (bioMérieux, Marcy l’Etoile, France) provide miniaturized biochemical identification schemes in a microwell tray, with results available in ≤5 h. The Crystal system employs 29 different growth substrates and is predicated on measuring the substrate conversion chromogenically and fluorogenically after 5 h of incubation. The API NH kit consists of 12 dehydrated substrates and a well to detect penicillinase, and it permits the identification of Haemophilus spp., Neisseria spp., and Moraxella spp. The test is performed by inoculating each well with an organism suspension equivalent to a 4 McFarland turbidity standard prepared from 24-h colony growth and incubating the plate for 2 to 2.25 h at 35°C. In addition to testing for penicillinase production, it tests for the following biochemicals: glucose, fructose, maltose, saccharose, ornithine decarboxylase, urease, lipase, alkaline phosphatase, β-galactosidase, proline aminolamidase, γ-glutamyl aminotransferase, and indole (79, 80). Independent studies evaluating the performances of the Crystal Neisseria/Haemophilus and API NH kits compared to accepted gold standards have not been published.

One instrument-based identification system has been developed for the species identification of Haemophilus spp., the Neisseria-Haemophilus identification cards for use with the VITEK 2 instrument (bioMérieux). This system is based on colorimetric detection of preformed enzyme complexes using chromogenic substrates. The database supporting these cards encompasses 27 taxa, including Neisseria, Haemophilus, Actinobacillus, Campylobacter, Campylocychaga, Cardiobacterium, Eikenella, Gardnerella, Kingella, Moraxella, Oligella, and Suttonella species. Studies with the VITEK 2 system using both collections of well-characterized stock strains and clinical isolates have demonstrated identification accuracies of 90 to 95%, with results varying by species (78, 81). In one recent study, >95% of isolates of H. influenzae, A. segnis, H. parahemolyticus, H. parainfluenzae, and A. actinomycetemcomitans were correctly identified, while none of the test strains of H. haemolyticus were correctly identified (81).

Mass Spectrometry

Studies evaluating MALDI-TOF MS largely demonstrate excellent performance for HACEK group organisms (i.e., Haemophilus spp., Aggregatibacter spp., Cardiobacterium spp., Eikenella corrodens, and Kingella spp.), including Haemophilus species (82, 83). Couturier et al. (82) demonstrated that >90 and >98% of H. parainfluenzae and H. influenzae strains, respectively, could be identified to the species level using MALDI-TOF. Similarly, van Veen et al. (83) demonstrated >98% identification of HACEK organisms to the species
level. Branda et al. (84) recently evaluated the VITEK MS IVD (bioMérieux) and found 96 and 92% correct identification to the species level for *H. influenzae* and *H. parainfluenzae*, respectively.

Comparisons of the Bruker MALDI Biotyper (Bruker Daltonics, Billerica, MA) to the VITEK MS are limited; however, Frickman et al. (85) compared the VITEK MS RUO (bioMérieux) with both the Biotyper and fluorescence in situ hybridization for identification of *H. influenzae*, *H. parainfluenzae*, and *H. parahaemolyticus*. With formic acid extraction, the Biotyper identified 100% of *H. influenzae* (50/50), 88% of *H. parainfluenzae* (22/25), and 100% of *H. parahaemolyticus* (2/2) strains to the species level. Results were not significantly different for the Biotyper without prior formic acid extraction, although identification of *H. parainfluenzae* dropped to 72% (18/25) and the Biotyper missed an additional *H. parahaemolyticus* identification. The VITEK MS RUO identified 82% of *H. influenzae* (41/50), 68% of *H. parainfluenzae* (17/25), and 50% of *H. parahaemolyticus* (1/2) strains. All identifications on the VITEK MS were performed without prior formic acid extraction (85).

Neither system identified any of the seven *H. haemolyticus* strains analyzed (85), likely due to poor representation of the organism in the databases. Martiny et al. (86) compared the performance of the VITEK MS IVD to the Biotyper IVD and found 100% identification (n = 30) of *H. influenzae* by both systems. Evaluation of species other than *H. influenzae* in this study was limited by the lack of diversity of species included in the study (86).

Performance of MALDI-TOF on *Haemophilus* strains other than those discussed above and performance of MALDI-TOF for typing *H. influenzae* have not been evaluated, and further study is warranted.

**Molecular Identification**

Several molecular methods, including 16S rRNA gene sequencing, next-generation sequencing, PCR, microarrays, and fluorescence in situ hybridization, have been described in the literature as being effective tools for the species identification of *Haemophilus* spp. when performed on organisms recovered in culture (51, 87–89).

Molecular targets for the detection and identification of *Haemophilus* spp. are numerous. Previous studies have described the detection of *H. influenzae* using the cap locus (which includes the capsule bexA) (53, 63, 90, 91), the 16S rRNA gene (51, 63, 92, 93), the insertion-like sequence (IS1016) (91), the fumarate reductase iron-sulfur gene B (frdB) (94), the manganese-dependent superoxide dismutase (sodA) (95), and the outer membrane protein P6 gene (ompP6) (63, 92, 96). Many of these targets are then combined with PCR (real time or traditional), microarrays, or sequencing to identify the organism. Widely utilized for sequencing, 16S rRNA frequently resolves the identities of strains to the species level; however, identification of *H. influenzae*, *H. aegyptius*, and *H. influenzae* biogroup aegyptius can be problematic due to the high degree of homology in their sequences. In these instances, sequencing of other targets, such as ropD, should be considered, or the use of combined sequencing and biochemical studies can be used.

Application of highly multiplex disease-state panels such as the FilmArray (BioFire Diagnostics, Salt Lake City, UT) or Verigene (Nanosphere, Inc., Northbrook, IL) to positive blood cultures has demonstrated reduction in length of stay and enhanced antimicrobial stewardship (87). Application of these technologies to identification of *Haemophilus* spp. from positive blood cultures may offer a significant reduction in turnaround time; however, peer-reviewed studies evaluating these technologies in *Haemophilus* have not been published.

Next-generation sequencing has been applied to *Haemophilus* spp. in two recent studies without the need for prior culture. In a study by Salipante et al. (98), the authors conducted deep sequencing on 66 sputum specimens from cystic fibrosis patients and identified *H. influenzae* in 5 specimens. Of the 5 specimens that yielded *H. influenzae*, 4 could be detected only via sequencing and 1 could be detected only in culture (98). The discrepancy between the results of culture and sequencing illustrates the challenge of correlating cultures with sequencing. While the presence of an organism on culture definitively confirms the presence of a viable organism, the presence of DNA detected in a sequencing reaction may still represent an infectious process but can also represent a remnant of a previous infection. Attempts to resolve this dilemma are important since, at a cost of less than $75 in reagents per sample, sequencing has quickly become affordable for the routine clinical microbiology laboratory (98).

**Problems in Identification**

A significant challenge in the species identification of *H. influenzae*, *H. aegyptius*, and *H. influenzae* biogroup aegyptius is a lack of biochemical diversity and sequence divergence (1, 5, 7). Biochemical profiling and standard 16S rRNA gene sequencing fail to adequately distinguish these organisms (1, 5, 7), necessitating the use of alternate sequencing targets, such as those mentioned in the previous section, or a combination of sequencing and biochemical testing. This is problematic, since *H. aegyptius* lacks the potential to cause Brazilian purpuric fever, while strains of *H. influenzae* biogroup aegyptius cause the disease. Xylose fermentation by most *H. influenzae* isolates combined with the lower growth rate of *H. influenzae* biotype aegyptius and the ability of *H. aegyptius* to agglutinate human erythrocytes may be of some value in distinguishing these organisms (1, 7, 99).

**Typing Systems**

**Capsular Serotyping and Biotyping**

The capsular antigen of *H. influenzae* is a principal virulence determinant of this organism. Six different capsular antigens have been recognized, each of which is characterized by a distinct carbohydrate chemical composition and given a letter designation from “a” to “f.” Prior to the introduction of the pediatric Hib vaccine, capsular type b strains were recovered from human clinical material most often. However, today, at least among populations in which there is widespread use of the Hib vaccine, non-b encapsulated strains occur with nearly equal frequency. For this reason, it may be instructive to know the capsular serotypes of *H. influenzae* strains recovered from clinical specimens, especially those representative of invasive disease. This may be accomplished using both phenotypic and genotypic methods.

Capsular serotyping of *H. influenzae* is best accomplished by the use of a slide agglutination assay that employs polyclonal antisera specifically reactive with each of the six capsular antigens (5, 100, 101). It is advisable to perform serotyping as soon as possible after isolation of *H. influenzae*, as the amount of capsular antigen produced may diminish over time, especially with repeated subculture. A thick, homogenous suspension of test organism is prepared in saline, 1 to 2 drops are placed on a glass slide, and then a drop of type-specific antisera is added. The antisera is mixed with the organism suspension, and then the glass slide is rocked gently for ca. 1
min before being examined for the presence of clumping, an indication of a positive reaction. The reagents for performing slide agglutination serotyping of *H. influenzae* are commercially available in kit form from Remel and BD.

Alternatively, primary type-specific antibodies can be directly or indirectly detected with fluorescent molecules, and binding of the antibody to the homologous capsular antigen can be determined by fluorescence microscopy (102, 103). While these technologies remain viable, reagents are not commercially available.

Whether a slide agglutination test or fluorescent antibody tests are used to determine the capsular serotype of an isolate of *H. influenzae*, positive- and negative-control strains should always be processed simultaneously with clinical isolates as a means of validating test results.

As noted above, based on three phenotypic properties, the production of indole, ornithine decarboxylase, and urease, strains of *H. influenzae* and *H. parainfluenzae* can be distinguished into multiple different biotypes (Table 2). Also, as outlined previously, at least with *H. influenzae*, certain biotypes have been found to have specific disease associations. Assessment of indole, ornithine decarboxylase, and urease production with clinical isolates of *H. influenzae* and *H. parainfluenzae* can be accomplished using the conventional methods described above (Fig. 9) or by use of commercially available miniaturized biochemical kit systems (11). In one recent study that compared the API NH strip kit (bioMérieux) with the RapID NH system (Remel) and the *Neisseria-Haemophilus* identification card (bioMérieux) as a means for determining the biotypes of a large collection of recent clinical isolates of both *H. influenzae* and *H. parainfluenzae*, the API NH kit yielded the most reliable results, correctly classifying the biotypes of >97% of the strains tested (80).

### Typing by Molecular Methods

Molecular methods have the advantage of enhanced sensitivity and specificity (104) due to the use of standardized techniques and a lack of false-positive reactions observed with nonencapsulated strains in slide agglutination tests.

Capsular typing of *H. influenzae* can also be accomplished by molecular methods. Most such assays rely on the amplification of genes in the cap locus, the outer membrane protein D gene (*glpQ*), the capsule-producing gene (*bexA*), the 16S rRNA gene, and the insertion-like sequence (*fcsA*). One algorithm was used for detection of the *cap* genes to determine capsular serotypes through f, while the capsule-producing gene, *bexA*, was used to separate strains that produce capsule from those that do not (105). Detection of the *ompP2* (outer membrane lipoprotein P2) gene was used as a control. Using this system, both a conventional PCR and a real-time PCR assay were found to be more sensitive than a slide agglutination test for serotyping *H. influenzae* (105). Similarly, Wroblewski et al. (106) described a two-step algorithm combining a two-plex real-time PCR with a five-plex serotype-specific real-time PCR (*type a, acsA; type c, ccB; type d, dcsC; type e, eccc; and type f, fcsA*). In this algorithm, the two-plex PCR containing primers targeting *bexA* (capsule transport gene) and *bcsB* (type b-specific gene) is used to screen isolates for NTHi and serotype b-specific strains. Strains that are positive for *bexA* but negative for *bcsB* are referred to the five-plex PCR for serotype-specific amplification (106). This method demonstrated 100% concordance with slide agglutination (106).

As with the *Enterobacteriaceae*, pulsed-field gel electrophoresis (PFGE) is considered the gold standard for strain typing of *Haemophilus*. The method demonstrates excellent separation of clones but is laborious and time-consuming (107–109). Other molecular methods for typing have also been applied to *Haemophilus* species. Studies evaluating repetitive-element sequence-based PCR using intergenic dyad sequence (IDS)-specific primers (IDS-PCR) for nonencapsulated *Haemophilus* strains have been developed and demonstrate excellent separation of NTHi strains (108). In one study evaluating the performance of IDS-PCR with 69 NTHi isolates, the assay demonstrated 65 different banding patterns that were epidemiologically classified as fingerprints similar to those obtained by PFGE (108). Other typing technologies applied to *Haemophilus* with a high degree of separation include ribotyping, restriction fragment length polymorphism analysis, multilocus enzyme electrophoresis, randomly amplified polymorphic DNA profile analysis, and multilocus sequence typing (108). While all of these techniques have demonstrated excellent separation, many are laborious and time-consuming (multilocus enzyme electrophoresis, PFGE, and ribotyping), others produce overly complex banding patterns (restriction fragment length polymorphism analyses), and others lack reproducibility (randomly amplified polymorphic DNA profile analysis) (108). Multilocus sequence typing offers the advantage of superior discriminatory power because it combines sequence typing of seven housekeeping genes with results that can readily be compared between laboratories (7).

Next-generation sequencing offers the promise of detection of an organism, classification of antimicrobial resistance factors, and typing of the organism in a single assay. Furthermore, with turnaround time for sequencing and annotation of the sequence decreasing to <24 h, real-time identification of outbreaks will become the standard of care. A recent investigation by Power et al. (110) sequenced the genome of 85 strains of *H. influenzae* and aligned the sequences by Mauve alignment. The study demonstrated distinct clusters of strains associated with serotype and regions of significant variation in sequence, likely due to transformation events. While preliminary, this study demonstrates the principle of typing based on genome sequence and may result in significant improvement in our ability to resolve strains into sequence types with much greater precision (110).

A comprehensive review of the available typing methods for *Haemophilus* species has been provided by Harrison et al. (104).

### SEROLOGIC TESTS

Antibody tests have been developed for the detection of *Haemophilus* antibodies; however, they are of little clinical value and are not readily available. Studies evaluating the performances of the enzyme-linked immunosorbent assay (111) and immunofluorescent assays (112) have been conducted; however, because immunity to *Haemophilus* is derived from an eclectric combination of antibodies against the *H. influenzae* capsule and membrane proteins, assays to detect a single class of antibody are of little value. Further complicating the use of *Haemophilus* serology is the individual variation in antibody level (many adults have undetectable antibody levels), avidity, and persistence (18).

### ANTIMICROBIAL SUSCEPTIBILITIES

#### Resistance Rates

*H. influenzae* may produce one of two β-lactamases, TEM-1 and ROB-1. Both enzymes are plasmid associated, are extracellular, and are produced constitutively in large
amounts (113). β-Lactamase-producing strains should be considered resistant to ampicillin and amoxicillin, as these drugs typically have MICs of ≥128 μg/ml against these strains (114).

The prevalence of β-lactamase-producing NTHi declined in the United States during the 1990s, possibly due to the increased use, beginning in the early 1990s, of non-β-lactam antimicrobials, such as the macrolides and fluoroquinolones, in the empiric management of infections such as otitis media, sinusitis, and bronchopulmonary infections, i.e., infections with which NTHi is most often associated (115). As a consequence of this therapeutic paradigm shift, β-lactams such as ampicillin and amoxicillin were used less often, with resulting diminished selective pressure on the emergence and persistence of β-lactamase-producing NTHi. This trend toward decreasing rates of β-lactamase-producing NTHi, however, seems paradoxically to have changed during the past 10 years, possibly as a result of the widespread use of pediatric pneumococcal conjugate antigen vaccines. As S. pneumoniae has become less common as a cause of acute otitis media, NTHi has reemerged as the most common cause of the infection, with a proportionate increase in rates of β-lactamase-mediated ampicillin resistance (116).

β-Lactamase-producing strains of H. influenzae remain susceptible to oral and parenteral cephalosporins and carbapenems (114, 115, 117, 118). They are also susceptible to combination agents in which a β-lactamase inhibitor, such as clavulanate, sulbactam, or tazobactam, is combined with a β-lactam agent (114, 115, 117, 118). Examples include amoxicillin-clavulanate, amoxicillin-sulbactam, and piperacillin-tazobactam.

Strains of H. influenzae that fail to produce β-lactamase but for which the MICs of ampicillin and amoxicillin are elevated have been described (119). These strains, which are often referred to as β-lactamase negative and ampicillin resistant (BLNAR), have altered penicillin-binding proteins, which abrogates the binding of drugs such as ampicillin and amoxicillin to their cell wall targets, in turn resulting in elevated MICs (120, 121). The activities of cephalosporins are also diminished with such strains. If one uses an ampicillin or amoxicillin MIC of ≥4 μg/ml to define resistance within Haemophilus spp., as is recommended by the Clinical and Laboratory Standards Institute (CLSI) (122), the prevalence of BLNAR strains of H. influenzae remains at levels of <1% in the United States (115).

Among other antimicrobials that are relevant to the management of Haemophilus infections, with the exception of trimethoprim-sulfamethoxazole (TMP-SMX), resistance rates remain at levels of <1% (114, 115). These antimicrobials include both oral and parenteral cephalosporins, macrolides, fluoroquinolones, and tetracycline. TMP-SMX resistance rates approach 20% (114, 115). Currently, in the United States, ca. 27% of clinical isolates of NTHi produce β-lactamase (123).

Susceptibility Test Methods

β-Lactamase production by Haemophilus spp. can be determined rapidly with either a chromogenic cephalosporin spot test or an acidimetric penicillinase assay, as described in chapter 74 in this Manual. Because the β-lactamases of H. influenzae are extracellular, constitutive, and produced in large amounts, assuming the test is performed carefully and with adequate positive and negative controls, both methods yield reliable results.

Disk diffusion susceptibility tests can be performed using Haemophilus test medium (HTM) agar (118), with incubation of plates for 16 to 18 h at 35°C in 5 to 7% CO₂, as described by the CLSI (122). Zone diameter interpretive criteria have been developed for 39 different antimicrobial agents (124). The details of disk diffusion susceptibility tests are presented in chapter 71.

MICs can be determined with Haemophilus spp. by use of broth microdilution (BMD). The CLSI advocates the use of HTM broth (118) when determining MICs by the BMD method (125). Following inoculation, trays are incubated for 20 to 24 h in ambient air at 35°C prior to determination of MICs; MIC interpretive criteria have been developed for 43 different antimicrobial agents (124). The details of BMD MIC tests are presented in chapter 71. In circumstances in which HTM is not available or when equivocal results have been obtained with this medium, BMD MICs can be determined with Haemophilus spp. using Mueller-Hinton broth supplemented with 3 to 5% sterile lysed horse blood and 10 μg/ml NAD (126). The MIC interpretive criteria for Haemophilus promulgated by the CLSI for BMD tests in HTM can also be applied to MICs determined by BMD in medium containing lysed horse blood. Unfortunately, there exist almost no published data validating the use of the Etest method with Haemophilus spp., and therefore, use of this method is not recommended for susceptibility tests with this organism group.

Susceptibility tests with clinical isolates of H. ducreyi should not be attempted in routine clinical microbiology laboratories, as standardized susceptibility test methods of proven reliability for this organism have not yet been developed. Similarly, instrument-based susceptibility tests for other Haemophilus spp., including H. influenzae, have not been proven to be effective and are not recommended for testing this organism group.

Irrespective of the method used for performing susceptibility tests with Haemophilus spp., it is essential that adequate quality control is applied using two H. influenzae quality control strains, ATCC 49247 and ATCC 49766.

Susceptibility Testing Algorithm

Susceptibility testing with clinical isolates of Haemophilus spp. should be applied only to those strains known to be of clinical significance. Further, in the vast majority of instances, only a β-lactamase assay as a means for assessing the activities of ampicillin and amoxicillin need be performed. The prevalence of BLNAR strains of H. influenzae and their resistance to other agents that are commonly used to treat the types of infections with which Haemophilus spp. are associated are simply too low to justify routine testing. One exception might be resistance to TMP-SMX. This agent, however, is used almost exclusively for oral therapy of community-acquired respiratory tract infections that are invariably managed empirically without performance of laboratory studies aimed at elucidating the specific cause of an individual patient’s infection. In other words, in settings where knowledge of the activity profile of TMP-SMX versus H. influenzae could be of value, rarely, if ever, is a patient isolate available for testing. In those rare circumstances when the assessment of the activities of agents other than ampicillin or amoxicillin is found to be warranted, either a disk diffusion susceptibility test or a BMD MIC test should be performed.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

The genus Haemophilus is a diverse group of organisms that may exist as part of the normal bacterial biota of healthy humans or may be associated with significant
As a result, simple recovery of Haemophilus from a human clinical sample may not always indicate that the organism is clinically significant. In the following three circumstances, recovery of Haemophilus spp. in the laboratory is pathognomonic: (i) isolates from normally sterile sites, including blood cultures, are compatible clinically with illness; (ii) H. ducreyi is recovered from genital tract specimens obtained from patients with genital ulcers; and (iii) isolates of H. aegyptius from conjunctival specimens are obtained from patients with exudative inflammation of the conjunctiva.

Recovery of Haemophilus spp. from specimens that may be contaminated with commensal microbial biota represents a situation in which the clinical significance of the isolate must be questioned. This is often the case, for example, with isolates from respiratory tract sites. In such instances, the quantity of organism recovered, both the absolute quantity and the quantity of the isolate in comparison to quantities of other organisms recovered from the specimen, is of limited value in assessing clinical significance. It may be helpful to try to assess the quality of the specimen, as is possible, for example, with expectorated sputa and endotracheal aspirates. It may also be instructive to compare the results of a given culture with results obtained from previous and subsequent cultures from the same site. Generally speaking, repetitive recovery of the same organism from multiple specimens representative of a specific infectious disease process in an individual patient can be taken as an indication of clinical significance. And finally, it must be recognized that in some cases, it simply is not possible to know with certainty whether a given isolated of Haemophilus spp. is clinically significant. In such instances, active dialog with health care providers is encouraged.

**ESCHERICHIA**

**Taxonomy**

Members of the genus *Escherichia* are classified in the family Enterobacteriaceae, which is addressed in chapter 38 of this Manual (1–4). There are five species in this genus: *Escherichia albertii*, *Escherichia blattae*, *Escherichia coli*, *Escherichia fergusonii*, and *Escherichia hermannii*, and *Escherichia vulneris*. The G+C content is 48 to 59 mol%, and the type species is *E. coli* (Migula 1895) (5). Average DNA relatedness between the type species and other *Escherichia* species, as assessed by DNA–DNA hybridization, ranges from 38 to 64%. As more genomes become sequenced, refinements to the classification of members of the family Enterobacteriaceae will be possible. A recent publication proposes to reclassify *E. blattae* in a newly formed genus as *Shimwellia blattae*, based on sequence analysis of the 16S rRNA gene and four protein-coding genes (6). *E. blattae* exhibits about 43% DNA relatedness to *E. coli* by DNA–DNA hybridization.

Members of the genus *Shigella* are phenotypically similar to *E. coli* and, with the exception of *Shigella boydii* serotype 13, would be considered the same species by DNA–DNA hybridization analysis (4) and whole-genome sequence analysis (7). Findings from phylogenetic studies with nucleotide sequences of internal fragments from 14 housekeeping genes show that *S. boydii* 13 strains cluster in a neighbor-joining tree with *E. albertii* (8).

Comparative genomic analysis has provided important insights into the structure and organization of bacterial genomes and mechanisms by which they have evolved. The number of genomes available for the *E. coli/Shigella* group continues to increase (9–15), with a recent study comparing the gene content of 186 genomes from a diverse selection of commensal and pathogenic strains (15). Findings from these studies showed that the *E. coli* genome varies in size from 4,639,221 base pairs for *E. coli* K-12 (14) to 5,945,000 base pairs for a Shiga toxin-producing strain of *E. coli* serotype O26:H11 (10). In a comparison of 17 genomes by Rasko et al. in 2008 (11), the number of genes per genome ranged from 4,238 to 5,589, with an average of 2,344 (46%) of these being conserved among all strains (core genome). When >50 complete genomes were studied in 2012 by Kaas et al. (15), the average number of genes (homolog gene clusters) per genome was 4,837; however, the number of genes representing the core genome fell to 1,702. In the 2012 study, the estimated number of genes representing the “pangenome” in a set of 186 genomes was 16,363, and this number continued to increase in a linear fashion as genomes were added (16). Rasko et al. (11) found that strains representative of a pathotype contained shared genes as well as unique genes. Enterohemorrhagic *E. coli* (EHEC) strains shared the largest number of genes, with 122 group-specific genes, while uropathogenic *E. coli* (UPEC) strains shared 45 to 56 genes; enteropathogenic *E. coli* (EPEC), enterohaemorrhagic *E. coli* (EHEC), and enteroaggregative *E. coli* (EAEC) strains each shared 3 to 5 genes; and commensal strains shared 11 genes. The number of strain-specific genes varied widely and was not consistent within a pathotype (11).

Pathogenomic analysis of the numerous plasmids present within representative strains of each of the *E. coli* pathotypes and commensal *E. coli* has revealed considerable diversity and plasticity within these genetic elements (17). In contrast to the overall plasmid diversity, there is limited diversity in the virulence plasmids, which are restricted to a few plasmid backbones with conservation and linkage of their core components (17). These plasmids contain distinct regions for genetic exchange that appear to evolve via insertion sequence-mediated site-specific recombination. Many such plasmids have also acquired multidrug resistance-encoding islands. In addition to plasmids, bacteriophages play a major role in generating genome diversity by promoting homologous recombination and horizontal gene transfer between bacteria (18, 19). For example, the Sakai strain of *E. coli* O157:H7 contains 18 prophages and 6 prophage-like elements (16% of the total genome), which carry a wide range of virulence genes, including the genes for Shiga toxins 1 and 2 (20, 21). Although many of these prophages carry genetic defects, some are able to be induced and recombine with each other to generate new phages capable of transferring virulence genes to other bacteria (19). The dynamic nature of the Shiga toxin-converting phages has implications for diagnostic testing for Shiga toxin-producing *E. coli* (STEC). Since STEC strains can lose critical virulence genes, some researchers have proposed that multiple virulence-associated genes, as well as conserved genes, be used to diagnose infections by these bacteria (22, 23). This concept would also apply to other pathotypes of *E. coli*, as most of them carry critical virulence genes on mobile genetic elements.
Description of the Genus

The genus *Escherichia* is composed of motile or nonmotile bacteria that conform to the definitions of the family *Enterobacteriaceae* (1, 2). Species in this genus are Gram-negative, oxidase-negative rods that grow well on MacConkey agar (MAC). When these organisms are motile, it is by peritrichous flagella. They can grow aerobically or anaerobically. All ferment D-glucose, and most produce gas from the fermentation of this substrate and other fermentable carbohydrates. Lactose is fermented by most strains of *E. coli*, but its fermentation may be delayed or absent in all or most strains of *E. albertii*, *E. blattae*, *E. fergusonii*, and *E. vulneris*. Typical phenotypic properties are listed in Table 1.

Epidemiology and Transmission

*E. coli* occurs naturally in the lower part of the intestines of humans and warm-blooded animals. In humans, it typically colonizes an infant's gastrointestinal tract within hours of birth and subsequently becomes the predominant facultative anaerobe in the human colonic microbiota, where it exists in a mutually beneficial relationship with its host. *E. coli* generally remains confined to the intestinal lumen; however, in a debilitated or immunosuppressed host or when bacteria are introduced to other tissues following trauma or surgical procedures, even commensal, "nonpathogenic" strains of *E. coli* can cause infection. *E. coli* is typically transmitted through ingestion of contaminated food and water, person-to-person contact, contact with animals, or contact with environments or fomites contaminated with fecal material. Convincing evidence of respiratory transmission has not been reported. Most strains of *E. coli* do not cause disease in healthy persons; however, there are specific pathogenic groups, addressed below, whose members are capable of causing disease in humans and animals. The infectious dose for diarrheagenic *E. coli* varies by strain and pathotype and ranges from 10 to 100 bacteria for *E. coli* O157:H7 (24) to 10^8 or more bacteria for *ETEC* (25).

Because *E. coli* is ubiquitous in human and animal feces, the presence of this species in water is considered an indicator of fecal contamination. It can be isolated from feces-contaminated foods or water but probably does not occur as a free-living organism in the environment. *E. fergusonii*, *E. hermannii*, *E. vulneris*, and *E. albertii* have been isolated from a wide variety of human clinical specimens (stool, urine, sputum, blood, spinal fluid, peritoneal dialysis fluid, and wounds) (26–32). *E. fergusonii* and *E. albertii* have also been isolated from wild and domestic birds (33, 34). Recently *E. vulneris* strains with traits common to mammalian pathogens were found actively multiplying within legumes, raising the possibility that plants may represent a niche for transmission of clinically important strains (35, 36). In addition, *E. vulneris* was recovered in combination with other members of the *Enterobacteriaceae* from neonatal enteral feeding tubes, highlighting the potential importance of these devices as risk factors for neonatal infections (37). *E. blattae* occurs naturally in the hindgut of cockroaches and is not known to cause disease in humans.

Clinical Significance

Of the six *Escherichia* species, *E. coli* is the species usually isolated from human specimens and the one that we know the most about. We know little about the pathogenesis of the other *Escherichia* species; however, it is interesting to note that strains of *E. albertii*, which have been associated with diarrheal disease in children, contain the locus for enterocyte effacement (LEE) pathogenicity island that is also present in *EPEC* and *EHEC* (8, 30, 38). One restaurant-associated outbreak of *E. albertii* has been reported (39).

Extraintestinal *E. coli*

Pathogenic *E. coli* strains are broadly grouped into two categories—extraintestinal pathogenic *E. coli* and intestinal or diarrheagenic *E. coli*—depending on whether they cause disease outside or within the intestinal tract. The application of methods for phylogenetic grouping and DNA sequence typing has revealed extensive genetic substructure among strains within these broad groups and has facilitated studies to understand their evolution and transmission. For example, a recent study of *E. coli* causing community-associated and hospital-acquired urinary tract and bloodstream infections from across the world showed that a high proportion of infections were due to a globally disseminated, multidrug-resistant clone of *E. coli* subtyped as sequence type 131 (ST131) (40).

Commensal *E. coli* strains, which comprise the majority of the facultatively anaerobic intestinal microbiota in most humans and other mammals, typically do not cause disease. However, they can be opportunistic pathogens when certain conditions exist, such as the presence of a foreign body (e.g., urinary catheter), host compromise (e.g., local anatomical or functional abnormalities, such as urinary or bile tract obstruction or immunocompromise), or a breach in normally sterile sites causing the introduction of feces or high concentrations of mixed bacteria. Extraintestinal pathogenic *E. coli* strains carry a distinct set of virulence genes that enable them to cause disease outside the intestine. This category contains at least two well-recognized pathogenic groups or pathotypes—UPEC and meningitis/sepsis-associated *E. coli* (MNEC)—and a variety of disease-associated strains not yet classified into specific pathotypes.

**UPEC**

UPEC strains are a major cause of community-acquired urinary tract infections and possess a variety of chromosomally and plasmid-encoded virulence factors that are present in various combinations. Members of this group have a limited number of O antigens (six O groups cause 75% of urinary tract infections) and show combinations of traits, including expression of adhesins (P [Pap], type 1, and other fimbriae), toxins (hemolysin, cytotox necrotizing factor [CNF], and an autotransported protease [Sat]), or aerobactin, serum resistance, and encapsulation, that are epidemiologically associated with cystitis and acute pyelonephritis in individuals with normal urinary tracts. No single phenotypic profile defining UPEC has emerged. UPEC strains possess large and small pathogenicity islands containing blocks of genes not found in the chromosomes of fecal strains. For a review of the virulence genes and a proposed model of the pathogenesis of UPEC, see the work of Croxen and Finlay (41), Johnson and Russo (42), and Kaper et al. (43).

**MNEC**

MNEC strains are the most common Gram-negative organisms causing neonatal meningitis, which is associated with high morbidity and mortality. The MNEC pathotype comprises strains with a limited number of O antigens, and ~80% are positive for the K1 antigen. *E. coli* strains that cause meningitis are spread hematogenously. Levels of bacteria correlate with the development of meningitis; levels of >10^3 CFU/ml of blood are significantly associated with the development of meningitis (44). After entering the blood, these bacteria invade brain microvascular endothelial cells through membrane-bound vacuoles. Within these

*Values are percentages of isolates tested with positive test results within 1 or 2 days of incubation at 35 to 37°C. Reactions for isolates that become positive after 2 days are not considered. Data were compiled from findings published by Ewing et al. (247), Wathen-Grady et al. (248, 249), Ansaruzzaman et al. (250), Pryamukhina and Khomenko (251), and Farmer (252) and from unpublished findings from the reference laboratory at the CDC (1972 to 2005).

*Excludes strains previously identified as *S. boydii* 13.*
vacuoles, the organisms control intracellular trafficking to avoid lysosomal fusion and to gain access to the central nervous system without causing apparent damage to the blood-brain barrier. Recent studies have identified several bacterial determinants (IbeA, IbeB, IbeC, AsLA, CNFI, FinHI, and OmpA) that contribute to the pathogenesis of MNEC in vitro. For reviews, see the work of Kim et al. (45), Kaper et al. (43), and Crozen and Finlay (41).

**Diarrheagenic E. coli**

There are at least five categories of recognized diarrheagenic E. coli: STEC, which includes a subset of strains referred to as enterohemorrhagic E. coli for their ability to cause bloody diarrhea and hemorrhagic colitis; ETEC; EPEC; EAEC; and enteroinvasive E. coli (EIEC) (41, 43, 46). The clinical significance of several other groups of putative diarrheagenic E. coli, particularly diffusely adherent E. coli (DAEC), is unclear.

**STEC**

We refer to the STEC category of diarrheagenic E. coli according to the toxins that these organisms produce, i.e., as STEC rather than EHEC, because the essential genetic features that define organisms capable of causing hemorrhagic colitis and hemolytic-uremic syndrome (HUS) are not clear. E. coli serotypes O157:H7 and O157:nonmotile (O157:NM) (collectively called O157 STEC) produce one or more Shiga toxins, also called verotoxins, and are the most frequently identified diarrheagenic E. coli identified in North America and Europe. Each year, an estimated 63,000 cases of illness and 20 deaths are caused by O157 STEC and 112,000 cases with no deaths are caused by other STEC serotypes in the United States (47).

E. coli O157:H7 and other STEC serotypes cause illness that can present as mild nonbloody diarrhea, severe bloody diarrhea (hemorrhagic colitis), or HUS (reviewed in reference 48). Additional symptoms of E. coli O157:H7 infection include abdominal cramps and lack of a high fever. Among patients with O157 STEC diarrhea, 4% or more develop HUS (49), a condition characterized by microangiopathic hemolytic anemia, thrombocytopenia, and acute renal failure. The fatality rate of HUS has declined in recent years due to improvements in case management. O157 STEC is thought to cause at least 80% of cases of HUS in North America and is recognized as a common cause of bloody diarrhea in developed countries (49). In the United States, the rate of isolation of O157 STEC from fecal specimens is highest in the Northern Tier states, where it may approach the rates for common diarrheal pathogens. Many U.S. clinical laboratories do not routinely culture or otherwise test stools for O157 STEC; as a result, many illnesses are not detected (50). O157 STEC colonizes dairy and beef cattle, and therefore ground beef has caused more O157 STEC outbreaks than any other vehicle of transmission (49, 51). Other known vehicles of transmission include raw milk, sausage, roast beef, unchlorinated municipal water, apple cider, raw vegetables, and sprouts; these vehicles are typically exposed to water contaminated by bovine manure. O157 STEC spreads easily from person to person because the infectious dose is low (<200 CFU); outbreaks associated with person-to-person spread have occurred in schools, long-term care institutions, families, and day care facilities.

More than 150 non-O157 STEC serotypes have been isolated from persons with diarrhea or HUS (http://www.microbionet.com.au/frames/feature/vtec/brief01.html). In some countries, non-O157 STEC strains, particularly E. coli serotypes O111:NM and O26:H11, are more commonly isolated than O157 STEC strains, although most outbreaks and cases of HUS are attributed to the latter (serotypes characteristic of diarrheagenic E. coli pathotypes are presented in Table 2). In 2011, the largest known outbreak of hemorrhagic colitis occurred in Germany, with 3,800 cases, 800 of which resulted in the development of HUS, and 54 deaths. The outbreak was caused by a strain of E. coli serotype O104:H4 with virulence genes and a genome characteristic of EAEC, which had acquired a bacteriophage encoding Shiga toxin 2a (52). In the United States, E. coli O157:H7 is the most frequently isolated STEC serotype, but increasingly, non-O157 STEC strains are identified as causes of outbreaks and sporadic illness (53). At the Centers for Disease Control and Prevention’s (CDC) E. coli Reference Laboratory, 71% of all non-O157 STEC isolates received between 2003 and 2008 belonged to six serogroups (O26, O103, O111, O121, O45, and O145) (54). Because most laboratory methods for the detection of O157 STEC do not detect non-O157 STEC, the numbers of infections with serotypes other than O157:H7 or O157:NM are probably underestimated.

**ETEC**

ETEC, which produces heat-labile E. coli enterotoxin (LT) and/or heat-stable E. coli enterotoxin (ST), is an important cause of diarrhea in developing countries, particularly among young children (46). ETEC also is a frequent cause of traveler’s diarrhea. From 1975 to 2008, 33 U.S. outbreaks were reported to the CDC (C. A. Bopp, unpublished data; 55). ETEC is infrequently isolated in the United States, but this may be attributable in part to the fact that few laboratories are capable of identifying this pathogen. ETEC strains, particularly those associated with outbreaks, tend to cluster in a few serotypes (Table 2).

The most prominent symptoms of ETEC illness are diarrhea and abdominal cramps, sometimes accompanied by nausea and headache, but usually with little vomiting or fever (55). Although ETEC is usually associated with relatively mild watery diarrhea, illness in some recent ETEC outbreaks has been notable for its prolonged duration (56).

**EPEC**

In the past, EPEC strains were defined as certain E. coli serotypes that were epidemiologically associated with infantile diarrhea but did not produce enterotoxins or Shiga toxins and were not invasive. The traditional EPEC serotypes are listed in Table 2; typically, these serotypes show a distinct pattern of localized adherence to HeLa and HEp-2 cells (57). These serotypes usually also demonstrate actin aggregation in the fluorescent actin stain test, which correlates with the attaching-and-effacing (A/E) lesion in vivo (46). Because of the lack of simple diagnostic methods for EPEC strains, few laboratories attempt to identify these organisms. Full EPEC pathogenicity requires two genetic elements: the EPEC adherence factor (EAF) plasmid, which encodes, most importantly, the bundle-forming pilus; and the chromosomal LEE, which mediates the A/E phenotype. The term “typical EPEC” has been suggested for those organisms harboring both the EAF plasmid and the LEE pathogenicity island (see below). Typical EPEC strains correspond to EPEC strains of the classical serotypes and are important causes of diarrhea in developing countries (46, 58); these organisms were implicated in highly lethal nursery outbreaks in the United States and the United Kingdom before 1970. The infection is currently rare in the industrialized world. More recently, atypical EPEC strains have been implicated as enteric pathogens in the United States, including in an outbreak of diarrheal disease (59, 60). These strains possess

*STECEAEC O111:H2 strain identified from patients associated with an outbreak of HUS in France (254).

A functional LEE apparatus but do not carry the EAF plasmid. The full role of these pathogens has yet to be elucidated, but they may be considered potential causes of diarrheal outbreaks when no other pathogens are identified.

Symptoms of often severe and prolonged notbloody diarrhea, vomiting, and fever in infants or young toddlers are characteristic of EPEC illness (46). Infection with EPEC has been associated with chronic diarrhea; sequelae may include malabsorption, malnutrition, weight loss, and growth retardation.

**EIEC**

EIEC strains invade cells of the colon and produce a generally watery, but occasionally bloody, diarrhea by a pathogenic mechanism similar to that of Shigella. EIEC is rare in the United States and is less common than ETEC or EPEC in the developing world (46). EIEC strains, like ETEC and EPEC, are associated with a few characteristic serotypes (Table 2). Three large outbreaks of diarrhea caused by EIEC have been reported in the United States (46), and an outbreak of EIEC O96:H19 was recently detected in Italy using a commercial diagnostic PCR kit (61).

**EAEC**

EAEC, as originally defined by its specific pattern of aggregative adherence to HEp-2 cells in culture, has been associated with diarrhea in a variety of clinical settings, including endemic diarrhea in children of both impoverished and industrialized countries, epidemic diarrhea, diarrhea of travelers to developing countries, and persistent diarrhea among patients with HIV infection or AIDS (62). The pathogenicity of EAEC has been confirmed in volunteer studies (63) and by implication of EAEC in diarrheal outbreaks (64). Early studies frequently failed to find an association of EAEC with pediatric diarrhea, but this association has been strengthened by the use of molecular techniques that discriminate the true pathogens exhibiting the aggregative pattern (65, 66). The term “typical EAEC” describes organisms harboring virulence genes under the control of the global EAEC regulator AggR (66). Typical EAEC may be a common cause of pediatric diarrhea in U.S. infants (65) and should be considered a potential cause of foodborne outbreaks and diarrhea in HIV-infected and AIDS patients (62). EAEC-diarrhea is accompanied by signs and symptoms of mild inflammation (abdominal pain and fever), but stools usually do not contain blood or fecal leukocytes (62).

In 2011, a typical EAEC strain lysogenized with a Shiga toxin-encoding phage caused a large outbreak of foodborne illness in Europe (67). The illness was clinically indistinguishable from that caused by E. coli O157:H7, although most of the cases and complications occurred in adults. Whether or not Shiga toxin-producing EAEC strains will become more common is unknown.

**Putative Diarrheagenic E. coli**

Several putative pathotypes have been described. Virulence has not been demonstrated clearly for any of these types by either volunteer studies or outbreak investigations. DAEC strains, which exhibit a characteristic diffuse pattern of adherence to HEp-2 cells, have been implicated as causes of diarrhea in some epidemiologic studies but not others (46), and a prototypical DAEC strain did not elicit diarrhea in adult volunteers (68). In several studies, DAEC infections were significantly associated with watery diarrhea among children 1 to 5 years of age but were not associated with illness among infants (69). DAEC may occur in industrialized countries (46). A complex signal transduction cascade has been suggested as the mechanism of DAEC pathogenesis (70).

---

*a* Outbreak-related serotypes are shown in bold. NM, nonmotile; NT, not typeable.

*STEC/EAEC O111:H2 strain identified from patients associated with an outbreak of HUS in France (254).
CNF-producing E. coli strains produce a toxin that induces morphological alterations (multinucleation) and death in tissue cultures (71). Two forms have been described: CNF1 and CNF2. CNF1-producing strains were originally detected in infants with enteritis and later in humans with extraintestinal infections (71, 72). Most CNF1-producing strains are also hemolytic, although the toxin is distinct from hemolysin. CNF2-producing strains have been isolated from animals with diarrhea (73–75). The role of these strains in human diarrheal disease has not been determined definitively (46).

Cytolethal distending toxin-producing E. coli strains produce a heat-labile factor that induces cytotonic and cytotoxic changes in Chinese hamster ovary cells similar to those caused by LT (76). This factor does not affect Y-1 cells. The results of one study in Bangladesh suggested that cytolethal distending toxin-producing E. coli strains are associated with diarrhea (77), but other studies are needed to establish their status as etiologic agents.

Several diarrheal outbreaks have been linked to E. coli strains that do not belong to any of the established pathotypes. Some of these strains carry the gene encoding the enterohemorrhagic ST-like toxin (EAST1), which is related to the ETEC ST enterotoxin. Further studies are needed to prove the pathogenicity of these strains, but the EAST1 gene can be identified using molecular techniques (78).

**Collection, Transport, and Storage of Specimens**

Information on the collection, transport, and storage of specimens from extraintestinal sites is provided in chapter 18 of this Manual. Fecal specimens should be collected in the early stages of any enteric illness (preferably within 4 days of onset), when pathogens are usually present in the stool in highest numbers and before antimicrobial therapy has been started. Whole stools are usually the specimen of choice, but carefully collected rectal swabs with visible fecal staining may be preferable for diagnosis of Shigella (79–81). Collection of multiple specimens may enhance the recovery rate of E. coli, Shigella, and Salmonella (82).

Transport of fecal specimens to the laboratory in a timely fashion is critical, particularly for more delicate organisms such as Shigella (83). Ideally, fecal specimens should be examined as soon as they are received in the laboratory, but if not processed immediately, they should be either refrigerated or frozen at −70°C. Fecal specimens that will not be examined within 1 to 2 h of collection and all rectal swabs should be placed in cold transport medium and kept at 4°C (84). Transport and storage of fecal specimens at 4°C is very important for Shigella as well as Campylobacter spp. Manufacturers of commercial transport media, including the acceptable media listed below, commonly state that fecal specimens may be transported and stored at ambient temperature. For Shigella and Campylobacter spp., this is not advised because there are data showing that transport at ambient temperature may deleteriously affect recovery of these organisms (85).

Many of the commercially available transport media (e.g., Cary-Blair, Stuart, and Amies transport media) and buffered glycerol saline are satisfactory for E. coli, Salmonella, and Shigella. Although acceptable for the transport of the organisms addressed in this chapter, buffered glycerol saline should not be used for specimens that must also be tested for Campylobacter and Vibrio (85, 86).

**Direct Examination**

**Microscopy**

Gram stains of patient specimens from normally sterile body sites can provide a preliminary indication of which category of bacteria to cultivate from the specimen and if inflammatory cells or blood are present; however, E. coli and other *Escherichia* species cannot readily be distinguished from other Gram-negative rods by staining or microscopy methods.

**Antigen Detection**

Several commercial immunassays are available to diagnose STEC infections by detecting Shiga toxin or the O157 antigen (lipopolysaccharide [LPS]) in fecal specimens (Table 3) (87, 88). These assays are usually more sensitive when performed on enriched specimens than on stool directly. Isolation and serotyping of STEC from fecal specimens that are positive by nonculture assays should always be attempted because serotype information is important for public health purposes and may also help in clinical decisions. Determination of the subtype of O157 STEC and the serotype of a non-O157 STEC isolate is valuable for outbreak investigations and surveillance purposes (see “Typing Systems” and “Identification” below).

**Nucleic Acid Detection**

At the time of publication, we are aware of four Food and Drug Administration (FDA)-cleared nucleic acid detection methods for the clinical diagnosis of STEC, *Salmonella*, and *Shigella/EIEC*. These include the xTAG Gastrointestinal Pathogen Panel (Luminex Molecular Diagnostics, Inc., Toronto, Ontario, Canada), ProGastro SSSC (Hologic Gen-Probe, Inc., San Diego, CA), FilmArray Gastrointestinal Panel (BioFire Diagnostics, Salt Lake City, UT), and BD MAX Enteric Bacterial Panel (Becton Dickinson and Co., Franklin Lakes, NJ). In addition to the pathogens listed above, the xTAG and FilmArray panels claim to be able to identify ETEC and E. coli O157, while the FilmArray panel also claims to detect EPEC and EAEC. Published findings from the initial evaluations of two of these assays have been promising, with reported overall sensitivities and specificities compared to conventional methods of 99.9 to 99.9% and 98.5 to 99%, respectively, for the xTAG panel (89, 90) and 100% and 99 to 100%, respectively, for the ProGastro SSSC panel after resolution of discrepant results (91). Individual sensitivities and specificities of the xTAG panel for STEC, O157 STEC, ETEC, and Shigella/EIEC ranged from 93.7 to 100% and 97 to 100%, respectively, but were slightly lower for *Salmonella*, at 87.2 to 90% and 95.4 to 98.5 to 100%, respectively (89, 90). When the panel was cleared by the FDA, confirmation of positive xTAG results was recommended in the manufacturer’s product insert, and this recommendation was affirmed for *Salmonella* and *Entamoeba histolytica* by Wessels et al. (92). The individual sensitivities and specificities of the ProGastro SSSC panel for STEC, Shigella, and Salmonella were each 100% (91). Published peer-reviewed evaluations were not available for the FilmArray and BD MAX panels, which received FDA clearance in May 2014. Validation studies for gastrointestinal panels targeting diarrheagenic E. coli other than STEC will be a challenge to perform due to the cost and complexity of the phenotypic assays required to isolate or confirm these organisms and the lack of consensus within the scientific community for a generic definition of certain pathotypes, e.g., EAE and EPEC.

Overall, the gastrointestinal panels offer physicians a valuable diagnostic tool for managing the health of individual patients; however, strategies to support surveillance systems intended to protect the health of the public are urgently needed. According to guidelines published in 2009, all fecal specimens or enrichment broths positive for Shiga toxin

</table>

*This table is not intended to be a comprehensive listing. The FDA has not cleared all of these reagents for use with clinical specimens. This table does not include reagents or tests specifically intended for examination of food, water, or environmental specimens. The online version of the *Bacteriological Analytical Manual* lists many tests for food specimens ([http://www.fda.gov](http://www.fda.gov)). Inclusion does not constitute endorsement by the CDC or ASM.*

Genes but from which O157 STEC strains are not recovered should be forwarded by the diagnostic laboratory to the appropriate public health laboratory to attempt to obtain a STEC isolate (93).

### Isolation Procedures

**Isolation Procedures for Extraintestinal *E. coli***

Isolation procedures for *E. coli* and other *Escherichia* species from sites outside the intestines are covered in chapter 18 in this *Manual*. Any *E. coli* strain isolated in large numbers (particularly >10⁵ CFU/ml of urine) or from normally sterile body sites should be considered a potential pathogen. Although *E. coli* strains with particular virulence in the urinary tract cannot be easily distinguished on differential and selective plating media from organisms of lower virulence, they are commonly hemolytic on sheep blood agar and express one or more of several urinary tract adhesins. Several chromogenic media have been proposed for use in detecting UPEC; these have been compared in published studies (94, 95).

**Isolation Procedures for Diarrheagenic *E. coli***

Guidelines published in 2009 (93) recommend that all stools submitted for testing for routine enteric pathogens (*Salmonella*, *Shigella*, and *Campylobacter*) at clinical diagnostic laboratories and all patients with suspected HUS should...
be cultured for O157 STEC on selective and differential agar and assayed for non-O157 STEC with a test that detects the Shiga toxins or genes encoding these toxins. The recommendations to isolate O157 STEC and detect non-O157 STEC were extended to all stools from patients with acute, community-acquired diarrhea because selective testing strategies such as testing only bloody stools or specimens from children, limiting testing to summer months, or basing testing on the presence of indicators such as white blood cells will miss many STEC infections. The absence of blood in the stool does not negate the possibility of a STEC-associated diarrheal illness (96–98). In several studies, most STEC isolates, including both O157 and non-O157 strains, were from patients with apparently nonbloody diarrhea (91, 99–102). Also, STEC strains are isolated more frequently from children, but almost half of all isolates are obtained from persons >12 years of age (51, 102–104), so limiting STEC testing to children would miss many infections. Although STEC infections are more common in the summer months, sporadic cases and outbreaks do occur year-round (51, 53, 101). Leukocytes are often but not invariably observed in the stools of patients with STEC infection; thus, determination of white blood cells in stool should not be used as a criterion for STEC specimen selection (51, 105).

**Enrichment.** Although broth enrichment is widely used for the recovery of O157 STEC from foods, there is little evidence that it enhances isolation from human fecal specimens. However, immunomagnetic separation (IMS), a technique shown to increase the rate of isolation of O157 STEC from food specimens, has been adapted to culture of fecal specimens (106). IMS enhances the detection of O157 STEC from patients with HUS, patients presenting an extended period of time after the onset of illness (>5 days), asymptomatic carriers, or specimens that have been stored or transported improperly. IMS beads for O157, O111, and O26 are available commercially (Table 3), or laboratories may produce beads with other O-specific antibodies (107).

**Plating media.** Because O157 STEC strains ferment lactose, they are impossible to differentiate from other lactose-fermenting organisms on lactose-containing media. Most O157 STEC strains do not ferment the carbohydrate D-sorbitol overnight, in contrast to the ~80% of other E. coli strains that ferment sorbitol rapidly. Thus, sorbitol-containing selective media are often used for isolation of O157 STEC. Sorbitol-nonfermenting colonies are suspected (but not definitively known) to be E. coli O157:H7 (108). In some areas of central Europe, sorbitol-fermenting O157 STEC strains are commonly isolated from patients with HUS (109); these organisms are very rare in North America (Strockbine, unpublished data).

Specific culture media have been developed to exploit phenotypic and antibiotic resistance traits that are characteristic of STEC strains. Although sorbitol-containing MAC (SMAC) is widely used, cefixime-tellurite-containing SMAC (CT-SMAC) and CHROMAgar O157 have been shown to increase the sensitivity of culture for O157 STEC (110). It has been reported that some nonmotile strains of O157 STEC fail to grow on CT-SMAC (106). Several chromogenic agar media are available commercially to assist in rapid identification (Table 3); these media generally perform well for O157:H7 and for some non-O157 STEC strains (111–114).

**Screening procedures for STEC strains.** For the isolation of O157 STEC from SMAC, colorless (nonfermenting) colonies are tested with O157 antiserum or latex reagent (115) (Table 3). If the O157 latex reagent is used, it is important to test positive colonies with the latex control reagent to rule out nonspecific reactions. The manufacturers of these kits recommend that strains that react with both the antigen-specific and control latex reagents be heated and retested. However, in a study that followed this procedure, none of the nonspecifically reacting strains were subsequently identified as O157 STEC (116).

Unlike most other E. coli strains, O157 STEC strains do not express β-glucuronidase; therefore, the MUG reaction (4-methylumbelliferyl-β-d-glucuronide for detection of β-glucuronidase activity) is helpful for screening for O157 STEC (117). MUG-positive, urease-positive O157 STEC strains have been isolated in the United States but are still rare (118; Strockbine, unpublished data).

For the recovery of STEC strains from stool specimens that test positive for Shiga toxin, CT-SMAC, CHROMAgar O157, or a similar selective agar for isolation of O157 STEC should be used. If sorbitol-nonfermenting colonies are negative with O157 latex, then sorbitol-fermenting colonies (because most non-O157 STEC strains ferment sorbitol) and a representative sample of sorbitol-nonfermenting colonies may be selected for Shiga toxin testing. Latex reagents and antisera (Table 3) for detecting certain non-O157 STEC serotypes are now available and could also be used to test colonies from Shiga toxin-positive specimens or to serogroup Shiga toxin-positive isolates.

Virtually all O157 STEC strains and 60 to 80% of non-O157 STEC strains produce a characteristic E. coli hemolysin, referred to as enterohemolysin (Ehly), which is distinct from the alpha-hemolysin produced by other E. coli strains (119). Washed sheep blood agar supplemented with calcium (WSBA-Ca) is used as a differential medium for the detection of enterohemolysin activity (119). Ehly-producing colonies can be differentiated from alpha-hemolysin-producing colonies on WSBA-Ca because the latter are visible after 3 to 4 h of incubation. After 3 to 4 h, colonies are marked for the appearance of alpha-hemolysin, and the plates are examined again after 18 to 24 h. Incorporation of mitomycin C into WSBA-Ca enhances the appearance of the Ehly hemolysis and increases the proportion of non-O157 STEC strains that exhibit this activity (120). Because some non-O157 STEC strains do not demonstrate the enterohemolysin phenotype, nonhemolysis colonies should also be screened for Shiga toxin (121).

Presumptive STEC isolates should be sent to a reference laboratory or a public health laboratory for further characterization.

**Isolation Procedures for Other Diarrheagenic E. coli.**

Methods for the isolation of ETEC, EPEC, EIEC, EAEC, and putative diarrheagenic E. coli strains are generally available only in reference or research settings. Public health and reference laboratories usually examine specimens for these pathogens only when an outbreak has occurred and specimens are negative for routine bacterial pathogens. ETEC and EAEC should be considered possible etiologic agents of watery diarrhea when no other pathogen has been identified, especially for travelers. EPEC should be considered a possible pathogen in outbreaks of severe nonbloody diarrhea occurring in infants or young toddlers, particularly in nursery or day care settings (65). EIEC should be considered a possible etiologic agent in outbreaks of nonwatery diarrhea (bloody or nonbloody).

To capture E. coli for further testing, fecal specimens should be plated on a differential medium of low selectivity (e.g., MAC). Five to 20 colonies, mostly lactose fermenting
but with a representative sample of nonfermenting colonies, should be selected and inoculated onto noneselective agar slants (such as L agar or nutrient agar). These colonies are then sent to a reference laboratory for testing or are screened for virulence-associated characteristics if assays are available. Strains can be kept frozen for long periods in L broth with 15 to 50% glycerol at −80°C. Arrangements for sending E. coli isolates from well-characterized outbreaks to the CDC for testing can be made through local and state health departments.

Screening procedures for ETEC, EPEC, EAEC, and EIEC strains. E. coli pathotypes other than STEC cannot be distinguished from other E. coli strains by phenotypic screening techniques. Many EIEC strains are nonmotile and fail to decarboxylate lysine; however, some EIEC strains are motile or lysine positive. Use of commercial antisera to detect EPEC is no longer recommended due to the number of false positives this approach yields.

Identification

Phenotypic Identification

With the exception of E. albertii, the commercial identification systems do a good job of identifying most Escherichia strains (122–124). Identification of E. albertii with these systems remains problematic because representative strains of this species are not yet included in commercial databases (125). Abbott and colleagues, who extensively characterized five strains of E. albertii by conventional phenotypic methods and by commercial identification panels, reported that E. albertii is an indole-negative species that ferments D-mannitol but not D-xylose (125). In their study, E. albertii strains were identified by commercial systems as Hafnia alvei, Salmonella or Salmonella enterica serotype Cholenedesus, E. coli (inactive or serotype O157:H7), or Yersinia ruckeri. Although some strains were clearly misidentified, the majority of the strains generated probability scores for the final identification that were unacceptable, or the identification was inconsistent with the source of the specimen (e.g., identification of the fish pathogen Y. ruckeri from a human specimen), which should have triggered additional phenotypic tests to establish a more reliable identification. The authors found that the most reliable clue to the possible presence of E. albertii was an unacceptable first-choice identification of H. alvei for an isolate that is both L-threonine and D-xylose negative.

Phenotypic tests that can help discriminate E. albertii strains from selected members of the Enterobacteriaceae family with similar phenotypic traits are shown in Table 1. Two biogroups of E. albertii are listed in Table 1. These correlate with two of the distinct clusters of strains identified in the E. albertii lineage by phylogenetic studies (8). Biogroup 1 comprises the five strains isolated from Bangladeshi children with diarrhea, while biogroup 2 comprises strains formerly identified as S. boydii 13. The strains in the two biogroups differ from each other in their abilities to produce indole from tryptophan, decarboxylate lysine, and ferment D-sorbitol. Antigenic relationships between members of the E. albertii lineage and other members of the Enterobacteriaceae family have been observed (e.g., S. boydii 7 and E. coli O28). A diagnostic PCR assay using three housekeeping genes was described by Hyma et al. (8) for E. albertii; this assay is independent of phenotypic or antigenic traits and should facilitate studies to learn about the diversity within the lineage, the natural habitat of the species, and its role in enteric disease. The identification of presumptive O157 STEC isolates is necessary because other species may cross-react with O157 antiserum or latex reagents, including Salmonella O group N (O:30), Yersinia enterocolitica serotype O9, Citrobacter freundii, and E. hermannii. Additional phenotypic tests (cellulose fermentation and growth in the presence of potassium cyanide [KCN]) may be necessary to differentiate E. hermannii from E. coli, but because E. hermannii is rarely detected in stool specimens, use of these tests is not cost-effective for most laboratories.

In recent years, matrix-assisted laser desorption ionization–time-of-flight mass spectrometry (MALDI-TOF MS) has been adopted in many clinical laboratories for identification. The method is rapid, is substantially less expensive than conventional culture methods, and has performed well in identifying E. coli to the species level (126–129). It holds promise for the identification of other Escherichia species (E. hermannii, E. vulneris, and E. fergusonii) to the species level, but not unexpectedly, it was unable to distinguish Shigella from E. coli (126, 127). Clark et al. (128) recently reported success using custom evaluation criteria (informative spectral peaks) as a screening tool to differentiate most E. coli pathotypes for subsequent testing.

In response to the growing problem of multidrug-resistant bacteria, labs are seeking rapid methods to screen bacteria to identify resistance mechanisms to inform and expedite the management of patients to control the spread of resistance. Several groups recently reported MS methods to rapidly test for antimicrobial resistance mechanisms. Jung et al. (130) described a MALDI-TOF MS assay to detect β-lactamase activity against aminopenicillins. The assay works by detecting a specific pattern of fragments generated from the digestion of the drug by the resistance-conferring enzyme. The assay took just 2.5 h to complete and had a sensitivity and specificity of 100 and 91.5%, respectively, when evaluated on a set of 128 isolates. Another assay using MALDI-TOF MS to detect class D carbapenemase OXA-48-like-producing Enterobacteriaceae was reported by Sautet et al. (131). This assay had a turnaround time of 90 min and a sensitivity and specificity of 98.9 and 97.8%, respectively, when tested on 372 strains. A third assay that uses liquid chromatography-tandem MS to detect carbapenemase KPC, NDM, OXA, IMP, and VIM activity produced against imipenem, meropenem, and etazabol was described by Kulhari et al. (132). The sensitivity and specificity of the assay were best with imipenem—96 and 95%, respectively, for a group of 402 Gram-negative bacteria—and the assay took only 75 min to complete. These assays offer valuable information quickly to facilitate interventions to limit the dissemination of resistant organisms and prevent outbreaks. Additional information on the use of MS to detect antibiotic resistance mechanisms is reviewed by Hrabak et al. (133).

Serotyping

The serologic classification of E. coli is generally based on the O antigen (somatic) and the H antigen (flagellar) (134). The O and H antigens of E. coli are stable and reliable strain characteristics, and although 181 O antigens and 56 H antigens have been described (a few of which are no longer recognized), the actual number of serotype combinations associated with diarrheal disease is limited (Table 2). Determination of the O and H serotypes of E. coli strains implicated in diarrheal disease is particularly useful in epidemiologic investigations (Table 2). Even though antisera for microtiter or tube agglutination tests are available from manufacturers, most laboratories do not attempt to perform complete E. coli serotyping because it is costly. For well-
characterized outbreaks with no identified etiologic agent, arrangements may be made through state health departments to send E. coli isolates to the CDC for virulence testing and serotyping.

Serologic Confirmation of O157 STEC

Confirmation of E. coli O157:H7 requires identification of the H7 flagellar antigen. H7-specific antisera and latex reagents are commercially available (Table 3), but detection of the H7 flagellar antigen often requires multiple passages (115). Isolates that are nonmotile or negative for the H7 antigen should be tested for the production of Shiga toxins or the presence of Shiga toxin gene sequences.

Approximately 85% of O157 isolates from humans received by the CDC are serotype O157:H7, 12% are nonmotile, and 3% are H types other than H7 (Strockbine, unpublished data). E. coli O157:NM strains often produce Shiga toxin, and those that do produce Shiga toxin have the same flaC restriction profile as that observed for E. coli O157:H7 (135). No O157 strain from human illness with an H type other than H7 has been found to produce Shiga toxin (Strockbine, unpublished data).

Nucleic Acid-Based Methods

Accurate identification of bacterial isolates is important for directing patient care and management. Compared to traditional phenotypic approaches, which can be influenced by phenotypic variation or subjective interpretation, 16S rRNA gene sequencing is a more objective identification tool and has the potential to reduce laboratory errors. Some clinical laboratories have begun using molecular methods to aid in the identification of organisms that cannot be cultivated due to unusual growth characteristics or antibiotic treatment or cannot be classified by phenotypic methods (136–141). In one study, results obtained with 16S rRNA gene sequencing and the SmartGene IDNS (Zug, Switzerland) database and software compared favorably to those obtained by conventional phenotypic methods and were better than those obtained with a similar rRNA gene method employing a smaller database for a collection of 300 clinical isolates (137). The performance differences between the two 16S rRNA gene methods highlight the importance of the size and breadth of the database for successful classification. Difficulties in separating E. coli from Shigella with 16S rRNA gene sequencing should be expected. These are genetically the same species and have been maintained as separate taxa for medical expedience. The limited findings reported in the studies above and those reported by others (142) show that a small region of the 16S rRNA gene alone will not provide reliable separation of certain medically relevant members of the Enterobacteriaceae family (E. coli/5. somei [137] and Escherichia/Shigella/Hafnia [136]). The incorporation of virulence genes that define the Shigella/EIEC pathotype should help discriminate it from noninvasive pathotypes or communal E. coli. Another approach that has potential to improve microbial identification involves MS. The Ibis T5000 Biosensor System (Abbott Molecular, Des Plaines, IL), which is currently used in nonclinical and research settings, uses multiple regions of the 16S and 23S rRNA genes plus several housekeeping genes to discriminate between species within 6 h (143). Validation studies are needed to assess the performance of this technology on clinical specimens.

Simple and cost-effective strategies to use whole-genome sequencing to differentiate bacterial species, determine antibiotic resistance potential, detect virulence determinants, and conduct pathogen surveillance for outbreak detection are developing rapidly. The application of this technology in the clinical microbiology setting is reviewed by Didelot et al. (144), who highlight its recent successful use to rapidly characterize the novel E. coli O104:H4 variant that caused the 2011 outbreak of bloody diarrhea in Germany and France (145).

Virulence Testing

Extraintestinal E. coli

Numerous virulence factors have been identified for extraintestinal E. coli (43), particularly the K1 antigen, but these are usually identified only in epidemiologic studies.

Diarrheagenic E. coli

Detection of diarrheagenic pathotypes is typically performed on E. coli colonies chosen from selective or nonselective media. If PCR techniques are used, a sweep of confluent growth from a MAC plate may be screened; if the PCR assay is positive, isolated colonies may then be picked and screened individually. Multiplex PCR assays are capable of simultaneously detecting multiple E. coli pathotypes (146).

STEC. Two distinct Shiga toxins, Stx1 and Stx2, also referred to as verocytotoxins 1 and 2, have been described in E. coli. STEC may produce either Stx1 or Stx2 or both toxins. The toxin produced by Shigella dysenteriae serotype 1 was recognized first and is designated Stx1, while the toxins in E. coli include an Arabic number in association with “Stx.” The Shiga toxins comprise a family of toxins that have similar biologic, genetic, and structural features. Stx1 and Stx1x are essentially identical. Subtypes of Stx1 and Stx2 have been identified, and a standardized nomenclature for the toxins and PCR protocols for their detection were recently published by Schuetz et al. (147). The toxin subtypes vary in their association with severe disease, with Stx2a, Stx2c, and Stx2d being associated with bloody diarrhea and HUS (148–150); however, host factors, dose, and other bacterial factors play a role in the severity of disease.

The production of Stx or the genes encoding Stx can be detected by a variety of biologic, immunologic, or nucleic acid-based assays (46, 151). FDA-approved diagnostic PCR assays for STEC that discriminate between the two toxin types are now available (see “Nucleic Acid Detection” above). Stx has also been directly detected in the blood of HUS patients by use of flow cytometry, even in the absence of serologic or microbiologic evidence of STEC infection (152).

STEC strains represent a spectrum of virulence potentials, ranging from the highly virulent O157:H7 serotype that has been responsible for the majority of outbreak cases to low-virulence serotypes that have been isolated only from nonhuman sources. The presence of additional virulence factors other than Stx correlates with disease potential. The most important of these virulence factors are the intimin adhesin and the type III secretion system encoded by the LEE pathogenicity island (43). The eae gene probe for intimin and the hlyA (E-hlyA or ehxA) gene probe for a plasmid-encoded hemolysin have been the most frequently employed methods to determine virulence potential, but probes for at least 25 different virulence-associated genes have been employed to characterize STEC strains (153, 154). STEC strains have been classified into five “seropathotypes” (A through E) based on the occurrence of serotypes in human disease, in outbreaks, and in severe disease (HUS or hemorrhagic colitis) and on possession of specific virulence genes (155).
ETEC. The ST and LT enterotoxins produced by ETEC may be detected by a variety of biologic, immunologic, and nucleic acid-based assays (46). Two distinct ST variants (STh and STp) have been identified in human strains. Strains that produce ST only or ST in combination with LT have caused most ETEC outbreaks in the United States (55).

Immunoassays for the identification of ST or LT in culture supernatants of ETEC strains are available from at least two commercial sources (Table 3). The ST EIA assay (Denka Seiken Co., Ltd., Tokyo, Japan; and Oxoid Ltd., Basingstoke, United Kingdom) is a competitive enzyme immunoassay for the detection of ST only (156). A reversed passive latex agglutination assay (VET-RPLA; Oxoid [a similar kit is available from Denka Seiken]) detects both cholera toxin and LT, which are highly related antigenically. The effectiveness of the VET-RPLA may be optimized by use of a culture medium designed for LT production, such as Biken’s medium, rather than the medium recommended by the manufacturer (157).

EPEC. EPEC, AEIC, and DAEC can be detected by their characteristic patterns of adherence to HEp-2 or HeLa cells in culture (57). These patterns are also observed on formalin- or glutaraldehyde-fixed cells, obviating the need to prepare cells expressly for the assay (158).

EPEC strains are defined on the basis of the A/E histopathology produced on epithelial cells and the lack of STx (reviewed in references 58 and 43). The A/E phenotype can be detected by tissue culture cell assays or by DNA probe or PCR tests for the eae gene, encoding intimin, or the LEE pathogenicity island. The EAF plasmid of typical EPEC (see above) is detected by use of fragment or oligonucleotide probes or PCR primers (46). Atypical EPEC strains possess only the A/E phenotype (LEE pathogenicity island) but do not possess the EAF plasmid. It is likely that only a subset of atypical EPEC strains comprise true human pathogens, although no tests can reliably identify pathogenic isolates.

EAEC. Several simple assays have been described as surrogates for the cell adherence test for identification of EAEC. These include a simple biofilm formation assay on polystyrene (159) and screening for the presence of a pellicle at the surface of broth media (160). EAEC can be identified more definitively by use of a specific DNA probe (the AA or CVD432 probe) (161), which is superior to tissue culture adherence assays in identifying pathogenic strains of EAEC (65). More recent data suggest that the AA probe corresponds to a putative virulence gene called aatA (162), which is under the control of a regulator termed AggR. AggR, in turn, controls several other virulence factors (66). Thus, the aggR gene (which defines typical EAEC) may represent a superior diagnostic target, although data to support this notion are not available.

EIEC. EIEC can be identified by various in vitro assays, immunoassays, and nucleic acid-based assays for invasiveness. EIEC can be detected along with Shigella with two commercial kits, one of which targets the invasion plasmid-associated gene etsH (See “Nucleic Acid Detection” above). Cell culture invasion assays or DNA-based assays for other invasion-related factors are, for the most part, practical only in research settings (46). Plasmid DNA electrophoresis may be used to detect the large, 120- to 140-MDa plasmid associated with invasiveness, but this plasmid is easily lost when the isolate is subcultured. Because of shared invasiveness-related characteristics, these assays also detect Shigella strains.

DAEC. DAEC strains were initially defined on the basis of a diffuse adherence pattern to cultured epithelial cells, but this phenotype is not specific for enteric strains (70). Various DNA probes and PCR assays have been proposed for DAEC identification, as reviewed previously (46).

Typing Systems
Several methods for subtyping have been used for E. coli O157:H7 isolates. In particular, pulsed-field gel electrophoresis (PFGE) methods and multilocus variable-number tandem-repeat analysis (MLVA) methods are useful (46, 163). A national molecular subtyping network, PulseNet, was established in 1996 by the CDC to facilitate subtyping of bacterial foodborne pathogens, including E. coli O157:H7, Shigella, non-typhoidal Salmonella serotypes, and Listeria monocytogenes (164). Successful detection of outbreaks by this network of state and local public health laboratories is dependent on submission of isolates by clinical laboratories for confirmation and subtyping.

Determination of the serotype and the antimicrobial susceptibility pattern is usually adequate for defining outbreak strains of ETEC, EPEC, and EIEC. Plasmid typing or PFGE methods may also be helpful for distinguishing between sporadic isolates and outbreak strains, but neither method has been widely used for these groups of E. coli.

Serologic Tests
At present, serodiagnostic tests for diarrheagenic E. coli are valuable only for seroepidemiology surveys and are not useful for the diagnosis of sporadic infections. Assays that measure serum antibody response to LPS have been used to detect STEC infection in culture-negative HUS patients (46). Enzyme-linked immunosorbent assays have been described to detect saliva antibodies to LPS (165) and serum antibodies to the secreted EspB protein in HUS patients (166).

Antimicrobial Susceptibilities
Extraintestinal E. coli
In the past 20 years, E. coli strains producing CTX-M-β-lactamases and AmpC β-lactamases have emerged as significant causes of extraintestinal infections in the United States and globally (35, 167–170). CTX-M-producing E. coli strains are often isolated from urinary tract infections, both health care and community acquired, and have also been detected in retail meat samples in the United States (35). Recently, a single pandemic clone of multiresistant E. coli ST131 has emerged as the predominant extended-spectrum β-lactamase (ESBL)-positive E. coli strain isolated from urinary tract infections and bacteremia in hospitalized patients and community-acquired infections in the elderly (40, 169–171). In addition to being resistant to fluoroquinolones, E. coli ST131 is often associated with the CTX-M-15 ESBL (169) and often possesses multiple virulence genes (sha, sat, and iutA).

AmpC β-lactamases are problematic for clinical laboratories because these enzymes can interfere with ESBL confirmatory tests, resulting in a false report of cephalosporin susceptibility (169, 170). The AmpC β-lactamase CMY-2 has the broadest geographic distribution and has been found in E. coli and other Enterobacteriaceae (reviewed by Jacoby [172]).

Carbapenemases are β-lactamases that confer resistance to the carbapenems, and the Klebsiella pneumoniae carbapen-
emase (KPC) is the most frequently encountered enzyme of this class in *E. coli* and other carbapenem-resistant *Enterobacteriaceae*. It is important to detect KPC and other carbapenemases in patients colonized with carbapenem-resistant *Enterobacteriaceae* so that isolation precautions may be instituted to prevent transmission in health care settings (173).

Until laboratories can implement the carbapenem interpretative criteria published in the 2014 CLSI guidelines (174), performance of the modified Hodge test (MHT) as described in the guidelines (Table 3C) is advised. If the 2014 CLSI interpretive criteria are used, the MHT does not need to be performed other than for epidemiologic or infection control purposes and no change in the interpretation of carbapenem susceptibility test results is required for MHT-positive isolates. Results of the MHT should be reported to infection control or those requesting epidemiologic information.

When identifying carbapenemase-producing isolates for infection control or epidemiologic purposes, a targeted strategy for testing isolates can be used. Selection of isolates for testing in the MHT with the following characteristics is suggested: intermediate or resistant to one or more carbapenem classes when using the CLSI 2014 interpretive criteria (etapenem nonsusceptibility is the most sensitive indicator of carbapenemase production) and resistant to one or more agents in cephalosporin subclass III (174).

Current automated susceptibility test systems may not be able to accurately detect ESBLs, AmpCs, and KPCs (175, 176). Issues surrounding the testing for these enzymes are reviewed by Thomson (177).

In January 2010, the CLSI published interpretative criteria for phenotypically assessing the susceptibility of the *Enterobacteriaceae* to the cephalosporins and aztreonam (178). Under these guidelines, lower breakpoints were recommended, thereby eliminating the need to perform routine ESBL tests and to edit the results on reports from susceptible to resistant for cephalosporins, aztreonam, or penicillins. No reduction in breakpoints was proposed at this time for cefuroxime (parenteral) and cefepime; however, in 2014, the CLSI substantially revised only the cefepime interpretive criteria (breakpoints) and introduced the “susceptible-dose dependent” (SDD) category to replace the “intermediate” category (174). The SDD interpretive category, which has been used successfully to guide antifungal therapy, is a new category for antibacterial susceptibility testing that implies that the susceptibility of an organism is dependent on the dosing regimen that is used in the patient. The CLSI recommends that the following comment be reported with the new cefepime breakpoints: “The interpretive criterion for susceptible is based on a dosage regimen of 1 gram every 12 hours. The interpretive criterion for susceptible-dose dependent is based on dosing regimens that result in higher cefepime exposure, either higher doses or more frequent ones or both, up to approved maximum dosing regimens.” Educating physicians and other stakeholders about the meaning of the SDD category will be important to maximizing the useful life span of cefepime. Additional guidance for implementing the new criteria is discussed in the 2014 CLSI guidelines (174).

Until the FDA revises its breakpoints for manufacturers to update their instruments, laboratories using automated antimicrobial susceptibility devices are advised to consult with manufacturers for guidance on how to manually adjust the cefepime breakpoints. A validation study should be performed when altering manufacturers’ settings, and guidelines for performing such a study are described by Clark et al. (179). Implementation of the revised breakpoints and SDD category currently applies only to cefepime susceptibility testing of members of the *Enterobacteriaceae*. The SDD category has been adopted due to the growing need to refine susceptibility reporting to maximize clinicians’ use of available drugs.

The CLSI suggests that routine antimicrobial susceptibility testing for *Enterobacteriaceae* include ampicillin, ceftazolin (MIC only), gentamicin, and tobramycin testing. Urinary isolates of *E. coli* may be tested against fosfomycin and other drugs used only for these infections (trimethoprim-sulfamethoxazole). For *E. coli* and other *Enterobacteriaceae* isolates recovered from cerebrospinal fluid (CSF), cefotaxime or ceftriaxone should be tested and reported in place of ceftazolin. The following antimicrobial agents should not be routinely performed for *E. coli* or other *Enterobacteriaceae* isolated from CSF because they are not the drugs of choice and may not be effective for treating CSF infections: agents administered by the oral route only, first- and second-generation cephalosporins (except cefuroxime parenteral), cephamycins, clindamycin, macrolides, tetracyclines, and fluoroquinolones.

### Diarrheagenic *E. coli*

#### STEC

Antimicrobial therapy for O157 STEC diarrhea or HUS is controversial: some publications have suggested that antibiotics increase the risk of HUS (48, 180), while a meta-analysis of published reports found no significantly increased risk (181). There is a lack of evidence to support routine antimicrobial susceptibility testing of STEC strains.

Until recently, *E. coli* O157:H7 isolates were almost uniformly susceptible to antimicrobial agents. However, since the early 1990s, O157 and other STEC strains have demonstrated slowly increasing levels of resistance to certain antibiotics, particularly streptomycin, sulfonamides, and tetracycline (http://www.cdc.gov/narms/index.html).

**ETEC, EPEC, EAEC, and EIEC Strains and Other Diarrheagenic *E. coli* Strains**

Treatment with an appropriate antibiotic can reduce the severity and duration of symptoms of ETEC infection (46). Antimicrobial resistance, particularly to tetracycline, is common among ETEC strains isolated from outbreaks in the United States (55). Antibiotic treatment may be helpful for diarrhea caused by EPEC (46). Most EPEC strains associated with outbreaks are resistant to multiple antimicrobial agents (58). EAEC strains are commonly resistant to most antibiotics, though these strains are typically susceptible to fluoroquinolones. Clinical studies have demonstrated the effectiveness of ciprofloxacin for travelers with diarrhea caused by EAEC (182). Little information about the efficacy of antimicrobial treatment or the prevalence of resistance is available for EIEC or other putative diarrheagenic *E. coli* strains, but determination of the antimicrobial susceptibility pattern may be helpful in establishing whether the isolates are associated with an outbreak.

#### Evaluation, Interpretation, and Reporting of Results

**Extraintestinal *E. coli***

The final written report should include the final Gram stain result, the final identification as *E. coli*, and the antimicrobial susceptibility test results. Any supplemental tests used to detect resistance markers like KPCs should be highlighted. Laboratories should determine what resistance markers are important for institutional infection control practices.
Diarrheagenic *E. coli*

**STEC**

A presumptive diagnosis of an O157 STEC (isolate positive for O157 antigen) or a non-O157 STEC (isolate positive for Shiga toxin) infection should be reported to the clinician as soon as the laboratory obtains this result. The 2009 recommendations for clinical diagnosis of STEC include examples of how to word the final report for results from testing for Shiga toxin immunnoassays or PCR for Shiga toxin genes as well as culture results (93; http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5812a1.htm [Table 2]). When O157 STEC is not found in a specimen, it is advisable to include a comment in reports stating that non-O157 STEC strains can cause diarrhea and HUS. Cases of STEC infection and HUS should be reported to public health authorities. O157 STEC isolates or specimens in which Shiga toxin or STEC genes are detected (e.g., stool, other primary specimens, and enrichment broths) should be forwarded to a local or state public health laboratory (93).

**ETEC, EPEC, EAEC, and EIEC Strains**

Generally, the ETEC, EPEC, EAEC, and EIEC classes of diarrheagenic *E. coli* are identified only during outbreak investigations. A laboratory reporting these results, which usually will be a retrospective diagnosis obtained by a reference laboratory, should provide an explanation of the clinical significance of these organisms and may refer the clinician to the reference laboratory for further information. All suspected outbreaks should be reported to public health authorities.

**SHIGELLA**

**Taxonomy**

*Shigella* is classified in the family *Enterobacteriaceae*, which is addressed in chapter 38 of this Manual (2, 3). There are four subgroups of *Shigella* that historically have been treated as species: subgroup A as *S. dysenteriae*, subgroup B as *Shigella flexneri*, subgroup C as *S. boydii*, and subgroup D as *Shigella sonnei*. From a genetic standpoint, the four species of *Shigella* for species, the four species of *Shigella*–single genomospecies (183), there are two subgroups within the genus *Shigella* (Table 4). From the DNA-DNA hybridization showed that these strains represent a new species (185); however, it was not until recently that findings from phylogenetic studies showed that they cluster in a neighbor-joining tree with *E. albertii*, a newly described species of *Escherichia* associated with diarrheal disease in Bangladeshi children (8, 30).

**Description of the Genus**

The genus *Shigella* is composed of nonmotile bacteria that conform to the definition of the family *Enterobacteriaceae* (2, 187). Species in this genus are Gram-negative rods that grow well on MAC. All strains of *Shigella* spp. are nonmotile; do not decarboxylate lysine; do not utilize citrate, malonate, or sodium acetate (with exceptions for *S. flexneri*); and do not grow in KCN or produce H₂S. Compared with *Escherichia*, *Shigella* strains are less active in their use of carbohydrates (Table 4). All ferment D-glucose without the production of gas (a few exceptions produce gas, e.g., certain strains of *S. flexneri* serotype 6 and *S. boydii* serotype 14). *S. sonnei* strains ferment lactose and sucrose on extended incubation, but other species generally do not use these substrates in conventional medium. Salicin, adonitol, and myo-inositol are not fermented. There are numerous identical and reciprocal serologic reactions between *Shigella* and *E. coli* (188).

**Epidemiology and Transmission**

Humans and other large primates are the only natural reservoirs of *Shigella* bacteria. Most transmission is by person-to-person spread, but infection is also caused by ingestion of contaminated food or water. Shigellosis is most common in situations in which hygiene is compromised (e.g., child care centers and other institutional settings). In developing populations without running water and indoor plumbing, shigellosis can become endemic. Sexual transmission of *Shigella* among men who have sex with men also occurs.

In the United States, an estimated 495,000 cases of shigellosis occur each year, with 38 deaths (47). Up to 15% of all U.S. cases of shigellosis are related to international travel. Most infections in the United States and other developed countries are caused by *S. sonnei*; *S. flexneri* is the second-most-common subgroup (http://www.cdc.gov/nationalsurveillance/shigellosis-surveillance.html). In the developing world, the majority of endemic dysentery cases are caused by *S. flexneri*, with the balance of cases caused by subgroups that vary temporally and geographically (189–191). Epidemic dysentery is most commonly caused by *S. dysenteriae* 1, whose prevalence rises dramatically during outbreak periods and then falls as the epidemic resolves. Infection with *S. dysenteriae* 1 is associated with high rates of morbidity and mortality in developing countries, particularly when antimicrobial resistance or misdiagnosis delays appropriate treatment. In the United States and other developed countries, *S. sonnei* is endemic and causes large, protracted outbreaks in day care facilities without running water and indoor plumbing.

Nonmotile, anaerogenic biotypes sometimes referred to as Alkalescens-Dispar bioserotypes.
centers (192–194) and among men who have sex with men (195, 196). The protracted nature of these outbreaks is attributed to a large number of asymptomatically infected individuals in the population and the tendency for secondary spread (197). For most individuals, antibiotic treatment reduces the number of symptomatic days and the length of shedding (198); however, the decision to treat is nuanced and is influenced by a variety of factors, including severity of disease, immune status of the host, likelihood of transmission to others, preservation of the microbiome, and development of antibiotic resistance. Because resistance to ampicillin and trimethoprim-sulfamethoxazole is common in day care-associated S. sonnei infections, azithromycin has been recommended for treatment of pediatric shigellosis. The effectiveness of this recommendation will require careful monitoring in light of an outbreak in 2012 caused by a S. sonnei strain with reduced susceptibility to azithromycin (199).

Clinical Significance

Members of the genus Shigella have been recognized since the late 19th century as causative agents of bacillary dysentery. Shigella causes bloody diarrhea (diabetes) and nonbloody diarrhea. Shigellosis often begins with watery diarrhea accompanied by fever and abdominal cramps but may progress to classic dysentery with scant stools containing blood, mucus, and pus. Ulcerations, which are restricted to the large intestine and rectum, typically do not penetrate beyond the lamina propria. Bloodstream infections can occur but are rare. Appropriate antimicrobial therapy will decrease the duration, transmission, and severity of symptoms and is customarily prescribed based on the severity of illness or the need to protect close contacts. Patients in certain occupations (i.e., food handlers, child care providers, and health care workers) and children who attend day care often are required to have a documented negative stool culture following treatment. The infectious dose is low (1 to 100 organisms), and the incubation period is 1 to 4 days. Shigelae are shed in stools for several days to several weeks after illness, and persons who receive appropriate antimicrobial therapy will be culture negative at 72 h (198). All four subgroups of Shigella are capable of causing dysentery, but S. dysenteriae serotype 1 has been associated with a particularly severe form of illness thought to be related in part to its production of Shiga toxins. Infection can occasionally be asymptomatic, particularly infection with S. sonnei strains. Complications of shigellosis include HUS, which is associated with S. dysenteriae 1 infection, and reactive arthritis or Reiter’s chronic arthritis syndrome, which is associated with S. flexneri infection (200). The identification of Shigella species is important for both clinical and epidemiologic purposes.

Collection, Transport, and Storage of Specimens

See “Collection, Transport, and Storage of Specimens” in the Escherichia section.

Direct Examination

Microscopy

Shigella cannot readily be distinguished from other Gram-negative rods by staining or microscopy methods.

Antigen Detection

Because there is no single somatic antigen common to all Shigella strains, antigen detection in clinical specimens is not practical and has not been validated, and no commercial FDA-approved kits are available.

Nucleic Acid Detection

There are four FDA-cleared nucleic acid detection methods for clinical diagnosis of Shigella infections. See “Nucleic Acid Detection” under “Direct Examination” in the Escherichia section for more information.

Isolation Procedures

Enrichment and Plating Media

There is no reliable enrichment medium for all Shigella isolates, but Gram-negative broth and Selenite broth (SEL) are frequently used. For the optimal isolation of Shigella, two different selective media should be used: a general purpose plating medium of low selectivity (e.g., MAC) and a more selective agar medium (e.g., xylose-lysine-deoxycholate agar [XLD]). Statens Serum Institut enteric medium, deoxycholate-citrate agar, and Hektoen enteric agar (HE) are suitable alternatives to XLD as media with moderate to high selectivities. Salmonella-shigella agar should be used with caution because it inhibits the growth of some strains of S. dysenteriae 1.

Screening Procedures

Shigella strains appear as lactose- or xylose-nonfermenting colonies on the isolation media described above. S. dysenteriae 1 colonies may be smaller on all of these media, and these strains generally grow best on media with low selectivities (e.g., MAC). S. dysenteriae 1 colonies on XLD agar are frequently very tiny, unlike those of other Shigella species. S. sonnei colonies often appear flattened and spread out on blood agar plates.

Suspect colonies may be screened phenotypically on Klöger iron agar (KIA) or triple sugar iron agar (TSI). Shigella species characteristically produce an alkaline slant because strains do not ferment lactose (or sucrose) and do not produce gas or H₂S. A few strains of S. flexneri 6 and a very few strains of S. boydii produce gas in KIA or TSI. The motility and lysine decarboxylase tests are characteristically negative for Shigella and can be used to further screen isolates before serologic testing (Table 4). Serologic testing should be performed as recommended by the manufacturer of the product being used. Due to the many antigenic cross-reactions between E. coli and Shigella, Shigella antiserum are typically validated to be used in the identification of bacteria that biochemically conform to the definition of Shigella. For this reason, the initial screening of isolates for which there is no phenotypic evidence that they conform to the definition of Shigella is discouraged. Isolates that react appropriately with the screening tests should then be identified with a complete set of phenotypic tests, with automated systems or self-contained commercial kits being satisfactory, and should be tested with group-specific antisera. Confirmation requires both phenotypic and serologic identification, and laboratories that do not perform both types of tests should send Shigella isolates to a reference laboratory for confirmation.

Identification

Phenotypic Identification

Shigellae are biopathotypes of E. coli that are identified conventionally using a combination of biochemical tests and O serogrouping (188). Shigella and inactive E. coli (anaerogenic or lactose-nonfermenting) strains are frequently difficult to distinguish by routine phenotypic tests.
See Table 4 for the phenotypic reactions characteristic of Shigella spp. Although S. dysenteriae and S. sonnei are phenotypically distinct, S. flexneri and S. boydii are often phenotypically indistinguishable, so serologic grouping is essential to identify them to the species (subgroup) level.

The ability of commercial methods to identify Shigella was assessed several years ago by O’Hara and Miller (122–124), who found that these systems correctly identified only 50 to 70% of the 10 Shigella strains in their test panel and misidentified several other members of the Enterobacteriaceae as Shigella. MALDI-TOF MS systems for the rapid identification of bacteria were similarly disappointing and could not correctly identify Shigella (they identified Shigella as E. coli) (126, 127). This is not surprising because the accurate identification of Shigella requires performing serogrouping in Shigella-specific antisera in addition to biochemical profiling. Molecular assays targeting Shigella virulence genes (e.g., ipaH, ipaB, ipaC, inv, and ial) have been very useful for detecting Shigella/EIEC and identifying potential new serotypes.

Serotyping
Serotyping is essential for the identification of Shigella. Three of the four subgroups, A (S. dysenteriae), B (S. flexneri), and C (S. boydii), are made up of a number of serotypes. Subgroup A has 15 serotypes; subgroup B has 8 serotypes (with serotypes 1 to 5 subdivided into 11 subserotypes); and subgroup C has 19 serotypes, numbered 1 through 20, with S. boydii 13 reclassified as E. albertii. Subgroup D (S. sonnei) is made up of a single serotype. Subgroups A and C are rare. Several provisional Shigella serotypes have also been described, which are held sub judice until findings from the characterization of representative isolates show them to be unique and of sufficient prevalence to merit inclusion in the Shigella scheme. Antisera for the identification of provisional serotypes are typically available only at reference laboratories.

Serotyping is typically performed by slide agglutination with polyvalent somatic (O) antigen grouping sera, followed, in some cases, by testing with monovalent antisera for specific serotype identification. Monovalent antiserum to S. dysenteriae 1 is required to identify this serotype and is not widely available. Because of the potentially serious nature of illness associated with this serotype, isolates that agglutinate in subgroup A antigen should be sent to a reference laboratory immediately for further serotyping.

Phenotypically typical Shigella isolates that agglutinate poorly or that do not agglutinate at all should be suspended in saline and heated in a water bath at 100°C for 15 to 30 min. After cooling, the antigen suspension should be tested in normal saline to determine if it is rough (agglutinates spontaneously). If the heated and cooled suspension is not rough, it may then be retested for agglutination in antiserum.

Typing Systems
A variety of methods have been used to subtype Shigella, including colicin typing (particularly for S. sonnei), plasmid probing, restriction fragment length polymorphism analysis, PFGE, and ribotyping (201). More recently, MLVA and a single nucleotide polymorphism typing scheme for the rapid and discriminatory typing of Shigella have been developed (202, 203). For an overview of the epidemiologic use of typing methods, see chapter 10.

Serologic Tests
Several serodiagnostic assays based on different antigens possessed by Shigella have been described (204, 205). These assays are practical only in research settings for seroepidemiology surveys and are not currently used for the diagnosis of infection in individual patients.

Antimicrobial Susceptibilities
Because of the widespread antimicrobial resistance among Shigella strains, all isolates should undergo susceptibility testing. The CLSI recommends that susceptibility results be reported routinely for only ampicillin, trimethoprim-sulfamethoxazole, and a fluoroquinolone and warns that Shigella should not be reported as susceptible to first- and second-generation cephalosporins, cephemycins, and aminoglycosides, because these drugs are often not effective clinically (206). Because of widespread resistance in the United States, ampicillin and trimethoprim-sulfamethoxazole, two safe drugs that were the most commonly prescribed for treating children with S. sonnei infections, are no longer options for empiric treatment. Macrolides, in particular azithromycin, are being used to treat these infections, but there are no interpretive criteria for antimicrobial susceptibility testing for Shigella, making it problematic to monitor for development of resistance (199).

Reporting of susceptibility results to the clinician is particularly important for S. dysenteriae 1 isolates. Infections caused by these strains are often acquired during international travel to areas where most strains are multidrug resistant (207). In many areas of Africa and Asia, S. dysenteriae 1 strains are resistant to all locally available antimicrobial agents, including nalidixic acid (190, 208), and fluoroquinolone-resistant strains have been reported in Asia (191, 209, 210).

Evaluation, Interpretation, and Reporting of Results
A preliminary report of suspected Shigella infection may be issued if serologic or biochemical screening tests are positive or consistent with Shigella. If serotyping results (O antigen determination) are available, these should also be reported, particularly if the isolate is S. dysenteriae 1. All Shigella isolates should be tested for antimicrobial susceptibility. Before issuing a final report, isolates should be confirmed by both biochemical and serologic methods, because the definition of Shigella is dependent on both the biochemical profile and O antigen expressed. Isolates, particularly those from individuals with dysentery-like illness, that are biochemically identified as Shigella but that are serologically negative may be new serotypes of Shigella and should be sent to a reference laboratory for further characterization. Isolates from sites other than the gastrointestinal tract that resemble Shigella should be scrutinized carefully for gas production and other differentiating characteristics because extraintestinal Shigella infections are rare. These isolates should be sent to a reference laboratory for confirmation because they are more likely to be anaerogenic E. coli, certain strains of which may cross-react with Shigella antiserum.

**SALMONELLA**

**Taxonomy**
Members of the genus Salmonella are classified in the family Enterobacteriaceae (2, 3). Species of this genus are motile, Gram-negative, facultative rods. Salmonellae are typically defined by their ability to use citrate as a sole carbon source and lysine as a nitrogen source and by the production of H2S on triple sugar agar; exceptions to these traits are used to define species, subspecies, and some serotypes (2, 211).
The genus *Salmonella* is composed of two species, *Salmonella enterica* and *Salmonella bongori* (212, 213). *S. enterica* is subdivided into six subspecies: *S. enterica* subsp. *enterica*, often called subspecies I; *S. enterica* subsp. *salaamae*, or subspecies II; *S. enterica* subsp. *arizonae*, or subspecies IIIa; *S. enterica* subsp. *diarrhoeae*, or subspecies IIIb; *S. enterica* subsp. *houtenae*, or subspecies IV; and *S. enterica* subsp. *indica*, or subspecies VI. The type species is *S. enterica* subsp. *enterica*. Subspecies IIIa and IIIb represent organisms originally described in the genus “*Arizona*”; subspecies IIIa contains the monophasic strains and subspecies IIIb the diphasic strains of “*Arizona*” (214). Despite their common history, subspecies IIIa and IIIb are more closely related to some of the other subspecies of *S. enterica* than they are to each other and thus should be considered separate entities (215, 216).

Genome analysis of the salmonellae has revealed a high degree of genetic variability. Serotypes within *S. enterica* subspecies I have been shown to differ by as much as 10% in gene content (i.e., presence or absence of whole genes) (217, 218). Recombination, particularly among strains of *S. enterica* subspecies I, likely contributes to this diversity (219). The use of whole-genome sequence analysis to characterize strains continues to expand, with more than 500 complete or partial sequences from *Salmonella* strains available as of the end of 2013 (http://www.ncbi.nlm.nih.gov/genome/browse/). Characterization of whole-genome sequences continues to increase our understanding of *Salmonella* biology and phylogeny. Analysis of genome sequences revealed two distinct lineages among *S. enterica* subsp. *enterica*; differences in gene content were noted that may contribute to differences in ecology or transmission (220, 221). The development of tools for the analysis of whole-genome sequences based on single nucleotide polymorphisms, core genes, or other markers has already begun and will undoubtedly lead to a revolution in epidemiologic strain typing (221–223).

**Description of the Genus**

Subspecies I strains are commonly isolated from humans and warm-blooded animals. Subspecies II, IIIa, IIIb, IV, and VI strains and *S. bongori* are usually isolated from cold-blooded animals and the environment. Non-subspecies I strains are typically considered rare human pathogens; they make up about 1 to 2% of *Salmonella* isolates reported to the U.S. National *Salmonella* Surveillance System (http://www.cdc.gov/nationalsurveillance/salmonella-surveillance.html). The phenotypic traits useful for identification of *Salmonella* are given in Table 5 and for subspecies differentiation are given in Table 6.

The nomenclature employed to describe the genus *Salmonella* was problematic for many years due to the use of multiple schemes in the literature and the historical practice of considering different serotypes of *Salmonella* to be different species. The publication of Judicial Opinion 80 in the *International Journal of Systematic and Evolutionary Microbiology* in 2005 (212) hopefully served to clarify nomenclatural issues regarding the genus *Salmonella*, and the conventions set forth in that opinion are used here. *Salmonella* history and nomenclature are reviewed at http://www.bacterio.net/salmonella.html.

### Epidemiology and Transmission

Salmonella organisms are isolated most frequently from the intestines of humans and animals. Some serotypes are isolated only from humans (e.g., Salmonella serotype Typhi), while others (e.g., Salmonella serotype Gallinarum and Salmonella serotype IV 48:51:– [formerly serotype Marina]) are strongly associated with certain animal hosts. Members of this genus can be isolated from feces-contaminated food or water but probably do not occur as free-living organisms in the environment. Historically, Salmonella has been considered a pathogen of meat and poultry products, but it has recently been associated with other food vehicles, such as fresh produce and manufactured products (224–226).

### Salmonella Serotypes

Salmonella serotyping is a subtyping method based on the immunologic characterization of three surface structures: O antigen, which is the outermost portion of the LPS layer that covers the bacterial cell; H antigen, which is the filament portion of the bacterial flagella; and Vi antigen, which is a capsular polysaccharide present in specific serotypes. Serotyping of Salmonella is commonly performed to facilitate public health surveillance for Salmonella infections and to aid in the recognition of outbreaks. While molecular methods such as PFGE and MLVA have become the cornerstone of public health subtyping (227, 228), serotyping remains an important tool. The serotype of an isolate often correlates with a particular disease syndrome or food vehicle, making serotype data particularly useful in identifying cases and defining outbreaks. For example, Salmonella serotype Typhi causes typhoid fever, a more severe disease syndrome than those caused by most other Salmonella serotypes. Salmonella serotype Enteritidis is often associated with infections acquired from chicken or egg products (223). Furthermore, Salmonella serotyping is performed worldwide and has aided in the recognition of international outbreaks (229).

### Clinical Significance

Strains of Salmonella are categorized as typhoidal and nontyphoidal, corresponding to the disease syndrome with which they are associated. Strains of nontyphoidal Salmonella usually cause intestinal infections (accompanied by diarrhea, fever, and abdominal cramps) that often last 1 week or longer (230). Less commonly, nontyphoidal Salmonella can cause extraintestinal infections (e.g., bacteremia, urinary tract infection, or osteomyelitis), especially in immunocompromised persons. Persons of all ages are affected, but the incidence is highest in infants and young children. Salmonella is ubiquitous in animal populations, and human illness is usually linked to foods. Salmonellosis is also transmitted by direct contact with animals, by water, and occasionally by human contact. Each year, an estimated 1 million cases of illness and 378 deaths are caused by nontyphoidal salmonellosis in the United States (47).

Typhoid fever, caused by Salmonella serotype Typhi, is a serious bloodstream infection common in the developing world. However, it is rare in the United States, where on average an estimated 1,800 cases, with <1 death, occur each year; >60% of U.S. cases are related to foreign travel (47). Typhoid fever typically presents with a sustained debilitating high fever and headache. Adults characteristically present without diarrhea. Illness is milder in young children, where it may manifest as nonspecific fever. Humans are the only reservoir for Salmonella serotype Typhi, indicating that this serotype is adapted to the human host; healthy carriers have been noted. Typhoid fever typically has a low infectious dose (<10^3 organisms) and a long, highly variable incubation period (1 to 6 weeks). It is transmitted through person-to-person contact or feces-contaminated food and water. Fatal complications of typhoid most commonly occur in the second or third week of illness.
A syndrome similar to typhoid fever is caused by "paratyphoidal" strains of Salmonella, i.e., Salmonella serotypes Paratyphi A, Paratyphi B, and Paratyphi C. Serotypes Paratyphi A and Paratyphi C are rare in the United States (http://www.cdc.gov/nationalsurveillance/salmonella-surveillance.html). Serotype Paratyphi B is a diverse serotype that is associated with both paratyphoid fever and gastroenteritis (231). The two pathovars are typically differentiated on the basis of the ability to ferment tartrate. Isolates causing paratyphoid fever, the systemic pathovar, are tartrate negative. Isolates associated with gastroenteritis, the enteric pathovar, are typically tartrate positive and are referred to as Salmonella Paratyphi B variant t (+)-tartrate + or Salmonella Paratyphi B variant Java. The systemic pathovar of Salmonella Paratyphi B is considered rare in the United States; however, the tartrate reaction is often not reported, making it impossible to distinguish between the two pathovars (http://www.cdc.gov/nationalsurveillance/salmonella-surveillance.html).

Salmonella serotypes Choleraesuis and Dublin are host adapted to pigs and cattle, respectively, causing serious disease in these two animal species. They rarely cause human infection, but such infections are typically severe, with spread to extraintestinal sites (232).

Collection, Transport, and Storage of Specimens
See “Collection, Transport, and Storage of Specimens” in the Escherichia section.

Direct Examination
Microscopy
Salmonella cannot be distinguished from other Gram-negative rods by microscopy or staining methods.

Antigen Detection
A number of commercial rapid diagnostic tests are available for the testing of foods, but to our knowledge, none are FDA approved for clinical specimens.

Nucleic Acid Detection
There are four FDA-cleared methods for nucleic acid detection of Salmonella in clinical specimens. All four detect multiple pathogens, including Salmonella. See “Nucleic Acid Detection” under “Direct Examination” in the Escherichia section for additional information.

Isolation Procedures
Enrichment
Maximal recovery of Salmonella from fecal specimens is obtained by using an enrichment broth, although isolation from acutely ill persons is usually possible by direct plating of specimens. Enrichment broths for Salmonella are usually highly selective and inhibit certain serotypes of Salmonella, particularly Salmonella serotype Typhi. The selective enrichment medium most widely used to isolate Salmonella from fecal specimens is SEL. SEL may also be used for the recovery of Salmonella serotype Typhi and for Shigella, although its value as enrichment for the latter has not been clearly established. Specimens that might contain organisms inhibited by selective enrichment medium should be plated directly or cultured in a nonselective enrichment broth (e.g., Gram-negative broth).

Plating Media
Many differential plating media, varying from slightly selective to highly selective, are available for isolation of Salmoneilla from fecal specimens. Media of low selectivity include MAC and eosin-methylene blue. Media of intermediate selectivity include XLD, deoxycholate-citrate agar, salmonella-shigella agar, HE, Statens Serum Institut enteric medium, and CHROMagar Salmonella. Highly selective media include bismuth sulfite agar, the preferred medium for the isolation of Salmonella serotype Typhi, and brilliant green agar. Bismuth sulfite agar, XLD, and HE all have H2S indicator systems, which are helpful for the detection of lactose-fermenting Salmonella. Many laboratories use HE or XLD because these media may also be used for the isolation of Shigella.

In the developing world, typhoid fever is frequently diagnosed solely on clinical grounds, but isolation of the causative organism is necessary for a definitive diagnosis. Salmonella serotype Typhi is isolated more frequently from blood cultures than from fecal specimens. Blood cultures are positive for 80% of typhoid patients during the first week of fever but show decreasing positive results thereafter.

Screening Procedures
A latex agglutination kit has been described for Salmonella screening in SEL enrichment broth (Wellcolex Color Salmonella; Remel, Inc., Lenexa, KS) (233). This kit can also be used to screen individual colonies from primary plates. In using this kit, it should be kept in mind that it identifies only those Salmonella isolates belonging to the more common O serogroups and does not differentiate between O groups C1 (O:7) and C2 (O:8).

Suspect colonies may be inoculated onto a screening medium such as KIA or TSI. On KIA or TSI, most Salmonella strains produce an alkaline slant, indicating that only glucose is fermented, with gas and H2 S. On these media, Salmonella serotype Typhi isolates characteristically produce an alkaline slant but do not produce gas, and only a small amount of H2S will be visible at the site of the stab and in the stab line. Lysine iron agar is also a useful screening medium because most Salmonella isolates, even those that ferment lactose, also decarboxylate lysine and produce H2S. Alternately, isolates may be identified by a battery of phenotypic tests or by slide agglutination with antisera for Salmonella O groups. Isolates suspected of being Salmonella serotype Typhi should be tested serologically with Salmonella Vi and O group D antisera (see below); serotype Typhi can also be identified by its unique phenotypic profile (Table 5).

If the phenotypic traits for a particular isolate are not characteristic of Salmonella but Salmonella antigens are found, the cultures should be plated to obtain a pure culture, tested with a complete set of phenotypic tests, or forwarded to a reference laboratory.

Identification
Clinical laboratories may issue a preliminary report of Salmonella when an isolate is positive either with Salmonella O group antisera or by phenotypic identification methods. An isolate is confirmed as Salmonella when the specific O serogroup has been determined and phenotypic identification has been completed.

Phenotypic Identification
Suspect colonies from one of the differential plating media mentioned above can be identified phenotypically as Salmonella spp. by use of traditional media in tubes or commercial identification systems. Methods for phenotypic identification and specific commercial manual and automated identification systems are covered in chapter 4. The species and subspecies of Salmonella can be identified phenotypically,
as indicated in Tables 5 and 6. However, Salmonella is a diverse group, and phenotypically atypical strains are not uncommon. Phenotypic identification is commonly combined with serogrouping or serotyping for culture confirmation. Perhaps due to strain diversity, commercial identifications systems sometimes misidentify Salmonella (122–124).

Identification Using MS
MS has emerged as a rapid, accurate means of identifying many bacteria, offering substantial cost and time savings over phenotypic methods. Several diagnostic systems based on MS are available in Europe (234) and either moving toward FDA approval or already FDA cleared in the United States. The ability of MS to identify bacteria is somewhat dependent on the bacterial taxon itself. For Salmonella, MALDI-TOF MS appears to easily identify an isolate as Salmonella (234, 235). MALDI-TOF MS was also shown to correctly discriminate serotype Typhi from other serotypes (236). Identifying Salmonella to the serotype level may be possible for at least some serotypes (237), although such applications are still in the research phase.

Serogrouping and Serotyping
Serogrouping and serotyping
Serotypes are designated according to the conventions of the Kauffmann-White scheme (239). Many of the O and H antigenic types are found in multiple subspecies, and isolates from different subspecies can have the same antigenic profile. Thus, subspecies determination is an integral component of serotype determination for Salmonella. The serotypes for all Salmonella strains can be designated by antigenic formulae; additionally, serotypes belonging to subspecies I are given a name, which is typically related to the geographical place where the serotype was first isolated. The antigenic formulae of Salmonella serotypes are listed in the Kauffmann-White scheme and are expressed as follows: O antigen(s), Vi antigen (when present); phase 1 H antigen(s); phase 2 H antigen(s) (when present). For example, the antigenic formula for Salmonella serotype Typhimurium is 4,5,12:i1,l2. Serotype names for subspecies I serotypes are written in roman (not italicized) letters, and the first letter is a capital letter (for example, Salmonella serotype Typhimurium). Serotypes belonging to other subspecies are designated by their antigenic formulae following the subspecies name (for example, S. enterica subs. salamae serotype 50:e,e,x or S. enterica serotype II 50:e,e,x).

The WHO Collaborating Centre for Reference and Research on Salmonella, which is located at the Pasteur Institute in Paris, France, maintains the Kauffmann-White scheme for the designation of Salmonella serotypes (239). Most common serotypes belong to O groups A, B, C1, C2, D1, and E1 (also known as groups O2, O4, O7, O8, O9, and O;3,10, respectively).

Determination of O Antigens
O (heat-stable, somatic) antigens are typically identified by first testing the isolate in antisera that detect one or multiple antigenic factors corresponding to the O groups (O grouping antisera). Once the O group is determined, antisera that recognize single antigenic factors are used to confirm the O group and identify any additional antigenic factors that are associated with that O group (238). The approach most commonly used for determining O antigens is to initially test the isolates by slide agglutination in antisera against O groups A to E1 because ~95% of Salmonella isolates from human specimens belong to one of these O groups. If no agglutination occurs in antisera for these O groups, the isolate is tested in pools containing the remaining Salmonella O antisera, for groups O:11 through O:67.

Determination of H Antigens
H (flagellar) antigens are typically determined by tube or slide agglutination tests. Isolates are initially tested with antisera pools that recognize multiple antigenic factors, and then with antisera that recognize individual antigenic factors corresponding to the appropriate pool. Typically, the flagellar antigens in a diphasic strain are coordinately regulated so that only one antigenic type is expressed at a time in a single bacterial cell; however, both phases may be detected in the whole culture. When only one phase is detected (either phase 1 or phase 2), the strain should be inoculated into a semisolid medium to which sterile antisera for the detected flagellar antigen has been added aseptically. Growth of the strain in this semisolid agar immobilizes cells expressing the detected antigen and allows the movement of bacteria expressing the antigen in the other phase through the semisolid medium. Cells are recovered away from the area of initial inoculation, and the strain is tested in appropriate H typing and single-factor antisera to complete the serotyping. A strain must be actively motile to ensure the good expression of H antigens; sometimes a
Detection of the Vi Antigen and Identification of Salmonella Serotype Typhi (9,12,[Vi]:d−)

If Salmonella serotype Typhi is suspected, a heat-labile capsular polysaccharide, is useful for the identification of Salmonella serotype Typhi. It is also occasionally detected in Salmonella serotypes Dublin and Paratyphi C and some Citrobacter strains, so its detection does not constitute definitive evidence of Salmonella serotype Typhi. The Vi antigen is identified by slide agglutination with a specific antiserum.

If Salmonella serotype Typhi is suspected, the culture is first tested live (unheated) in O group D1 (O:9) antiserum and Vi antiserum via slide agglutination. The Vi capsular polysaccharide can mask the O antigens, blocking their reactivity with the O grouping antiserum. If only the Vi antiserum is positive, the bacterial suspension is heated in boiling water for 15 min to remove the capsule, cooled, and tested again in the same antiserum. After being heated, Salmonella serotype Typhi isolates will be negative in the Vi antiserum but positive in the O group D1 antiserum. The Vi antigen of Salmonella serotype Typhi is more frequently detected in freshly isolated cultures than in subcultures. If the strain has a typical reaction for Salmonella serotype Typhi on TSI or KIA (see “Screening Procedures” above), it is usually negative, and reacts in O group D or Vi antiserum, a presumptive report is made. The identity of the isolate is typically confirmed by phenotypic testing and determination of the H (flagellar) antigen. However, because serotype Typhi has a unique phenotypic profile, it can and should be reported based on phenotype alone (i.e., identification of the O and H antigens is not required to identify an isolate as Salmonella serotype Typhi).

Molecular Methods for the Determination of Serotype

Given the specialized reagents and skills required to perform traditional serotyping and the continued utility of serotype data, it is not surprising that a plethora of molecular methods for determination of serotype have appeared in the literature (246). The methods fall into two general categories: methods based on the genes responsible for serotype and methods based on random genetic markers. Methods based on the genes responsible for serotype have the advantages of duplicating the Kauffmann-White scheme fairly closely and of having the potential to identify most described serotypes by identifying the complement of antigens that determine any given serotype. Methods based on random genetic markers can only identify serotypes for which a profile has already been determined; i.e., when a new profile is encountered, the serotype that it represents is unknown. To date, no single molecular method has risen to a level of widespread use, and it seems unlikely that any one molecular method will gain the worldwide acceptance that traditional serotyping enjoys. With the increasing availability of whole-genome sequencing, the ability to determine serotype by detecting the genes responsible for serotype directly in a whole-genome sequence may not be far off.

Notes on Serotype Designations

The Salmonella serotyping scheme can be confusing because some serotypes actually represent biotypes or pathotypes that must be further characterized for full “serotype” determination. Salmonella serotypes Paratyphi B and Paratyphi B variant L (+)-tartrate + (also known as variant Java) have the same antigenic formula (4,5,12:b:1,2) and are distinguished phenotypically by their tartrate reaction. Similarly, Salmonella serotypes Choleraesuis and Paratyphi C have the same antigenic formula (6,7:c:1,5) but different phenotypic profiles. Some Citrobacter and Escherichia coli strains possess O, H, or Vi antigens that are related to those of Salmonella and cross-react in Salmonella antisera; phenotypic identification may be necessary to confirm that an isolate is Salmonella.

Typing Systems

PFGE is the current method of choice for subtyping Salmonella, since it is universally applicable and provides good strain discrimination for most serotypes. PulseNet, an international subtyping network that tracks Salmonella, is based on PFGE (164). MLVA is often used to complement PFGE by providing additional discrimination within PFGE types (228), e.g., for Salmonella serotype Enteritidis, which has limited diversity in PFGE analysis (241). Despite their utility in public health surveillance and epidemiologic investigations, PFGE and MLVA both have drawbacks. PFGE is fairly labor-intensive and challenging to standardize. MLVA has very high throughput, but typically a unique MLVA scheme must be developed for each serotype. Neither method provides information on phylogenetic relationships. The routine use of whole-genome sequencing as a subtyping method is on the horizon. It no doubt will have its own challenges, such as managing and analyzing the massive amounts of data, but it holds the promise of providing high levels of discrimination and detailed phylogenetic relationships.

Serologic Tests

Serodiagnostic tests are not used for routine diagnosis of Salmonella infections in the United States. Serodiagnosis can be helpful in areas where typhoid fever is endemic, but its lack of specificity limits its utility. The Widal test measures agglutinating antibodies to the O and H antigens of Salmonella serotype Typhi. It produces false-positive reactions, likely due to cross-reaction with antibodies produced during infections with other Salmonella serotypes, as well as false-negative reactions; it does not provide a definitive diagnosis of individual cases of infection. Two other rapid serodiagnostic tests have proved more useful than the Widal test for the serodiagnosis of typhoid fever (242): Tubex (IDL Biotech, Sollentuna, Sweden) and TyphiDot (Malaysian Bio-Diagnostics Research Sdn. Bhd., Kuala Lumpur, Malaysia). Neither of these tests is FDA approved, and TyphiDot is not available in the United States.

Antimicrobial Susceptibilities

Antimicrobial therapy is not recommended for uncomplicated Salmonella gastroenteritis, and routine susceptibility testing of fecal isolates is not warranted for treatment purposes. However, determination of antimicrobial resistance patterns is often valuable for surveillance purposes and may be performed periodically to monitor the development and spread of antimicrobial resistance among Salmonella isolates. In contrast to the case for uncomplicated salmonellosis, treatment with the appropriate antimicrobial agent can be crucial for patients with invasive Salmonella and typhoidal infections, and the susceptibilities of these isolates should be reported as soon as possible (243). The untreated case mortality rate for typhoid fever is >10%; when patients with typhoid fever are treated with appropriate antibiotics, the
rate should be <1%. However, increasing levels of resistance to one or more antimicrobial agents in Salmonella isolates, particularly Salmonella serotype Typhi, make selection of an appropriate antibiotic problematic. In particular, reduced susceptibilities to ciprofloxacin among Salmonella serotype Typhi isolates and increasing numbers of treatment failures are of concern (244, 245). In 2013, the CLSI recommended testing Salmonella isolates from extraintestinal infections and serotypes Typhi and Paratyphi A, B, and C for susceptibility to both nalidixic acid and ciprofloxacin; it also established separate interpretive criteria for Salmonella for fluorquinolones with lower MIC breakpoints (206). In addition, susceptibility to chloramphenicol and a broad-spectrum cephalosporin should be tested and reported for extraintestinal isolates of Salmonella. Salmonella should not be reported as susceptible to first- and second-generation cephalosporins, cephemycins, and aminoglycosides because these drugs are not effective clinically.

Antimicrobial resistance varies by serotype in Salmonella; resistance to multiple antibiotics is a particular concern (246). In 2011, 9.1% of Salmonella isolates tested as part of the National Antimicrobial Resistance Monitoring System for Enteric Bacteria (NARMS) were resistant to three or more CLSI drug classes; in particular, 26, 27, and 30% of serotype Typhimurium, I 4,[5]12:i:-, and Heidelberg isolates, respectively, were resistant to three or more CLSI classes. Additional information regarding these and other antimicrobial-resistant strains can be found at the CDC’s NARMS website, including interactive displays of susceptibility data by pathogen and serotype (http://www.cdc.gov/narms/).

Evaluation, Interpretation, and Reporting of Results

A preliminary report can be issued as soon as a presumptive identification of Salmonella is obtained. In most situations, a presumptive identification is based on phenotypic traits determined either by traditional or commercial systems, or by reactivity with Salmonella O grouping antisera. A confirmed identification requires both phenotypic identification and O group or serotype determination. Because national surveillance systems depend on the receipt of serotype information for Salmonella strains isolated in the United States, laboratories should follow the procedures recommended by their state health departments for submitting Salmonella isolates for further characterization, including complete serotyping. The antimicrobial susceptibility of typhoidal Salmonella strains and strains from normally sterile sites should be determined, and the strains should be forwarded to a reference or public health laboratory for complete phenotypic identification and serotyping.

BACTERIOLOGY

Klebsiella, Enterobacter, Citrobacter, Cronobacter, Serratia, Plesiomonas, and Other Enterobacteriaceae

STEPHEN J. FORSYTHE, SHARON L. ABBOTT, AND JOHANN PITOUT

This chapter deals with a number of both major and less prominent members of the Enterobacteriaceae family. The genera Klebsiella, Enterobacter, Citrobacter, Serratia, Plesiomonas, and Cronobacter cause a range of infections in humans. These continue to warrant serious consideration since many of these infections are poorly characterized, are likely to be underreported, and have the capacity to resist antimicrobial agents. The Infectious Diseases Society of America recognizes Klebsiella and Enterobacter as members of the ESRAPE pathogens (Enterococcus faecium, Staphylococcus aureus, Klebsiella pneumoniae, Acinetobacter baumannii, Pseudomonas aeruginosa, and Enterobacter spp.) which exhibit antimicrobial resistance and present new challenges in their pathogenesis and transmission. Therefore, this chapter contains a wide breadth of information not only on the taxonomy, detection, and identification of these genera but also on the global issue of antimicrobial resistance.

TAXONOMY

Despite years of research, the taxonomic designation of strains into specific species within the Enterobacteriaceae has been a matter of much debate and change. This frequent reclassification of organisms with clinical significance can lead to confusion for both microbiologists and regulatory authorities responsible for the monitoring and control of such organisms. This situation is not unique to the Enterobacteriaceae but is very apparent due to their clinical importance. Many of the Enterobacteriaceae genera are composed of heterogeneous groups of bacterial species, most of which were originally described based on morphological and phenotypic information several decades ago.

In this context, improvements in DNA sequence-based analysis, including whole-genome sequencing, are expected to have a major influence on the taxonomy of this very important bacterial family. The advent of 16S rRNA gene sequencing and the subsequent polyphasic approach to bacterial taxonomy have resulted in some major taxonomic revisions (1, 2). A polyphasic approach is especially needed for the taxonomy of Enterobacteriaceae. Although sequence analysis of the 16S rRNA gene is commonly used in bacterial phylogenetic studies, it is often unreliable for closely related members of the Enterobacteriaceae due to microheterogeneities within multiple copies of the genes (3–5). Consequently, it can be impossible to assign an unknown isolate to a specific species. It can be expected that in the future, whole-genome sequence comparisons could be used to resolve some problems in Enterobacteriaceae classification and identification, though currently the number of sequenced genomes of species type strains is limited (6).

The current trend is to use combinations of single-copy housekeeping gene regions (alleles or loci) to produce a multilocus sequence analysis (MLSA). Such housekeeping genes must be present within the taxon under study, must occur as single-copy genes, and must be independent of each other (7). In parallel, a large number of international multilocus sequencing typing (MLST) schemes based typically on seven loci have been established and can be accessed via curated centralized databases such as http://www.pubMLST.org. As is covered later in this chapter, the application of MLST has led to the recognition of a number of definable sequence types of particular clinical significance, e.g., Escherichia coli ST131, methicillin-resistant S. aureus (MRSA) 15 ST22, and Klebsiella pneumoniae ST258.

MLSA of the loci from several housekeeping genes is able to give better phylogenetic resolution than the single 16S rRNA gene sequence analysis. The application of MLSA to taxonomic description of members of the Enterobacteriaceae frequently uses only four or five loci, such as recA, gpoA, gpoB, thdF, mfb, atpD, and gyrB (8–11). On occasion three loci have been used, but this is not desirable. The use of such housekeeping genes can result in different, or more discriminatory, phylogenetic classifications than 16S RNA gene sequencing. However, these may not correspond with data generated by the “gold standard” of DNA-DNA hybridization (12).

Correlation between sequence differences for determining genus and species definition thresholds has been problematic in the Enterobacteriaceae, as well as genera outside this family. The use of whole-genome sequencing has led to the development of a few in silico alternatives to DNA-DNA hybridization, such as the average nucleotide identity (13). Although a universal cutoff value to delineate bacterial species does not exist, a DNA-DNA hybridization value of <70% and average nucleotide identity of <95% ± 0.5% have been applied in general.

A small number of additions or taxonomic changes within the Enterobacteriaceae have occurred since publication of the 10th edition of this Manual. Those of clinical relevance include new species designations in the genera Cronobacter, Pantoea, and Hafnia. There have also been some reclassifications of some Enterobacter species into the
Cronobacter genus and into the new genera Lelliottia, Pluralibacter, and Kosakonia. There is also the description of a new genus named Pseudocitrobacter. Nevertheless, the Pantoea and Enterobacter genera remain polyphyletic, and it is likely that there will be further taxonomic changes in the future following further polyphasic analysis (14, 15).

Tables 1 and 2 cover all of the Enterobacteriaceae species discussed in this chapter. For completeness, Table 2 does include genera which are not isolated from human clinical specimens. These may not be of clinical significance and may be unfamiliar to clinical microbiologists. Enterobacteriaceae genera which are exclusively isolated from insects, plants, fish, marine animals, or birds are not included in the tables or text of this chapter; however, information on them is available elsewhere (16).

DESCRIPTION OF THE GENERA

Members belonging to the family Enterobacteriaceae are Gram-negative, facultative anaerobic rods or coccobacilli ranging from 0.3 to 1.0 µm wide to 0.6 to 6.0 µm long. They ferment glucose with the production of various end products depending upon species as determined using the methyl red and Voges-Proskauer tests. Typically Enterobacteriaceae are oxidase negative and non-spor forming. Growth parameters for the Enterobacteriaceae are on the order of temperatures of 18 to 47°C, a pH range of 4.0 to 8.0, and salt concentrations of 0 to 5%. Motility is variable and may be due to peritrichous or polar flagella. Of those organisms in Tables 1 and 2 which are isolated from human specimens, all Klebsiella, Leminorella, Moellerella, and Tatumella organisms are nonmotile. The majority of Enterobacter asburiae strains are nonmotile, with only a few motile strains reported (17). Some strains of Serratia plymuthica may not grow at 37°C, but most other members of the genera discussed in this chapter grow well between 25°C and 37°C. Strains from all genera may grow as mucoid or rough colonies. Klebsiella, Raoultella, and Enterobacter spp. are encapsulated, and there is cross-reactivity between the capsular antigens of Klebsiella and Enterobacter aerogenes. Pigment production is restricted to a few genera. Some strains of Serratia marcescens and most Serratia rubidaea and S. plymuthica strains produce a red pigment, prodigiosin, which may appear throughout the entire colony or only as a red center or margin. Yellow pigment-producing organisms include ~80% of strains in the Cronobacter genus, Pantoea agglomerans, Lecidella acarboxydata, and Photobacterium asymbiotica. Yellow pigment production may be enhanced by incubation at 25°C as opposed to 37°C. Weak pigment producers may be most easily noted by placing the agar plate growth on a bench in sunlight for a short period. Serratia odorif-era, as indicated by its name, and some Cedecia spp. produce a pungent (potato-like) odor due to the production of alkylmethoxypyrazines (18). Species of Proteus and Providencia oxidatively deaminate α-amino acids, producing pyruvic acids. 1-Phenylalanine deamination yields a green color when ferric chloride is added; however, deamination of dL-tryptophan produces the deep reddish brown pigment often seen in media inoculated with these organisms without the addition of ferric chloride (19). Proteus species also produce swarmer cells, i.e., elongated forms created when cells fail to septate or divide. These cells, which are profusely covered with flagella, act in concert to produce swimming motility on solid media (20). Photobacterium luminescens and P. asymbiotica cultures are luminescent, giving a visible glow in a darkroom after 5 min.

There are some exceptions to the general description of the Enterobacteriaceae. Serratia marcescens subsp. sakuisensis and Serratia ureilytica are the only reported spore-forming organisms in the Enterobacteriaceae (21, 22). Plesiomonas shigelloides strains are oxidase positive, do not produce gas from glucose (Enterobacteriaceae are variable), and are susceptible to O/129 (2,4-diamo-no-6,7-diisopropyltetridine), a vibriostatic agent. A luxotrophic strains of Enterobacteriaceae from clinical specimens are uncommon. However, cysteine-requiring urinary isolates of Klebsiella pneumoniae, which grow as pinpoint colonies on routine media, do occur. When encountered, these strains require supplementation of biochemical media or commercial identification systems with 0.63 mM cysteine for accurate identification. Klebsiella granulomatis is extremely fastidious and is culturable only by in vitro cell culture techniques not usually employed by routine clinical microbiology laboratories.

EPIDEMIOLOGY, TRANSMISSION, AND CLINICAL SIGNIFICANCE

The Enterobacteriaceae are widely distributed throughout the environment (Tables 1 and 2). Many species of the genera in Table 1 are commonly recognized pathogens, consistently ranking among the top 10 organisms seen in health care-associated infections (23–25). In the United States between 2009 and 2010, there were 69,475 health care-associated infections and 81,139 pathogens reported from 2,039 hospitals (26). Eighty percent of the isolates were in one of eight pathogen groups: Staphylococcus aureus (16%), Enterococcus spp. (14%), Escherichia coli (12%), coagulase-negative staphylococci (11%), Candida spp. (9%), Klebsiella pneumoniae-Klebsiella oxytoca (8%), Pseudomonas aeruginosa (8%), and Enterobacter spp. (5%). Nearly 20% of these eight pathogen groups were multidrug-resistant phenotypes: MRSA (8.5%); vancomycin-resistant Enterococcus (3%); extended-spectrum cephalosporin-resistant K. pneumoniae-K. oxytoca (2%), E. coli (2%), and Enterobacter spp. (2%); and carbapenem-resistant P. aeruginosa (2%), K. pneumoniae-K. oxytoca (<1%), E. coli (<1%), and Enterobacter spp. (<1%).

European data on infection rates for 2010–2011, which are similar to those above, can be obtained from the European Centre for Disease Prevention and Control (http://ecdc.europa.eu/en/publications); rates for individual European countries can be obtained from the appropriate regulatory health authority, such as Public Health England (http://www.hpa.org.uk/Publications/InfectiousDiseases).

Pediatric patient data collected in 2004 from three continents (North America, South America, and Europe) indicated that Klebsiella spp., Enterobacter spp., Proteus mirabilis, and Serratia spp. ranked 4th, 7th, 11th, and 12th, respectively, in the top 15 most frequently isolated organisms (23). Both Klebsiella and Enterobacter were more prevalent (3rd to 5th versus 10th) in North and South America than in Europe. In all geographic areas there was a 2-fold decrease in prevalence for both Klebsiella and Enterobacter species in children older than 1 year.

Klebsiella and Raoultella

Klebsiella is carried in the nasopharynx and the bowel; however, feces are arguably the most significant source of patient infections (27). K. pneumoniae bloodstream infection isolation rates are 1.5 times greater during the warmest months of the year (28). These rates most likely reflect increased fecal carriage in humans, which, in turn, is a reflection of increased organisms in the environment during warm months. This has important implications since colonized patients have a 4-fold-increased risk of infection over non-carriers. Similar isolation rate increases were not seen with Enterobacter or Serratia.

aReferences are given in parentheses. Genomspecies listed cannot be biochemically separated from other species within their genus and/or only a single strain exists.

bRare human isolates of no, or questionable, significance.

cEnvironmental isolates; fish, marine, animal, or bird isolates; insect isolates or pathogens; plant isolates or phytopathogens.

*K. pneumoniae*, primarily strains with capsular type K1, has emerged as an important cause of community-acquired pyogenic liver abscess worldwide (29–32). The majority of patients with *Klebsiella* pyogenic liver abscesses are Asian males, 50 to 60 years of age, who present primarily with a right-lobe, solitary, monomicrobial abscess. Studies by Brisse et al. (29) indicate that pyogenic liver abscess-associated K1 isolates belong to a clonal complex designated CC23K1, whereas K1 strains associated with severe pneumonia isolated from the respiratory tract and bloodstream infections belong to a different complex, CC23K1, magA (mucoviscosity-associated gene), which resides within the cps (capsular polysaccharide synthesis) operon in all K1 isolates, is not an indicator for primary liver abscess. Conversely, the gene allS (an activator of the allantoin regulon) has been detected, to date, only in K1 strains isolated from primary liver abscesses (29, 33). allS may confer an advantage on these strains because levels of allantoic, which can serve as a carbon source, are elevated in non-insulin-dependent diabetics (33). Primary liver abscess K1 strains also appear to be separable by conventional biochemical methods (see “Identification” below). Mouse lethality studies show that *Klebsiella* liver abscess isolates that possessed both the hypermucoviscosity phenotype and the rmpA (regulator of mucoid phenotype) gene, regardless of the K type, had a 50% lethal dose of $<10^{6}$ CFU, versus $>5 \times 10^{6}$ CFU for type K1 or K2 urine isolates that were not hypermucoviscous and without rmpA or aerobactin genes (33).

The hypervirulent (hypermucoviscous) clinical variant hvKP has become established in the Pacific Rim and is emerging in Western countries but is underrecognized. A hypermucoviscous phenotype is used as a laboratory surrogate marker for this variant. The propensity of hvKP strains for metastatic spread in noncompromised hosts is both a defining and an unusual trait. The hvKP1 strains are more resistant to complement and neutrophil-mediated bactericidal activity and can be more virulent in a rat subcutaneous abscess model than cKP1 to cKP4. The recognition of the hypermucoviscous phenotype (defined by a positive string test) is indicative that the clinical strain may be an hvKP strain, which is hypervirulent compared to cKP. An improvement in our understanding of the epidemiology and clinical spectrum of infection by hvKP is needed since it may be more prevalent than appreciated.

*Klebsiella rhinoscleromatis* and *Klebsiella ozaenae* have adapted to cause specific chronic infectious diseases, i.e., rhinoscleroma and atrophic rhinitis (ozena), respectively (29). Neither organism is isolated from the environment or the intestinal tract, and both have lost the ability to utilize substrates involved in plant product degradation pathways. However, isolates from the bloodstream, urinary tract, and other infection sites indicate that *K. ozaenae* is more diverse in its ability to cause disease than *K. rhinoscleromatis*. Atrophic rhinitis is restricted to the nose, but rhinoscleroma may spread to the trachea and larynx (32). Both of these tissue-destructive diseases occur more frequently in tropical areas of the world and are spread by person-to-person transmission, although prolonged contact with persons producing airborne nasal secretions is required. A retrospective study has updated the epidemiological and clinical features of rhinoscleroma (34).

*Klebsiella granulomatis* is the agent of donovanosis or granuloma inguinale, a disease characterized by chronic genital ulcers (29, 35). It also occurs predominantly in tropical countries and is thought to be sexually transmitted, with humans as the only known reservoir. *K. oxytoca* strains carrying a chromosomally encoded heat-labile cytotoxin have been increasingly recognized as a cause of antibiotic-associated hemorrhagic colitis (36, 37). Antibiotic-associated hemorrhagic colitis, associated with the use of β-lactam antibiotics, is self-limiting and resolves spontaneously with the withdrawal of the contributing antibiotic. It differs from *Clostridium difficile* disease in that there is no pseudomembrane formation and *K. oxytoca* antibiotic-associated hemorrhagic colitis stools are bloody. The majority of isolations reported to date for *Klebsiella variicola* are from sterile sites, mainly blood and urine (38, 39). Isolates of this organism (three of five from urine), identified by rpOB sequencing reported from a Brazilian study, provide increased evidence that this organism is a human pathogen (39).

*Raoultella planticola* and *Raoultella terrigena* share pathogenicity characteristics with *K. pneumoniae* and are difficult to distinguish from it biochemically without special tests. In European studies, 3.5% to 19% of clinical strains initially identified as *Klebsiella* were *R. planticola*, while in U.S. and Brazilian surveys of 436 and 122 strains, respectively, only 1 isolate in each was identified as *R. planticola*, indicating that the prevalences of these species may differ geographically (39–41). *Raoultella planticola* has rarely been documented as a cause of human infections. *Raoultella terrigena*
is an aquatic and soil organism, and human infections are rare. The first reported human infection caused by this organism was in 2007; a 45-year-old patient developed endocarditis due to R. terrigena after liver transplantation (42).

**Erwinia, Enterobacter, and Pantoea**

Since the early 1970s, the Erwinia herbicola-Enterobacter agglomerans complex has been subjected to continuous reevaluation and taxonomic revisions. The Erwinia genus has been a depository for plant-associated members of the Enterobacteriaceae. Yet many Erwinia species were phenotypically similar or showed strong DNA-DNA hybridization to each other and closely related species of other Enterobacteriaceae genera. Many clinical isolates may be misassigned as P. agglomerans due to the reliance on commercially available biochemical test kits.

The majority of Pantoea species either are associated with plants or are plant pathogens. Pantoea species, especially Pantoea agglomerans and Pantoea ananatis, can also cause human infections (49, 52). Pantoea agglomerans is the species of Pantoea most commonly isolated from humans. Sporadic infections are associated with penetrating trauma by objects contaminated with soil or vegetation resulting in soft tissue infections, septic arthritis, or osteomyelitis, whereas health care-associated infections and outbreaks often involve contaminated intravenous fluid, parenteral nutrition, or other administered fluids. Pantoea agglomerans infections in children, most of whom have severe underlying conditions, are predominantly polymicrobial and therefore of questionable significance even when specimens are from sterile sites (49).

**Cronobacter**

The Cronobacter genus (formerly Enterobacter sakazakii) currently contains seven species: Cronobacter sakazakii, Cronobacter malonicatus, Cronobacter universalis, Cronobacter turicensis, Cronobacter muytjensii, Cronobacter dublinensis, and Cronobacter condimenti (43, 53, 54). The Cronobacter genus used to include Cronobacter helveticus, Cronobacter pulveris, and Cronobacter turicensis, which were formerly known as Enterobacter helveticus, Enterobacter pulveris, and Enterobacter turicensis. These have been taxonomically reassigned to Francochromobacter helveticus, Francochromobacter pulveris, and Sticcherbac turicensis. Of these, C. sakazakii and Cronobacter malonicatus are the species most frequently isolated from clinical samples (55, 56), with Cronobacter sakazakii predominating in neonatal infections and Cronobacter malonicatus in adult infections. The others are primarily environmental in origin, although few clinical cases have been documented (57).

Although not common, C. sakazakii is associated with severe cases of neonatal meningitis and necrotizing enterocolitis with relatively high mortality rates in neonates. This species is the only member of the genus to utilize sialic acid (2-keto-3-deoxy-5-acetamido-D-glycero-D-galacto-nonulosonic acid). This may contribute to its propensity to cause neonatal and infant infections, since sialic acid is found in breast milk, infant formula, mucin, and gangliosides (58).

Limited studies to date indicate that C. malonicatus may predominate the more numerous adult infections and may be carried in the laryngopharynx (59). Isolates of Cronobacter cannot be identified to the species level in clinical laboratories due to a lack of discriminatory biochemical tests. The most reliable and robust method is DNA sequence analysis of the fusA and rpoB genes, for which an open-access MLST database is available (http://pubMLST.org/cronobacter). The recognition and expansion of the Cronobacter genus have caused much confusion in the literature. Two common mistakes are (i) referring to all pre-2007 E. sakazakii isolates as C. sakazakii and (ii) the continued use of commercially available biochemical kits with supporting databases that both continue to use the name Enterobacter sakazakii and do not encompass all the species in the Cronobacter genus.

**Lelliottia, Pluralibacter, and Kosakonia**

The new genus Lelliottiella has been formed and Enterobacter nimipressuralis and Enterobacter amnigenus have been reclassified as Lelliottia nimipressuralis and Lelliotiella amnigena, respectively (43). Enterobacter gergoviae and Enterobacter pyrivirus have been transferred to the new genus Pluralibacter as Pluralibacter gergoviae and Pluralibacter pyrivirus, respectively. The new genus Kosakonia includes the former Enterobacter cowani, Enterobacter radiicinctans, Enterobacter oryzae, and Enterobacter arachidis as Kosakonia cowani, Kosakonia radiicinctans, Kosakonia oryzae, and Kosakonia arachidis, respectively (43).
**Serratia**

Serratia spp. are notorious healthcare-associated pathogens and colonizers. Transmission is predominately from person to person, but medical apparatuses, intravenous fluids, and other solutions are often implicated as well (46). Indwelling catheters, particularly for urinary tract infections, serve as a primary reservoir for transmission via hospital personnel. In children, the gastrointestinal tract is a common source of infections. Outbreaks transmitted by hand are often insidious, occurring over long periods, and may subside and peak a number of times before recognition and infection control efforts can contain them. Some species and biotypes of Serratia produce a nondiffusible red pigment, prodigiosin, or 2-methyl-3-amyI-6-methoxyprodigiosene. The pigment may be toxic to protozoa and therefore of ecological advantage in water and soil. Pigment production in S. marcescens appears to be a marker that the strain is environmental in origin and of low virulence (60). Community-acquired infections are rare, except for S. marcescens contact lens-induced acute red eye (61). Most of the other species of Serratia have also been isolated from humans, in whom they too are usually transient or cause opportunistic infections. Water is probably the principal habitat of S. plymuthica.

Serratia does not usually infect a healthy human being, but it frequently colonizes or infects hospitalized patients. S. marcescens is currently the only known nosocomial species of Serratia. Although Serratia liquefaciens and Serratia rubidaea are occasionally isolated from clinical specimens, their pathogenic role has not been established. Serratia infections are broad and similar to those by other opportunistic pathogens: respiratory and urinary tract infections, surgical wound infections, and septicemia in patients with intravenous catheterization. Meningitis, brain abscesses, and intra-abdominal infections are frequent.

**Citrobacter**

Citrobacter organisms are responsible for diverse serious enteric diseases as well as extraintestinal disorders. Citrobacter infections include urinary tract infections, superficial wound infections, respiratory tract infections, intra-abdominal infections, bacteremia, endocarditis, infant meningitis (accompanied by brain abscess formation), and sepsis. The organisms are ubiquitous and can be isolated from soil, water, and food as well as the intestinal tracts of humans and animals. Citrobacters are primarily inhabitants of the intestinal tract, and their presence in the environment may reflect fecal excretion by humans and animals; the natural habitat of some newer Citrobacter species is unknown.

The Citrobacter genus contains 12 species, of which 3 are most commonly involved in hospital infections: Citrobacter freundii, Citrobacter koseri, and Citrobacter braakii. Citrobacter is an opportunistic pathogen which has been recognized as an important cause of nosocomial infection, especially in neonates and immunocompromised patients. Two important types of Citrobacter infection are healthcare associated and community acquired. Patients are usually older adults (>65 years), more often males, and the urinary tract is the most common site of infection (62, 63). One-third to one-half of Citrobacter infections, including septicemias, are polymicrobial and are associated with higher mortality rates (18% to 50%) or longer hospital stays (62, 63). Meningitis is almost exclusively associated with Citrobacter koseri and involves children <2 months of age, with the highest onset rates recorded in newborns with a mean age of 7 days (46, 64). Brain abscesses occur in 75% of infected infants, and neurological defects are common sequelae in surviving infants. The most prominent risk factor is prior colonization; during outbreaks, colonization rates of 27% have been noted, versus a normal rate of <1% (65, 66). Person-to-person spread by hospital personnel and, less often, from mother to offspring is the most likely source of infection. Sampling of inanimate or environmental reservoirs in hospitals usually fails to yield Citrobacter. Other Citrobacter species, including Citrobacter gillenii and Citrobacter muelii, have been found in human clinical, animal, food, and environmental specimens (67, 68). The role of many Citrobacter spp. in human infections is unclear because reports in the literature are insufficient to determine either clinical significance in humans or potential reservoirs for infection. Citrobacter rodentium causes murine colonic hyperplasia, which is self-limiting in adult mice but causes significant morbidity and mortality in infant mice in mouse colony outbreaks (69). The organism is used in mice as a model for enteropathic E. coli and enterohemorrhagic E. coli infections in humans.

**Pseudocitrobacter**

The new genus Pseudocitrobacter has been defined based on four fecal isolates from hospitalized patients and outpatients attending military hospitals in Pakistan (70). The strains were of particular importance for accurate identification, as three of them produced NDM-1 carbapenemase, and the fourth was phenotypically very similar. Initially the strains were phenotypically identified as Citrobacter species. However, 16S rRNA gene sequence comparison showed that the strains formed a separate cluster with only 97% to 98.3% shared identity with members of the genera Citrobacter, Kheruvira, Pantoea, Enterobacter, and Raoultella. MLSA based on the DNA and predicted amino acid sequence of only three loci (recN, τροA, and τρoB) also demonstrated that the strains were in unique clusters from the remaining Enterobacteriaceae. The thdB gene could not be amplified for all strains. DNA-DNA hybridization supported the recognition of the new genus, which currently is composed of Pseudocitrobacter faecalis and Pseudocitrobacter anthropi; these species differ in their fermentation of raffinose and β-mannitol. The former species represent the strains which produced NDM-1.

**Proteus, Providencia, and Morganella**

Members of the genera Proteus, Providencia, and Morganella are widespread in the environment, are normal inhabitants of the gut, and are relatively common in clinical laboratories, especially P. mirabilis. In a large 6-year population-based survey of Proteaceae, 85% (4,290 of 5,047) of isolates were community acquired, although providencias were more likely to be acquired in nursing homes (71). Females (69%) and the elderly (median age, 70 years) were at the highest risk of infection, and the most common specimen sources were urine (86%), soft tissues (7%), blood (3%), miscellaneous fluids (2%), and the respiratory tract (2%). P. mirabilis, predominantly from urine, was the most frequently isolated agent (77%). Non-P. mirabilis species (primarily Proteus vulgaris) were isolated from wounds and soft tissue more often than urine. Of the Providencia species, P. stuartii was isolated twice as often as other species. P. mirabilis, Proteus penneri, Morganella, and Providencia alcalifaciens are seen in diarrheal stools with greater frequency than in normal stools, leading to speculation that they may cause diarrhea. Some strains of P. alcalifaciens are invasive in HEp-2 cell assays and elicit diarrhea in the RITARD (reversible intestinal-tie adult rabbit diarrhea) model, while other strains isolated in pure culture or in large numbers from
diarrheal stools fail to invade cell lines (72, 73). However, a number of noninvasive \textit{P. alcalifaciens} strains have been shown to be nonadherent to cell lines \textit{in vitro}, which may provide insight to their inability to invade (74). Yob et al. (75) used a specialized medium to isolate nine strains of \textit{Providencia rettgeri} from 130 persons with traveler’s diarrhea; eight of these strains were invasive in Caco-2 cells, indicating their potential for virulence in humans. Notably, vomiting was present in five \textit{P. rettgeri} cases but was not seen in patients from whom other providenciae were isolated.

\textbf{Hafnia}

\textit{Hafnia} organisms are commonly isolated from the gastrointestinal tracts of humans and animals (including mammals, birds, reptiles, fish, and insects) and from foods (including meat and dairy products) (76). They are associated with a range of animal infections and have been recovered from human clinical specimens during cases of bacteremia and gastroenteritis and respiratory tract infections. Their status as primary human or animal pathogens, however, remains controversial because these organisms are usually found together with other pathogens and/or opportunists at the site of infection (76).

Few systematic investigations regarding the ecological distribution of \textit{Hafnia} have been published, although it is a common inhabitant of the gastrointestinal tracts of various animals (76). Isolation from consumables, especially meats, is not uncommon, and presumably its presence indicates prior contact of the item with feces. \textit{Hafnia alvei} has been linked to gastrointestinal disease, although putative virulence characteristics have not been demonstrated (77, 78). However, a toxigenic strain producing a cytotoxic effect on Vero cells indistinguishable from that of Shiga toxin, but not neutralized by anti-Shiga toxin antibody, has been reported (79). Although seen infrequently in extraintestinal disease, such infections occur both in healthy and in immunocompromised patients, with monomicrobial infection rates varying from 12 to 75%; the correlation with disease increases when the organism is isolated in pure culture and in high numbers (76). \textit{Hafnia} appears to have a predilection for the biliary tree and may produce abscesses at the site of infection (80).

Until recently, \textit{Hafnia alvei} has been the only recognized species in the genus. However, previous DNA-DNA hybridization studies and partial 16S RNA gene sequencing have indicated that \textit{Hafnia alvei} is genetically heterogeneous and consists of at least two DNA hybridization groups (HGs) (81). Previously published and new phenotypic data revealed that a combination of malonate assimilation and β-glucosidase activity enabled correct assignment of \textit{Hafnia} isolates to one of the two HGs. \textit{Hafnia alvei} corresponds to HG1 and includes the type strain ATCC 13337. The new species \textit{Hafnia paralvei} is given for the former members of \textit{H. alvei} HG2 (82, 83). \textit{Hafnia} isolates can be unambiguously assigned to the correct species (\textit{H. alvei} or \textit{H. paralvei}) based upon the following five tests: β-glucosidase, malonate utilization, α-arabinose fermentation, salicin fermentation, and esculin hydrolysis. Both species can be frequently isolated from clinical laboratory samples (82). Although \textit{H. alvei} strains are more likely to be toxigenic than \textit{H. paralvei} isolates, both species produce a Vero cytolytic toxin. Other reported virulence characteristics include siderophores, resistance to complement-mediated lysis, and possession of type 1 and 3 fimbriae (84).

\textbf{Plesiomonas shigelloides}

\textit{Plesiomonas shigelloides} is the only species of the genus \textit{Plesiomonas} and is the only oxidase-positive member of the \textit{Enterobacteriaceae} family (85). Freshwater and estuarine water are considered to be the natural environment of the organism, and it is a cause of waterborne infections. It is found in a wide range of hosts, including amphibians, birds, fish, and animals (86). There is no evidence that the organism is the cause of diarrheal disease in any of these hosts, with the possible exception of cats. It is regarded as an emerging and significant enteric pathogen of water- and foodborne human infections and is a major cause of traveler’s diarrhoea in Japan and China (85). Three major types of \textit{P. shigelloides} gastroenteritis in humans occur: (i) a secretory, watery type; (ii) an invasive, dysentery-like type; and (iii) a subacute or chronic form, lasting between 2 weeks and 3 months (87-89). Outbreaks are generally related to consumption of seafood or untreated water. The pathogenicity of \textit{P. shigelloides} is poorly understood. There are reports of several toxins being secreted \textit{in vitro}: cholera-like toxin, thermostable and thermonolable toxins, β-hemolysins, and cytotoxin complex (90, 91). The somatic antigen may also play a role in pathogenicity, since the gene encoding the most common type, O17, shares almost complete identity with the form 1 (smooth) antigen gene of \textit{Shigella somiae} (92).

\textit{P. shigelloides} is responsible for rare incidents of extraintestinal infections in humans, most notably, meningitis in neonates, bacteremia, sepsis, and septic shock with high fatality rates (85, 93). Wound infections associated with water contact are not encountered with plesiomonads despite their aquatic reservoir. \textit{Plesiomonas} bacteremia, which is rare and usually polymicrobial, is generally community acquired, and major risk factors include biliary tract disease and advanced age (>75 years) (94).

\textbf{Edwardsiella}

The \textit{Edwardsiella} genus includes \textit{Edwardsiella tarda}, \textit{Edwardsiella ictaluri}, \textit{Edwardsiella piscicida}, and \textit{Edwardsiella hoshinae}. These are primarily fish pathogens and cause economic losses to the aquaculture industries worldwide. \textit{Edwardsiella tarda} is a broad-host-range pathogen that infects various species of fish and animals as well as humans. \textit{Edwardsiella ictaluri} is highly host adapted to channel catfish and is not of clinical concern. The ability of \textit{Edwardsiella hoshinae} to cause disease has not been established, and little is known regarding its habitats. \textit{Edwardsiella tarda} is also associated with opportunistic infections in humans. These are most commonly gastroenteritis and wound infections and less frequently cases of sepsis, meningitis, and liver abscess. Most \textit{Edwardsiella tarda} human infections are linked to contact with fish or turtles. Other than in tropical areas, there is only a low carriage rate in humans. The pathogenicity of \textit{Edwardsiella tarda} is probably linked to the production of a cell-associated hemolysin and its ability to invade intestinal cells, as demonstrated with HEp-2 cells in tissue culture studies (95). Serious wound infections, including myonecrosis, have been reported to occur in immunocompetent individuals who have aquatic exposure. Systemic infections have been reported to occur patients with liver disease or iron overload conditions (96). Initial genomic studies indicate that \textit{Edwardsiella tarda} can be split into two genotypes, with EdwGII strains being associated with human infections (97).

\textbf{Miscellaneous \textit{Enterobacteriaceae}}

Miscellaneous members of \textit{Enterobacteriaceae} that are infrequently encountered in clinical laboratories are primarily opportunistic pathogens in compromised patients or are present as transients or commensals in clinical specimens (46). For some, like \textit{Cedecea}, \textit{Lemnorea}, \textit{Moellerella}, and \textit{Tatumella}, a reservoir has not been determined because they
are rarely isolated from nonhuman sources, while Ewingella, Leclercia, and Kluyvera are found in a variety of foods, water, or animals (snails and slugs) and, like many enterics, appear to be ubiquitous in the environment (46, 98–104). Other genera isolated from humans have more specific natural habitats such as Rahmella (water) or Yokenella and P. asymbiotica (insects and infections from insect bites) (46, 105–107). There have been increased reports of clinically significant isolations of L. adecarboxylata and Kluyvera species, all of which cannot be covered here. Kluyvera infections occur in immunocompetent and immunosuppressed patients of all age groups (108, 109). The organism is isolated from a broad spectrum of sources, including blood, tissue, urine, cerebrospinal fluid, and peritoneal fluid, although urinary tract and bloodstream infections each account for approximately one-third of the infections. When strains are identified to the species level, Kluyvera arsenaria accounts for more than twice the number of Kluyvera cryocrescens infections. Originally considered to be an opportunistic pathogen, L. adecarboxylata is quite often isolated from polymicrobial infections in healthy patients without underlying disease (110). This suggests that the coinfected agent(s) might alter the local tissue environment, allowing growth of Leclercia, or that a transfer of genetic factors occurs, enhancing its virulence. The isolation of Leclercia in pure culture from previously healthy persons (from a foot abscess and blood and wound caused by a hydrofluoric acid chemical injury) described in two reports would indicate that at least some strains may be pathogenic (110, 111). Moellerella wisconsinensis, a rarely reported organism first isolated from stools of diarrheal patients, has been reported from an additional series of five patients with disease ranging from self-limited acute watery diarrhea without mucus to protracted diarrhea, lasting several weeks. No other common diarrheal bacterial pathogens or parasites were present in the stools, and specimens taken after clinical recovery were negative (112).

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

The organisms covered in this chapter are, in general, readily isolated from clinical material, and the principles in chapter 18 of this Manual on specimen collection, handling, and processing are applicable. Most of these organisms survive in culture deeps for approximately a year. Long-term storage methods as recommended in chapter 11 work well for these organisms. Plesiomonas cells do not survive for more than 1 to 2 months when held at room temperature and should be maintained at −70°C. Cronobacter isolates do not survive well at 5°C. Tatumella strains have failed to survive longer than a year even at −70°C.

**ISOLATION PROCEDURES**

Few of the clinically relevant strains covered in this chapter present difficulties in isolation from sterile body sites. Isolation from nonsterile body or environmental sites may require specialized media such as CHROMagar Orientation (Becton Dickinson, Sparks, MD) and chromID CPS (bioMerieux, Hazelwood, MO), which perform similarly for the detection of urinary tract pathogens covered in this chapter and can reliably replace MacConkey and blood agars (113, 114). These media prevent swarming of Proteus and limit the spread of mucoid colonies, which reduces overgrowth of pathogenic colonies. Additionally, colonies on CHROMagar can be used to inoculate antimicrobial susceptibility tests directly without subculture. CHROMagar media can also be used for specimens from other nonsterile sites; when colony color was combined with indole, lysine, and ornithine decarboxylase tests and serology, 98.7% (466 of 472) of the above-listed organisms were correctly identified from nonurine samples (115).

Both of the diarrheal pathogens covered in this chapter are easily isolated. E. tarda is a lactose-negative, H$_2$S-positive organism, indistinguishable from Salmonella on enteric plating media (opaque or opaque with black centers). A positive indole reaction and failure to agglutinate in specific Salmonella antisera separate the two organisms. Plesiomonas produces non-lactose-, non-sucrose-fermenting colonies on enteric plating media. It does not grow on thiosulfate-citrate-bile salts-sucrose medium, but on cefsulodin-Irgasan-novobiocin medium, opaque colonies without a pink center (mannitol not fermented) are suspicious for plesiomonas. Two other oxidase-positive organisms, Pseudomonas and Aeromonas, grow on cefsulodin-Irgasan-novobiocin as well, although Aeromonas colonies have a pink center with an opaque apron. Inositol fermentation and a positive reaction in Moeller’s lysine, arginine, and ornithine tests differentiate Plesiomonas from these agents as well as other organisms.

Other Enterobacteriaceae involved in opportunistic infections and that may be isolated from a variety of specimen types generally grow well on commonly used laboratory media. Some genera are lactose or sucrose fermenters and give the appearance of normal biota on enteric plating media, while others may produce H$_2$S and appear Salmonella-like. Rahmella, Ewingella, and Tatumella may require 48 h for growth. Tatumella also grows poorly on Mueller-Hinton agar, and a broth dilution method may be required for susceptibility testing. K. granulomatis does not grow on conventional laboratory media but has been grown in HEP-2 monolayers (116). Detection of Donovan bodies from tissue smears using the Giemsa or Wright stain is the method most commonly used to detect this organism. However, these pleomorphic, bipolar staining bodies shaped like a closed safety pin are not always present and are not reliable for diagnosis.

**IDENTIFICATION**

The biochemical tests most useful for separating members covered in this chapter are given in Tables 3 through 13. Correct identification to the species level is increasingly important in recognizing strains that are of high risk for carrying extended-spectrum β-lactamases (ESBLs), cephalosporinases, or carbapenemases. It should be noted that identification problems arising from the use of commercial phenotyping systems vary with each genus. The percentage of correct identifications for many commercial systems increases significantly when additional biochemical tests are performed on organisms with “low-probability” identifications. Even when unusual enterobacteria covered in this chapter are included in commercial system databases, the number of strains available to use in challenge studies is very limited; therefore, the ability of these systems to accurately identify these organisms is really unknown. O’Hara (117) has published a comprehensive review on manual and automated systems for the identification of bacteria in clinical laboratories. It provides the component substrates used and the additional reagents that are needed, if any, as well as quality control, database content, accuracy of identification, important features of each automated identification system, and published evaluations, among other information, for each commercial system.
Alternative methods of identification are based on DNA sequence and protein profiling; Matrix-assisted laser desorption ionization–time-of-flight (MALDI-TOF) mass spectrometry is increasingly being applied in clinical laboratories to generate the reference profiles used correctly identified methods can be reliable provided the culture database used and has been evaluated in multicenter studies (118). These methods can be reliable provided the culture database used to generate the reference profiles used correctly identified strains initially. MALDI-TOF has been evaluated for the profiling of antibiotic-resistant Enterobacteriaceae from blood cultures (119). This can be an issue with genera that have undergone taxonomic reevaluations, such as Cronobacter (120).

**Klebsiella and Raoultella**

*K. pneumoniae* CC23K1 isolates associated with pyogenic liver abscess may be distinguished biochemically from CC82K1 and type K2 *K. pneumoniae* strains by their utilization of d-ribose, 3-hydroxybutyrate, d-tagatose, and dulcitol as sole carbon sources (78). *K. ozaenae* and *K. rhinoscleromatis* are slow-growing organisms and thus do poorly in commercial systems; however, they can be difficult to separate using conventional biochemicals as well. *R. planticola* and *R. terrigena* require temperature growth and carbon assimilation tests to separate them from *Klebsiella* species.

<sup>c</sup>See Table 3, footnote b.

<sup>d</sup>P. vulgaris genomospecies 4, 5, and 6 cannot be differentiated phenotypically.

<sup>e</sup>See Table 3, footnote b.

<sup>f</sup>Some members of some biogroups are ornithine decarboxylase positive.
R. terrigena can be separated from R. planticola by fermentation of β-gentibiose. K. variicola is not found in commercial systems, and information from additional isolates has shown that adonitol fermentation is of limited usefulness for its separation from K. pneumoniae (47, 87). At this point, sequencing of housekeeping genes (rpoB and others) is the only method of correctly identifying this organism. \( \beta \)OHE and scrA (sucrose regulon) genes have been used to identify and to separate K. granulomatis (\( \beta \)OHE positive and scrA negative) from other Klebsiella species (\( \beta \)OHE and scrA positive) (121).

### Enterobacter and Pantoea

Because of the genetic heterogeneity in several species, members of the genera Enterobacter and Pantoea appear to confound commercial systems more often than other genera (46). E. ludwigi and E. hormaechei, species previously residing within the E. cloacae complex, can be separated from E. cloacae by growth on 3-O-methyl-D-glucopyranose and putrescine and on 3-hydroxybutyrate, respectively (17, 45). By using commercially available tests, the three subspecies of E. hormaechei can be separated with adonitol, dulcitol, and \( \alpha \)-soritol (Enterobacter hormaechei subsp. hormaechei tests negative, positive, and negative, respectively; E. hormaechei subsp. steigerwaltii tests positive, negative, and positive, respectively; and E. hormaechei subsp. oharae tests negative, negative, and positive, respectively) (17). P. agglomerans is very difficult to identify with either commercial systems or conventional biochemicals (117, 122). Yellow pigmented and lysine-, arginine-, and ornithine-negative organisms should raise suspicion that the strain is P. agglomerans; Leceridia adcaaroxyylata and P. asymbiotica also share these characteristics, but they can be separated from P. agglomerans by positive indole and negative \( \alpha \)-mannitol reactions, respectively. P. ananatis, P. dispersa, and Erwinia persicina most closely resemble P. agglomerans, but P. dispersa can be separated from P. agglomerans by negative reactions for raffinose, salicin, and sucrose and E. persicina can be distinguished by negative reactions for maltose and \( \alpha \)-xylose. P. ananatis is more difficult to differentiate, and all suspected isolates of this organism, as with other rare Enterobacteriaceae, should be sent to a reference laboratory for confirmation.

### Cronobacter

Cronobacter organisms form either mucoid colonies, smooth and irregularly round colonies, or rough and wrinkled colonies, which are difficult to remove from the agar surface. Biotyping was initially proposed as a means of identifying Cronobacter species but should no longer be followed given that DNA sequence-based (including whole-genome sequencing) studies have revealed that the biotyping scheme is in considerable variance with the known genus phylogeny and serves no useful purpose. Commercial kits have not been updated following the 2007 taxonomic revision and still use the former name of Enterobacter sakazakii. Therefore, these are of limited use for this genus. 16S ribosomal gene sequencing of the Cronobacter genus is not reliable for all species due to their close genetic relationships, in particular between Cronobacter sakazakii and Cronobacter malonicicus (55, 57, 123). Instead, a number of molecular methods have been developed, the most useful being the sequencing of the housekeeping gene fusA, which forms part of the online MLST scheme (http://pubMLST.org/cronobacter) and the phylogeny of which matches the whole-genome phylogeny (55).

### Serratia, Citrobacter, and Proteae

Serratia spp. are generally easily identified, except for the S. liquefaciens group; separation of members within this group can be achieved using a combination of API 50 CH (carbohydrate) and API ZYM (enzymatic) (bioMérieux, Hazelwood, MO) strips (18, 46). Citrobacter spp. may be included in databases individually or by subgroups (C. braakii-C. freundii-C. sedlakii, C. wermanni-C. youngae, or C. koseri-C. malonicicus); however, subgroup identification requires further biochemical testing by standard methodologies, and final species identification is delayed (46). A PYR (1-phenylglycine acid, OxoC) disk, which detects pyrrolidon peptidease, may be useful for separating biochemically atypical strains of Citrobacter (positive) and Salmonella (negative) (124, 125). Gram-negative, oxidase-negative organisms that swarm on blood agar and appear flat with tapered edges on MacConkey agar may be reported as Proteae. Spot indole-negative and ampicillin-susceptible strains may be reported as P. mirabilis, while spot indole-positive, ampicillin-resistant strains are reported as P. vulgaris (126).

*Abbreviations and symbols: VP, Voges-Proskauer; LDC, lysine decarboxylase; KCN, potassium cyanide; +, ≥90%; −, ≤10%. Klebsiella and E. tarda are also indole positive and VP negative and can be found in Tables 10 and 12, respectively.*

*Includes K. intermedia (K. cochleae and Enterobacter intermedius combined) (196).*
Proteus hauseri, previously a subgroup of P. vulgaris, can be differentiated from P. vulgaris by negative salicin/esculin and trehalose reactions (126). Proteus organisms that do not fit the above-listed criteria must be fully identified by commercial or conventional biochemical methods (126). Proteus species are identified with 95% to 100% accuracy by commercial systems, but Providencia identification rates vary from 79% to 100% (126). When Providencia spp. are misidentified, they are usually called Morganella or Proteus. Urea-positive P. stuartii may be misidentified as P. rettgeri, or the system may require additional tests for identification. Two-hour identification methods misidentify Morganella morganii subsp. morganii about 66% of the time.

Other Enterobacteriaceae

Averyella dalhousiensis is not in commercial system databases. It may be confused with K. ascorbata or misidentified as Salmonella enterica in commercial systems. It shares biochemical traits (positive for o-nitrophenyl-β-D-galactopyranoside, malonate, potassium cyanide, and fermentation of dulcitol and salicin) with S. enterica subsp. salamaiae, S. enterica subsp. arizonae, S. enterica subsp. diarizonae, and S. enterica subsp. indica. Averyella and Tatumella are biochemically inactive, and the latter organism grows poorly in vitro. Kluyvera can be identified only to the genus level by commercial systems, but species determination requires an ascorbate test and Irgasan susceptibility and/or gas-liquid chromatography profiles (46). P. asymbiotica is not in most commercial databases.

Molecular Identification

Information on molecular identification techniques is available elsewhere (chapter 6). For laboratories using partial 16S rRNA (~500 bp) gene sequencing to identify members of the Enterobacteriaceae, the Clinical and Laboratory Standards Institute (CLSI) provides extremely useful information, including guidelines with suggested cutoff values for percent identity scores and identification algorithms (127). Specifically, Table 3 of the MM18-A guideline (127) provides information on the usefulness of 16S rRNA gene sequencing for various enteric groups, comments regarding relatedness within groups, alternative DNA targets, indications for identification to the species level, and recommendations for resolving species identification. Suggested cutoff values help the laboratory provide clinicians with practical, recognizable identifications of clinically significant organisms and allow the same organism to be identified with consistency between laboratories. Appropriate cutoff values notwithstanding, accurate organism identification is ultimately dependent upon the availability of a reliable database of known sequences for comparison of the sequences generated for the unknown isolate. Both public and private databases are available, and each offers advantages (127). An evaluation of two commercially available reference sequence libraries, MicroSeq (Applied Biosystems, Foster City, CA) and SmartGene IDNS (SmartGene, Inc., Raleigh, NC), found that the second had a greater diversity of sequences for comparison and provided user-friendly software with enhancements such as the ability to add alternative gene target databases and to store and compare previous clinical sequences (128).

TYPING SYSTEMS

The ability to trace the spread of nosocomial pathogens in outbreaks caused by the Enterobacteriaceae has become a major responsibility for the laboratory. Chapters 9 and 10 of this Manual provide useful information on the molecular epidemiology of enteric outbreaks. Molecular techniques, including plasmid analysis, ribotyping, pulsed-field gel electrophoresis (PFGE), and various PCR methodologies, all appear to be satisfactorily discriminatory, with some working better for a specific genus or species than others (129). PCR techniques, particularly repetitive-element PCR methods for the Enterobacteriaceae, have proliferated at an astonishing pace and cannot be covered here more fully. To date, because economic constraints dictate the need for a single method that is applicable for a variety of organisms, PFGE remains the most universally accepted standardized technique and is considered the gold standard for typing of medically important bacteria, especially during outbreak investigations (129). The disadvantage of a long turnaround time (usually 4 days) has been partially overcome by a rapid PFGE protocol that is suitable for most enteric bacteria as well as other common clinical strains (130). Nevertheless, the method cannot determine that two strains are identical, only that the strains are indistinguishable, as only a small portion of the genome is analyzed.

As referred to above, MLST is a sequence-based typing method that is ideal for tracking certain clones or sequence types (STs) over time and to show common ancestry lineages.

2. L. grimontii is positive; L. richardii is negative.
3. Found in clinical specimens but of questionable or no significance.

Among bacteria (7, 131). MLST has been responsible for identifying certain successful international STs among Klebsiella pneumoniae isolates, i.e. ST16 with CTX-Ms (132) and ST258 with KPCs (133, 134), and neonatal meningitis Cronobacter sakazakii ST4 (55). There are three international open-access databases supporting an increasing range of organisms: http://pubMLST.org, http://www.mlst.net, and http://mlst.warwick.ac.uk/mlst/.

The high resolution obtained with whole-genome sequencing has the ability to rapidly identify single-nucleotide polymorphisms between isolates, and this has made it possible to reconstruct and redefine transmission pathways in outbreak situations (135). Snitkin and colleagues used whole-genome sequencing to gain insight into why an outbreak due to carbapenem-resistant K. pneumoniae progressed despite early implementation of infection control procedures (136). Integrated genomic and epidemiological analysis traced the outbreak to three independent transmissions from a single patient who was discharged 3 weeks before the next case became clinically apparent. They were also able to identify several unexpected transmission routes. It is therefore possible that the integration of genomics and epidemiological data can facilitate the control of nosocomial transmission in a real-time fashion, as can be demonstrated at http://epidemic.bio.ed.ac.uk/. The decreasing costs of next-generation sequencing and the increasing affordability of DNA sequencing equipment have already permitted the investigation of a number of outbreaks at the genome level (e.g., E. coli O104 in Germany and MRSA in the United Kingdom). It is reasonable to expect that this will become a trend in the future.

ANTIMICROBIAL SUSCEPTIBILITY

Increasing resistance in members of the Enterobacteriaceae (Table 13) has culminated in the emergence of pan-resistant strains of K. pneumoniae for which there are no therapeutic options (137, 138). While K. pneumoniae presents the most serious threat, K. oxytoca, S. marcescens, and Enterobacter, Proteus, Morganella, and Citrobacter spp. have all been reported to possess one or more Ambler class β-lactamases. The characteristics of β-lactamases are summarized in Table 13.

Most importantly, within several members of the family Enterobacteriaceae is the increasing recognition of isolates producing newer β-lactamases that consist of plasmid-mediated Amp C β-lactamases, ESBLs, and carbapenemases [e.g., class A (KPC types), class B (e.g., the metallo-β-lactamases [MBLs]), and class D oxacillinases (e.g., OXA-48-like)] (139). Frequently, plasmids encoding these enzymes also carry resistance genes for aminoglycosides, quinolones, and other antimicrobials (140).

The detection of antimicrobial-resistant organisms in laboratories is a critical step required for appropriate management of patients and infection prevention and control efforts. Although their clinical significance and the need to control intra- and interhospital transmission make detection of bacteria with newer β-lactamases important for the clinical laboratory, they are often unrecognized by routine susceptibility testing because of the difficulty in detecting these enzymes and the lack of standard techniques (141, 142). The methods for detection of bacteria that produce newer β-lactamases can be broadly divided into two groups. The first approach consists of phenotypic tests that essentially detect the ability of the enzymes to hydrolyze different cephalosporins and/or carbapenems. Another phenotypic type of approach is to use different inhibitors that inactivate different β-lactamases. Phenotypic methods, in general terms, are cost-effective and easy to perform and therefore have gained popularity among most clinical microbiology laboratories. The second approach consists of genotypic methods that use molecular techniques to detect the genes responsible for the production of the β-lactamases. Molecular methods are more expensive to perform than phenotypic tests and are mostly available in large referral or research laboratories. General antimicrobial susceptibility and specialized phenotypic testing procedures are discussed elsewhere in this Manual (chapters 70 to 72) and by Nordmann and Poirel (142), Patel et al. (143), and Sundin (144, 145).

Laboratory Detection of Enterobacteriaceae That Produce ESBLs

The CLSI in the United States before 2009 had published guidelines for ESBL detection in Enterobacteriaceae specifically for E. coli, Klebsiella spp., and P. mirabilis (127). The guidelines included an initial screening with 4 μg/ml of cefpodoxime (for E. coli and Klebsiella spp.) and 1 μg/ml each of cefpodoxime (for P. mirabilis), cefotaxime, ceftazidime, ceftriaxone, or aztreonam, followed by confirmatory tests using both cefotaxime and ceftazidime in combination with clavulanate (127). Automated systems using similar detection principles have proved to be popular in clinical laboratories, especially those in North America and certain European countries. These include Vitek 2 (bioMérieux, Durham, NC), Phoenix (Becton Dickinson), and MicroScan (Siemens Healthcare Systems, West Sacramento, CA) (146, 147). When ESBL-producing isolates are detected by automated systems, it is generally recommended...

<sup>a</sup>Abbreviations: S, susceptible; I, intermediate; R, resistant; BMD, broth microdilution; TEM, from patient’s name Temoneira; SHV, sulfhydryl reagent variable; CTX-M, active on cefotaxime, isolated in Munich; CMY, active on cephemycins; MOX, active on moxalactam; FOX, active on cefoxitin; DHA, discovered at Dhahran; KPC, *K. pneumoniae* carbapenemase; GES, Guiana-extended spectrum; SME, *S. marcescens* enzyme; IMI, imipenem-hydrolyzing β-lactamase; NMC, not metalloenzyme carbapenemase; IMP, active on meropenem; VIM, Verona integron-encoded MBL; CTX, cefotaxime; CAZ, ceftazidime; CPD, cepodoxime; ETP, ertapenem; MER, meropenem. Data are from references 143, 145, 148, 149, 168, and 180.

Class A and C mediators are serine β-lactamases, and class B mediators are MBLs (named for serine or zinc, respectively, present at the active site involved in hydrolysis of the β-lactam ring).
that they be confirmed using a manual method (144–149). Etest ESBL strips and commercial disks from MAST Group Ltd. (United Kingdom) that contain cefpodoxime with different inhibitors have become available for the detection of Enterobacteriaceae that produce ESBLs and/or AmpC β-lactamases (146). If clinical laboratories adhere to the CLSI published guidelines for detecting ESBLs, these methods will show high sensitivity for detecting these enzymes in E. coli, Klebsiella spp., and P. mirabilis (147, 148). In 2010, the CLSI changed their approach to the detection of ESBLs in E. coli, Klebsiella spp., and P. mirabilis (127). The CLSI now recommends that clinical laboratories report the susceptibilities of the 3rd- and 4th-generation cephalosporins as tested using lower breakpoints and not to edit β-lactams (144, 145). The confirmation of ESBL testing is now optional but may still be useful for epidemiological or infection control purposes.

The phenotypic detection of ESBLs in bacteria other than E. coli, Klebsiella, and P. mirabilis remains a problematic and controversial issue (141, 146, 147). The reason for this is that inhibition of the ESBL by clavulanate might be masked by other types of β-lactamas (e.g., AmpC) produced by bacteria such as Enterobacter spp., Citrobacter spp., and Serratia spp. Unfortunately, most of the tests described are technically demanding and difficult to interpret, and this has limited the widespread utilization of such methods to detect ESBLs in these bacteria. The methods include phenotypic tests that use cefepime with β-lactamase inhibitors (e.g., amoxillin-clavulanic acid), including specific commercial Etests and MAST Group Ltd. disk combinations (143–145, 150, 151).

The molecular method most commonly used to detect ESBLs is the PCR amplification of the TEM and SHV genes, followed by sequencing (152). The situation is different for CTX-M enzymes in that the PCR amplification of CTX-M-specific products without sequencing usually provides sufficient evidence that blaCTX-M genes are responsible for ESBL phenotypes (151). There are also several commercial DNA microarray and real-time PCR methods available for the detection for the different types of ESBLs, including the SHV, TEM, and CTX-M types (152).

The simplest method for direct detection of ESBL-producing Enterobacteriaceae in patient screening samples is the use of selective culture media (e.g., MacConkey and Drigalski agar) supplemented with cefotaxime and/or ceftazidime at different concentrations. Commercially, such media are available as biplates, such as BLSE agar (AES Chemunex, Bruz, France) and ESF ESBL agar (AlphaOmega B.V., The Netherlands) (153). Chromogenic media are the next generation of media and can be considered truly “rapid” culture-based methods, as they combine presumptive ESBL detection with organism identification. Currently available commercial chromogenic media for detection of ESBL producers include chromID ESBL (bioMérieux), Brillance ESBL (Oxoid Ltd., Basingstoke, United Kingdom), and CHROMagar ESBL (CHROMagar, Paris, France) (153) (see also chapter 19). The sensitivity of chromogenic agar for the detection of ESBL-producing bacteria is high, while the specificity depends on which Gram-negative bacteria were used in the evaluation.

Laboratory Detection of Enterobacteriaceae That Produce AmpCs

Enterobacteriaceae with inducible AmpC cephalosporinases, such as Enterobacter spp., Citrobacter freundii, Serratia marcescens, Morganella morganii, and Providencia stuartii, can develop resistance to the oxyimino-cephalosporins (e.g., ceftaxime, ceftriaxone, and ceftazidime) and 7-α-methoxy-cephalosporins (cephamycins, e.g., cefoxitin and cefotetan) and monobactams (e.g., aztreonam) by overproducing their chromosomal AmpC β-lactamase (154). The use of β-lactams in patients infected with these bacteria can result in treatment failure (155). Since these enzymes are present on the chromosomes of the above-mentioned bacteria, their presence is not routinely tested for. The disk approximation tests with cefoxitin and ceftazidime have been successful for detection of Gram-negative bacteria with inducible chromosomal carbapenemases (156).

In Klebsiella spp., Salmonella spp., and P. mirabilis, which lack chromosomal β-lactamases, this type of resistance is usually mediated by plasmid-encoded or imported AmpC β-lactamases (157). Although it has been over a decade since plasmid-mediated AmpC β-lactamases were discovered, most clinical laboratories and physicians remain unaware of their clinical importance (139, 143). The fact that AmpC genes are now plasmid mediated in a variety of Enterobacteriaceae adds to the need for laboratories to recognize AmpC-positive isolates, as they are an even greater risk for transmission within the hospital. Their recognition is also complicated by the fact that reduced susceptibility to cefoxitin, which may be used as a screen for AmpC activity, may reflect a loss of permeability through the outer membrane (158). Incorrect reporting of a strain as AmpC positive may result in the unnecessary use of carbapenems and the concomitant risk of developing resistance to these drugs (158). Nonetheless, intermediate or reduced susceptibility to cefoxitin is still a useful indicator of AmpC presence, signaling the need for further testing (158). There are no published guidelines available from the CLSI for the detection of AmpC β-lactamases in Klebsiella spp., E. coli, P. mirabilis, or Salmonella spp. The best approach would be to screen for resistance to the cephamycins (e.g., cefoxitin and cefotetan) and then to perform inhibitor-based confirmation tests with AmpC inhibitors such as boronic acid (PBA) or cloxacillin (145, 159). An approach that screens for resistance to cefoxitin (>16 μg/ml), followed by disk confirmation tests using cefotetan with the inhibitor PBA, has become popular in certain clinical laboratories (165). Commercial Etest strips for AmpC confirmation have also become available and consist of cefotetan and cefetetan-cloxacillin combinations. MAST Group Ltd. and Rosco Diagnostica released commercial disks and Sensitabs containing cefpodoxime with different inhibitors for the detection of Klebsiella spp., E. coli, P. mirabilis, and Salmonella spp. that produce AmpC β-lactamases. Multiplex and real-time PCR methods have been described and are useful for the detection of the different types of plasmid-mediated AmpC β-lactamases (161, 162). There are also commercial real-time PCR and DNA microarray methods available for the detection of these enzymes.

Unfortunately, not all organisms producing plasmid-mediated AmpC β-lactamases are resistant to the cephamycins, such as cefoxitin. One such enzyme, called ACC-1, originated from the chromosomal cephalosporinase of H. alvei. This enzyme is different from most other plasmid-mediated AmpC β-lactamases in that isolates with this enzyme are sensitive to the cephamycins but show decreased susceptibility to ceftazidime (149). Bacteria with ACC-1 are relatively rare and have mostly been reported from countries such as the United Kingdom, Germany, and France (154). Isolates (i.e., E. coli, Klebsiella spp., and P. mirabilis) that are intermediate to ceftazidime and sensitive to cefoxitin, combined with a negative ESBL confirmatory test, can be
further tested with the cefoxitin double-disk test to confirm the presence of ACC-1 (149).

**Laboratory Detection of Enterobacteriaceae That Produce Carbapenemases**

The acquired carbapenemases that are present among Enterobacteriaceae can be divided into three classes (Table 13). These include the class A (e.g., KPC, SME, IMI, and NMC-A types), class B (MBLs, such as VIM, IPM, and NDM), and class D (oxacillinases, e.g., OXA-48-like) (154, 163). Current recommendations from the CLSI for the detection of Enterobacteriaceae that produce carbapenemases (164) can be summarized as follows:

The carbapenem breakpoints (i.e. 0.5 µg/ml for ertapenem, and 1 µg/ml for meropenem, imipenem, doripenem) for Enterobacteriaceae will detect all clinically important resistance mechanisms (including the majority of carbapenemases). Some isolates that produce carbapenemases are categorized as susceptible with these breakpoints and should be reported as tested, i.e. the presence or absence of a carbapenemase does not in itself influence the categorisation of susceptibility. In many areas, carbapenemase detection and characterisation is recommended or mandatory for infection control purposes.

Several phenotypic confirmation tests have been described for the detection of carbapenemase-producing Enterobacteriaceae. These include bioassays that detect the ability of these enzymes to hydrolyze the carbapenems (e.g., modified Hodge test [MHT]) (128), indirect carbapenemase test (165), and Carba NP test (166) and inhibitor-based methods using metal chelators for MBLs (e.g., MBL Etest) and PBA for KPCs (167, 168). MAST Group Ltd. and Rosco Diagnostica released commercial disks and Sensitabs containing meropenem with different inhibitors for the detection of Enterobacteriaceae that produce carbapenemases (169).

Nordmann and colleagues tested a panel of various carbapenemase-producing Enterobacteriaceae (n = 97) with Carba NP test II (168). This phenotypic test is based on the detection of the acidification resulting from imipenem hydrolysis, combined with tazobactam and EDTA (153). The results suggest that the Carba NP test II is an easy and reliable technique with 100% sensitivity and specificity for detection and identification of carbapenemases among different members of the Enterobacteriaceae (170).

Several in-house multiplex PCR assays have been described that detect the different types of carbapenemases (171). There are also commercial real-time PCR and DNA microarray methods available for the detection of these enzymes in Enterobacteriaceae (152, 172).

Several selective commercial chromogenic media for screening of patients with carbapenem-resistant Enterobacteriaceae have also been introduced into clinical medicine and include chromID CARBA (bioMérieux), CHROMagar KPC (also available as a ready-to-use medium called Colorex KPC), Brilliance CRE (Oxoid), and Hardy CHROM carbapenemase (Hardy Diagnostics, Santa Maria, CA) (see also chapter 19). These CHROMagar media also combine presumptive carbapenem-resistant Enterobacteriaceae or carbapenemase detection with organism identification (153). The sensitivity and specificity of chromogenic agar for the detection of carbapenemase-producing bacteria are high, and several types of specimens (fecal, respiratory tract, urine, and wound) have been evaluated (153). The CDC has also published a procedure to screen for carbapenem-resistant Enterobacteriaceae (173). This consists of broth media (5 ml of Trypticase soy broth with a 10-µg meropenem disk or a 10-µg ertapenem disk). The supplies used for this procedure are readily available in most microbiology laboratories, and the sensitivity compares well to that of chromogenic agar. However, this method is labor-intensive, has lower specificity, and has a slower turnaround time (minimum of 2 days for negative specimens; longer for positive specimens).

Members of the Enterobacteriaceae (e.g., S. marcescens and Enterobacter spp.) can rarely produce chromosomal class A carbapenemases (e.g., SME, IMI-1, and NMC-A) (Table 13). These isolates are more of a curiosity than anything else and are not really considered infection control emergencies (174). However, if clinically indicated (e.g., a possible outbreak in an intensive care unit or ward), isolates should be referred to a reference laboratory for further analysis.

**Resistance in Miscellaneous Enterobacteriaceae**

Isolates of P. mirabilis are resistant to nitrofurantoin but susceptible to trimethoprim-sulfamethoxazole (SXT), ampicillin, amoxicillin, pipercillin, cephalosporins, aminoglycosides, and imipenem. Although most strains are susceptible to ciprofloxacin, resistance occurs with unrestricted use of the drug (175). P. penneri and P. vulgaris have resistance profiles similar to that of Morganella, although P. penneri is more resistant to penicillin than P. vulgaris. All three organisms are susceptible to broad-spectrum cephalosporins, cefotin, cefepime, aztreonam, aminoglycosides, and imipenem. They are resistant to pipercillin, amoxicillin, ampicillin, cefoperazone, cefuroxime, and cefazolin. P. rettgeri and P. stuartii are resistant to gentamicin and tobramycin but susceptible to amikacin. Urine isolates are susceptible to broad- and expanded-spectrum cephalosporins, ciprofloxacin, amoxicillin-clavulanic acid, imipenem, and SXT. Providencia heimbachiae, although infrequently seen in humans, is resistant to tetracycline, most cephalosporins, gentamicin, and amikacin. Human isolates of E. tarda are susceptible to cephalosporins, aminoglycosides, imipenem, ciprofloxacin, aztreonam, and antibiotic-β-lactamase inhibitor combination agents (176). Isolates from fish and pond may be more resistant because of the antibiotics used prophylactically in fish farming. Most strains of E. tarda produce β-lactamases, even though they are susceptible to β-lactams. Shigelloides is resistant to ampicillin, carbenicillin, pipercillin, and ticarcillin and is variably resistant to aminoglycosides and tetracycline (177). Cephalosporins, quinolones, carbapenems, and SXT show good activity against P. shigelloides.

Susceptibility results of uncommonly seen species of Klebsiella, Enterobacter, and Serratia are similar to those of conventional species within these genera (178). Susceptibilities for other Enterobacteriaceae vary from isolate to isolate, so no empirical guidelines are available for therapy prior to susceptibility testing of the suspected strain.

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

When commercial systems identify species included in this chapter with a high level of accuracy (>90% probability), the identification is probably reliable. However, for organisms isolated from sterile sites that are identified with a probability of <90%, the isolate should be confirmed by conventional or molecular methods or sent to a reference laboratory using these techniques. In the interim, the isolate may be reported to the physician with a presumptive identification. Rare species that are identified with low probabilities should always be sent to a reference laboratory accompanied by a brief history.
The clinical laboratory acts as an early warning system, alerting the medical community to new resistance mechanisms present in clinically important bacteria. The detection of antimicrobial-resistant organisms in laboratories is a critical step required for appropriate management of patients and infection prevention and control efforts. An increasing number of patients are infected or colonized with Enterobacteriaceae possessing ESBLs and carbapenemases, and they serve as reservoirs for transmission of these enzymes within and between health care institutions. The ability to recognize these isolates is critical not only for patient care but also to prevent the emergence of panresistant strains.

At the very least, all isolates of K. pneumoniae should be screened for ESBLs and plasmid-mediated AmpC β-lactamases using the CLSI 2013 breakpoints for cefpodoxime, cefotaxime, ceftriaxone, cefazidime, and aztreonam (for ESBLs) and cefoxitin (for AmpC β-lactamases) (164). The CLSI ESBL confirmation tests show a high sensitivity with Klebsiella spp. (165), and ESBL-positive isolates should be reported as resistant to all penicillins, expanded-spectrum cephalosporins, and aztreonam (166).

The presence of carbapenemases (especially KPC and NDM) in Klebsiella spp. and Enterobacter spp. is an infection control emergency, and clinical microbiology laboratories should be able to rapidly detect these enzymes among members of the Enterobacteriaceae. This is a critical step required for appropriate management of patients and infection prevention and control efforts. The initial screening with 0.5 μg/ml of ertapenem and 1 μg/ml of meropenem, imipenem, or doripenem, followed by the phenotypic confirmatory tests, provides a cost-effective approach for the rapid detection of carbapenemases. The MHT, when using meropenem as substrate, is able to reliably detect KPC- and OXA-48-producing isolates (179). Unfortunately, the MHT performs poorly in the detection of MBL-producing isolates (180). The MBL Etest using imipenem as a substrate is often difficult to interpret for detection of Enterobacteriaceae that produce MBLs (170). This is due to the fact that the MICs for imipenem are low. The MAST Group Ltd. and Rosco Diagnostica commercial disks and Sensitabs performed well for the detection of KPCs and NDMs but poorly for VIMs, IMPs, and OXA-48-like enzymes (170). The most accurate methods available for the detection of the different types of carbapenemases are the phenotypic Carba RP tests (142) and several in-house and commercial genotypic tests (173). It is important to remember that the screening process for ESBL- or carbapenemase-producing bacteria in patient specimens essentially looks for cephalosporin- and carbapenem-resistant bacteria, and additional tests are required to confirm the presence of ESBLs or carbapenemases.

Clinical microbiology urgently needs reliable, sensitive, and cost-effective phenotypic methods that will rapidly detect ESBLs, AmpC β-lactamases, and carbapenemases in all Gram-negative bacteria. These tests should also be manageable for all institutions regardless of size and capability.

REFERENCES

The pathogenic *Yersinia* species, *Y. pseudotuberculosis*, *Y. enterocolitica*, and *Y. pestis*, are zoonotic agents that cause disease in humans. Human clinical infections caused by *Y. pseudotuberculosis* and *Y. enterocolitica* occur after the ingestion of contaminated food or water and manifest primarily as mild gastroenteritis, whereas the etiologic agent of plague, *Y. pestis*, is transmitted to humans by the bite of an infected flea and results in life-threatening illness. Within the *Yersinia* genus, these three species are joined by 14 lesser-known *Yersinia* species which are largely considered environmental species and nonpathogenic to humans. Pathogenic *Yersinia* species share a highly conserved virulence plasmid and a chromosomal high-pathogenicity island (HPI) and show tropism for lymphoid tissue, where their ability to evade host innate immunity enables extracellular proliferation. Plague is a notorious disease, with strikingly high mortality rates of 40 to 100% if untreated; it is the cause of three major pandemics, including the Black Death of the 14th century, in which an estimated 17 to 28 million Europeans died. *Y. pestis* was weaponized by the United States, Japan, and the former USSR during and after World War II and remains a high-level biothreat agent (1). In 2012, *Y. pestis* was classified as a tier 1 agent, one of six bacterial agents considered to present the greatest risk of deliberate misuse with the most significant potential for mass casualties or devastating effects to the economy, critical infrastructure, or public confidence (www.gpo.gov/fdsys/pkg/FR-2012-10-05/html/2012-24389.htm).

**TAXONOMY**

*Y. pseudotuberculosis* (previously *Bacillus pseudotuberculosis*, *Bacterium pseudotuberculosis rodentium*, and *Pasteurella pseudotuberculosis*) was the first pathogenic *Yersinia* species described. Isolated by Malassez and Vignal in 1883, the bacterium derives its name from the tuberculosis-like granulomatous abscesses it causes in the spleens and livers of infected animals (2, 3). Alexander Yersin subsequently isolated *Y. pestis* (previously *Bacillus pestis*, *Bacillus pseudomonas*, and *Pasteurella pestis*) from lymph nodes of plague victims during an investigation of a bubonic plague outbreak in Hong Kong in 1894 (4). In 1939, Schleifstein and Coleman described five cultures of *Y. enterocolitica* (previously *Bacterium enterocoliticum*) isolated from the intestines of patients with enteritis and also from facial lesions (2).

By 1944, phenotypic differences of *P. pestis* and *P. pseudotuberculosis* from other Pasteurella species prompted van Loghem to propose transfer of these two bacteria into a new genus, *Yersinia*, in honor of the French bacteriologist Yersin (2). Ten years later, *Yersinia* species were included in the family *Enterobacteriaceae*, and in 1964, *Y. enterocolitica* was added to the genus (5). On the basis of taxonomic studies, the diverse members of *Y. enterocolitica* were subsequently divided into an additional eight species, *Y. intermedia*, *Y. frederiksenii*, *Y. kristensenii*, *Y. aldovae*, *Y. rohdei*, *Y. mollaretii*, *Y. bercevi*, and *Y. alesiaceae*. Similarly, isolates originally identified as *Y. pseudotuberculosis* have been assigned to an additional two species, *Y. pelkani* and *Y. similis*. Other *Yersinia* species include *Y. ruckeri* (serogroup 01, the agent of enteric red meat disease in rainbow trout), *Y. entomophaga*, *Y. massilensis*, and *Y. nurmii* (www.bacterio.net/xz/yersinia.html).

In the last 15 years, whole-genome sequences have been completed and assembled for the following *Yersinia* strains: 12 *Y. pestis* (including the three primary biotypes, orientalis, mediaevalis, and antiqua), 4 *Y. pseudotuberculosis*, and 3 *Y. enterocolitica* strains (http://www.ncbi.nlm.nih.gov/genome/?term=Yersinia). In addition, unassembled genomes for multiple strains of each of these three species are available in GenBank. Genome comparisons indicate that the sizes of completed *Yersinia* genomes range from 4.62 to 4.94 Mb, with G+C contents ranging from 47 to 47.7% (http://www.ncbi.nlm.nih.gov/genome/?term=Yersinia). All *Yersinia* genomes are comprised of a single chromosome; in addition, the pathogenic *Yersinia* genomes also consist of an ~70-kb virulence plasmid (termed pCD1 in *Y. pestis* and pYV in *Y. enterocolitica* and *Y. pseudotuberculosis*) (6). Two additional plasmids (pMT1 and pPla) make up *Y. pestis* genomes, while some *Y. pseudotuberculosis* strains harbor an additional plasmid (2, 7, 8).

Genome analyses reveal that *Y. pestis* is a clone of *Y. pseudotuberculosis* that emerged relatively recently, within the last 1,500 to 20,000 years, but that *Y. entomophaga* and *Y. pseudotuberculosis* diverged within the last 200 million years (9–14). The high degree of genetic similarity (75% of the 3,974 predicted genes in *Y. pseudotuberculosis* show ≥97% identity to homologues in *Y. pestis*) is the reason for *Y. pestis* and *Y. pseudotuberculosis* being previously classified as one species; however, their profoundly distinct pathogenesis mechanisms,
cl, clinical presentations, and modes of transmission warrant their separation into two distinct species (2, 14).

*Y. enterocolitica* is the only *Yersinia* species that has been further subdivided into subspecies. The two subspecies, *Y. enterocolitica* subsp. *enterocolitica* and *Y. enterocolitica* subsp. *paleaectica*, can be distinguished based on their 16S rRNA gene sequences (15).

**DESCRIPTION OF THE AGENTS**

*Yersinia* species, as members of the family *Enterobacteriaceae*, are Gram-negative, non-spore-forming bacilli that exhibit bipolar staining, particularly in primary specimens stained with Giemsa or Wayson’s dye. The bacilli are smaller (0.5 to 0.8 μm in diameter and 1 to 3 μm in length) than other members of their family and tend to grow more slowly as well. Most *Yersinia* species are motile at temperatures less than 30°C due to peritrichous or paripolar flagella (Table 1). Interestingly, the pathogenic *Yersinia* spp. either repress (*Y. pseudotuberculosis* and *Y. enterocolitica*) or, through mutation, have lost the ability to express (*Y. pestis*) the flagellar apparatus in the mammalian host; by either mechanism, they effectively avoid stimulation of innate immune responses (16).

*Yersinia* species are facultative anaerobes that grow at temperatures ranging from 4 to 43°C. *Yersinia* species ferment glucose (with the production of acid but no gas), are catalase-positive and oxidase-negative, and display nonfastidious growth. Most strains grow on MacConkey, blood, and chocolate agars but may be outcompeted by other bacteria in clinical specimens from nonsterile sites or sources and especially from environmental samples (see Isolation Procedures below), as *Yersinia* species grow more slowly than most *Enterobacteriaceae*. *Yersinia* species exhibit poor growth in liquid media and do not form a turbid suspension (17).

The cell walls of *Yersinia* species are very similar to those of other members of the *Enterobacteriaceae* family, and lipopolysaccharide (LPS) is a major component of their outer membrane (18). The LPS of *Y. pseudotuberculosis* and *Y. enterocolitica* (smooth forms) is complete (lipid A–oligosaccharide core–0-antigen polysaccharide), and O-chain variation within these species has enabled serodiscrimination of close to 100 O groups (17–19). In contrast, through inactivation of the O-antigen gene cluster and the pagP gene, as well as loss of the Ipfx gene, *Y. pestis* produces a rough-type LPS, which is limited to a short carbohydrate chain bound to lipid A (20).

Virulence genes, their environment-dependent expression control, and the complex mechanisms of their product action and coordination, which enable immune system evasion and disease progression, have been actively investigated and described. Comparison of orthologous genes between *Y. enterocolitica* (strain 8081), *Y. pestis* (strain CO92), and *Y. pseudotuberculosis* (strain IP32953) identified a shared core set of 2,747 coding sequences, as well as a number of coding sequences unique to *Y. enterocolitica* (~29%), *Y. pseudotuberculosis* (~9%), or *Y. pestis* (~11%) (13, 14). In comparison to *Y. pseudotuberculosis* and *Y. enterocolitica*, *Y. pestis* contains a larger number of pseudogenes, genes that were inactivated because they were not needed by this species, which does not survive outside insect or mammalian hosts (14, 21).

A key feature of *Y. pestis*, *Y. pseudotuberculosis*, and *Y. enterocolitica* biogroup 1B is the ability to scavenge iron from the host by a siderophore called yersiniabactin (Ybt) (13, 22, 23). The ybt genes are chromosomally located and clustered on an HPI located in a 102-kb chromosomal region termed the pgm (pigmentation) locus. Other chromosomal virulence genes include yst, encoding a heat-stable toxin unique to enteropathogenic *Y. enterocolitica* strains and absent in *Y. pseudotuberculosis*, and invA, an epithelial cell adhesion gene common to *Y. enterocolitica* and *Y. pseudotuberculosis* (3, 21). Invasin facilitates efficient binding to intestinal mucosal cells and translocation from the lumen to Peyer’s patches; an insertion element within the invA gene of *Y. pestis* renders it dysfunctional (3).

The pathogenic *Yersinia* species possess a common and genetically conserved 68- to 75-kb virulence plasmid (termed pCD1 in *Y. pestis* and pYY in *Y. enterocolitica* and *Y. pseudotuberculosis*). This plasmid carries the low-calcium response genes, components of the type 3 secretion system (TTSS), V antigen, and the associated effectors or *Yersinia* outer membrane proteins (Yops) (24–26). The TTSS forms a needle structure on the surfaces of pathogenic *Yersinia* species, with V antigen at the tip, and interacts with target cells (macrophages, dendritic cells, and granulocytes/neutrophils) to enable injection of Yops, which effectively interfere with phagocytosis and other innate host cell responses as well as the adaptive inflammatory cascade, ultimately resulting in target cell apoptosis (27, 28). YadA is also encoded on the *Yersinia* virulence plasmid. In *Y. enterocolitica* and *Y. pseudotuberculosis*, this adhesion protein facilitates pathogen binding to M cells of the intestinal mucosa, signal-induced internalization, and subsequent translocation to the Peyer’s patches and mesenteric lymph nodes (3). *Y. pestis* YadA is inactivated by point mutation through a base deletion resulting in a frameshift and a truncated product (3).

Two *Y. pestis* unique plasmids (~110 and 10 kb) encode proteins important for the organism’s utilization of a flea vector and its ability to cause acute disease in infected mammals. The 110-kb plasmid (pMT1) encodes the murine toxin (Ymt) and the fraction 1 antigen (F1) (7, 24). Ymt, expressed only at temperatures below those of mammalian systems, is a phospholipase whose activity is necessary for pathogen survival within the harsh environment of the flea digestive tract during blood meal digestion (29). In contrast to Ymt, F1 is expressed only at temperatures >33°C and during mammalian infection. F1 forms a capsule-like structure on the bacterial surface with antiphagocytic properties that enable dissemination and replication of the bacteria (7). Plasminogen activator (Pla), encoded by the 10-kb plasmid, is a surface protease that activates mammalian plasminogen and degrades complement; it is essential for dissemination after subcutaneous or intradermal inoculation (experimental proxies for flea bite transmission) in mouse models of bubonic disease (7, 24).

Whole-genome shotgun sequencing of eight nonpathogenic *Yersinia* species, *Y. aldovae*, *Y. bercoyeri*, *Y. frederiksenii*, *Y. kristensenii*, *Y. intermedii*, *Y. mollaretii*, *Y. rohdei*, and *Y. ruckeri*, identified no orthologs of genes found in the virulence-associated plasmids pYY, pMT1, and pPla or in the HPI of pathogenic *Yersinia*. Only 16 additional clusters of chromosomal proteins were found to be absent from all eight nonpathogens and common to pathogenic *Yersinia* species (*Y. pestis*, *Y. enterocolitica*, and *Y. pseudotuberculosis*). Acquisition of mobile elements therefore appears to be the defining feature of *Yersinia* spp. virulent for humans (6).

**EPIDEMIOLOGY AND TRANSMISSION**

Plague is an acute, often fatal disease caused by *Y. pestis*. It exists in natural enzootic cycles between wild rodents and...

their fleas. The most common mode of transmission to humans is by the bite of infected fleas. Less frequently, infection is the result of handling infected animals, directly contacting infectious body fluids or tissues, or inhaling infectious respiratory droplets. Most cases of human plague are sporadic and occur in rural areas. Epidemics occur occasionally when the disease spreads from wild rodents into populations of rats (genus Rattus) that live near human populations. Human risk is greatest when epizootics cause high mortality in these commensal rat populations, thereby forcing fleas to seek alternate hosts, including humans. Although many different species of fleas parasitize rodents and can transmit infection to them, transmission of plague is classically associated with the rat flea (Xenopsylla cheopis) (8). Y. pestis can survive and multiply in the midgut (stomach) and proventriculus (a valve that connects the esophagus to the midgut) of the flea (30, 31). Bacterial replication results in blockage of the proventriculus, which causes the flea to starve and triggers the infected flea to bite hosts in repeated attempts to acquire a blood meal, thereby increasing chances for disease transmission (30, 31).

Between 2004 and 2009, 12,503 human cases and 843 deaths were reported from 16 different countries (32). Of these cases, 97.6% were reported from Africa, 1.2% from Asia, and 1.1% from the Americas (32). In the United States between 1900 and 2010, 999 plague cases were reported. In recent decades, on average 7 human plague cases have been reported each year in the United States (range, 1 to 17 cases per year), with 50% of cases occurring in people ages 12 to 45 years (www.cdc.gov/plague). Plague occurs in rural and semirural areas of the western United States and has been found in wild animal populations in all of the 17 contiguous states west of the 100th meridian. More than 80% of human cases occur in New Mexico, Arizona, and Colorado, and approximately 10% occur in California (33–35).

Domestic dogs and cats may serve as carriers of Y. pestis-infected fleas into human dwellings. A study in New Mexico found that plague victims were significantly more likely than controls to have allowed pets to sleep on their beds (36). Cats are also highly susceptible to plague, acquiring infection by flea bite or ingestion of infected rodents, and develop all of the clinical forms of disease, including pneumonic plague. Infected cats serve as direct sources of human infection via aerosol transmission of organisms, leading to primary pneumonic plague, or via inoculation of organisms through scratches or bites (34). Dogs are most often resistant to clinical infection and develop antibody titers upon exposure.

Hunting in areas where plague is endemic is associated with human infections; transmission may occur during skinning and handling of animals or ingestion of undercooked meat. Although many animal species are susceptible to plague infection and thus pose a risk factor associated with hunting, documented cases of transmission in the United States are most frequently associated with rabbits, squirrels, prairie dogs, and pet cats (37).

Human-to-human transmission can occur with the pneumonic form of disease and therefore poses a special public health threat (38). Most transmissions are to unprotected, untrained family members and health care providers through close-contact inhalation of particles from infected persons who are coughing bloody sputum. In over 60 separate cases of pneumonic plague in the United States since 1924, there have been no human-to-human transmissions (1). Analysis of primary pneumonic cases in the United States indicates that the majority of cases fail to transmit, even in the absence of antimicrobial treatment or prophylaxis (39), consistent with the fact that outbreaks during the preantibiotic era were controlled quickly and effectively with routine measures. Nevertheless, the potential for sustained outbreaks exists due to superspreading events. Control measures included social distancing, isolation, quarantine, and simple barrier precautions (39).

Y. enterocolitica is a heterogeneous species with worldwide distribution and both pathogenic (human and animal) and nonpathogenic members (2). Incidence is higher in temperate and cold countries. Organisms are found in the gastrointestinal tracts of many animal species, most commonly swine, rodents, and dogs. Food products, particularly unpasteurized milk and raw and undercooked meats, have been found to contain these organisms. Transmission occurs primarily via the fecal-oral route; organisms are ingested via food or water contaminated by feces of infected animals. The species is divided into six biogroups—1A, 1B, 2, 3, 4, and 5—that are biochemically differentiated (Table 2) (40, 41). Group 1A (which lacks the 68- to 75-kb pYV virulence plasmid) is considered nonpathogenic, groups 2 through 5 (which lack the chromosomal HPI) are weakly pathogenic in mice, and group 1B (with pYV and the HPI) is highly pathogenic and lethal to mice (42). Y. enterocolitica bioserotypes most often associated with human illness are 1B/O:8, 2/O:5, 27, 2/O:9, 3/O:3, and 4/O:3, with bioserotype 4/O:3 now predominating as the most common type in the United States and Europe (43). Group 1B is generally restricted to North America and Japan, whereas group 3 is predominantly isolated in Japan and China (43). Serogroup typing, based on reactivity to O-antigen polysaccharides, has also been developed, and over 70 serotypes are characterized (44). Bioserotypes have been shown to be geographically focused, and only a small subset is associated with disease in animals or humans (43).

Y. pseudotuberculosis is found in the environment (soil and water) and in a diverse group of wild and domesticated animal species. The organism has a wide distribution in countries with cold climates; it is most common in northern Europe and Asia, including Japan. Y. pseudotuberculosis is not frequently isolated in the United States; FoodNet reported that the average annual incidence of Y. pseudotuberculosis infections was only 0.04 case per 1,000,000 persons from 1996 to 2007 (45). Y. pseudotuberculosis serotypes associated with human illness include O:1 and O:3, frequently isolated in Europe, and O:4 and O:5, isolated in Japan (43). The main reservoirs for the organism are rodents, rabbits, and wild birds. The mode of transmission of Y. pseudotuberculosis is via ingestion of contaminated food (vegetables and meat) or water contaminated by animal reservoirs or via contact with infected animals.

**CLINICAL SIGNIFICANCE**

Plague, one of nine quarantinable diseases in the United States, is a severe febrile illness and, without prompt and appropriate antibiotic treatment, is often fatal. There are three major forms of plague: bubonic, septicemic, and pneumonic (1). Bubonic plague, the most common clinical presentation, accounts for 80 to 90% of cases and is due to the bite of an infected flea (35). After a 2- to 6-day incubation period, a sudden onset of fever, headache, chills, and weakness and one or more swollen, tender, and painful lymph nodes (buboes) occur. The case fatality rate for untreated bubonic plague is 50 to 60% (35). Septicemic plague occurs when the organisms are introduced directly into the bloodstream without localizing in regional lymph nodes or
when the bacteria are directly introduced into the bloodstream via a cut or wound. Patients develop fever, chills, extreme weakness, abdominal pain, shock, and possibly bleeding into the skin and other organs. This form of the disease is rapidly fatal. Septicemic plague can also occur secondarily to bubonic plague that is not treated.

Pneumonic plague can be a secondary complication of bubonic or septicemic plague or can be the primary infection following direct inhalation of aerosolized organisms. After an incubation period of 1 to 3 days, symptoms include fever, headache, weakness, and a rapidly developing pneumonia with shortness of breath, chest pain, cough, and sometimes bloody or watery mucus (1). The pneumonia may cause respiratory failure and shock. Pneumonic plague is the most serious form of the disease and is the only form that can be spread from person to person (by infectious droplets).

In the preantibiotic era (1900 through 1941), mortality among those infected with all forms of plague in the United States was 66%. Antibiotics greatly reduced mortality, and by 1990 to 2010, overall mortality had decreased to 11% (http://www.cdc.gov/plague/faq/index.html). Plague can still be fatal despite effective antibiotics, though the risk of death is lower for bubonic plague cases than for septicemic or pneumonic plague cases. Mortality among untreated pneumonic cases is essentially 100%, and even among treated cases, mortality often exceeds 50%. In the United States between 1947 and 1977, approximately 50% of primary septicemic cases were fatal (35). It is hard to assess the mortality rate of plague in developing countries, as relatively few cases are reliably diagnosed and reported to health authorities. The WHO cites a global mortality rate of 6.7% for the time period of 2004 to 2009; however, mortality is likely higher in some areas where plague is endemic (32).

The most common form of disease due to *Y. pseudotuberculosis* is gastroenteritis associated with consumption of contaminated food or water. It is not unusual to isolate *Y. pseudotuberculosis* from raw meats, including beef, lamb, pork, and chicken. The organism has also been found as a contaminant of cooked, prepackaged deli meat and unpasteurized milk products. The majority of strains isolated from human food sources are of the nonpathogenic serotypes. carriage of the pathogenic serotypes of *Y. enterocolitica* is more common in swine; therefore, consumption of raw or undercooked pork, such as chitterlings, is the main risk factor for gastroenteritis (46–48). Severity of disease is related to the serotype and can range from self-limited gastroenteritis to terminal ileitis and mesenteric lymphadenitis, often misdiagnosed as appendicitis (49). Young children most commonly develop gastroenteritis and present with fever, watery diarrhea (occasionally bloody and severe), and abdominal pain following consumption of food contaminated by *Y. pseudotuberculosis*. Although symptoms typically resolve within approximately 7 days, patients can carry the organism in their gastrointestinal tracts for as long as several months. Organisms can migrate out of the gut via the lymphatics into local lymph nodes. An uncommon complication of gastroenteritis is septicemia. Persons at high risk for septicemia include the elderly and immunocompromised patients, particularly those with underlying metabolic diseases that are associated with iron overload, cancer, liver disease, and steroid therapy.

The production of urease allows *Y. enterocolitica* to survive in the stomach and colonize the small intestine of the human host. Pathogenic strains produce a heat-stable enterotoxin, Yst, as well as Yop effectors that enable them to resist the normal phagocytic and complement killing process that takes place in Peyer’s patches (13, 14). *Y. enterocolitica* is considered to be a common cause of transfusion-related infections due to contaminated red blood cells. Since the organism is able to survive and multiply at refrigeration temperatures, donated blood contaminated with small numbers of organisms from an asymptomatic person can transmit infection to the transfused patient (50, 51). Reactive arthritis is an uncommon sequela of diarrhea due to *Y. pseudotuberculosis* (49). Patients at increased risk include those who are carriers of the HLA-B27 allele and those with immunologic disorders. Symptoms appear several days to months after the onset of diarrhea and may persist for months. Other less common diseases associated with *Y. enterocolitica* infection include inflammatory bowel disease, most commonly associated with serotype O:3 (52), and autoimmune thyroid disorders, such as Graves’ disease and Hashimoto’s thyroiditis (53). Both *Y. enterocolitica* and *Y. pseudotuberculosis* have been isolated from patients with Crohn’s disease, although a causal relationship has not been proven (54).

*Y. pseudotuberculosis* usually produces a self-limiting disease, particularly in children and young adults. Rarely, *Y. pseudotuberculosis* can cause mesenteric lymphadenitis and terminal ileitis which clinically mimics appendicitis and septicemia and generally occurs in immunocompromised patients (diabetics and those with liver cirrhosis or iron overload) (55, 56). Long-term sequelae of *Y. pseudotuberculosis* infection include erythema nodosum, Reiter’s syndrome, and nephritis. *Y. pseudotuberculosis* has also been implicated in outbreaks of gastroenteritis/pseudoappendicitis associated with consumption of contaminated lettuce.

and carrots (57–59). In addition to causing gastrointestinal illness, *Y. pseudotuberculosis* is the causative agent of Far East scarlet-like fever in Japan and Russia (60, 61).

The lack of classic virulence markers, i.e., the 70-kb virulence plasmid and the HPI, in the other *Yersinia* species (Table 1) has led to their general classification as nonpathogenic. Nonetheless, several of them (Y. intermedius, Y. frederiksenii, and Y. kristensenii) have been isolated from stool specimens of up to 20% of diarrhea patients for whom etiologic agents were not determined (62). Possible predisposing correlates of infection include corticosteroid, acid suppressant, and antibiotic use and an immunocompromised host status (62, 63).

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

In the United States, *Y. pestis* is classified as a tier 1 select agent. To receive or possess *Y. pestis* strains, laboratories must be registered with the federal Select Agent Program (www.selectagents.gov). Clinical laboratories are exempt from the registration requirement of the Select Agent Program as pertains to conducting diagnostic testing for select agents. Diagnostic testing for select agents may be performed by clinical laboratories as long as the laboratory destroys or transfers any confirmed select agent within 7 days of identification. Laboratories identifying an organism as *Y. pestis* are required to report this finding immediately; laboratories need to complete form 4 and submit it to the Select Agent Program. If the organism is to be transferred following identification, then the laboratory must also complete form 2 and obtain transfer approval from the Select Agent Program. Select agent report forms, contact information, laboratory registration information, and pertinent citations of the U.S. Federal Code may be found at www.selectagents.gov.

All procedures for *Y. pestis* should be done in a facility with a biosafety level of at least 2 (BSL-2), and clinical laboratories should be aware of the sentinel-level clinical microbiology laboratory guidelines as outlined by the American Society for Microbiology (64; www.asm.org/index.php/issues/sentinel-laboratory-guidelines). All patient specimens should be handled in a BSL-2 facility; technicians should wear gloves and gowns and work in a biosafety cabinet (BSC). Subcultures should be performed in a class II BSC. Due to the severity of disease caused by *Y. pestis*, processes which increase the risk of creating an aerosol, such as liquid culture manipulation, should be performed under BSL-3 conditions. *Y. pestis* is a documented laboratory hazard. Laboratory-acquired cases of plague, several of which have been fatal, have been reported in the United States (39, 65, 66).

*Y. pestis* strains lacking either the *pgm* locus (a 102-kb chromosome region encoding yersiniabactin iron transport, the Hms biofilm, and other systems) or the 60- to 85-kb virulence plasmid (which encodes the TTSS and its effector Yop proteins) are exempt from select agent regulations in the United States (www.selectagents.gov) and can be handled under BSL-2 conditions. It is important to note, however, that *pgm* mutants of *Y. pestis* are still capable of causing disease, and in 2009, a fatal laboratory-acquired infection by an attenuated *pgm* mutant *Y. pestis* strain was described (66). *Y. pestis* strains lacking the virulence plasmid are considered avirulent (67).

For *Y. pestis*, preferred specimens for laboratory diagnosis are dependent on the clinical presentation; lymph node aspirates and blood are recommended in bubonic presentation, blood for septicemia presentation, and respiratory samples (e.g., sputum) and blood for pneumonic presentation. As bubonic plague patients may shed organisms into the blood intermittently, obtaining multiple sets of blood cultures over a 24-h period can increase the sensitivity of detection from this sample source.

Cary-Blair medium and swabs offer an excellent means of transport for the preservation of viable organisms if samples cannot be cultured immediately. Tissue samples from autopsy specimens, lymph node, spleen, liver, and lung can be utilized for testing. For animals suspected of having died from *Y. pestis*, blood remnants or tissue specimens can be collected for testing. Acute- and convalescent-phase sera can be collected from animals and humans to test for antibody to *Y. pestis*. Specimens should be sent to the laboratory immediately, and if a delay in transit of more than 2 h is expected, the sample should be transported at 2 to 8°C. Sera may be stored at 2 to 8°C for up to 14 days. If testing is delayed for a longer period, serum samples may be frozen.

The appropriate specimens for culture of *Y. enterocolitica* and *Y. pseudotuberculosis* as well as other *Yersinia* species are stool, blood, or lymph nodes, depending on the disease form suspected. If food is suspected as the source of an outbreak, the local health department should be involved in the processing of such specimens. Maintain food at 4°C, and transport it as soon as possible. Swabs should be transported to the laboratory at 4°C in Cary-Blair, Amies, or Stuart’s medium. Stool specimens can also be placed in transport media and should be maintained at 4°C if transport is expected to take longer than 2 to 4 h. Enrichment broths for recovery of *Y. enterocolitica* from surface waters have been evaluated, but the ability to recover clinically important strains from this source is uncertain (68).

**DIRECT EXAMINATION**

**Microscopy**

*Yersinia* species are small (1 to 2 μm by 0.5 μm) Gram-negative bacilli that appear either as single cells when slides are prepared from agar plates or as pairs or short chains when slides are prepared from liquid medium. Although not normally performed in the microbiology laboratory, Wright, Giemsa, or Wayson staining of peripheral blood or tissue may reveal the bipolar staining characteristics of *Y. pestis* (Fig. 1A) (www.asm.org/index.php/issues/sentinel-laboratory-guidelines). Bipolar staining, however, is not a unique feature of *Yersinia* species and may not always be evident.

A rapid and specific staining method for the detection of *Y. pestis* in specimens includes the use of a fluorescently labeled antibody (available from the CDC) to the capsular F1 antigen (69). Cultures, lesions, tissues (lymph node, liver, spleen, and lung) or aspirates may be rapidly assessed by this approach (Fig. 1B). As the F1 antigen is expressed only on infected cells, lymph node aspirates or lesions should be quickly processed to prevent loss of antigenicity (71). This antigen detection approach has been modified to a lateral-flow dipstick assay and successfully used under field conditions to diagnose plague infections in humans and

**DIRECT EXAMINATION**

**Microscopy**

*Yersinia* species are small (1 to 2 μm by 0.5 μm) Gram-negative bacilli that appear either as single cells when slides are prepared from agar plates or as pairs or short chains when slides are prepared from liquid medium. Although not normally performed in the microbiology laboratory, Wright, Giemsa, or Wayson staining of peripheral blood or tissue may reveal the bipolar staining characteristics of *Y. pestis* (Fig. 1A) (www.asm.org/index.php/issues/sentinel-laboratory-guidelines). Bipolar staining, however, is not a unique feature of *Yersinia* species and may not always be evident.

A rapid and specific staining method for the detection of *Y. pestis* in specimens includes the use of a fluorescently labeled antibody (available from the CDC) to the capsular F1 antigen (69). Cultures, lesions, tissues (lymph node, liver, spleen, and lung) or aspirates may be rapidly assessed by this approach (Fig. 1B). As the F1 antigen is expressed only at temperatures above 33°C, this staining procedure cannot be performed on environmental samples (fleas, food, etc.) or cultures that have been maintained at <33°C. Tissue biopsy specimens fixed in formalin can also be tested via an immunohistochemical (IHC) stain that utilizes a monoclonal antibody to the F1 capsular antigen of *Y. pestis* (70).

**Antigen Detection**

A capture enzyme-linked immunosorbent assay for detection of *Y. pestis* F1 antigen in bubo aspirates and serum shows high sensitivity (100% with buboes and 90% with sera; limit of detection, 4 ng/ml) and specificity (approximately 99%) (71). This antigen detection approach has been modified to a lateral-flow dipstick assay and successfully used under field conditions to diagnose plague infections in humans and
animals in Madagascar (72). F1 antigen capture-based immunochromatographic dipsticks, namely, *Yersinia pestis* (F1) Smart II test strips and Plague BioThreat Alert test strips, are commercially available in the United States and have been analyzed using purified F1 antigen, *Y. pestis* organisms, and whole-blood samples from mice experimentally infected with *Y. pestis* (73). To date, neither of these tests is FDA cleared for use in diagnosing plague in patients or for the identification of *Y. pestis* isolates.

**Nucleic Acid Detection**

PCR assays for the direct detection of *Yersinia* nucleic acids in patient specimens have been developed to increase diagnostic sensitivity. For *Y. pestis*, most real-time PCR assays are directed against the plasminogen activator gene (*pla*) or *cafl* gene, which encodes the F1 antigen; both targets are located on high-copy-number *Y. pestis*-specific plasmids. Of note, a *pla* gene with high homology to the *Y. pestis pla* gene (98.8% similarity) was identified in rats, suggesting that if PCR assays targeting the *pla* gene are used for diagnosis of plague, they should not be used as stand-alone assays (74). To date, validation of *Y. pestis* PCR assays using human clinical samples is limited. Real-time (5′ nuclease) PCR assays directed against both *cafl* and *pla* were tested using lymph node aspirates from plague patients, and diagnostic sensitivity was found to be higher than for both culture and an F1 antigen immunochromatographic test (75). Real-time PCR assays for diagnosis of plague are available in LRR reference laboratories in the United States.

Genome sequencing of *Y. pestis* and *Y. pseudotuberculosis* has allowed the identification of unique chromosomal genes in *Y. pestis* that allow for development of *Y. pestis*-specific PCR assays targeting chromosomal regions (11, 12). A multiplex real-time PCR assay for identification of *Y. pestis* and *Y. pseudotuberculosis* has been developed based on the *Y. pestis* chromosomal gene spo2088, the plasmid gene *pla*, and the w27 gene, common to both *Y. pestis* and *Y. pseudotuberculosis* (76). Due to the high degree of genetic relatedness between *Y. pestis* and *Y. pseudotuberculosis*, 16S rRNA PCR and sequencing cannot distinguish these two species; their 16S rRNA sequences are essentially identical (77).

PCR has also been used as a sensitive method to detect small numbers of *Y. enterocolitica* in foodstuff (78), as well as in stored red blood cells to prevent transfusion reactions (79). Use of multiplex PCR assays containing primer sets for the detection of up to five different virulence genes allows for the distinction between pathogenic and nonpathogenic serotypes and specifically identifies the presence of *Y. enterocolitica* serotype O:3 (78, 80). PCR methods have also been developed for identification of *Y. pseudotuberculosis* from *Y. enterocolitica* and include O genotyping as well as virulence typing (78, 80).

**ISOLATION PROCEDURES**

*Yersinia* species grow on most routine media, including blood, chocolate, and MacConkey agars incubated at 25 and 35°C for 24 to 48 h in ambient air. Incubation of *Y. pseudotuberculosis* on *Y. enterocolitica* cultures at 25°C is recommended due to the instability of the virulence plasmid at higher temperatures. Eosin-methylene blue, xylose-lysine-deoxycholate agar, and Hektoen enteric agar incubated at room temperature. Growth of many strains of *Y. pseudotuberculosis* is preferred for isolation. *Yersinia* species grow more slowly than most *Enterobacteriaceae*, selective medium is recommended for culturing *Yersinia* species from nonsterile sites. There are various selective media for the recovery of *Y. enterocolitica*, including cefsulodin-Irgasan-novobiocin (CIN) agar, which inhibits the growth of many other *Enterobacteriaceae*, CHROMagar *Yersinia*, and salmonella-shigella deoxycholate calcium chloride agar (81, 82). CIN agar has been found to provide better rates of recovery of *Yersinia* than either MacConkey or salmonella-shigella agar incubated at room temperature. Growth of many strains of *Y. pseudotuberculosis* can be inhibited on CIN agar, and therefore MacConkey agar is preferred for isolation. The use of pectin agar has also been described for the isolation of *Y. enterocolitica* from stool and for its differentiation from other *Enterobacteriaceae*. Although this medium was more sensitive than other currently used selective media and inhibitory to other enterics except *Klebsiella oxytoca* (which demonstrates a similar colony morphology), the medium is currently not commercially available (83). CHROMagar *Yersinia* has been shown to be as sensitive as CIN agar for the recovery of *Yersinia* and more specific for the isolation of pathogenic *Y. enterocolitica*, which may be useful for direct isolation of pathogenic strains from stool (82). However, as with CIN agar, *Y. pseudotuberculosis* can be inhibited on CHROMagar, and therefore MacConkey agar is preferred for isolation.

Recovery of *Y. enterocolitica* from food is more difficult than recovery from human clinical specimens, and samples are usually referred to a public health laboratory. Food must be enriched with saline (or a selective broth, such as modified Rappaport broth [MRB], containing magnesium chloride,
malachite green, and carbenicillin) at cold temperatures for approximately 21 days (2 to 4 days in MRB) (84).

On sheep blood agar incubated at 25°C, well-isolated single colonies of Y. enterocolitica and Y. pseudotuberculosis are about 0.5 to 1.0 mm and 3 to 4 mm in size after 24 and 72 h of growth, respectively (Fig. 2). Y. enterocolitica colonies have a bull’s-eye appearance, i.e., a red center on CIN agar. Other members of the Enterobacteriaceae family which grow on CIN agar, such as Serratia, Morganella, and Citrobacter species, produce colonies similar in appearance to those of Y. enterocolitica but larger.

Y. pestis can be isolated from sterile specimens (blood and lymph node aspirates) on sheep blood agar (SBA). Although Y. pestis grows faster at 28°C, this may not be readily observable in clinical laboratories. On agar plates, Y. pestis colonies are typically the same size at 28°C as at 37°C (or only slightly larger). Therefore, it is recommended that technicians in clinical laboratories look only for isolates that grow at both temperatures (28°C and 37°C) as opposed to looking for better growth at 28°C. For isolation of Y. pestis from nonsterile sources, including sputum samples, CIN agar should be used, as Y. pestis will rapidly be outcompeted by the growth of other organisms. CIN agar plates should be incubated at 25 to 28°C, which also aids in the isolation of Y. pestis, as the growth of other bacteria will be slowed at the lower temperature. Y. pestis will grow in blood culture bottles; whole blood should be directly inoculated into blood culture bottles, with subsequent culture of blood culture-positive specimens on agar. Cultures from suspected plague patients should be incubated for 5 to 7 days.

Well-isolated Y. pestis colonies are gray-white to opaque and ∼1 to 1.5 mm in diameter, with irregular edges, after 48 h of incubation on SBA and 3 to 4 mm in size after 72 h of incubation (Fig. 2). No hemolysis is seen on blood agar. Viewed with a dissecting microscope, the colonies are raised and have irregular edges, with a “hammered copper” appearance. After 48 to 72 h, a fried-egg appearance is observed, with the center of the colonies being more opaque (Fig. 2). Y. pestis grows more slowly on MacConkey agar than on SBA, and colonies are only pinpoint in size as well as colorless (non-lactose fermenters) after 48 h of growth. On CIN agar, Y. pestis colonies have a red center. The growth of Y. pestis is slowed on CIN agar compared to on SBA. Organisms growing in broth appear in clumps along the side of the tube in flocculent or stalactite-like formations if the tube is not shaken. After 24 h of incubation, the clumps settle to the bottom of the tube.

**FIGURE** 2  Y. enterocolitica (A) and Y. pseudotuberculosis (B) were grown on sheep blood agar at 25°C for 72 h, and Y. pestis was grown on sheep blood agar at 28°C for 72 h (C). doi:10.1128/9781555817381.ch39.f2

**IDENTIFICATION**

Yersinia species are catalase positive and oxidase negative and ferment glucose, as do all other members of the family Enterobacteriaceae. Y. enterocolitica and Y. pseudotuberculosis can be presumptively identified by reactions on triple sugar iron (TSI) and lysine iron agar slants. Y. enterocolitica produces a yellow color in the entire TSI tube without gas production, and Y. pseudotuberculosis, like Shigella, produces an alkaline slant and an acid butt. Both species are lysine decarboxylase negative and therefore produce a yellow butt in lysine iron agar slants. Yersinia species are included in the databases of some automated biochemical identification systems; however, most databases were established with only a few Yersinia isolates tested. Automated systems may not adequately identify Yersinia species due in part to their slow growth and biochemical inactivity. API 20E was shown to have the highest sensitivity and specificity for the identification of Y. enterocolitica and Y. pseudotuberculosis (85, 86).

Identification of suspected Y. pestis in clinical laboratories is based on the identification of small Gram-negative bacilli (0.5 by 1 to 2 μm), which are catalase positive and oxidase and urease negative, and display the following growth characteristics after 48 h: 1 to 1.5 mm gray-white irregular colonies on blood agar after growth at both 28°C and 37°C and
non-lactose-fermenting, pinpoint colonies on MacConkey agar. See the Sentinel Level Clinical Microbiology Laboratory Guidelines (64) on the American Society for Microbiology website (http://clinmicro.asm.org/index.php/bench-work-resources/guidelines/sentinel-guidelines) for Y. pestis-specific information, pictures, and flow charts. If isolates with the above-named Y. pestis characteristics are identified, clinical laboratories should notify the local public health laboratory and immediately refer the isolate for confirmatory testing. Rapid diagnosis and treatment are essential to reduce mortality associated with Y. pestis infection.

Automated biochemical systems are not recommended for the identification of Y. pestis due to its slow growth and the limited Y. pestis databases available with many of these systems. In 2010 to 2011, the misidentification of two Y. pestis human isolates by multiple automated systems was described (87). The two isolates were tested at several different commercial laboratories and misidentified by multiple automated systems; misidentifications included Acinetobacter baumannii by the MicroScan test, Pseudomonas luteola and Y. pseudotuberculosis by the Vitek-2 test, and Y. pseudotuberculosis by the Phoenix test. As a result, the isolates were not correctly identified until 2 to 4 weeks after the patients presented with illness (87). Data are currently unavailable in the literature with respect to the accuracy of the Biolog Microbial ID system in a clinical laboratory setting.

Because of the limitations in accurately identifying Y. pestis isolates by automated biochemical identification systems in clinical laboratories, a high level of suspicion by clinical microbiologists is essential for accurate and timely diagnosis of plague. Potential indications of misidentification by automated systems include a low probability or confidence value and/or an identification of a pathogen by automated systems in clinical laboratories, a high level of suspicion by clinical microbiologists is essential for accurate and timely diagnosis of plague. Potential indications of misidentification by automated systems include a low probability or confidence value and/or an identification of a pathogen inconsistent with the clinical or microbiology picture. Results from automated identification systems should be analyzed critically in the clinical laboratory, taking into consideration the reliability of these systems for accurate identification of slow-growing and/or rare organisms (87).

Isolates can be identified as Y. pestis in reference laboratories via specific bacteriophage lysis as well as molecular and antigen detection methods, including PCR, sequencing and direct fluorescent-antibody assay (DFA) (Fig. 1B). Bacteriophage lysis is the confirmatory method for identifying Y. pestis isolates in the United States; reagents and testing are available in LNR reference laboratories. 16S rRNA sequencing should not be used as the sole diagnostc test to identify Y. pestis isolates due to our inability to distinguish Y. pestis from Y. pseudotuberculosis.

Y. enterocolitica and Y. pseudotuberculosis can most easily be differentiated from Y. pestis by urease activity (highly positive at 25°C; positive at 37°C) and motility (25°C); Y. pestis is negative for both of these characteristics (Table 1). Because of the risk for aerosol exposure to Y. pestis, the slide motility test is not recommended; motility agar should be utilized to distinguish enteropathogenic Yersinia from Y. pestis. Y. enterocolitica can be differentiated from other Yersinia species since it typically does not utilize citrate or pyrazinamidase (except in 1A strains), and it does not ferment sucrose, trehalose, xylitol, or rhamnose; however, it does ferment rhamnose (Table 1). Y. pseudotuberculosis may be differentiated from other Yersinia species (non-Y. pestis) by a negative ornithine decarboxylase test. Identification of other Yersinia species can be performed by biochemical analysis (Table 1) (40, 88).

A number of methods other than the more traditionally based culture techniques have shown potential for the future identification of Yersinia species, but to date, commercially available instruments and existing databases in clinical laboratory settings for the identification of Y. enterocolitica, Y. pseudotuberculosis, and Y. pestis have not been evaluated. These methods include matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) mass spectrometry (MS) (MALDI Biotype system; Bruker) and fatty acid analysis (Sherlock Microbial ID system; MIDI, Inc.) (89, 90–92). Both methods are attractive for two reasons: identification is rapid, and the cost is low (<$1 U.S./identification). As with other identification systems, a limitation is that they require a database of well-characterized reference strains to avoid misidentifications. Additionally, as Y. pestis and Y. pseudotuberculosis strains are quite similar in major cellular fatty acids, fatty acid methyl ester (FAME) analysis cannot differentiate by simply comparing fatty acid profiles. A recent study, however, has shown that Y. pestis can be differentiated from Y. pseudotuberculosis by plotting the ratios of 14:0/18:0 versus 18:1ω7c/18:0, 3-OH-14:0/18:0 versus 18:1ω7c/18:0, 12:0/18:0 versus 18:1ω7c/18:0, and 12:0 ALDE/18:0 versus 16:0ω7c/18:0 fatty acids (92).

A culture-independent multiplex bead-based assay, xTAG gastrointestinal pathogen panel (Luminex Corporation), has been developed to identify the most common gastrointestinal pathogens directly from stool, including Yersinia enterocolitica (93). Only a few isolates were included in the evaluation; thus, the ability of this assay to accurately identify Yersinia enterocolitica isolates (including all pathogenic biotypes) in a clinical laboratory setting is unknown. In the future, it is likely that many other culture-independent methods will be developed in order to reduce the cost and turnaround time and improve the quality of patient care; however, there are important implications to consider with respect to preserving cultures (94, 95). Culture provides conclusive diagnosis of infection and is invaluable for public health surveillance systems, including PulseNet. Cultures are also essential for identifying and characterizing new or emerging species, monitoring antimicrobial resistance, and investigating outbreaks. It is therefore important that we continue to retain the valuable information gained from cultures as we shift into the era of culture-independent diagnostics.

**Typing Systems**

Once isolates have been identified as Yersinia spp., biochemical, serological, and molecular typing methods can be used to further differentiate within a given Yersinia species; typing is particularly useful for epidemiologic analyses to assess the pathogenesis and geographic distribution of different strains. Y. enterocolitica has six biogroups, 1A, 1B, 2, 3, 4, and 5, which can be differentiated based on reactivity to esculin, indole, d-xylene, trehalose, pyrazinamidase, β-D-glucosidase, and lipase. Although the issue is controversial, biogroup 1A is thought to be nonpathogenic, whereas biotypes 1B and 2 through 5 are pathogenic. Strains belonging to biotype 1A can be differentiated from the others by salcin and pyrazinamidase positivity (Table 2) (96). Serotyping may also help to determine the pathogenicity of the isolate, since only a small number of the >70 known serotypes are pathogenic; however, antisera are not readily available. Serotyping of pathogenic Y. enterocolitica may be performed at the CDC (Atlanta, GA) upon request. Other methods that have been evaluated to determine the pathogenicity of Y. enterocolitica are based on the presence of the virulence plasmid and include autoagglutination, calcium-dependent growth at 37°C, and pigmentation on Congo red. Selective media containing
Congo red as well as PCR assays have been evaluated for differentiating virulent from avirulent strains but are currently being used only in research laboratories (79).

Three classic biotypes (orientalis, mediaevalis, and antiqua) of Y. pestis have been defined based on differences in the strains' abilities to ferment glycerol and reduce nitrate. Although these three biotypes have historical significance and display differing geographic distributions, all appear to cause virtually identical signs and symptoms in humans; thus, biotyping is not clinically significant for Y. pestis. In the Americas, only the orientalis biotype (glycerol negative, nitrate positive) occurs. Whole-genome sequencing of Y. pestis strains to identify single nucleotide polymorphisms and screening of global isolates have defined a Y. pestis phylogenetic tree containing four distinct branches (97, 98).

For distinguishing individual strains within Yersinia spp., molecular typing methods, including pulsed-field gel electrophoresis (PFGE) and multilocus variable-number tandem-repeat analysis (MLVA), have been used. PFGE was found to be a more useful tool than ribotyping for typing of pathogenic isolates of Y. enterocolitica (78). A PFGE method for typing of Y. pestis isolates is available through the CDC PulseNet website and has been used in case investigations to epidemiologically link isolates and identify the source of human infections (70). Similarly, MLVA has also been used on Y. pestis strains to identify the source of human plague infections (99).

**SEROLOGIC TESTS**

Serology can play a role in the diagnosis of plague, particularly when a culture is not recovered or for retrospective diagnosis or epidemiologic studies in areas where plague is endemic. Most patients infected with Y. pestis seroconvert 1 to 2 weeks following the onset of symptoms. The most commonly used antigen in serologic assays for Y. pestis is the capsular F1 antigen, which is specific for Y. pestis, highly immunogenic, and produced in large amounts during mammalian infections. Studies have shown a persistence of anti-F1 antibodies in plague patients; antibody to F1 was shown in 88% and 69.5% of patients infected within the previous 5 and 10 years, respectively (100). Serologic methods include passive hemagglutination, which can be used to test both human and animal samples. A 4-fold rise in serum antibody titer to F1 antigen between acute- and convalescent-phase serum samples is confirmatory for plague. Reagents for passive hemagglutination are available only in some reference laboratories. Commercial reagents for the serodiagnosis of plague are not available or FDA approved in the United States.

Serology can be used as an adjunct in the diagnosis of disease due to Y. enterocolitica or Y. pseudotuberculosis. Antibody is detectable within the first week of illness and returns to normal levels 3 to 6 months later. The specificities of serologic assays range from 82 to 95% due to cross-reactivity between the two species and also with Brucella and Vibrio species, as well as Borrelia burgdorferi, Chlamydia pneumoniae, and some Escherichia coli serogroups. Another disadvantage of using serology for diagnosis is that antibodies to Y. enterocolitica O antigens are often found in healthy subjects due to the frequency of exposure to nonpathogenic serotypes.

Antibody to Yops that are present only in virulent strains of Y. enterocolitica may be more helpful. In a small study of healthy blood donors, immunoglobulin M (IgM) antibody to Yops was 97% specific for acute infection (101). Testing of blood donors for anti-Yop IgA in New Zealand, where a high incidence of Y. enterocolitica gastroenteritis is reported, showed promise in preventing transfusion-related infections (102). The presence of IgG and IgA antibodies to Y. enterocolitica Yops is also used as an aid in the diagnosis of autoimmune disorders that occur postinfection, such as rheumatic arthritis, erythema nodosum, Graves' disease, and Hashimoto's thyroiditis (53). IgM-, IgA-, and IgG-specific antibody reactivity against Yops in Western immunoblot formats has been correlated with clinical presentation and sequelae (103).

**ANTIMICROBIAL SUSCEPTIBILITIES**

Due to the severity of illness caused by Y. pestis, antimicrobial treatment is essential and should be initiated as soon as plague is suspected to ensure the highest chance of recovery. Streptomycin, gentamicin, tetracyclines, and levofloxacin are FDA approved for the treatment of plague. Chloramphenicol is recommended for the treatment of plague meningitis. Treatment guidance is available on the CDC website (http://www.cdc.gov/plague/healthcare/clinicians.html). Antimicrobial susceptibility testing of Y. pestis is not performed in clinical microbiology laboratories because of safety concerns in working with this organism and because resistance to antibiotics used for clinical treatment of plague has only very rarely been reported. The Clinical and Laboratory Standards Institute (www.clsi.org) has published interpretive criteria and quality control limits for broth microdilution testing of Y. pestis using Mueller-Hinton medium (104).

Antibiotic resistance among isolates of Y. pestis has never been documented in the United States and only very rarely elsewhere (105). No resistance was observed in 392 Y. pestis isolates from 17 countries (214 were from the United States and isolated from 1971 to 2009) against eight antimicrobials (gentamicin, streptomycin, tetracycline, doxycycline, ciprofloxacin, levofloxacin, chloramphenicol, and trimethoprim-sulfamethoxazole) used for treatment or prophylaxis of plague (105). Treatment failure due to antibiotic resistance in Y. pestis has also never been documented. An analysis of Y. pestis isolates from 10 fatal plague cases where patients had been treated with gentamicin, tetracycline, chloramphenicol, doxycycline, or streptomycin demonstrated no resistance to these antimicrobials (105). An isolate of Y. pestis from a 1995 plague case in Madagascar was found to be multidrug resistant, with resistance to streptomycin, sulfonamides, tetracycline, and chloramphenicol conferred by a multidrug resistance plasmid (106). Routine susceptibility testing of patient isolates in this region of endemicity has failed to identify any further evidence of multidrug resistance during the last 18 years (105–107). These surveillance data are consistent with the lack of a selective advantage for Y. pestis to acquire and maintain multidrug resistance plasmids in natural cycles.

Most cases of Y. enterocolitica gastroenteritis do not require treatment; however, treatment is necessary in cases of systemic disease, especially in immunosuppressed patients. Treatment options include trimethoprim-sulfamethoxazole and a fluoroquinolone. Y. enterocolitica produces two different β-lactamases, one of which is a class A constitutive enzyme and the other of which is an inducible class C enzyme that is not inhibited by β-lactamase inhibitors. The presence of one or both of these enzymes varies depending on the biogroup (108). Although the β-lactamase confers resistance to penicillin on Y. enterocolitica, the organism remains uniformly susceptible to the extended-spectrum cephalosporins (109). Resistance to fluoroquinolones is due to either a mutation in
the gyRA gene or efflux mechanisms. In a study conducted in Spain, 23% of Y. enterocolitica strains isolated from patients with gastroenteritis were nalidixic acid resistant. All resistant isolates had a mutation in gyRA, and some were resistant based on an efflux mechanism as well (108). Y. enterocolitica strains are susceptible in vitro to aminoglycosides, chloramphenicol, tetracycline, trimethoprim-sulfamethoxazole, and extended-spectrum cephalosporins.

Y. pseudotuberculosis is susceptible to ampicillin, tetracycline, chloramphenicol, cephalosporins, and aminoglycosides. Although self-limiting infections due to Y. pseudotuberculosis are not usually treated, patients with septicaemia should be treated with ampicillin, streptomycin, or tetracycline. Y. aldovae and Y. ruckeri are also susceptible to penicillin. Y. frederiksenii, Y. intermedia, and Y. rohdei produce a β-lactamase similar to that of Y. enterocolitica, which is expressed at different levels in different strains (10).

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

Isolation of a small Gram-negative bacillus (0.5 by 1 to 2 μm) that grows slowly at both 28°C and 37°C on blood agar (pinpoint, gray-white colonies after 24 h) and that is a non-lactose fermenter on MacConkey agar (pinpoint colonies after 48 h), oxidase negative, catalase positive, and urease negative should be strongly suspected of being Y. pestis and immediately referred to a reference laboratory. A positive test result for a primary clinical specimen via detection of F1 antigen, DFA, or IHC staining provides only a presumptive diagnosis of Y. pestis. A single positive serum sample is also considered presumptive for plague. Confirmation of Y. pestis infection includes (i) identification of a culture as Y. pestis and/or (ii) a 4-fold difference in serum antibody titers to Y. pestis F1 antigen in acute- and convalescent-phase serum samples. Isolation of Y. pestis from any human specimen is clinically significant and warrants further investigation. The sources most likely to yield Y. pestis are respiratory specimens, bubo (lymph node) aspirate, and blood. Due to the lack of accuracy of commercial systems for the identification of Y. pestis, the potential use of Y. pestis as a bioweapon, and the seriousness of the disease, all suspected Y. pestis isolates should be sent to a local public health laboratory for confirmation.

In the United States, plague is a nationally notifiable disease, and Y. pestis is also classified as a tier 1 select agent. Laboratories identifying an organism as Y. pestis are required to report this finding immediately; laboratories need to complete form 4 and submit it to the Select Agent Program. Report forms, contact information, laboratory registration information, and pertinent citations of the U.S. Federal Code may be found at [http://www.selectagents.gov](http://www.selectagents.gov).

Isolation of Y. enterocolitica or Y. pseudotuberculosis from stool culture is not sufficient for causal evidence of disease, since nonpathogenic serotypes may be normal stool biota. However, no readily available methods except those using routine biochemicals, which are not usually maintained in routine clinical laboratories, are available for differentiation of pathogenic serotypes. Isolation of either species in pure culture from a symptomatic patient with no other diagnosis should be considered suspect. Isolation of either species from blood or other normally sterile sites should be considered significant. Reporting of enteropathogenic Yersinia is not nationally notifiable, so the actual incidence of disease may be underreported.

It has not been shown to be cost-effective to screen all stools for Y. enterocolitica by using CIN agar. Isolation rates vary based on geographic locations, with the highest incidence in temperate regions, so the decision to routinely rule out these organisms in stool cultures should be evaluated in individual laboratories after consultation with the infectious disease physicians.

Although the Yersinia species besides Y. pestis, Y. enterocolitica, and Y. pseudotuberculosis are not considered human pathogens, they have been isolated from the gastrointestinal tracts of symptomatic patients with no other diagnosis. It has been recommended that the presence of these Yersinia species in pure culture be reported. These organisms may be underrecognized pathogens (62).

Aeromonas*

AMY J. HORNEMAN

TAXONOMY

The genus Aeromonas resides within the family Aeromonadaceae (1) and the newly proposed order Aeromonadales, ord. nov., along with the genera Oceanomonas and Tolomomas (2). Aeromonas is the only one of these three genera that is pathogenic for humans. The use of frequent reclassifications and constant amended or extended descriptions within Aeromonas taxonomy can often be initially puzzling to microbiologists not working with these organisms on a daily basis. However, information in this chapter should clarify the identification and significance of those species most often associated with human disease (Table 1). DNA hybridization group numbers, which no longer serve a meaningful purpose, and synonymous species designations for Aeromonas veronii bv. sobria (Aeromonas ichthiophia) and Aeromonas trota (Aeromonas enteropelogenes) (3) are not included for simplicity. Likewise, Aeromonas sp. DNA hybridization group 11, which is made up of Aeromonas eucrenophila/Aeromonas enecheleia-like organisms, is not addressed (4). Aeromonas culicicola, a species proposed in 2002 and isolated from mosquitoes, has subsequently been shown to be a later subjective synonym of Aeromonas veronii (5).

Newly proposed Aeromonas species and subspecies since the publication of the previous edition of this Manual include Aeromonas diversa, sp. nov., isolated from wounds (6); Aeromonas flavialis, sp. nov., isolated from a Spanish river (7); Aeromonas tainwanensis, sp. nov., and Aeromonas sanarela, sp. nov., both isolated from wounds (8); Aeromonas viridis, sp. nov., isolated from a karst water rivulet (9); Aeromonas cavernica, sp. nov., isolated from fresh water of a brook in a cavern (10); and Aeromonas australiensis, sp. nov., isolated from Australian irrigation water (11). The past controversy surrounding the proposal of Aeromonas aquariorum in 2008, which is purported to be both phenotypically and genetically identical to Aeromonas hydrophila subsp. dhakensis (first proposed in 2002), has been resolved. The original first author of the 2008 paper on Aeromonas aquariorum, sp. nov., recently coauthored a formal synonymization of A. aquariorum and A. hydrophila subsp. dhakensis with a concomitant reclassification of both as A. dhakensis, sp. nov., comb. nov. (12). This is significant, since there are numerous references in the clinical literature to this “arabinose-negative” A. hydrophila-like group of organisms being associated with serious wound infections, sepsis, and diarrhea and being misidentified as A. hydrophila (13–15).

Clinically significant strains formerly referred to as Aeromonas sobria are, in fact, Aeromonas veronii bv. sobria (esculin hydrolysis and ornithine decarboxylase negative and arginine dihydrolase positive) and should be reported as such. Nearly all rapid identification databases, excepting API 20E strips (bioMérieux, Inc., Durham, NC), have converted their A. sobria identifications to A. veronii bv. sobria. This is especially important because of A. veronii bv. sobria’s association with more-severe, extraintestinal infections, such as septicemia, meningitis following leech therapy, and disseminated intravascular gas production (16,17). It usually is not necessary to definitively separate members of the A. hydrophila complex (A. hydrophila, A. dhakensis, sp. nov., comb. nov., Aeromonas bestiarum, and Aeromonas salmonicida) or the Aeromonas caviae complex (A. caviae, Aeromonas media, and Aeromonas eucrenophila), especially when they are isolated from feces (see “Evaluation, Interpretation, and Reporting of Results” below).

The type strain Aeromonas hydrophila subsp. hydrophila ATCC 7966 was the first aeromonad to be completely sequenced, annotated, published, and deposited in GenBank (as accession number CP000462) (18). This was followed by the complete genome sequence of Aeromonas salmonicida subsp. salmonicida A449, an agent of furunculosis (a bacterial septicemia of salmonid fish), which was deposited in GenBank as accession number NC 00938 (19). Additional species whose genome sequences have been deposited in GenBank include A. veronii, A. caviae, and A. aurorium (now reclassified as A. dhakensis, sp. nov., comb. nov.).

DESCRIPTION OF THE GENUS

Members of the genus Aeromonas are Gram-negative facultative anaerobic species, which are straight, cocccobacillary to bacillary cells with rounded ends (0.3 to 1.0 μm in diameter and 1.0 to 3.5 μm in length). They can occur singly, in pairs, or, rarely, in short chains. Most species are motile by a single, polar flagellum with a 1.7-μm wavelength, but peritrichous flagella may be formed on solid media in young cultures, and lateral flagella occur in some species. Aeromonads are usually oxidase positive and catalase positive and are generally resistant to 150 μg of the vibriostatic agent 2,4-diamino-6,7-disopro-

*This chapter contains information presented in chapter 38 by Amy J. Horneman and Afsar Ali in the 10th edition of this Manual.

**EPIDEMIOLOGY AND TRANSMISSION**

Aeromonads are inhabitants of aquatic ecosystems, such as groundwater, reservoirs, and clean or polluted lakes and rivers, worldwide. *Aeromonas* may also be found in marine environments but only in brackish water or water with a low saline content. Most *Aeromonas* species, particularly those associated with human infections, are found in a wide variety of fresh produce, meat (beef, poultry, and pork), and dairy products (raw milk and ice cream) (20). *A. veronii* bv. sobria is a symbiont in the gut of medicinal leeches, where it may grow as a pure culture (21). Infections in frogs, pigs, cattle, birds, and marine animals have also been reported (20).

Most clinical infections with aeromonads are related to an exposure to some type of aquatic source, whether the clinical specimen is feces or extraintestinal, and, to a lesser extent, to the ingestion of foods. The majority of studies have found a seasonal relationship between the recovery of aeromonads from specimens and the warmer months of...
the year (22). This is not surprising, since the optimal temperatures for the growth of mesophilic aeromonads are those occurring in the warmer months. This therefore increases the likelihood of recreational human exposure to these bacteria, thereby resulting in an increased risk of colonization and/or infections with these indigenous aquatic microorganisms.

Since Aeromonas is not a reportable condition in the United States or in most other countries, the true incidence of Aeromonas infections worldwide is not known. Estimates from England/Wales and the United States for septicemia with aeromonads in 2004 revealed an incidence of 1.5 per million population (23). However, any estimates of incidence would most likely be an underestimation, particularly as relates to exposure through drinking water. A large 2010 study of the distribution of virulence factors and molecular fingerprinting of 227 Aeromonas isolates from water and clinical samples provided strong evidence of water-to-human transmission (24).

**CLINICAL SIGNIFICANCE**

Aeromonas gastroenteritis ranges from an acute watery diarrhea (most common form) to dysenteric illness to chronic illness. Stools from acute watery diarrhea are loose (take the shape of their container), and erythrocytes and fecal leukocytes are absent. Accompanying symptoms include abdominal pain (60 to 70% of patients), fever and vomiting (20 to 40%), and nausea (40%) (25). Infections are usually self-limiting, but children may require hospitalization due to dehydration. A. caviae is the most common species associated with these infections, and A. caviae infection can even mimic inflammatory bowel disease in children (26). A. veronii bv. sobria strains may be associated with rare cholera-like disease characterized by abdominal pain (60%) and fever and nausea (20%) (20). In cases of dysenteric diarrhea resembling shigellosis, patients suffer from severe abdominal pain and have bloody stools containing mucus and polymorphonuclear leukocytes. About 10 to 15% of patients with either cholera-like or dysenteric diarrhea are coinfected with another enteric pathogen(s).

A comprehensive Bangladesh study found that the presence of loose stools or severe watery diarrhea was associated with Aeromonas strains possessing an alt gene (for a heat-labile cytotoxic enterotoxin) alone or both alt and ast (for a heat-stable cytotoxic enterotoxin), respectively (27). A large traveler's diarrhea study in Spain found the predominant species to be A. veronii bv. veronii and A. caviae (28).

A third large study in India found seven different species among hospitalized patients with diarrhea, with A. caviae predominating, followed by A. hydrophila and A. veronii bv. sobria, along with the presence of the alt and ast genes as well as the act gene, which encodes a well-established cytotoxic enterotoxin often present in clinical aeromonad isolates (29).

Finally, in a large acute diarrheal outbreak in Brazil that involved 2,170 cases, Aeromonas was the species that was recovered in 19.5% of those cases (30). Although most diarrheal cases are generally self-limited, a combination of supportive therapy and antimicrobials is often indicated in the pediatric, immunocompromised, and immunocompromised populations (25). A 2007 article gives a nice summary of the latest data and theories related to the association of Aeromonas with diarrhea (31).

Complications from Aeromonas diarrheal disease include hemolytic-uremic syndrome (31, 32) and kidney disease requiring kidney transplantation (34). These more severe infections are usually associated with A. hydrophila or A. veronii bv. sobria. Also, nonresolvable, intermittent diarrhea can occur months after the initial infection and may persist for months or several years.

Aeromonas can also be isolated from a variety of extraintestinal sites, although blood and wounds are the most common sources. Aeromonas septicemia occurs rarely in immunocompetent hosts; most cases are in patients with liver disease and hematological malignancies and can be accompanied by necrotizing fasciitis (35, 36). However, a 2011 report describes three cases of bacteremia in pregnant women at the Thailand/Myanmar border (37).

The species more commonly isolated from patients with septicaemia are A. hydrophila, A. veronii bv. sobria, and Aeromonas jandaei. Wound infections are usually preceded by traumatic injury that occurs in contact with water, where the predominant species are A. hydrophila subsp. hydrophila and, now, A. dhakensis sp. nov., comb. nov. (formerly A. aquariorum). These infections range from uncomplicated cases of cellulitis to myonecrotic infections with a poor prognosis (38, 39). Two such scenarios are the reported outbreaks of wound infections with A. hydrophila associated with mud football (40) and wound infections among both the 2004 Asian tsunami survivors (41) and the 2005 Hurricane Katrina survivors in New Orleans, LA (42). Surveys indicate that only 17 to 52% of Aeromonas wound infections are monomicrobial (25). Use of medicinal leeches postoperatively to enhance blood flow to surgical sites has resulted in wound infection rates of 20%, primarily with A. veronii bv. sobria (21, 43). Most alarming are three recent reports of ciprofloxacin-resistant Aeromonas strains in patients after receiving leech therapy (44–46).

Other extraintestinal infections include ocular, respiratory, surgical, and urinary tract infections, meningitis, osteomyelitis, cholecystitis, pneumonia, endocarditis, peritonitis, portal pyemia, pancreatic abscess, and spa bath folliculitis (47–55). A few such examples were the isolation of A. caviae from a patient with keratitis associated with contact lens wear (56) and isolation of A. caviae and A. popoffii from separate cases of urinary tract infection (57, 58). A very recent case of serious cellulitis in a polymicrobial leg wound infection involved two different strains of A. hydrophila with different virulence patterns and antimicrobial resistance profiles, and the authors proposed an A. hydrophila wound pathotype based on comparative genomic and functional analyses of virulence genes (59).

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

Aeromonads survive well in specimens, and any of the widely used transport media are acceptable for transport (Amies, Cary-Blair, modiﬁed Stae’s), and buffered glycerol in saline), with Cary-Blair generally considered to be the best (see chapter 18). Feces are always preferable to rectal swabs for isolation of enteric pathogens, and stools should be collected in the acute phase of disease. Most strains grow equally well at room temperature (20 to 25°C) and incubator temperature (35 to 37°C). Because isolates being kept for long-term storage do not survive well at room or refrigerator temperature in the laboratory for long periods (>1 month), placing aeromonads in media, such as Trypticase soy broth with 30% glycerol, and deep-freezing them at −80°C is recommended for their long-term storage.

**DIRECT EXAMINATION**

The direct microscopic examination of wound or skin/superficial specimens or positive blood culture specimens is
somewhat unremarkable in that aeromonads appear as straight, Gram-negative bacilli, with or without the presence of white cells, which is not unlike the presentation of a similar infection with either enterics or pseudomonads. Although various DNA probe and multiplex PCR methods have been described for the possible identification of aeromonads (specifically, identification of genes for enterotoxins) from either water, food, or a veterinary source (60), there are no widely recognized antigen detection and/or nucleic acid detection methods available for accurate species identification from clinical specimens.

**ISOLATION PROCEDURES**

Aeromonads generally grow well on a variety of enteric differential and selective agars, although sucrose- and/or lactose-fermenting strains usually resemble nonpathogens on these media. Blood agar with 20 μg of ampicillin per ml had previously been considered useful for isolating all Aeromonas species; however, a substantial percentage (15 to 57%) of A. caviae isolates are resistant to ampicillin, and certain species, like A. trota, are intrinsically susceptible to ampicillin (61, 62). In fact, a recent environmental sampling study to detect aeromonads showed that when ampicillin is used as a selective agent, a significant portion (17.3%) of the aeromonad population, in at least some environments, cannot be isolated using such media (63). Therefore, laboratories should use caution when medium with ampicillin is used in the setup of stool specimens for detecting the presence of all clinically relevant aeromonad species as bacterial enteropathogens.

Modified cefsulodin-irgasan-novobiocin (CIN) (4 μg of cefsulodin per ml, versus 15 μg/ml in unmodified CIN) is also an excellent isolation medium for aeromonads. On this medium, Aeromonas colonies have a pink center with an uneven, clear apron and are indistinguishable from A. caviae isolates resistant to ampicillin, and certain species, like A. trota, are intrinsically susceptible to ampicillin (61, 62). In fact, a recent environmental sampling study to detect aeromonads showed that when ampicillin is used as a selective agent, a significant portion (17.3%) of the aeromonad population, in at least some environments, cannot be isolated using such media (63). Therefore, laboratories should use caution when medium with ampicillin is used in the setup of stool specimens for detecting the presence of all clinically relevant aeromonad species as bacterial enteropathogens.

Modified cefsulodin-irgasan-novobiocin (CIN) (4 μg of cefsulodin per ml, versus 15 μg/ml in unmodified CIN) is also an excellent isolation medium for aeromonads. On this medium, Aeromonas colonies have a pink center with an uneven, clear apron and are indistinguishable from Yersinía enterocolitica morphologically. One can incubate CIN at 25°C to enhance the recovery of Yersinia cells and still be able to recover Aeromonas within 24 h at this temperature.

Aeromonas agar, available from Lab-M (http://www.labm.com), is a relatively new alternative medium to CIN agar that uses β-xylene (which aeromonads do not ferment) as a differential characteristic (64).

Since most clinically relevant species are beta-hemolytic, including an increasing number of A. caviae strains, beta-hemolytic colonies on blood agar should be screened with oxidase and a spot indole test. Any colonies positive by both tests should be characterized further, although occasional indole-negative A. caviae strains do occur, and nearly all known Aeromonas schuberti isolates (which are generally associated with severe aquatic wounds) are indole negative (65). Thiosulfate-citrate-bile salts-sucrose medium is usually inhibitory to aeromonads. Enrichment in alkaline peptone water enhances the recovery of Aeromonas spp. from populations that are generally expected to shed low numbers of organisms (carriers, convalescent-phase patients, and those with subclinical infections). For patients with acute diarrhea, enrichment is probably unnecessary (66).

**IDENTIFICATION**

Aeromonas spp. are most easily confused in the laboratory with other oxidase-positive fermenters, i.e., Vibrio and Plesiomonas spp. Plesiomonas is easily differentiated from Aeromonas by positive reactions in Moeller’s lysine, ornithine, and arginine tests and by fermentation of m-inositol. Vibrios may be more difficult to distinguish from aeromonads (67), which is particularly true for Vibrio fluvialis and A. caviae, and in laboratories where the sole means of identification is a rapid miniaturized system (68, 69). Resistance to an O/129 vibriostatic agent (150 μg), string test negativity (with 0.5% sodium deoxycholate), and the inability to grow in salt concentrations of >6% usually indicate the genus Aeromonas. Vibrio cholerae O139, a cholera toxin-positive, non-salt-requiring, O/129 vibriostatic-agent-resistant vibrio, is a major exception to this rule. However, the decarboxylase pattern (positive for lysine and ornithine), a negative reaction for arginine dihydrodase, no production of gas from glucose, and no fermentation of salicin separate this organism from most aeromonads. Unfortunately, strains of ornithine decarboxylase-positive A. veronii bv. veronii will often yield an excellent to very good identification for V. cholerae with the rapid identification API-20-E strip (bioMérieux, Inc.), and serotyping and/or additional testing is required to resolve the issue. A. veronii bv. veronii is string test negative, O/129 resistant, and able to produce gas from glucose fermentation, does not require additional salt for growth, and is inhibited on thiosulfate-citrate-bile salts-sucrose agar. V. cholerae strains have the opposite reactions. Once it has been determined that you have a glucose-fermenting, oxidase-positive, motile Gram-negative rod that is resistant to O/129, a small number of biochemical tests can be used for separating Aeromonas species into the three major species complexes (Table 2). If warranted, even more discriminatory results for separating members of each complex can be found in bold text in Table 3 (65), which should

<sup>a</sup>Data were compiled from Tables 2, 6, 7, and 8 in reference 65 and reprinted with permission. +, ≥85% of the strains positive; −, <15% positive; V, 15 to 85% positive (results at 48 h). Numbers in parentheses indicate percentages of strains positive for the test at the final day of reading, which for gluconate was 2 days; D-lactate and urocanic acid, 3 days; citrate, 4 days; carbohydrates, indole, and lipase, 7 days; pyrazinamidase (PZA), 2 days; Amp<sup>r</sup> positive (results at 48 h). Numbers in parentheses indicate percentages of strains positive for the test at the final day of reading, which for gluconate was 2 days; D-lactate and urocanic acid, 3 days; citrate, 4 days; carbohydrates, indole, and lipase, 7 days; pyrazinamidase (PZA), 2 days; Amp<sup>r</sup> (resistance to 10 μg of ampicillin), 1 day; Voges-Proskauer, 3 days. ND, not done. For each of the three Aeromonas species complexes, the discriminatory reactions between the species within each complex are presented in bold type.

<sup>b</sup>Aeromonas dhakensis, sp. nov., comb. nov. (formerly A. aquaticum/A. hydrophila subsp. dhakensis) is considered to have positive reactions in the esculin, Voges-Proskauer, and glucose (gas) tests but negative reactions for utilization of L-arabinose and L-fucose, negative fermentation of L-arabinose, and positive utilization of urocanic acid (96).

<sup>c</sup>Biavar sobria (DNA hybridization group 8). The separation of A. veronii bv. veronii (DNA hybridization group 10) from A. veronii bv. sobria is achieved with A. veronii bv. veronii having positive reactions for ornithine decarboxylase and esculin hydrolysis and a negative reaction for arginine dihydrolase.

Other Identification Methods

Both the sequencing of a single housekeeping gene, the 16S rRNA gene (73), and the development of an extended method using 16S ribosomal DNA (restriction fragment length polymorphism) analysis (74) were initially promising as methods to identify aeromonads to the species level. However, data on the intragenomic heterogeneity within the 16S rRNA gene in Aeromonas strains suggest caution in using this single gene for anything beyond genus-level identification (75). Therefore, the use of other housekeeping genes as multiple molecular markers, such as gyrB and rpoD (76), dnaJ (77), and cmr60 (78), or an even broader approach like multilocus (seven gene loci) phylogenetic analysis (MLPA), appears to be a credible avenue for accurate species identification (79). Extensive studies by Chopra et al. have delineated several DNA probes for the detection of a number of possible virulence-related factors. This was the result of the public release of the *Aeromonas hydrophila* ATCC 7966<sup>1</sup> genome sequence and comparative work with the diarrheal *A. hydrophila* strain SSU (80). These include, but are not limited to, the discovery of a new hemolysin and the presence of a functional type VI secretion system, a cold shock exoribonuclease R (VacB), and a surface-associated enolase.

One promising new method of species identification is matrix-assisted laser desorption ionization–time of flight (MALDI-TOF), which was first described for *Aeromonas* species identification in 2007 (81), with further validation in 2011 (82), and resulted in a 2012 rapid MALDI-TOF mass spectrometry (MS) *Aeromonas* database for clinical and environmental isolates (83).

**SEREOLOGIC TESTS**

Most serologic assays that have been used to detect antibodies to *Aeromonas* (tube agglutination, immunoblotting, and enzyme-linked immunosassay) have low sensitivity and specificity and are not considered reliable.
ANTIMICROBIAL SUSCEPTIBILITIES

Two of the earliest articles on Aeromonas antimicrobial susceptibilities (84, 85) included only strains well characterized to the species level and expanded previously known susceptibility information on aeromonads isolated less frequently from clinical specimens. A general antimicrobial susceptibility profile for Aeromonas derived from both of these investigations as well as other studies (20, 86, 87) is given in Table 4. There are Clinical and Laboratory Standards Institute (CLSI) testing guidelines for the major clinical Aeromonas species that relate to antimicrobial dilution and disk susceptibility testing in document M45-A2 for infrequently isolated or fastidious bacteria (88).

Ciprofloxacin, commonly used to treat Gram-negative infections, was initially reported as active against all species of Aeromonas, with little or no resistance reported in studies in the United States and most of Europe (84, 85). However, 2 to 3% of A. caviae, A. hydrophila, and A. veronii bv. sobria strains in Asia were reported to be ciprofloxacin resistant as early as 1996 (86). As previously reported above, there are increased reports of ciprofloxacin-resistant strains associated with the use of leech therapy after surgery (44-46).

Aeromonas species can express three chromosomal β-lactam-induced β-lactamases, including a group 1 molecular class C cephalosporinase, a group 2d molecular class D penicillinase, and a group 3 molecular class B metallo-β-lactamase (carbapenemase). Further, the presence of these β-lactamases in Aeromonas, in particular the carbapenemase, may not be detected by conventional susceptibility methods. CphA, one of several enzymes responsible for resistance to carbapenems, hydrolyzes nitrocefin poorly or not at all, indicating that the nitrocefin test is not reliable for detecting carbapenemases (89).

A 2004 case of A. hydrophila necrotizing fasciitis with probable in vitro transfer of a TEM-24 plasmid-borne extended-spectrum β-lactamase (ESBL) gene from Enterobacter aerogenes and a 2009 report on the development of imipenem resistance in an Aeromonas veronii bv. sobria clinical isolate recovered from a patient with cholangitis warrant concern among physicians as to the possible emergence of multidrug resistance within this genus (90, 91). Antimicrobial susceptibility testing of local isolates is necessary for the detection of species-related patterns, because susceptibilities may differ from one geographic area to another. This was very apparent in a study on the in vitro activities of tigecycline, a novel glycycline antimicrobial agent, against clinical isolates of Aeromonas, Salmonella, and Vibrio in Taiwan. It was found that 200 of 201 Aeromonas isolates were susceptible to tigecycline, with the MIC for 1 A. caviae isolate being 4 μg/ml, and past references to species-related patterns that varied with geographic areas were confirmed (92).

Aeromonas caviae strains carrying New Delhi metallo-beta-lactamase 1 (NDM-1) on the chromosome have been isolated from the New Delhi aquatic environment (93), and an examination of 51 consecutive Aeromonas blood isolates in Taiwan for the distribution of cphA MBL genes found the distribution of these genes to be species specific among A. hydrophila, A. veronii, and A. dhakensis, sp. nov., comb. nov. (formerly A. aquatilium) (94). The complexity of beta-lactamases among clinical Aeromonas isolates can result in resistance to a broad spectrum of beta-lactams, and therefore both conventional in vitro susceptibility testing and additional testing for ESBL production and carbapenemases using the modified Hodge test are strongly suggested, with the caveat that not all resistance mechanisms are detected with these additional phenotypic tests (95).

### EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Regardless of the site of isolation (intestinal or extraintestinal), aeromonads should be identified as belonging either to the A. hydrophila or A. caviae complex or to the A. veronii complex and not “A. sobria,” which is now A. veronii bv. sobria, a member of the A. veronii complex. For routine isolates recovered from uncomplicated cases of gastroenteritis, this level of identification may be sufficient. Although there is very strong evidence that some aeromonads are gastrointestinal pathogens, there is
no convincing evidence, at present, that all fecal isolates of Aeromonas are involved in diarrheal disease. Thus, the significance of the recovery of aeromonads from stool specimens should be interpreted cautiously and must rely on both laboratory information and clinical interpretation. Because of this, the relative quantity of Aeromonas organisms recovered on enteric media (few colonies, moderate growth, or predominant organism) should be reported in conjunction with the Aeromonas complex or species identification. For complicated cases of diarrhea, e.g., prolonged bloody diarrhea in pediatric patients or chronic gastroenteritis of >1 month’s duration or in cancer patients with positive fecal cultures (in whom Aeromonas tends to disseminate), a definitive species identification is warranted.

For extraintestinal isolates (from blood or wounds), the same general rules should apply to species identification of aeromonads. Although it is clear that both the in vitro pathogenic potentials of Aeromonas species and strains vary considerably, for the present time, there are no universal markers or indicators available that dictate when isolates should be definitively identified to the species level. Thus, for extraintestinal isolates, identification of aeromonads beyond complexes should be reserved (i) for strains isolated from sterile body sites (blood and cerebrospinal fluid) and serious wound infections (cellulitis and necrotizing fasciitis), (ii) for strains exhibiting unusual resistance patterns associated with nosocomial outbreaks, and (iii) for publications describing traditional species associated with new disease processes or newly described species isolated from new anatomic sites.

**Vibrio** and Related Organisms*

CHERYL L. TARR, CHERYL A. BOPP, AND J. J. FARMER III

---

**TAXONOMY**

The family *Vibrionaceae* is presently composed of six genera (*Vibrio, Photobacterium, Salinivibrio, Enterovibrio, Grimontia,* and *Allivibrio*) and over 110 species with standing in bacterial nomenclature ([http://www.bacterio.cict.fr/](http://www.bacterio.cict.fr/)). *Vibrio* is the type genus for the family, and *Vibrio cholerae*, which includes strains that cause pandemic cholera, is the type species (1). Pathogenic species for humans can be found in three genera: *Vibrio* (10 species), *Photobacterium*, and *Grimontia* (one species each). Phylogenetic investigations indicate that multiple clades (separate or distinct groups in a phylogenetic sense) exist within *Vibrio*, which has led to the reclassification of some species into different genera. *Photobacterium damselae* is currently the accepted taxon for *Vibrio damselae*, and most scientific and medical publications now report infections associated with this taxon as *P. damselae*.

**DESCRIPTION OF THE VIBRIONACEAE**

The *Vibrionaceae* involved in clinical specimens are Gram-negative, facultatively anaerobic, straight, curved, or comma-shaped rods, 0.5 to 0.8 μm in width and 1.4 to 2.6 μm in length, that are catalase and oxidase positive (except *Vibrio metchnikovii* (1)). Most species are motile by means of sheathed monotrichous or multitrichous polar flagella when grown in liquid media. Strains of some species, such as *Vibrio parahaemolyticus* and *Vibrio alginolyticus*, swarm on solid media by production of numerous lateral flagella (1, 2). All *Vibrionaceae* require Na+ for growth, with the minimal concentration for optimum growth ranging from 0.029 to 4.1% NaCl (1). They also ferment D-glucose but rarely produce gas, reduce nitrate to nitrite (except *Vibrio metchnikovii*), or grow on thiosulfate-citrate-bile salts-sucrose (TCBS) medium. The G+C content of the DNA is 38 to 51 mol% (1). Key properties or characteristics useful in separating clinically significant *Vibrionaceae* from phylogenetically related or phenotypically similar species are listed in Table 1.

**EPIDEMIOLOGY, TRANSMISSION, AND CLINICAL SIGNIFICANCE**

The genera covered in this chapter are ubiquitous in aquatic environments, primarily marine waters. *Vibrios*, such as *V. cholerae* and *V. mimicus*, that require minimal amounts of Na+ for growth can be found in freshwater rivers and lakes as well as estuarine and marine environments. *Vibrionaceae* are commonly isolated from a variety of bivalves and crustaceans, and like other genera found in marine environments, their concentrations peak during the warmer months of the year. In aquatic environments, vibrios can persist in a free-living state or in association with phytoplankton and zooplankton (3–5). In the environment, vibrios may enter a state referred to as viable but nonculturable, in which cells retain basic metabolic processes even though they fail to grow on standard laboratory media (6). Because the viability of these cells is still in question, the term “active but nonculturable” has been proposed (4). Recent studies have shown that in mixed populations of nonculturable and culturable cells of *V. cholerae*, the latter appear to be the main contributors to human infections (4).

The *Vibrionaceae* can be isolated from a wide variety of intestinal and extraintestinal human illnesses. These illnesses include diarrhea, soft tissue disease (cellulitis and necrotizing fasciitis), septicemia, and eye and ear infections (1). In some cases of gastroenteritis and extraintestinal infections, it may be difficult to determine if a positive vibrio culture represents true infection or merely colonization because of its widespread occurrence in marine and estuarine waters. Ten *Vibrio* species (with perhaps two additional ones described in subsequent paragraphs) and one species each of *Photobacterium* and *Grimontia* occur in clinical specimens and are listed in Table 2 (1). Extraintestinal *Vibrio* infections are frequently associated with traumatic injuries or inapparent exposure to estuarine or marine waters. Primary septicemia may occur after ingestion of raw seafood (oysters) or as a secondary bacteremia subsequent to a wound infection.

**V. cholerae**

*V. cholerae* is divided into more than 200 serogroups, of which only *V. cholerae* serogroups O1 and O139 cause epidemic and pandemic cholera (7, 8). Cholera is associated with poor sanitation, and direct contact with contaminated surface water for drinking, bathing, cooking, and irrigation is a major risk factor (13). *V. cholerae O1*

In 2011, the WHO reported over 580,000 cases of cholera worldwide, with more than 7,800 deaths ([http://www.who.int/gho/epidemic_diseases/cholera/cases/en](http://www.who.int/gho/epidemic_diseases/cholera/cases/en)). From 1996 through 2009, most cholera cases occurred in Africa (9),...
but since the start of the large outbreak in Haiti in October of 2010, more than 60% of cholera cases have been reported from the Americas. A total of 604,634 cases of infection and 7,436 deaths occurred over the first 2 years of the epidemic (10). The majority of V. cholerae O1 infections are asymptomatic, and these undetected infections may serve as an ongoing reservoir in regions where cholera is endemic (11). Severe infections of cholera typically result in copious watery diarrhea, with fluid loss reaching 200 mL/kg of body weight/day. If untreated, the patient becomes prostrate with symptoms of severe dehydration, electrolyte imbalance, painful muscle cramps, watery eyes, loss of skin elasticity, and anuria. Dehydration subsequently leads to hypovolemic shock, acidosis, circulatory collapse, and death, even in previously healthy adults (12). In the United States, occasional cases of cholera are seen in travelers returning from regions of the world where cholera is highly endemic. Traditional therapy consists of fluid replacement by oral rehydration and/or intravenous fluids.

The unique ability of V. cholerae serogroup O1 to cause this fulminant form of diarrhea is due to the presence of virulence cassette regions and pathogenicity islands on the bacterial chromosome. These regions contain a number of key determinants, including the ctxAB genes, encoding cholera enterotoxin, which is responsible for the large secretion of fluid and electrolytes into the lumen, and the TCP gene cluster, which includes tcpA, the gene encoding the major protein subunit of the toxin-coregulated pilus (responsible for attachment to the gastrointestinal epithelium) (13). Vibrio cholerae O1 strains are divided into two serotypes, Inaba and Ogawa (a third serotype, Hikojima, is very rarely isolated), and two biotypes, El Tor and classical. The classical biotype caused the sixth pandemic, while the El Tor biotype, which was first isolated in 1905, is the cause of the ongoing seventh pandemic that began in 1961 (8). Recently, new variants of V. cholerae O1 have emerged in Africa and Asia (14, 15). These atypical or hybrid El Tor strains may be more virulent than most El Tor strains based upon projected case fatality rates (16). Hybrid strains differ from prototypical El Tor isolates in that they share some characteristics with the classical biotype (e.g., an El Tor strain may have the classical ctxB gene on its chromosome) (17). These hybrid strains appear to have evolved via lateral gene transfer and recombination events (14).

### V. cholerae O139

In 1992, a new serogroup of V. cholerae, O139 (synonym, V. cholerae O139 Bengal), emerged throughout Asia (18). This serogroup probably resulted from the lateral transfer of a novel somatic antigen and capsule from an unknown bacterium to an El Tor strain (18). O139 and O1 strains carry similar virulence factors, including the ctx and tcpA genes (19). Clinical diseases due to O1 and O139 V. cholerae strains are also strikingly similar, except that adults are more frequently affected with O139, since previous infection with O1 cholera is not protective (20). In 2002, O139 reemerged in Bangladesh, causing an estimated 30,000 cases of cholera, primarily in older patients (20). To date, no cases of V. cholerae O139 infection have been identified in Africa, and in 2011, China was the only country which reported O139 infections (21).

Unlike O1 strains, V. cholerae non-O1 strains (non-O1, non-O139) rarely produce cholera toxin. While the diarrhea produced is watery and severe disease is reported, infections are usually milder than typical cholera. Non-O1 strains of V. cholerae that carry the cholera toxin genes, such as strains of serogroups O75 and O141, have caused sporadic cases of cholera-like disease in the United States and elsewhere (22, 23). Risk factors for infection appear to be similar to those for other vibrios and include consumption of oysters and other seafood. In 2011, there was a small outbreak of serogroup O75 infections linked to consumption of raw or lightly cooked oysters from Apalachicola Bay, FL. The diarrheal symptoms were mild, and no cases required rehydration or hospitalization (24).

Non-O1 vibrios, in contrast to O1 V. cholerae, are associated with extraintestinal infections, such as septicemia and epidural brain abscess (25, 26). Persons at increased risk of developing non-O1 bacteremia include those with liver disease/cirrhosis or hematologic malignancies (26). The case fatality rate in these patients ranges from 10% to 65% (26–28). Strains have also been isolated from ears, wounds, the respiratory tract, and urine (29).

### V. mimicus

V. mimicus, another nonhalophilic species, is phenotypically similar to V. cholerae except that it does not ferment sucrose. Human infections are uncommon, but it is recovered from patients with diarrhea, in which it may or may not have a causal role and is usually associated with consumption of

uncooked seafood, particularly raw oysters. Very few strains carry the ctxAB genes and can produce cholera-like symptoms. Symptoms generally include watery diarrhea, vomiting, and severe dehydration. Most descriptions of V. mimicus gastroenteritis involve individual case reports, but a large-scale foodborne outbreak of gastroenteritis was reported in Thailand in 2004 (30). In that outbreak, over 300 persons were ill, and rectal swabs collected from 24 patients all yielded V. mimicus. Presumptive causes of this outbreak included freshwater fish, seafood, and seafood soup. In 2010, a small outbreak in Washington state was associated with consumption of crayfish and was attributed to a V. mimicus strain encoding cholera toxin (31).

**V. parahaemolyticus**

*V. parahaemolyticus* is the leading cause of bacterial foodborne intestinal infections in Asia and is almost invariably associated with the consumption of raw fish or shellfish (32). In Japan, 50 to 70% of the cases of foodborne diarrhea are due to *V. parahaemolyticus*. In the United States, it is the *Vibrio* species most frequently isolated from clinical specimens and is associated primarily with watery diarrhea but also may be isolated from bloody stools, or other extraintestinal sites (28). Symptoms of *V. parahaemolyticus*-associated gastroenteritis often include nausea, vomiting, abdominal cramps, low-grade fever, and chills. Fatalities are extremely rare but can occur in cases of severe dehydration. Rehydration is usually the only treatment needed, but antimicrobial therapy may be beneficial in some instances. A recent outbreak of gastroenteritis involving 22 passengers aboard a cruise ship was linked to Alaskan oysters (33). A now widely dispersed clone of *V. parahaemolyticus*, serotype O3:K6, emerged worldwide in 1997 (34). Strains of this serotype caused an unusually high proportion of *V. parahaemolyticus* foodborne disease outbreaks in Taiwan from 1996 to 1999, which suggests that there is something unusual regarding its ecology, epidemiology, or virulence. This clone, with several of its serovarants (O4:K68, O1:K25, and O4:K12), has continued to spread throughout Asia and to the United States, Canada, Mexico, Russia, France, Italy, Brazil, Chile, Peru, and Mozambique (34). The serologic variants that have arisen since O3:K6 do not appear to have the same capacity to spread or a propensity for causing severe infections requiring hospitalization (34).

**V. vulnificus**

*V. vulnificus* causes primary septicemia and wound infection and is responsible for more than 90% of deaths due to vibrios in the United States yearly. Primary septicemia has a fatality rate exceeding 50%, even with hospitalization, and occurs predominantly in men over 50 years old (35, 36). Patients usually have predisposing conditions, such as liver disease, immunosuppression, increased serum iron, or other chronic diseases (35, 36). CDC data indicate that >95% of patients consumed raw oysters within 7 days of their infection. Patients typically present with a sudden onset of fever and chills, vomiting, diarrhea, and abdominal pain. Secondary skin lesions often appear, progressing to bulla formation and necrosis. Endotoxemic shock often occurs and can rapidly lead to death. Both blood cultures and biopsy samples (scrapings) from skin lesions are usually positive. *V. vulnificus* also causes severe wound infections, usually after trauma and exposure to marine animals or the marine environment (35, 36). Wound infections may progress to cellulitis with extensive necrosis (often requiring surgical debridement), myositis, and necrotizing fasciitis that may mimic gas gangrene, as well as to secondary septicemia. The fatality rate for wound infections ranges from 20 to 30%. Three biogroups have now been defined for *V. vulnificus* (35, 36). Most infections in the United States are due to biogroup 1; biogroup 2 has been isolated principally from diseased eels and also isolated from one human wound infection. *V. vulnificus* biogroup 3 was described in 1999 and has been limited to wound and blood-borne disease in Israeli patients exposed to live tilapia grown in aquaculture.

**V. alginolyticus**

*V. alginolyticus* is very common in the marine ecosystem and is the fourth most commonly isolated *Vibrio* species in the United States. It is most frequently isolated from ear specimens and wound infections following seawater exposure. A woman was diagnosed with a *V. alginolyticus* infection after sea bathing in the British Isles and applying an unsterile seaweed dressing to a preexisting wound (37). *V. alginolyticus* has also been isolated from ocular infections and from infrequent cases of monomicrobial or polymicrobial bacteremia, mostly in immunocompromised persons (38, 39). It is occasionally isolated from diarrheal stool, but there is no evidence that it actually causes diarrhea (40).

**Photobacterium damsela (formerly V. damsela)**

*P. damsela* is an aggressive pathogen that causes serious life-threatening illnesses. Fatality rates for *P. damsela* are unknown, but many reports in the literature describe fatal infections, suggesting a fairly high attributable mortality rate (41). Disease syndromes associated with this bacterium include soft tissue infections (cellulitis and necrotizing fasciitis) and bacteremia. Most wound infections develop as indolent processes that progress to more-severe disease within a matter of hours, and vibrios are often not suspected during the initial diagnosis. In addition to antibiotics, medical intervention, including irrigation, fasciectomy, debridement, and sometimes amputation, is often required. Typically, *P. damsela* wound infections occur in fishermen and result from penetrating traumas caused by fish fins, fish hooks, or harpoons (41–43). More recently, however, other sources of infection have been reported for this organism. These include a case of cellulitis in a healthy teenage surfer who sustained a laceration to his hand from his surfboard, a 30-month-old child with sickle cell anemia who developed bacteremia after handling fish and then scratching an open wound on her buttock, and a urinary tract infection in a pregnant female with increased frequency of urination and dysuria who had sexual intercourse in the Caribbean Sea 1 week prior to infection (36, 44, 45).

**Vibrio fluvialis and Vibrio furnissii**

*V. fluvialis* appears to cause sporadic cases of diarrhea worldwide, with severe cases of gastroenteritis sometimes linked to bacteremia or associated with cholera-like symptoms (46, 47). Based upon published reports, there appears to be a small but increasing incidence of extraintestinal *V. fluvialis* infections. These include acute infectious and continuous ambulatory peritoneal dialysis-associated peritonitis, soft tissue infections (cellulitis) associated with cerebritis, and bacteremia (47–50). For many of these systemic infections, some of which have poor outcomes, vibrios are not initially suspected as a cause. They are eventually associated with seafood consumption or exposure to seawater. *V. furnissii* is rarely isolated from human clinical specimens, but when it is recovered, it is usually from fecal specimens of patients with diarrhea (51). A case of bacteremia caused by *V. furnissii* following ingestion of seafood was recently described (52).
Miscellaneous Vibrios and Vibrio-Like Organisms

*Vibrio harveyi* is an important pathogen of marine fish and invertebrate species. *Vibrio carchariae* is another name formerly used for this organism before it was determined that it was a later synonym. *V. harveyi* is now the accepted name based on priority. To date, there are only two published case reports of human infection attributed to *V. harveyi*. The first report was of a wound infection resulting from a shark bite (53). The second report involved a 9-year-old boy with anaplastic large-cell lymphoma and central-line sepsis who, after completing chemotherapy and autologous stem cell transplantation, developed a febrile episode after swimming in the Mediterranean Sea (54). There is an anecdotal report of two isolates from blood and gallbladder (history unavailable) that were retrospectively identified by *rpoB* sequencing (55). *Grimontia hollisae* is a halophilic, vibrio-like species associated primarily with moderate to severe cases of diarrhea, sometimes involving hypovolemic shock (56). Most recorded cases of infection involve a history of consumption of seafood, such as oysters. *V. metschnikovii* is frequently isolated from freshwater and brackish and marine waters. It was first reported to cause peritonitis and bacteremia in a patient with an inflamed gallbladder. Since then, it has been isolated from additional patients with bacteremia and, rarely, from wound infections; it has also been reported from cases of cholecystitis, diarrhea, and pneumonia (57, 58).

*Vibrio cincinnatiensis* was first reported from a patient with bacteremia and meningitis. Subsequent isolates have been from the stool of a person with diarrhea, from aborted bovine fetuses, and from mussels (59). CDC data indicate that two additional *Vibrio* species are occasionally isolated from human clinical specimens. One species, provisionally named *Vibrio metaceae* (60), is closely related to *V. cholerae*. Like its close relative, it is sucrose positive and nonhalophilic. *Vibrio navarrensis* is a halophilic species that was first isolated from sewage (61). The CDC used *rpoB* sequencing and phylogenetic analysis (62) to identify 15 human isolates collected since 1983 as *V. navarrensis*. Both species have been isolated from cases of gastroenteritis and extraintestinal infections, but their causative role requires additional investigation.

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

Pertinent clinical histories (when known) should accompany specimens to alert the laboratory to include appropriate isolation media for the *Vibrionaceae* in their stool workup; this is especially important in areas where the isolation of vibrios is infrequent (63). Helpful information includes history of travel, consumption of seafood, activity associated with marine or brackish water (or wounds associated with such exposure), and hobbies associated with aquaria.

*Vibrionaceae*, like other enteric organisms, are particularly susceptible to drying, so stool specimens that cannot be inoculated onto plating media within 2 to 4 h should be placed in a transport medium. Cary-Blair or any noninhibitory transport medium is acceptable for vibrios. For specimens collected in the field, if necessary, liquid stool may be placed on strips of blotting paper or gauze and then inserted in air-tight plastic bags with a few drops of saline to maintain moisture and sent to the laboratory. Detailed information on the collection and transport of specimens for vibrio isolation is available elsewhere (64). Special methods for the collection and processing of extraintestinal specimens (blood, wounds, etc.) for vibrio isolation are not required, as vibrios are, as a rule, isolated in pure culture from these sites and the concentration of salt in primary plating media is usually sufficient for their recovery. Upon isolation, however, salt may need to be added to subsequent media to attain growth of salt-requiring vibrios. *Vibrionaceae* may die within weeks in vitro, even in moist environments at room temperature, and should be maintained at −70°C in tryptic soy broth with 15% glycerol as directed in chapter 11.

**DIRECT EXAMINATION**

Direct microscopic detection of vibrios in stool is not routinely recommended, since it may not be possible to distinguish pathogenic vibrios from other members of the enteric microbiota.

**Direct Detection of *V. cholerae* O1 in Stool**

Direct detection of *V. cholerae* from stool is typically conducted only in laboratories in areas where cholera is epidemic or endemic or in field situations where laboratory services are unavailable and rapid diagnosis is required. One of the oldest assays, the microscopic immobilization test, detects loss of motility of *V. cholerae* O1 organisms by the addition of O1 antibody and can be used to detect *V. cholerae* O139 by using O139 antibody. Two membrane antigen rapid tests, the Smart Cholera O1 (sensitivity 83%, specificity 88%) and Bengal Smart O139 (sensitivity 100%, specificity 97%) tests, are available from New Horizons Diagnostics Corp., Columbia, MD. Two rapid immunochemical dipstick assays which detect the presence of *V. cholerae* O1 or O139 antigens in stool are commercially available from Span Diagnostics (Surat, India) and Standard Diagnostics (Kyonggi-do, South Korea). The Span Crystal Vc for O1 and O139 demonstrated a sensitivity of 92% and a specificity of 73% (65). For the SD Bioline Cholera Ag O1/O139 test (Alere Inc., Waltham, MA), the manufacturer claims a sensitivity of 95.4% for the O1 antigen and 99.2% for O139, with respective specificities of 94.1% and 98%.

**Molecular Detection in Clinical Specimens**

Publications on molecular methodologies for detection of *V. cholerae*, *V. parahaemolyticus*, and *V. vulnificus* in stool can be found in the literature starting in the 1990s and are too numerous to cover here. Most of the advantages of PCR-based assays over culture methods apply to vibrios and include the ability to freeze stools for epidemiological studies for delayed testing. Also, in areas where vibrios are rarely isolated and laboratory experience or resources are limited, molecular methods may be more reliable and may provide a shorter turnaround time. Inhibitors in stool may affect the analytical sensitivity of an assay of PCR but can be overcome by dilution of the sample. Current PCR assays for *V. cholerae* use a multiplex PCR that includes primers for the ctxA gene, *rfb* genes (O antigens O1 and O139, allowing differentiation of serotypes), and tcpA genes (specific for the El Tor and classical biotypes, useful for epidemiological purposes) (66, 67). For clinical strains of *V. parahaemolyticus*, the thermostable direct hemolysin, a major virulence determinant, is a common target for detection, but it is not universally present in strains isolated from human infections (68, 69). In areas where *V. cholerae* is seldom isolated or in noncoastal areas where *V. parahaemolyticus* is an infrequent pathogen, the use of PCR is impractical and costly by comparison to alkaline peptone water and TCBS medium. The multiplexed Luminex xTAG gastrointestinal pathogen panel was evaluated for detection...
of *V. cholerae* from three stool specimens, with 100% sensitivity and specificity (70); however, the study did not include closely related species, such as *V. mimicus*, as negative controls.

**ISOLATION PROCEDURES**

*Vibrionaceae* associated with human disease can be isolated from routine enteric media, but recovery is enhanced when specific media are used. On MacConkey or salmonella-shigella (SS) agar, vibrios (with the exception of the rapidly lactose-fermenting strains of *V. vulnificus* present as colorless colonies. Some strains of *V. cholerae* are inhibited on MacConkey and SS agar. On sucrose-containing media, such as Hektoen agar and xylose-lysine-deoxycholate, sucrose-positive vibrios associated with human disease, such as *V. cholerae*, *V. fluvialis*, *V. alginolyticus*, and some strains of *V. vulnificus*, cannot be differentiated from strains of other enteric bacteria that rapidly ferment sucrose. The addition of a blood agar plate allows colonies to be screened for oxidase, which may improve the recovery of vibrios as well as colonies of *Aeromonas* spp. and *Plesiomonas* shigelloides. *G. hollisae* may grow poorly or not at all on any enteric isolation medium, including TCBS medium; it is probably most reliably isolated from blood agar.

TCBS agar is formulated specifically for the isolation of vibrios (1). Both powdered formulations and prepared plates are readily available from a number of commercial sources. Inclusion of sucrose allows for preliminary differentiation of *Vibrio* species, with *V. cholerae*, *V. fluvialis*, and *V. alginolyticus* producing yellow colonies, while *V. parahaemolyticus*, *V. mimicus*, and most strains of *V. vulnificus* produce green colonies (sucrose not fermented). It should be noted that yellow colonies may convert to green if plates are examined after more than 24 h or are refrigerated after incubation. Oxidase testing is unreliable when performed directly on colonies growing on this medium. Growth from a non-sugar-containing medium, such as blood or nutrient agar, should be used for oxidase testing.

A chromogenic agar, CHROMagar Vibrio (CHROMagar Microbiology, Paris, France), has been developed primarily for the recovery of *V. parahaemolyticus* from seafood and supports the growth of other vibrios as well (71). *Vibrio* colonies on this medium range in color from milk white to pale blue to violet. Other members of the enteric biota usually do not grow, with the exception of *Proteus mirabilis* and *Providencia rettgeri*, which also produce milk white colonies. Marine agar (BD Biosciences, Sparks, MD), which does not contain any inhibitory or selective ingredients, may be more appropriate for isolation of vibrios from the environment, especially salt-requiring vibrios, because of its high salt content.

It is common for pure cultures of vibrios to produce multiple colony morphologies (as many as five) on any medium, but this phenomenon is most readily noticeable on nonselective media, such as blood or heart infusion agars. Variations in morphology include smooth, rough, convex, flat, spreading, and compact cells in various combinations. Occasionally, *V. cholerae* produces rugose (extremely wrinkled) colonies on non-carbohydrate-containing media (72). Like their smooth counterparts, they are fully virulent for humans (73). Rugosity, which is due to production of a unique extracellular polysaccharide, confers biofilm formation and resistance to chlorine, acid pH, and serum killing (72, 73). Although it is believed to enhance survival in aquatic environments, to date it has been demonstrated only in vitro. Isolates of the classical biotype of *V. cholerae* also possess the tcp (vibrio polysaccharide synthesis) gene cluster, which encodes this phenotype, but rugose variants have been demonstrated only from El Tor strains (73).

In acute diarrheal disease, stool enrichment is generally not required; however, when enrichment is necessary, alkaline peptone water (1% NaCl, pH 8.5) is the most commonly used enrichment broth for human specimens. It should be incubated at 36°C and subcultured at 18 h on TCBS medium. Occasionally, vibrios are recovered only after a shorter incubation (6 h), and for these specimens, longer incubation times fail to yield a vibrio, probably due to overgrowth by other organisms (S. Abbott, personal observation).

**IDENTIFICATION**

**Conventional Phenotypic Tests**

Phenotypic properties that separate members of the *Vibrionaceae* from the *Enterobacteriaceae* (including *Plesiomonas shigelloides*) and the *Aeromonadaceae* are found in Table 1, and phenotypic profiles of the 12 species that occur in human clinical specimens are given in Table 2. Generally, 0 to 10% of species are positive for the following: H<sub>2</sub>S in triple sugar iron, urea (except *V. parahaemolyticus*, 15%), phenylalanine deaminase (except *V. vulnificus* biogroup 1, 35%), malonate, mucate, yellow pigment production, and fermentation of d-adonitol, dulcitol, melibiose (except *V. vulnificus* biogroup 1, 40%), raffinose, L-rhamnose (except *V. furnissii*, 45%), d-sorbitol (except *V. metschnikowii*, 45%), α-methyl-β-D-glucoside, and D-xylose (except *V. cincinnatiensis*, 57 and 43%, respectively). Variable reactions are seen with methyl red, growth in potassium cyanide broth, D-galactose, glycerol, sodium acetate, DNase at 25°C, and lipase. All species are 99 to 100% positive for growth in 1% NaCl and fermentation of maltose (except *G. hollisae*, 0%) and D-mannose (except *V. cholerae*, 78%, and *V. harveyi*, 50%). Many commercial standard tube tests have sufficient salt to support growth without salt supplementation (0.5 to 1%), but some tests—such as the Voges-Proskauer test, Moeller's test for decarboxylases and dihydrolase, and the nitrate broth test—may contain no or insufficient NaCl to support the growth of some NaCl-requiring strains, and these tests' media should always have salt added to them (to a final concentration of 1%).

It should be noted that many *V. cholerae* O1 strains from Bangladesh and surrounding areas and all strains of *V. cholerae* O139 are resistant to both 10- and 150-μg disks of the vibriostatic compound O/129 (Remel, Lenexa, KS), a test historically used to distinguish vibrios (Table 1). In areas of the world where cholera is uncommon, complete phenotypic testing should be performed and all cultures identified as *V. cholerae* should be sent to public health laboratories for further characterization, including O1 and O139 agglutination, PCR tests for the presence of the ctxA gene, and other molecular typing or standard testing to determine the biotype variant. Prototypical as well as hybrid El Tor biotypes can be differentiated by a number of phenotypic tests, including hemolysis of sheep erythrocytes, production of acetyl methylcarbinol (Voges-Proskauer test), and resistance to polymyxin B, and positivity for the prototypical El Tor biotype (14). Except in their serogroup and O/129 reactions, *V. cholerae* O139 strains are phenotypically similar to *V. cholerae* O1 El Tor strains. Strains of *V. cholerae* that fail to agglutinate in either O1 or O139 antiserum are reported as *V. cholerae* non–O1. Serogrouping for non–O1 strains is available in only a limited number of reference
laboratories, which typically use only some of many possible sera. *V. cholerae* and *V. mimicus* are separated from other species by growth in media lacking NaCl (Difco BD Biosciences; nutrient broth is the only broth that accurately determines NaCl requirement). Strains of *V. paraaemolyticus*, *V. alginolyticus*, and *P. damselae* may be urea positive. Most vibrios isolated from humans produce a buff or tan pigment; however, strains of *V. paraaemolyticus* may produce a dark-brown pigment. *G. hollisae* generally grows poorly, especially in Moeller’s decarboxylase and dihydroxyde broths, even after salt supplementation, and produces extremely large zones of inhibition, often necessitating the use of two plates when disk antimicrobial susceptibility testing is performed. *V. metschnikovi* is distinctive because it is an oxidase- and nitrate-negative vibrio. *V. fluvialis* and *V. furnissii* are frequently confused with *Aeromonas caviae*, especially as some strains are weakly halophilic and only moderately susceptible to O/129, and because some strains of *A. caviae* grow on TCBS agar. *V. furnissii* is the only vibrio isolated from humans that is positive for gas production from D-glucose.

**Commercial Systems**

There are no recent studies evaluating commercial systems’ abilities to identify organisms covered in this chapter; however, based on individual case reports, identification of these organisms by commercial systems remains problematic (74–76). One evaluation that compared six commercial systems (77) indicated that when tested only against those species listed in their databases, API 20E (bioMérieux Inc., Durham, NC), Crystal E/NF (BD Biosciences), MicroScan Neg ID type 2 and type 3 (Siemens Healthcare Systems, West Sacramento, CA), and Vitek GNI+ and ID-GNB cards (bioMérieux) correctly identified only 63 to 81% of these organisms to the species level. Correct identifications of the three most commonly isolated species of *Vibrio* from clinical samples varied. For *V. cholerae*, API 20E gave the least (50%) and Crystal E/NF the most (97%) accurate identification. For *V. paraaemolyticus*, Rapid ID 32 (bioMérieux) identified the worst (40%) and API 20E and GNI+ the best (97%) each, while for *V. vulnificus*, group 1 strains, GNI+ (50%) and Crystal E/NF (97%) gave the lowest and highest rates, respectively (64). Only Crystal E/NF was able to correctly identify ≥90% of *V. cholerae* or *V. vulnificus* strains, and only API 20E and the two Vitek cards correctly identified ≥90% of *V. paraaemolyticus* strains in another study using only *V. vulnificus* biotype 3 strains, the MicroScan (98%) and Phoenix (90%) systems did the best in identifying 51 well-characterized isolates to the correct species, while the identification rate with Vitek (13.7%) was much less satisfactory (73). Croci et al. (74) found that for the identification of *V. paraaemolyticus*, API 20NE exhibited greater sensitivity than API 20E (20 versus 16 of 27 specimens) but that API 20E was more specific (100% versus 82%). In another study, a mixture of 111 clinical and environmental *V. vulnificus* strains; API 20E, API 20NE, and Biolog (Biolog, Inc., Hayward, CA) correctly identified 60, 0, and 85% of strains, respectively. Manufacturers’ instructions should be checked prior to testing of salt-requiring vibrios to determine if salt supplementation is required. A recent publication indicated that API 20E gave incorrect identifications for clinical isolates of *V. paraaemolyticus* if 2.0% NaCl was used for the diluent, versus 0.85% (74). For clinical isolates of *V. alginolyticus*, either concentration yielded identifications with high probabilities, but for *V. vulnificus*, the 0.85% diluent failed to identify 1 of 2 isolates, whereas 2.0% NaCl identified both strains with ≥94% probabilities.

**Molecular Methods**

Molecular identification of vibrios is commonplace in surveys and in research studies. However, it is not commonly employed in clinical laboratories for routine identification because vibrios are relatively rare pathogens in noncoastal areas or in regions where cholera is not endemic. The use of 16S rRNA gene sequencing alone is less than ideal for *Vibrio* identification, as interspecies sequence differences can be very small and polymorphism has been shown to be fairly common in 16S rRNA genes (78). Tarr et al. (55) developed a multiplex PCR assay, using primers directed at *V. cholerae* sodB, *V. mimicus* sodB, *V. paraaemolyticus* flaE, and *V. vulnificus* hsp genes, that correctly identified 109 isolates and found an additional 4 strains of *V. paraaemolyticus* that either had not been identified to the species level (n = 3) or had been identified incorrectly as *V. alginolyticus* (n = 1). Additionally, rpoB gene sequencing was used to identify 12 of 15 isolates not previously identified to the species level by phenotypic methods. In other studies, the tcpR gene (*V. paraaemolyticus*), vvhA gene (hemolysin, *V. vulnificus*), vcg genes (virulence-correlated gene, *V. cholerae*), and vrbG and wgb genes (for the O1 and O139 serotypes, respectively), and tcpA genes (specific for the El Tor and classical biotypes) have been used for identification (67, 74, 76, 79). Matrix-assisted laser desorption/ionization–time of flight mass spectrometry (MALDI-TOF MS) promises to be a valuable new tool for identification of closely related bacterial species, with a rapid turnaround time and modest test cost. MALDI-TOF MS was shown to be a rapid and reproducible method of identification for *V. paraaemolyticus* (80). MALDI-TOF MS produced phylogenetic classification results comparable to those of rpoB sequencing for *Vibrio* spp. (81).

**V. cholerae and V. paraaemolyticus**

**Toxin Detection**

Historically, reference laboratories detected cholera toxin by fluid accumulation in animal assays or detection of a cytopathic effect in Y1 adrenal or Chinese hamster ovary cell cultures. A reverse passive latex agglutination (VET-RPLA) assay (Denka Seiken) which detects both cholera toxin and the heat-labile toxin of *Escherichia coli* is commercially available. The majority of human strains of *V. paraeae*olyticus produce a thermostable direct hemolysin encoded by two genes, *tdh* and *tdh2x*. These toxins are rarely produced by environmental strains of *V. paraaemolyticus* but have been detected in *V. cholerae* non-O1, *V. mimicus*, and *G. hollisae* strains. Like cholera toxin, thermostable direct hemolysin can be detected by a commercial latex assay (KAP-RPLA; Denka Seiken), but there are no commercial products that detect the related thermostable hemolysin seen in *V. paraaemolyticus* strains. PCR assays for cholera toxin genes and both *V. paraaemolyticus* hemolysins have been developed but are not commercially available (82).

**Typing Systems**

**Serotyping**

Serotyping is a widely utilized subtyping procedure. Typing schemes have been described for a number of species, including *V. cholerae*, *V. paraaemolyticus*, and *V. vulnificus*; however, commercial typing sera are available only for
V. cholerae and V. parahaemolyticus (83, 84). V. cholerae O1 (polyvalent, Inaba and Ogawa) and O139 antisera are available from BD Biosciences, Denka Seiken, Remel, and New Horizons. V. parahaemolyticus antisera (11 O groups and 9 polyvalent and 65 monovalent K groups) are available from Denka Seiken.

Molecular Typing of Vibrios

Pulsed-field gel electrophoresis using NotI and SfiI enzymes is a well-standardized approach to molecular typing of vibrios for surveillance purposes (79, 85, 86). Ribotyping appears to be less discriminatory (76). Multilocus sequence typing (MLST) schemes are available for the three most commonly isolated species (V. cholerae, V. parahaemolyticus, and V. vulnificus) (http://www.pubmlst.org). Kotetishvili et al. (87) reported that MLST was more discriminatory than pulsed-field gel electrophoresis for V. cholerae. MLST and repetitive extragenic palindromic PCR (REP-PCR) were similar to each other in resolving the population structure of V. parahaemolyticus strains in the northwestern United States (88). Likewise, for V. vulnificus, REP-PCR is an effective subtyping method (35). Genotyping systems based on nucleotide sequence polymorphisms in several genes (16S rRNA gene, gyrA, and parC) were originally thought to distinguish clinical from environmental isolates, but these methods do not clearly differentiate pathogenic from non-pathogenic strains (76). The subtyping methods currently in use are likely to be replaced by whole-genome sequencing and in silico analysis of traditional epidemiological markers in the near future.

SEROLOGIC TESTS

Reagents for the serodiagnosis of cholera are available only in specialized reference laboratories, but titration of acute- and convalescent-phase sera in agglutination, vibriocidal, or antitoxin tests is considered reliable (89).

ANTIMICROBIAL SUSCEPTIBILITIES

Generally, for most V. cholerae and V. parahaemolyticus gastrointestinal infections, treatments by rehydration is recommended over antimicrobial therapy and has the added benefit of reducing the risk of antibiotic resistance. Antimicrobial therapy, however, can reduce the duration of diarrhea, the duration of shedding of the organism, and the volume of rehydration fluids needed for recovery, and patients are often treated before culture results are known (23). Clinical and Laboratory Standards Institute (CLSI) document M45-A2 (96) includes susceptibility testing guidelines for non-cholera vibrios; the CLSI interpretive guidelines are limited to ampicillin, tetracyclines, folate pathway inhibitors, and chloramphenicol for V. cholerae (87, 88). In vitro susceptibility surveys show V. cholerae strains to be susceptible (>90%) to aminoglycosides, azithromycin, fluoroquinolones, extended-spectrum cephalosporins, carbapenems, and monobactams (90, 91). However, a conjugative transposon designated the SXT element and carrying resistance to sulfamethoxazole, trimethoprim, chloramphenicol, and streptomycin emerged first in V. cholerae O139 strains in India and is now seen in O1, non-O1, and O139 cholera strains and V. fluvialis (92). Ahmed et al. (92) have reported on a V. fluvialis isolate with the SXT element and a novel aminoglycoside acetyltransferase gene encoding resistance to gentamicin; resistance to ampicillin, furazolidone, and nalidixic acid was also reported. Multidrug-resistant strains of V. fluvialis have also been noted among other strains from India (45, 93). V. parahaemolyticus is generally susceptible to most antibiotics used for traveler’s diarrhea (69). The fluoroquinolones alone or the synergistic combination of ciprofloxacin and cefotaxime show excellent in vitro activity against V. vulnificus strains (94, 95).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Isolation of V. cholerae O1 or O139 should be reported immediately to the attending physician because of the severe dehydration that cholera can produce. The case should also be phoned to public health authorities and the isolate sent to a public health laboratory for confirmation and toxin testing. When vibrios are isolated from blood or cerebrospinal fluid (bacteremia and meningitis are associated with high mortality rates) or wound infections which cause extensive tissue damage (V. vulnificus and P. damselae), the results should also be phoned immediately to the attending physician so that rapid and appropriate antibiotic therapy can be initiated. This is especially true for V. vulnificus infections, which have a high mortality rate without rapid, appropriate intervention. The clinical significance of Vibrio strains (V. mimicus, V. alginolyticus, G. hollisae, V. harveyi, and V. metschulovii) in other specimens, particularly stool, may be more difficult to determine and requires prompt consultation with the attending physician to better understand the clinical context. Most physicians are not familiar with many Vibrionaceae species, and a phone consultation would be mutually beneficial to the clinician and laboratory provider. Information helpful to the physician includes the presence or absence of other pathogens and the relative amount of growth (pure or almost pure culture) of the vibrio. Vibrionaceae isolates should also be submitted to public health laboratories, as they are monitored under the CDC’s Cholera and Other Vibrio Illness Surveillance (COVIS) system; they may also be needed for subtyping.

Vibrionaceae species that are known to cause diarrhea should be considered clinically significant, particularly if they are present in large numbers and no other potential pathogens are present. Isolation of vibrios from stool in small numbers may reflect only rehydration colonization; however, species such as V. cholerae, V. mimicus, and V. parahaemolyticus have documented virulence factors that correlate with their ability to cause intestinal infections. Laboratory tests helpful in determining pathogenic potential are available primarily only in reference laboratories. Vibrionaceae isolation from sites such as the ears may represent infection, transient colonization, or merely their presence after exposure to seawater. Again, isolation of Vibrionaceae requires prompt consultation with the clinician to better understand the clinical context, which can help direct the need for further laboratory investigations. Finally, readers should also be cautioned that misidentification of Vibrio species and their relatives can be a problem in the literature unless investigators used methods that are very sensitive in differentiating all of the species in the family Vibrionaceae (1).

REFERENCES

Vibrio vulnificus infection in which 16S rDNA sequencing was useful for diagnosis. Jpn J Infect Dis 59:108–110.

Chapter 40 of the 10th edition of this manual may be very low, the total number of bacteria of importance, as it includes species with both clinical and environmental implications. Many species are saprophytic or pathogenic for plants. The metabolic versatility of species within this genus allows many to degrade low-molecular-weight organic and aromatic compounds (1) and environmental pollutants (2-4). The genus Pseudomonas first proposed by Migula in 1894 (5) has undergone many taxonomic revisions since the seminal study of Stanier et al. (1966) (6) as methodologies of species identification continue to improve, and it comprised five unrelated groups, as determined by rRNA-DNA hybridization studies in the early 1970s by Palleroni (7). The genus Pseudomonas (sensu stricto) is rRNA homology group I (8) in the gamma subclass of the Proteobacteria (9). The other rRNA homology groups are II, Burkholderia and Ralstonia spp.; III, Comamonas, Acidovorax, Delftia, and Hydrogenophaga spp.; IV, Brevundimonas spp.; and V, Stenotrophomonas spp. (1). The genus Pseudomonas is reduced to include only those species belonging to rRNA group I, and of the currently listed species, 12 are of clinical relevance to humans. These 12 clinically relevant species have been sequenced (http://www.pseudomonas.com).

The highest level of genetic diversity of any species known is found in P. stutzeri (11), as established by multilocus enzyme electrophoresis. P. stutzeri has at least nine genovars, with clinical isolates being found in genovars 1 and 2. There are currently no consistent phenotypic differences to justify splitting P. stutzeri into unique species (10).

P. fluorescens was originally divided into biotypes A, B, C, D, E, F, and G (biotypes A to E are also referred to as biovars I, II, III, IV, and V). Biotype B was reclassified as Pseudomonas marginalis. Biotypes D and E (Pseudomonas chlororaphis and Pseudomonas aureofaciens) have now been combined into the single species P. chlororaphis, which is no longer considered a member of the fluorescens group.

Pseudomonas putida consists of biovars A and B. Biovar A should be regarded as the “typical” P. putida (12), while biovar B may have a closer affinity with P. fluorescens. More biovars of P. putida are warranted (12).

P. stutzeri, P. fluorescens, and P. putida are of interest in plant, marine, soil, and biotechnical sciences. They are of limited importance in clinical medicine. As polyphasic taxonomy continues to advance, more changes will doubtless arise; the clinical laboratory must keep abreast of such changes in order to differentiate these isolates from other clinically important Pseudomonas species.

**DESCRIPTION OF THE AGENT**

*Pseudomonas* spp. are aerobic, non-spore-forming, Gram-negative rods that are straight or slightly curved and are 0.5 to 1.0 by 1.5 to 5.0 μm depending on the growth phase.
They are usually motile, with one or several polar flagella. They possess a strictly aerobic respiratory metabolism with oxygen as the terminal electron acceptor; in some species, e.g., *P. aeruginosa*, nitrate can be used as an alternative electron acceptor that allows anaerobic growth, and some species can use arginine fermentation for anaerobic growth (13). This is of pathogenic relevance, since anaerobic conditions are found in sputum in the bronchi and in mucus in the paranasal sinuses in cystic fibrosis (CF) patients with chronic infections in these two locations (14–16). Most species of clinical interest are oxidase positive (except *P. luteola* and *P. oryzihabitans*). *Pseudomonas* spp. are catalase positive and are chemolithotrophs.

**EPIDEMIOLOGY AND TRANSMISSION**

**Endogenous versus Exogenous Infection**

Endogenous infection can only occur in those whose colonization resistance has been perturbed: bacteremia secondary to gastrointestinal colonization in neutropenic hosts and pneumonia in individuals who have required endotracheal intubation (ventilator-associated pneumonia) (17). Exogenous infection likely occurs in patients with CF, as their initial infecting isolates usually resemble environmental morphotypes, although patient-to-patient spread has been demonstrated in CF centers in several countries (see below). Most other infections caused by *P. aeruginosa* are probably acquired exogenously, such as in burn wound infection, conjunctivitis and keratitis, urinary tract infection, otitis externa, folliculitis, and osteomyelitis, e.g., in the diabetic foot.

**Exposure to Inanimate Reservoirs**

Although efforts to prevent colonization with *P. aeruginosa* have been made, none has proven uniformly successful. Strict infection control procedures and the practice of compulsory hand hygiene are most effective at preventing patient-to-patient spread, particularly in hospitals.

**Special Considerations for Patients with CF**

*P. aeruginosa* is the predominant respiratory tract pathogen in patients with CF (18). Several studies have each demonstrated a common clone in particular groups of patients who have received their care at the same center (19, 20); the most likely explanation for this finding is patient-to-patient spread (21). Most patients tend to carry a unique strain during the course of infection (22), so one assumes that the infection was acquired from a contaminated environmental source or from other CF patients. Evidence has been presented that the paranasal sinuses are the initial focus for lung infection (23, 24). In chronic respiratory infections in CF, isolates of *P. aeruginosa* from patients displayed a high prevalence of DNA mismatch repair system-deficient hypermutable strains on isogenic backgrounds for each patient (25).

**Species Other than *P. aeruginosa***

*Pseudomonas* species other than *P. aeruginosa* are usually acquired from the environment, and some species (*P. fluorescens* and *P. syringae*) are actually used as biocontrol products—as also some *Burkholderia* species—against soil-borne crop diseases (26, 27).

**CLINICAL SIGNIFICANCE**

**Normal Host Defenses against *P. aeruginosa***

Polymorphonuclear neutrophil leukocytes (28) are the most important defense against invasive, systemic *P. aerugi-

nosa* infection. Individuals with intact host defenses are not at risk for serious infection with *P. aeruginosa*. *P. aeruginosa* rarely colonizes the pharynx, gut, or skin of healthy persons. An exception is the outer ear of swimmers and divers who spend many hours in the water. When *P. aeruginosa* is recovered from a normally sterile body site, such as blood, pleural fluid, or joint space, it usually constitutes a true infection. However, pseudoinfection (29) should sometimes be considered if the patients are neither severely ill nor at enhanced risk of such infection. A search for the source of the cluster should include culture of the antiseptic used for skin preparation for venipuncture or similar procedures.

*P. aeruginosa* is able to colonize wounds and mucosal surfaces, such as the oropharynx of patients receiving intensive care and broad-spectrum antibiotics or the endotracheal tubes or the tracheostomies of patients receiving mechanical ventilation, causing ventilator-associated pneumonia.

**Infection in Patients with Neutropenia**

Patients with neutropenia (neutrophil count of $<0.5 \times 10^9$ per liter) are at risk for invasive disease if the neutropenia is prolonged ($\geq 10$ days). Patients at greatest risk are adults undergoing induction chemotherapy for acute leukemia or marrow ablation for autologous or allogeneic bone marrow transplantation (30–33).

**Infection in Patients with CF**

*P. aeruginosa* is the predominant respiratory tract pathogen in patients with CF due to the reduced volume of the periciliary fluid in the respiratory tract, which leads to delayed clearance of aspirated microbes (34). The focus of the lung infection seems to be the paranasal sinuses (23, 24). Once infection is established, it usually persists as a biofilm (36), and the bacteria undergo a transition to the adapted “chronic CF phenotype” due to mutations in the global regulator genes (*mucA, algT* [= *algU*], *rpoN*, and *lasR*), consisting of the following: (i) a rough lipopolysaccharide (LPS) (37), in which the O polysaccharide is incompletely expressed, rendering the bacteria susceptible to the bactericidal effect of human serum; (ii) mucoid colonial morphology causing biofilm mode of growth in vivo (38), resulting from the exuberant production of a mucoid exopolysaccharide composed of O-acetylated guluronic and mannuronic acids; (iii) nonmotility (38) in which the bacteria lack normal functional flagellar function; and (iv) hypoexpression of various exotoxins due to mutations in the *lasR* gene of the quorum-sensing system, which regulates the production of these virulence factors—especially the rhamnolipid, which destroys polymorphonuclear leukocytes—and other exoproducts (25, 39, 40).

Transition of *P. aeruginosa* from nonmucoid to mucoid in the CF lung is usually associated with an accelerated decline in pulmonary function and an adverse prognosis (41), because of the capacity of the mucoid exopolysaccharide to interfere with normal host phagocytic defenses (42) and to facilitate the formation of biofilms. Another colonial form, small-colony variants (previously known as dwarf colonies), which are very resistant to antibiotics, is also found in CF sputum (43, 44). Different colony morphologies of *P. aeruginosa* from sputum of a patient with CF are presented in Fig. 1. Furthermore, CF patients receive frequent courses of anti-*Pseudomonas* antimicrobial therapy, leading to occurrence of multiresistant strains (18, 45).

**Ventilator-Associated and Nosocomial Pneumonia**

The normal respiratory tract is well protected against infection by means of mucociliary clearance of inhaled particles...
and potentially infectious agents. Placement of an endotracheal tube or a tracheostomy for mechanical ventilation allows upper respiratory tract microbes to gain access to the lower respiratory tract, where infection can be established. Adults receiving mechanical ventilation are at high risk for developing P. aeruginosa ventilator-associated pneumonia (46), particularly after or during treatment with broad-spectrum antimicrobial agents. Ventilator-associated pneumonia—which is a biofilm infection—is seen in 10 to 30% of mechanically ventilated patients, and the pathogenesis is aspiration of bacteria from the biofilm on the tube (47, 48). Initial empiric therapy, until an etiologic agent is identified, should include a drug effective against P. aeruginosa.

**Burn Wound Infections, Chronic Wound Infections, and Diabetic Foot Infections**

Thermal burns of the skin abrogate an essential component of the body’s defense against infection, the physical barrier of the intact skin (49). The resulting damaged tissue is a rich culture medium and is at great risk for colonization and infection by P. aeruginosa, which is transmitted to the burn wound by the initial hydrotherapy; such infections have been one of the leading causes of morbidity and mortality in victims of burns. Topical therapy is designed to prevent P. aeruginosa and other pathogens from causing infection. Infections of burn wounds with P. aeruginosa typically occur about 1 week after the injury. The extent of the burn has a profound influence on risk of infection and prognosis.

P. aeruginosa can cause chronic ulcers, and here they are located as biofilm aggregates below the surface of the ulcer (50). Biopsies, rather than swabs of the surface, are required to detect P. aeruginosa in the ulcers. P. aeruginosa is the most common Gram-negative rod found in moderate to severe diabetic foot infections, which sometimes spread to the bones of the foot and give rise to osteomyelitis (51, 52). Practical guidelines have been published for diagnosis and treatment of these infections (53).

**Folliculitis, Otitis Externa, and Infectious Keratitis**

Since P. aeruginosa can survive at temperatures as high as 42°C, it has the propensity to cause infection in people who are exposed to heated water for extended periods. Hot tub users are at risk of P. aeruginosa folliculitis (54), a condition that is self-limited for healthy hosts and resolves rapidly. People who spend extended periods swimming or diving are at risk of external ear infections (“swimmer’s ear”), another self-limiting condition in immunocompetent people that responds readily to therapy with topical antimicrobial agents (55).

The cornea is relatively resistant to infection except when its integrity has been broken. Users of contact lenses are at risk of P. aeruginosa keratitis, especially if hygiene is poor or lenses are used for extended periods, possibly due to contamination during daily cleaning of the lenses (56).

**Other Infections with P. aeruginosa**

P. aeruginosa can cause meningitis (usually following trauma or surgery), malignant otitis externa in which the cartilage of the ear is invaded (57), sepsis and meningitis in newborns (58), endocarditis or osteomyelitis in users of intravenous drugs (59), chronic pneumonia in people with underlying lung disease such as bronchiectasis (60), and urinary tract infections in patients with complex urinary tract abnormalities (61, 62). Each of these presentations is unusual and is superimposed on some abrogation of normal host defenses.

**Infections with Pseudomonas Species Other than P. aeruginosa**

Healthy individuals are resistant to serious infections by all Pseudomonas species, including P. aeruginosa. However, immunocompromised hosts are occasionally infected with one of the many non-aeruginosa species, including (but not limited to) P. fluorescens, P. putida, P. stutzeri, P. oryzihabitans, P. putida, P. alcaligenes, P. mendocina, and P. veronii. Several of these species have been recovered from the respiratory secretions of patients with CF, but their role in the
P. fluorescens and P. putida have the ability to grow at 4°C, and P. fluorescens and various other Pseudomonas species have been implicated in outbreaks of pseudobacteremia (63–67).

P. stutzeri is an unusual cause of human infection. It can cause bacteremia in immunosuppressed persons (70), meningitis in HIV-infected individuals (71), pneumonia in alcoholics (72), and osteomyelitis (73). Iatrogenic infections due to P. stutzeri include endophthalmitis following cataract surgery (74) and bacteremia in hemodialysis patients as a result of contaminated dialysis fluid (75). P. stutzeri has also been recovered from wounds, the respiratory tract of intubated patients, and the urinary tract; although its pathogenic role in those settings is unclear (76).

P. oryzae is being recognized increasingly as a cause of bacteremia in immunocompromised patients with central venous access devices. Synthetic bath sponges can be a source of bacteremia with this organism in patients with Hickman catheters (65). This organism has also been reported to cause peritonitis in patients undergoing chronic ambulatory peritoneal dialysis and in patients with cellulitis, abscesses, wound infections, and meningitis following neurosurgical procedures (63).

P. luteola is a rare cause of infections in humans. There have been case reports of a variety of different infections, including bacteremia, cellulitis, osteomyelitis, peritonitis, endocarditis, and postsurgical meningitis (66, 77).

Other Pseudomonas species are found even less frequently in human infection. P. alcaligenes has been associated with catheter-related endocarditis in a bone marrow transplant recipient (78). P. mendocina has been isolated from patients with endocarditis (79). P. serotinus has been reported to be associated with an intestinal inflammatory pseudotumor (80). P. monteilii has been recovered from stool, bile, placenta, bronchial aspirates, pleural fluid, and urine, but its clinical significance is uncertain (81, 82). P. mosselii has also been isolated from various specimens, but its clinical significance is not known (83).

COLLECTION, TRANSSPORT, AND STORAGE OF SPECIMENS

Pseudomonas spp. are able to survive in diverse environments and through a wide temperature range. Some species prefer incubation temperatures lower than 25°C, while P. aeruginosa can grow at temperatures up to 42°C. These organisms are easily recovered from clinical specimens using standard collection, transport, and storage techniques as outlined in chapter 18. Samples of Pseudomonas spp. can be refrigerated at 2 to 8°C for up to 4 weeks. Organisms can be kept in long-term storage at ~80°C using standard laboratory freezing protocols.

DIRECT EXAMINATION

Microscopy

Gram stain morphology cannot easily distinguish Pseudomonas spp. from other nonfermenting bacilli, although they are usually thinner than Enterobacteriaceae. Among the pseudomonads, there is some variation in Gram stain morphology. Certain strains of P. putida can appear elongated. Organisms from older cultures may appear slightly pleomorphic. Flagellar stains reveal one or more polar flagella. P. aeruginosa has a single polar flagellum (monotrich), which gives a diagnostically significant different swimming motility compared with peritrichous bacteria, as can be observed microscopically on wet mounted slides of, e.g., positive blood cultures.

Mucoid phenotypes may be distinguished on direct examination by the presence of clusters or long filaments of short, Gram-negative bacilli surrounded by light pink-staining material (alginate) (Fig. 2A to E). The reason for the mucoid phenotype is mutations in the mucA gene. It is important to note this on direct examination, as the organisms may grow very slowly (84).

Simultaneously, nonmucoid phenotypes (revertants frequently due to additional mutations in the algT gene) and small-colony variants may be observed on the culture plate (Fig. 1). They always belong to the same clone and represent adaptation to different niches in the respiratory tract (83).

The presence of these mucoid forms, which represent biofilms in the lungs, should be documented on clinical reports and antibiotic susceptibility testing should be performed on the different phenotypes and reported to the clinician, although the biofilm mode of growth makes the mucoid phenotype resistant to antibiotic treatment in spite of in vitro susceptibility of the planktonic bacteria. The reason is that antibiotic therapy can still suppress the spread of the infection and maintain the pulmonary function (18). Many strains from chronically infected CF patients are mutator strains with mutations rate >20 times that of the reference strain PAO1, and they rapidly become multiresistant to antibiotics (25, 85, 86). Because Pseudomonas spp. may be colonizers, their isolation does not always link them to clinical disease. However, their presence intracellularly in polymorphonuclear cells is clinically significant and should be documented and direct further workup.

Nucleic Acid Detection and Mass Spectrometry Detection

P. aeruginosa and other Pseudomonas species are ordinarily detected by culture techniques; these methods are particularly important for determining antimicrobial susceptibility, as these organisms have a high degree of intrinsic and acquired resistance (87, 88). However, situations exist in which rapid, non-culture-dependent methods such as PCR amplification of the 16S rRNA gene followed by sequencing (turnaround time, 5 to 6 h) or fluorescence in situ hybridization (FISH) of fluorescent probes to 16S rRNA (turnaround time, 1 to 2 h) can be instituted, such as for rapid identification of Gram-negative rods in tissue biopsies evaluating the sputum of patients with CF or in blood cultures for precise localization of the planktonic or biofilm-growing bacteria (36, 89–92). One example of this is the peptide nucleic acid (PNA) FISH method (AdvanDx, Woburn, MA) (93) (Fig. 2F). For blood cultures and pure samples, matrix-assisted laser desorption ionization–time-of-flight mass spectrometry (MALDI-TOF MS) is the fastest method to date (94, 95). PCR amplification of the 16S rRNA gene followed by sequencing or MALDI-TOF MS can be particularly valuable in identification of non-aeruginosa Pseudomonas species.

ISOLATION PROCEDURES

Pseudomonas species have very simple nutritional requirements and grow well on standard broth and solid laboratory
media such as tryptic soy agar with 5% sheep blood, chocolate agar, and MacConkey agar, which are recommended to isolate Pseudomonas spp. from clinical specimens. MacConkey agar is also a differential medium helpful in identifying different strains of Pseudomonas spp., including mucoid strains of P. aeruginosa from CF patients. Multiple selective media containing inhibitors such as acetamide, nitrofurantoin, phenanthroline, 9-chloro-4-[4(diethylamino)phenyl]-9,10-dihydro-10-phenylacridine hydrochloride (C-390), and cetrimide have been used in the past for the isolation and presumptive identification of P. aeruginosa from clinical and environmental samples. Cetrimide and a combination of phenanthroline with C-390 are the most commonly used selective agents. Inhibition of some strains of P. aeruginosa from sputum specimens from CF patients has been reported using a selective agar containing cetrimide (200 mg/liter) and nalidixic acid (15 mg/liter), and some strains are auxotrophic, emphasizing the need to use both selective and nonselective rich media for recovery of bacteria from these patients, such as MacConkey agar, horse or sheep blood agar, and chocolate agar. This range of media is required since CF patients may simultaneously harbor other CF pathogens such as Staphylococcus aureus, Haemophilus influenzae, Stenotrophomonas maltophilia, Achromobacter xylosoxidans, or Burkholderia spp., in addition to P. aeruginosa. The plates should be incubated for 48 to 72 h since some isolates grow slowly. Some of the non-aeruginosa Pseudomonas, like P. fluorescens, P. putida, and P. oxytoca, may grow better at the lower temperatures of 28 to 30°C. Good growth is usually achieved after 24 to 48 h of incubation. For cultures from CF patients, it is recommended that solid medium plates be held at 35 to 37°C for 5 days since some strains from chronic infections grow very slowly (84).

IDENTIFICATION

Identification of fluorescent and nonfluorescent pseudomonads has become less difficult using MALDI-TOF MS technology, which has replaced conventional phenotypic identification systems in many European clinical microbiology laboratories. However, the latter methods are still used in smaller laboratories and in many non-European countries, and these methods also give information about the physiological and biochemical capabilities of the bacteria, which may sometimes be important for the pathogenesis of infections.

Fluorescent Group

Members of the fluorescent pseudomonad group produce the pigment pyoverdin, which fluoresces under short-wavelength UV light. King’s medium B facilitates the detection of pyoverdin (96). Most strains of P. aeruginosa—except those from CF patients with chronic lung infection—produce the blue pigment pyocyanin. King’s medium A facilitates the detection of pyocyanin, and extraction of pyocyanin with chloroform results in a bluish color (96). This organism may also produce other water-soluble pigments such as pyorubrin (red) or pyomelanin (brown-black). Conditions of iron limitation enhance pigment production, as these pigments act as siderophores in iron uptake systems of the bacteria. Non-dye-containing media enhance visualization of pigments.

P. aeruginosa

Most P. aeruginosa organisms are easily recognizable on primary isolation media on the basis of characteristic colonial morphology, production of diffusible pigments, and a grape-like odor. Cultures may exhibit a corn tortilla-like odor. Colonies are usually flat and spreading and have a serrated edge and a metallic sheen that is often associated with autolysis of the colonies (97). Other morphologies exist, including smooth, mucoid, and dwarf (small-colony variants) (44, 86, 98, 99). Mucoid colonial variants are particularly prevalent in respiratory tract specimens from CF patients and are a hallmark of chronic infection (also in non-CF patients) in contrast to intermittent colonization (36, 100) (Fig. 1).
P. aeruginosa is distinct from the rest of the clinically relevant fluorescent pseudomonads in its ability to grow at 42°C. In addition to pigment production, other tests that confirm its identification are positive oxidase and arginine tests and an alkaline over no-change reaction in the triple sugar iron test. Microbiologists must be aware of certain variations in the phenotypes of P. aeruginosa. Isolates lacking oxidase activity have occasionally been reported, but they exhibit the other characteristic features. Prior antibiotic therapy with agents that affect protein synthesis may cause the aberrant phenotype. Mucoid isolates of P. aeruginosa from CF patients may undergo several phenotypic changes, the aberrant phenotype. Mucoid isolates of P. aeruginosa and P. fluorescens do not possess distinctive colony morphology or odor. Their inability to reduce nitrates to nitrogen gas and their ability to produce acid from xylose distinguish these two species from the other fluorescent pseudomonads. P. fluorescens can be differentiated from P. putida by its ability to grow at 4°C and to hydrolyze gelatin; P. putida can do neither. P. fluorescens isolates may require 4 to 7 days of incubation for accurate detection of gelatin hydrolysis. According to the package insert for API 20NE (version 7.0; bioMérieux, Inc., Durham, NC), only 39% of P. fluorescens isolates hydrolyze gelatin in 24 to 48 h.

P. fluorescens and P. putida P. fluorescens and P. putida do not possess distinctive colony morphology or odor. Their inability to reduce nitrates to nitrogen gas and their ability to produce acid from xylose distinguish these two species from the other fluorescent pseudomonads. P. fluorescens can be differentiated from P. putida by its ability to grow at 4°C and to hydrolyze gelatin; P. putida can do neither. P. fluorescens isolates may require 4 to 7 days of incubation for accurate detection of gelatin hydrolysis. According to the package insert for API 20NE (version 7.0; bioMérieux, Inc., Durham, NC), only 39% of P. fluorescens isolates hydrolyze gelatin in 24 to 48 h.

P. veronii, P. monteilii, and P. mosselii P. veronii can reduce nitrates to nitrogen gas but is unable to hydrolyze acetamide. The type strain of P. veronii (LMG 17761) is negative for acid from lactose and maltose and does not grow at 36°C. P. monteilii can be distinguished from the other members of the fluorescent group by its inability to reduce nitrates to nitrates or nitrogen gas, hydrolyze gelatin, or produce acid from xylose. P. mosselii can reduce nitrates neither to nitrates nor to nitrogen gas, nor can it produce acid from xylose, but most isolates (92%) can hydrolyze gelatin (Table 1).

Other fluorescent pseudomonads are rarely encountered in clinical specimens. Many of these isolates are negative for arginine dihydrolase activity. Identification as “Pseudomonas species, not aeruginosa” and susceptibility testing of the isolates, when appropriate, are sufficient in most circumstances. When necessary, these isolates can be referred to reference laboratories.

Nonfluorescent Group

P. stutzeri and P. mendocina P. stutzeri isolates are easily recognized on primary isolation media by their distinctive dry, wrinkled colony morphology, similar to the morphology of Burkholderia pseudomallei. P. stutzeri can be distinguished from the latter species by its lack of arginine dihydrolase activity and inability to produce acid from lactose. P. stutzeri colonies can pit or adhere to the agar and are buff to brown. The adherence can make removal of colonies from agar medium difficult. Because of the difficulty in making suspensions of specific turbidity, commercial susceptibility systems may not work well with this organism. Not all isolates of P. stutzeri produce wrinkled colonies; such strains can be distinguished from other pseudomonads by their ability to hydrolyze starch, a unique reaction for this species.

P. mendocina colonies are smooth, nonwrinkled, and flat, producing a brownish yellow pigment. Key biochemical characteristics of this species include the ability to reduce nitrates to nitrogen gas, positive arginine dihydrolase activity, and inability to hydrolyze acetamide or starch.

P. alcaligenes and P. pseudoalcaligenes P. alcaligenes and P. pseudoalcaligenes have rarely been encountered in clinical samples (78) and do not have a distinctive colony morphology. Compared to other pseudomonads, they are biochemically inert. Characteristics that distinguish them from other biochemically inert Gram-negative rods are a positive oxidase reaction, motility due to a polar flagellum, and growth on MacConkey agar. P. alcaligenes is distinguished from P. pseudoalcaligenes by its inability to oxidize fructose. Although growth at 42°C was thought to be a distinguishing feature between them, further studies now indicate that growth at 41°C (and probably 42°C) is also present in most strains of P. alcaligenes. These organisms are difficult to identify by many commercial systems, and for most clinical situations, they can simply be referred to as “Pseudomonas spp., not aeruginosa.” If the clinical situation dictates a definitive identification, assistance from reference laboratories should be sought.

P. luteola and P. oryzihabitans P. luteola and P. oryzihabitans can be distinguished from other pseudomonads by their negative oxidase reaction and production of an intracellular, nondiffusible yellow pigment. Both organisms typically exhibit rough, wrinkled, adherent colonies or, more rarely, smooth colonies. P. luteola can be differentiated from P. oryzihabitans on the basis of its ability to hydrolyze o-nitrophenyl-β-D-galactopyranoside and esculin.

Use of Commercial Identification Systems Commercial identification systems rather than conventional biochemical tests increasingly are used in many laboratories to identify Pseudomonas spp. Commercial products can be divided into manual and automated systems. The more frequently used manual systems are the API 20NE (bioMérieux), Crystal E/NF (Becton Dickinson, Franklin Lakes, NJ), and RapID NF Plus (Innovative Diagnostic Systems, Norcross, GA), whereas the OmniLog Phenotype MicroArray system (Biolog, Inc., Hayward, CA), which gives a very comprehensive description of the metabolic capabilities of bacteria, is mostly used in research laboratories. The manual systems usually provide accurate identification of P. aeruginosa, including mucoid isolates as well as other Pseudomonas species, and are preferred over automated systems for isolates from CF patients.

Automated systems are commonly used in many medium to large clinical laboratories. As P. aeruginosa is easily identified by a few conventional biochemical tests, it is often not necessary to use a more expensive commercial system. Several of the automated systems are not very accurate and may require additional testing for non-P. aeruginosa species; thus, their labor-, cost-, and time-saving benefits are lost. Automated systems can identify P. aeruginosa from non-CF sources with 90 to 100% accuracy (101, 102), but some systems may require additional tests to achieve these results (103, 104). Most reviews focus on the evaluation of P. aeruginosa, with only a few, if any, other Pseudomonas species represented in the organisms being tested. When other Pseudomonas species were included, the VITEK 2 GN panel (bioMérieux) performed well (102, 105), while other systems often relied on

gKing's medium A(96).
additional testing to obtain an identification (18, 103, 104, 106). Hence, it is wise to consider carefully the clinical significance, colonial morphology, and other key features before accepting results from automated systems.

Identification of *Pseudomonas* species, especially those isolated from CF patients, is not always optimal with rapid systems. The MicroScan system (Negative Combo 15) (Cruinn Diagnostics, Dublin, Ireland), when incubated for 20 to 24 h according to the manufacturer’s method, performed poorly for CF isolates, with only 57% of nonmucoid and 40% of mucoid *P. aeruginosa* isolates correctly identified (107). Extended incubation for 48 h improved accuracy to 86 and 83%, respectively. Misidentified species were most commonly either *Alcaligenes* spp. or *P. fluorescens*/*P. putida*.

For *P. aeruginosa* from non-CF samples, the overall accuracy has been reported as 94% (107). Other automated systems have not been evaluated to date specifically for the identification of CF isolates, so caution in interpreting results is advised. The importance of non-aeruginosa *Pseudomonas* species as the cause of significant infection has not been established in most cases. The need to pursue species identification beyond the ruling out of *P. aeruginosa* will depend on the individual institution’s requirements.

**TYPING SYSTEMS**

**Phenotypic Typing Methods**

Historically, typing of *P. aeruginosa* for epidemiological purposes has relied on phenotypic characteristics of the bacteria; examples include pyocyan, phage, O, and flagellum typing. The most widely used method was based on differences in LPS O polysaccharide (LPS serotyping) and used either polyonal or monoclonal antibodies. *P. aeruginosa* produces two species of LPS: the common A-band, with only shorter-chain polysaccharides, which most strains produce; and the high-molecular-weight, type-specific B-band. During chronic infection in CF patients, the B-band LPS disappears and is replaced by the A-band and the strains then become polyagglutinable (108). These phenotypic methods have therefore largely been replaced by genotypic methods except in studies of the efficacy of *P. aeruginosa* vaccines in, e.g., minks, which are susceptible to acute pneumonia caused by *P. aeruginosa* (109).

**Genotypic Typing Methods**

Several genotypic methods have been developed over the past 2 decades for typing *P. aeruginosa* for epidemiological purposes (110). These are briefly described in the order in which they were developed. Each is useful, even for typing isolates from patients with CF, but they are not available in most clinical diagnostic laboratories.

**RFLP**

Restriction fragment length polymorphism (RFLP) relies on the genetic diversity at a specific site within the bacterial genome. Such diversity exists upstream of the gene for exotoxin A (*exoA*) in *P. aeruginosa*. In a study of different typing methods, *exoA* RFLP proved superior to all phenotypic methods for typing *P. aeruginosa*. This method was also the first to demonstrate convincingly that patients with CF were usually each infected with a unique strain that was usually present durably (without eradication or replacement) for extended periods. Pilin gene RFLP has demonstrated that individual CF patients are durably infected with the same strain despite changes in pilin protein expression. The disadvantages of RFLP are its relatively weak discriminatory power (compared to that of newer methods), its cumbersome nature, and its predominant use of radioactive probes.

**PFGE**

Pulsed-field gel electrophoresis (PFGE) has long been considered the gold standard for bacterial typing, as it provides a view of the entire genome. The banding pattern is unique to each strain (or clone) and can be used for any bacterial species, and the phylogenetic relatedness can be shown by dendograms using commercial software (111).

**PCR-Based Typing Methods**

Several different PCR-based methods have been used for typing *P. aeruginosa*. They are directed at known elements within the genome or against random but relatively frequently encoded sequences. The latter, random amplified polymorphic DNA analysis, has proved quite robust for typing *P. aeruginosa*, but it must be run consistently on the same equipment to yield reproducible results. Data from random amplified polymorphic DNA analysis usually are highly consistent with those from PFGE. PCR-amplified products can be digested with restriction enzymes to yield more discriminatory data.

**Single-Nucleotide Polymorphism Typing**

Single-nucleotide polymorphism typing by means of AT biochips (ClondiagChip Technologies, Jena, Germany) was developed by L. Wiehlmann and B. Tümmler (Hannover Medical School, Hannover, Germany). This method allows simultaneous detection of 13 single-nucleotide polymorphisms in highly conserved genomic regions such as *oriC*, *citS*, *ampC*, *oprI*, *fliC*, *oprL*, and *alkB2*, and in addition, the AT chip allows detection of several gene islands, pathogenicity factors, and variable genes, providing some insight into the repertoire of the accessory genome of a given isolate (113). This method has been shown to be especially useful in studying the epidemiology and evolution of chronic *P. aeruginosa* lung infection in CF (114–116).

**SEROLOGIC TESTS**

Serologic tests are useful for discrimination between intermittent colonization and chronic infection and for evaluation of the effect of treatment and prognosis in CF patients with *P. aeruginosa*. Several methods have been published, and two approved commercial tests are available: the *Pseudomonas*-CF-IgG ELISA Kit (Statens Serum Institut, Copenhagen, Denmark), which measures antibodies against sonicates from 17 O groups of *P. aeruginosa*; and the Anti-*Pseudomonas aeruginosa* ELA (Mediagnost, Reutlingen, Germany), which detects serum antibodies against three *P. aeruginosa* antigens (alkaline phosphatase, elastase, and exotoxin A) (100, 117–119). The *Pseudomonas*-CF-IgG ELISA Kit can also be modified to measure seroconvert IgG in, e.g., saliva or mucosal secretions for diagnosis of chronic *P. aeruginosa* rhinosinusitis (120).
ANTIMICROBIAL SUSCEPTIBILITIES

*P. aeruginosa* possesses intrinsic resistance to many antibiotic classes and has the ability to develop resistance by mutations in different chromosomal loci or by horizontal acquisition of resistance genes carried on plasmids, transposons, or integrons. The various mechanisms of resistance, substrate specificities, and geographic distributions are discussed below. The frequent acquisition of antimicrobial resistance in *P. aeruginosa* limits the utility of antimicrobial susceptibility patterns (antibiogram) as a tool in epidemiological typing. Only the resistance mechanisms of planktonic-growing bacteria are discussed, since biofilm-growing *P. aeruginosa* organisms are physiologically resistant to the concentrations of antibiotics that can be obtained by systemic administration (18), but may be susceptible to local application (121). The routine methods for measuring of susceptibility of planktonic-growing bacteria—dilution or diffusion methods—are not relevant for biofilm-growing bacteria and do not give any guidance for the clinical choice of antibiotic therapy against biofilm infections (45). Although biofilm-growing *P. aeruginosa* organisms are much more resistant to antibiotics than planktonic-growing cells, the pharmacokinetics and pharmacodynamics of β-lactams, aminoglycosides, ciprofloxacin, and colistin follow the same general rules (122, 123).

The adaptive tolerance of biofilms depends on the presence of the antimicrobial agent and is mediated by a transient induction of resistance mechanisms, rendering the bacterial population temporarily refractory to their action. Transient tolerance does not require genetic changes; it is channeled through regulatory networks and is switched off when antibiotic exposure stops (for an extensive review of adaptive resistance, see reference 124). These types of tolerance are not due to mutations and are reversible.

Induction of β-lactamase transcription in response to the presence of a β-lactam antibiotic is an example of a specific adaptive tolerance response that impairs the penetration of the β-lactam molecules through the biofilm layers (125). Upregulation of efflux pumps is a nonspecific mechanism that has been shown to affect the tolerance to several classes of antibiotics, including macrolides such as azithromycin (126); the antimicrobial peptide colistin (127); as well as biocides such as EDTA, SDS, and chlorhexidine. Upregulation of efflux pumps in biofilms might be triggered not only by the presence of antibiotics but also as part of the bacterial stress response to, for example, oxidative and nitrosative stress (128), representing a mechanism for elimination of toxic compounds that are accumulated in biofilms (129) (for a detailed description of efflux pump regulation, see reference 124).

Mechanisms of Resistance

Intrinsic Resistance

Intrinsic resistance is mediated through multiple mechanisms. *P. aeruginosa* has an inducible chromosomal AmpC β-lactamase that renders it resistant to ampicillin, amoxicillin, amoxicillin-clavulanate, and first- and second-generation cephalosporins, as well as cefotaxime and ceftiraxone. Although impermeability was originally thought to be responsible for resistance to other antibiotic classes, efflux pump systems have been identified as a more prevalent intrinsic mechanism of resistance.

Multidrug efflux systems of the resistance-nodulation-division family exist in *P. aeruginosa* that can result in expulsion of β-lactams, chloramphenicol, fluoroquinolones, macrolides, novobiocin, sulfonamides, tetracycline, trimethoprim, and aminoglycosides (124). Sequencing of the *P. aeruginosa* genome indicates that a high proportion of genes, including regulatory genes, are involved in the efflux of organic compounds, accounting for this organism's ability to adapt to diverse environments and to resist most antimicrobial agents. Efflux systems also export virulence determinants in *P. aeruginosa*, enhancing their toxicity to the host.

Acquired Resistance

Various antibiotics overcome the intrinsic resistance of *P. aeruginosa* and are active against this organism. These include extended-spectrum penicillins (piperacillin and ticarcillin), certain third- and fourth-generation cephalosporins (ceftazidime and cefepime), carbapenems (imipenem, meropenem, and doripenem), monobactams (aztreonam), fluorquinolones (ciprofloxacin and levofloxacin), aminoglycosides (gentamicin, tobramycin, and amikacin), and colistin. Unfortunately, mutational resistance to all the antipseudomonal antibiotics can develop.

Efflux Pumps

Although multidrug efflux pump systems play a significant role in the intrinsic resistance of *P. aeruginosa*, they also are critical to the development of multidrug resistance. The overexpression of efflux systems is frequently associated with a loss of fitness and virulence properties. For this reason, microorganisms need to ensure that genes encoding efflux pumps are expressed only when necessary, and therefore, their expression is tightly regulated by both local and global regulators. MexAB-OprM is expressed constitutively in all strains of *P. aeruginosa*. Upregulation or a mutation in the mexR repressor gene (nalB mutant) results in efflux pump overproduction and significant increase in the MICs of multiple antibiotics, including quinolones, penicillins, cephalosporins, aztreonam, and meropenem (low-level resistance MIC, 8 to 32 μg/ml), but not imipenem. Upregulation of efflux pumps (MexCD-OprJ and MexXY-OprM) is an important determinant of resistance to quinolones and aminoglycosides, respectively, in *P. aeruginosa* from CF patients (130, 131). Interestingly, mexXY genes are induced by oxidative stress (see “Adaptive Resistance” below), which is present in the CF lung (128).

Impermeability Mutations

Impermeability mutations may result in resistance to carbapenem, aminoglycosides, colistin, and quinolones. They are important in carbapenem resistance and result from the loss of the OprD porin, a protein that forms a narrow transmembrane channel permeable to carbapenems.

β-Lactamases

Mutations in the regulatory mechanisms of the chromosomally encoded AmpC β-lactamase (132) lead to constitutive expression of high-level enzymes, rendering *P. aeruginosa* resistant to uredopenicillins and cephalosporins. The acquisition of β-lactamases (133) is not as common for *P. aeruginosa* as it is for Enterobacteriaceae. Nevertheless, β-lactamases are being recognized increasingly and are very diverse in this organism. Genes for these enzymes are encoded on plasmids, transposons, or integrons, making their further dissemination likely. They confer resistance predominantly to antipseudomonal penicillins, ceftazidime, ceftepime, and aztreonam but not carbapenems. Their activity is inhibited poorly by clavulanic acid or tazobactam.

Carbapenemases

With the exception of GES-2, all carbapenemases in *P. aeruginosa* belong to Ambler class B, commonly referred to
as metalloenzymes. Metalloenzymes are not inhibited by clavulanic acid but are susceptible to inhibition by divalent ion chelators such as EDTA. They hydrolyze all β-lactam antibiotics, except aztreonam, and are associated with high-level (MIC, >32 μg/ml) carbapenem resistance. Underreporting of carbapenem resistance may occur, as expression of the carbapenemases varies, resulting in a wide range of MICs (2 to 128 μg/ml) that may go undetected in clinical laboratories that rely only on automated systems.

Genes for these enzymes are plasmid mediated and are located on mobile gene cassettes inserted in variable regions of integrons, resulting in enhanced potential for expression and dissemination. Of concern is the close proximity of these genes to those for aminoglycoside resistance (88).

Carbapenemases are spreading throughout Asia, Europe, and the Americas (134–139). The plasmid-mediated IMP family of enzymes was first described in Japan. The VIM family was first described in Italy. Enzymes from both of these carbapenemase families have been found in Pseudomonas spp. (138, 140, 141). New Delhi metallo-β-lactamase-1, first described in 2008 in Enterobacteriaceae from the Indian subcontinent, has been identified in P. aeruginosa strains from central Europe (142).

**Aminoglycoside-Modifying Enzymes**

Although impermeability mutations can result in aminoglycoside resistance, especially in CF and intensive care patients, drug inactivation by plasmid-encoded or chromosomally encoded enzymes is the most common mechanism for resistance worldwide to this class of antimicrobials (143). Aminoglycoside-modifying enzymes have been detected in P. aeruginosa for more than 30 years; these result in various combinations of resistance to gentamicin, tobramycin, and/or amikacin. P. aeruginosa isolates, especially those from Europe and Latin America, increasingly carry multiple modifying enzymes resulting in broad-spectrum aminoglycoside resistance. These enzymes are often encoded on transposons and/or integrons that carry resistance determinants for other classes of antibiotics such as sulfonamides, β-lactams, and chloramphenicol. Multiresistance genes for both aminoglycosides and extended-spectrum β-lactamases and metalloenzymes are of particular concern (143). Aminoglycoside-modifying enzymes can occur together with impermeability mutations, resulting in broad-spectrum aminoglycoside resistance. Broad-spectrum aminoglycoside resistance due to a gene (rmtA) encoding a 16S rRNA methylase has been described (144).

**Transmissible Quinolone Resistance**

The discovery of a plasmid-borne quinolone resistance determinant (qnr) in Gram-negative organisms is of significance for several reasons: (i) it has been transferred by conjugation to multiple organisms, including P. aeruginosa; (ii) it is associated with high-level quinolone resistance (up to 250-fold increase in MICs); (iii) it appears to be associated with integrons that carry determinants for resistance to β-lactams and aminoglycosides; and (iv) it expands the spectrum of high-level plasmid-mediated resistance to quinolones.

Adaptive Resistance

Adaptive resistance is inducible and depends on the presence of either an antibiotic or another environmental stimulus. A number of triggering factors are now recognized to induce this type of resistance, including antibiotics, oxidative stress (also antibiotic induced [145]), anaerobiosis, cations, and carbon sources. These triggering factors modulate the expression of many genes, leading to effects on efflux pumps, the cell envelope, and enzymes (128). The importance of adaptive resistance in P. aeruginosa is consistent with the large repertoire of regulatory genes (9.4% of all genes) in its genome. An important feature of adaptive resistance is that once the inducing factor or condition is removed, the organism reverts to its wild-type susceptibility (124). Polycationic antimicrobials such as aminoglycosides, polymyxins, and cationic antimicrobial peptides pass across the outer membrane by self-promoted uptake, which involves the interaction of the polycations with divalent cation-binding sites on LPS to competitively displace these cations, causing local disruption that enables the passage of the polycation across the membrane. The ambCADTF operon mediates the addition of 4-aminoarabino to lipid A of LPS, which blocks self-promoted uptake, leading to resistance. Adaptive resistance to polymyxins and host cationic antimicrobial peptides can be mediated by low concentrations of divalent cations (Mg²⁺ and Ca²⁺), leading to the activation of two-component regulatory systems such as PhoPQ, PmrAB, and ParRS, and consequent induction of the am operon and adaptive resistance in the presence of the antipseudomonal drug colistin. The adaptive resistance is, as previously shown, of particular concern where P. aeruginosa grows as biofilms. Mutations in the different two-component systems that regulate the adaptive resistance to colistin can cause acquired resistance to colistin and have been described in P. aeruginosa from CF patients (22, 146, 147).

**Multidrug Resistance**

Worldwide, despite some geographic variability, antimicrobial resistance, including multidrug (three or more antimicrobial classes) resistance to P. aeruginosa, is widespread and increasing (148, 149). According to the European antimicrobial resistance surveillance report from 2011, high percentages of resistance in P. aeruginosa isolates were reported, especially by countries in southern and eastern Europe; 34.7% of the P. aeruginosa isolates were resistant to one or more of the five considered antimicrobial classes (fluoroquinolones, piperacillin-tazobactam, ceftazidime, carbapenems, and aminoglycosides). Combined resistance was common; 15.3% of the isolates were resistant to at least three antimicrobial classes and 4.6% of the isolates were resistant to all five antimicrobial classes.

The percentage of isolates with combined resistance to at least three of the five classes varied considerably between countries, from <1% in some countries to >50% in other countries. The genetic background of the multidrug- or pan-drug-resistant P. aeruginosa has been shown to be a combination of AmpC hyperproduction, OprD inactivation, target mutations conferring high-level fluoroquinolone resistance, mutations involved in efflux pump overexpression, and the production of a class 1 integron harboring aminoglycoside-hydrolyzing enzymes (150).

**ANTIMICROBIAL SUSCEPTIBILITIES**

Worldwide, susceptibility methods vary in terms of choice of media, inoculum preparation, antimicrobial disk content, breakpoints, and interpretation of those breakpoints. Even when these variables are taken into consideration, susceptibility testing of P. aeruginosa remains challenging given the multiple mechanisms of resistance, both intrinsic and acquired, which are frequently expressed concurrently, often at low levels.
In clinical laboratories, susceptibility testing for *Pseudomonas* species may be performed by disk diffusion, agar or broth dilution, Etest (bioMérieux), or automated susceptibility systems using broth microdilution, which have been shown to perform very well using the European Committee on Antimicrobial Susceptibility Testing (EUCAST) breakpoints (151). Disk diffusion tests perform satisfactorily for most clinical isolates of *P. aeruginosa* (152). Limitations to this method include the lack of a quantitative result (MIC) and the potential to miss low-level resistance. Etest has been shown to correlate well with agar dilution for isolates from CF (153, 154) and non-CF (155) patients. Breakpoint interpretation for disk diffusion zones and MICs is standardized by national committees in several European countries such as the British Society for Antimicrobial Chemotherapy and by international committees such as EUCAST (http://www.eucast.org) in Europe and the Clinical and Laboratory Standards Institute (CLSI) (http://www.clsi.org/) in North America and elsewhere, and since 2013 the United States Committee on Antimicrobial Susceptibility Testing (USCAST) has initiated similar work in the United States (http://www.uscast.org). Although some harmonization has been shown to correlate well with MIC results, possibly due to the adaptive resistance mechanism described above (163). Susceptibility testing of colistin should be performed by a MIC method such as agar dilution, Etest, or broth microdilution. Prolonged incubation (for 48 h) is recommended for broth microdilution (164).

Isolates of *P. aeruginosa* from CF patients pose specific difficulties for microbiology laboratories. Isolates from these patients often exhibit mixed morphotypes, including mucoid phenotypes, small-colony variants, and bacterial microcolonies in biofilms. Susceptibility testing is complicated by several factors, including lack of correlation between susceptibility results and clinical response (165), different susceptibility patterns within a morphotype (166), lack of reproducibility of susceptibility tests, undercalling resistance, and presence of hypermutable strains (86). Mucoid and small-colony phenotypes of *P. aeruginosa* are often coisolated from patients with CF. Mucoid isolates tend to be more susceptible and have lower β-lactamase activity than nonmucoid isolates (167). One explanation may be that these isolates are protected from selective antibiotic pressure. Selective antibiotic pressure, notably from inhalational tobramycin or colistin therapy, gives rise to small-colony variants of *P. aeruginosa* with properties of increased antimicrobial resistance, autoaggregative growth behavior, and enhanced ability to form biofilms (44, 98, 168). In turn, bacterial cells in biofilms adapt into symbiotic bacterial communities in which the mucoid alginate-producing bacterial cells provide physical protection to the biofilm, while the highly antibiotic-resistant nonmucoid cells protect against antibiotic killing (167). Increased ability of biofilm bacteria to acquire resistance phenotypes (169) and selection of hypermutable strains following antimicrobial therapy (86, 170) may further explain the lack of eradication of *P. aeruginosa* from chronically infected CF patients. Since bacteria found in biofilms exhibit MICs 100- to 1,000-fold higher than those for free-living bacteria, routine susceptibility testing of planktonic bacteria (171) may underestimate resistance and may contribute to treatment failures. In a study of 597 CF isolates (152), both disk diffusion and Etest were found to be generally acceptable as routine susceptibility testing methods. However, poor correlation was found with diffusion testing of mucoid isolates for piperacillin, piperacillin-tazobactam, and meropenem. Underreporting of resistance was more frequent with disk diffusion than with Etest, especially when testing ceftazidime, piperacillin, and piperacillin-tazobactam.

Hypermutable strains may be detected using either disk diffusion or Etest methods by the presence of resistant mucoid isolates from patients with CF. Mucoid isolates tend to be more susceptible and have lower MICs and MBCs than nonmucoid isolates (167). One explanation may be that these isolates are protected from selective antibiotic pressure. Selective antibiotic pressure, notably from inhalational tobramycin or colistin therapy, gives rise to small-colony variants of *P. aeruginosa* with properties of increased antimicrobial resistance, autoaggregative growth behavior, and enhanced ability to form biofilms (44, 98, 168).

Overestimating susceptibility may occur, as mucoid isolates often demonstrate insufficient growth and are difficult to culture. Automated systems that allow for longer incubation may be preferable. On the other hand, overcalling resistance may result from the presence of large amounts of exopolysaccharide, resulting in turbidity without adequate bacterial growth. These limitations have led many microbiologists to routinely work with mucoid isolates of *P. aeruginosa* to avoid using automatic methods for mucoid isolate testing. Using phenotypically different colonies directly from
sputum cultures, or from subcultures of isolated colonies, has been shown to correlate well with disk diffusion and MIC susceptibility methods and may provide clinically useful susceptibility data with significant time and cost savings. However, the correlation appears to be better for susceptible strains than for resistant strains. Direct sputum susceptibility testing using the Etest method has been suggested as an alternative to morphotype testing in assessing the in vivo situation by evaluating bacterial population susceptibility as well as potential interactions with other organisms, including commensal microbes (174). Other methods have been recommended in an attempt to better predict susceptibility results. Biofilm susceptibility assays have been developed that confirm that minimal biofilm inhibitory concentrations are much higher than conventionally determined MICs for multiple antibiotics (171). These values should guide pharmacokinetics/pharmacodynamics-based antibiotic treatment. A multicenter, randomized, double-blind, controlled clinical trial looked at whether using the results of testing of antibiotics against P. aeruginosa grown as a biofilm rather than in liquid improved outcomes in people with CF with lung infections (175). There was no difference in the reduction of sputum bacteria or in the improvement in lung function between the two groups. However, further studies including larger numbers of CF patients and younger patients with less advanced lung disease should be conducted in the future. Synergy testing using microtiter checkerboard, time-kill test, broth macrodilution breakpoint combination sensitivity test, or Etest methods (174, 176, 177) has been used to assess the activities of antibiotic combinations in vitro in order to predict in vivo synergistic activity. This testing is labor-intensive, time-consuming, and difficult to reproduce, and it remains controversial, as very few clinical data exist demonstrating correlation with prediction of outcomes.

Pseudomonas species other than P. aeruginosa are generally susceptible to most antipseudomonal antibiotics as well as to trimethoprim-sulfamethoxazole (except most P. fluorescens/putida isolates), a property that differentiates them from P. aeruginosa. P. fluorescens, P. putida, and P. oxycitri- nans may be more resistant to aztreonam and ticarcillin-clavulanate. P. stutzeri is usually very susceptible to all antipseudomonal agents (35).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

P. aeruginosa may be associated with colonization or clinically significant infections. Interpretation of the Gram stain often dictates the further workup of this organism. The presence of small clusters of Gram-negative organisms surrounded by amorphous material is indicative of biofilm formation compatible with a chronic infection. This finding should be reported to physicians, and incubation should be prolonged, as these isolates usually exhibit slower growth characteristics. The presence of these organisms intracellularly in polymorphonuclear cells is a strong indication of true infection rather than colonization. Isolation of P. aeruginosa from sterile body sites should always be interpreted as indicative of probable infection. Isolation in mixed culture requires correlation with the direct smear, other organisms isolated, and clinical history. Isolates from sites of chronic infection, such as CF respiratory sites, often exhibit multiple morphotypes that can make identification difficult. Molecular methods increasingly are finding a role in the identification of this organism, especially for epidemiological studies. Susceptibility testing of this organism is difficult, especially for mucoid isolates, due to increasing resistance, lack of reproducibility of results, and lack of clinical correlation. Piperacillin and piperacillin-tazobactam results obtained from automated systems may be unreliable for Pseudomonas spp., and in particular for mucoid isolates, and results should be confirmed by disk diffusion or Etest systems. A basic understanding of the multiple mechanisms of resistance, both intrinsic and acquired, is essential to interpret susceptibility testing results and give therapeutic recommendations to physicians. Other Pseudomonas species are infrequently isolated in the laboratory and are usually not clinically significant. Clinical correlation and correlation with the Gram stain are essential before further workup is undertaken.

Burkholderia, Stenotrophomonas, Ralstonia, Cupriavidus, Pandoraea, Brevundimonas, Comamonas, Delftia, and Acidovorax

JOHN J. LIPUMA, BART J. CURRIE, SHARON J. PEACOCK, AND PETER A. R. VANDAMME

TAXONOMY

Many of the bacteria discussed in this chapter formerly belonged to the genus Pseudomonas; others were described and named after the taxonomic dissection of this genus to conform to a modern phylogeny-based taxonomy. In this reclassification process, the name Pseudomonas was confined to rRNA homology group I organisms because they included reclassification process, the name and named after the taxonomic dissection of this genus to belong to the genus Pseudomonas (see chapter 42).

rRNA group II pseudomonads belong to the class of the Betaproteobacteria and were reclassified into the genera Burkholderia and Ralstonia (1, 2). They form a remarkable group of primary and opportunistic human, animal, and plant pathogens, as well as environmental species with a considerable potential for biological control, remediation, and plant growth promotion. During the past 2 decades, the interest in several peculiar characteristics of these organisms led to the discovery and description of a multitude of novel species. The genus Burkholderia now contains >70 validly named species, many of which have been isolated from soil and water samples. Some other Burkholderia-like species were found to represent a distinct phylogenetic lineage with a position intermediate between those of the genera Burkholderia and Ralstonia and were classified in the novel genus Pandoraea (3).

Comparative 16S rRNA gene sequence analysis, further supported by phenotypic differences, indicated that two distinct sublineages existed within the genus Ralstonia (4). It was proposed that species of the Ralstonia eutropha lineage be classified in a novel genus named Wautersia, whereas the name Ralstonia was preserved for the lineage comprising Ralstonia pickettii, the type species. Shortly thereafter, it became known (5) that Wautersia eutropha, the type species of the genus Wautersia, was a junior synonym of Cupriavidus necator, the type (and only) species of the genus Cupriavidus, an environmental organism that was validly named in 1987, i.e., long before 16S rRNA gene sequence studies were performed routinely (6). To conform to the International Code of Nomenclature of Bacteria (7), the name Wautersia had to be replaced by Cupriavidus and all species of the genus Wautersia became species of the genus Cupriavidus.

Several Burkholderia species have been isolated from human clinical samples, but only B. cepacia complex, B. gladioli (including strains previously classified as B. coccovenerans [8]), B. mallei, and B. pseudomallei are generally recognized as human or animal pathogens. Polyphasic taxonomic studies revealed that B. cepacia-like bacteria belong to at least 18 distinct genomic species, referred to collectively as the B. cepacia complex (9, 10). Ongoing surveys of the diversity of B. cepacia-like bacteria recovered from specimens from cystic fibrosis (CF) patients and other specimens revealed the presence of several additional groups in the B. cepacia complex that cannot be assigned to one of the established species within this complex by using traditional or molecular identification approaches (11). Further polyphasic taxonomic analyses are needed to determine if these groups represent additional novel species within the B. cepacia complex or if they represent new variants of established species. All B. cepacia complex species have been recovered from human clinical samples. Within this group, however, B. multivorans and B. cenocepacia are the most common opportunistic pathogens in CF patients (11).

Apart from the B. cepacia complex species, B. gladioli, B. mallei, and B. pseudomallei, the genus Burkholderia now comprises another 50 validly named species. Most of these organisms are not associated with human disease. Species that rarely have been reported as associated with human infections include B. fungorum, B. glauca, B. thailandensis, B. tropica, B. endofungorum, and B. rhizoxinica (12–16). A complete overview of validly named species can be obtained through Internet sites such as http://www.bacterio.net/.

There are now five species in the genus Ralstonia. The human pathogens include R. pickettii, R. mannitolilytica (previously known as R. pickettii biovar 3/"thomasii") (17), and R. insidiosa (18). Other validly named Ralstonia species are now classified as Cupriavidus species (5). The latter genus consists of C. paucida (previously known as Centers for Disease Control group IVc-2) (19), C. gilardii (20), C. respraculi (21), C. taiwanensis (22), and nine additional species, which thus far have only been recovered from environmental samples.

The genus Pandoraea presently comprises five species that have been isolated from human clinical specimens—these are P. apista, P. pulmonicola, P. pnomenis, P. spotonum,
and _P. norimbergensis_—but also several unnamed strains, each representing a distinct additional _Pandoraea_ species (3). _P. faecalgillanum_ was isolated from chicken feces; other, more recently named _Pandoraea_ species are of environmental origin only (23, 24).

Organisms in the _Pseudomonas_ rRNA homology group III also belong to the _Beta proteobacteria_ and are now classified in the family _Comamonadaceae_, which includes the genera _Comamonas_, _Delftia_, and _Acidovorax_ (25, 26). The genus _Comamonas_ was created in 1985 and included a single species, _C. terrigena_. Shortly thereafter, _Pseudomonas acidovorans_ and _Pseudomonas testosteroni_ were reclassified as members of the genus _Comamonas_; the former was, however, again reclassified as _Delftia acidovorans_ (27). _C. terrigena_ encompassed three strain clusters with human clinical isolates (28), which are now known as _C. terrigena_, _C. aquatica_, and _C. kerstersii_ (29). The genus _Comamonas_ at present totals 16 validly named species, which are primarily of environmental origin. The genus _Delftia_ comprises another 3 validly named species of environmental origin (30). The genus _Acidovorax_ comprises 15 species. It includes several well-known plant-pathogenic bacteria and environmental species (31). Only _A. delafeldii_, _A. temperans_, and more recently _A. waeterans_ have been isolated from human clinical samples (32).

_Pseudomonas_ species of the rRNA homology group IV belong to the _Alphaproteobacteria_ and are now classified in the genus _Brevundimonas_. The latter consists of 24 validly named species, most of which are of environmental origin. _B. diminuta_, _B. vesiculans_, and _B. tancamneyi_ have been isolated from human clinical samples (33, 34).

Finally, _Pseudomonas maltophilia_ represented _Pseudomonas_ rRNA homology group V. Based on genotypic and phenotypic characteristics, its transfer to the genus _Xanthomonas_, a member of the _Gamma proteobacteria_, and subsequently to the novel genus _Stenotrophomonas_ was proposed (35, 36). _S. maltophilia_ is a well-known opportunistic pathogen (37) and is considered taxonomically heterogeneous (38); 10 other _Stenotrophomonas_ species are exclusively known as environmental bacteria.

### DESCRIPTION OF THE AGENTS

_Burkholderia_, _Ralstonia_, _Cupriavidus_, _Pandoraea_, _Brevundimonas_, _Comamonas_, _Delftia_, and _Acidovorax_ spp. are aerobic, non-spore-forming, straight or slightly curved, Gram-negative rods. They are 1 to 5 μm in length and 0.5 to 1.0 μm in width (39). _Stenotrophomonas_ spp. are straight rods and tend to be slightly smaller than members of the other genera (0.7 to 1.8 μm in length and 0.4 to 0.7 μm in width) (39).

With the exception of _B. mallei_, these organisms are motile due to the presence of one or more polar flagella (40). These bacteria are catalase positive, and most are either weakly or strongly oxidase positive. All grow on MacConkey agar, except for certain strains of _B. vesiculans_, and appear to be nonfermenters. The majority of species degrade glucose oxidatively, and most degrade nitrate to either nitrite or nitrogen gas. Certain species have distinctive colony morphologies or pigmentation. They are nutritionally quite versatile, with different species being able to utilize a variety of simple and complex carbohydrates, alcohols, and amino acids as carbon sources. Certain species can multiply at 4°C, but most are mesophilic, with optimal growth temperatures of between 30 and 37°C (40). For some genera, growth at higher temperatures (i.e., 42°C) can be useful for species identification.

### EPIDEMIOLOGY AND TRANSMISSION

_Burkholderia_, _Ralstonia_, _Cupriavidus_, _Pandoraea_, _Comamonas_, _Delftia_, _Acidovorax_, _Brevundimonas_, and _Stenotrophomonas_ spp. are environmental organisms found in water, soil, the rhizosphere, and in and on plants including fruits and vegetables. They have a worldwide distribution. Members of these genera are widely recognized as phytopathogens, and many species were first described in that context. Because of their ability to survive in aqueous environments, these organisms have become particularly problematic as opportunistic nosocomial pathogens in hospitals and health care settings.

The natural distribution of _B. cepacia_ complex species is being intensively studied because of interest in their biotechnological properties and their pathogenicity in persons with CF (41). _B. cepacia_ complex bacteria often have antifungal, antinemotil, or plant growth-promoting properties, which make them attractive as biological pesticides and fertilizers (42). Because of their nutritional versatility, _B. cepacia_ complex bacteria also have applications for bioremediation of contaminated soils. These species are infrequently recovered from sites such as sinks, swimming pools, and showers (43). However, some species within the complex, especially _B. ambifaria_, _B. anthina_, and _B. pyrocemia_, can be readily recovered from certain soil samples (44), provided that appropriate growth conditions are used to inhibit the growth of vast numbers of other environmental bacteria. Of particular note, _B. multivorans_, which is among the most common _B. cepacia_ complex species recovered from CF patients, has been only infrequently recovered from environmental sources. Studies of a variety of foodstuffs and bottled water have shown that _B. cepacia_ complex bacteria have been found in unpasteurized dairy products (45). Due to their intrinsic resistance to antibiotics and disinfectants, _B. cepacia_ complex bacteria are also notorious contaminant of pharmaceutical preparations (46, 47). Numerous health care-associated outbreaks of _Burkholderia_ infection due to contaminated medical devices and products, including mouthwashes, ultrasound gels, skin antiseptics, and medications, have been described (41).

Genotypic and conventional epidemiologic investigations provide compelling evidence for interpatient transmission of shared or “epidemic” _B. cepacia_ complex strains among persons with CF (41). One such strain, referred to as the ET21 (for electrophoretic type 12) lineage, is common among CF patients in eastern Canada and the United Kingdom (48, 49). This organism is a _B. cenocepacia_ strain that is characterized by the presence of a distinctive cable-like plasm and an associated adhesin that mediates adherence to respiratory epithelium. _B. cenocepacia_ strain PHDC dominates among infected CF patients in the mid-Atlantic region of the United States and has been identified in agricultural soil as well as in CF patients in several European countries (50–52). _B. cenocepacia_ “Midwest clone” is common among CF patients in the midwestern United States (53).

_B. pseudomallei_ and _B. thailandensis_ are found in soil and surface water primarily in tropical and subtropical areas. Both species have been isolated in the rice-growing regions of northeast Thailand, western Cambodia, Laos, and southern and central Vietnam (54–56). In northern Australia, associations have been made between _B. pseudomallei_ and native grasses in undisturbed land and the presence of livestock animals, lower soil pH, and different combinations of soil texture and color in environmentally disturbed sites (57, 58). Recent environmental studies have identified _B. thailandensis_-like organisms from Australia (59).
The known endemic distribution of *B. pseudomallei* is being expanded beyond the traditional regions of endemicity for melioidosis to Southeast Asia and northern Australia, with recent case reports of the disease from the Americas, Madagascar, several countries in Africa, Mauritius, India, and elsewhere in south Asia, China, and Taiwan. To what extent this reflects a true expansion of endemicity rather than unmasking of the long-standing presence of the bacterium remains unclear (60–62). What is apparent is that *B. pseudomallei* can occasionally persist in temperate environments after introduction via animals infected with melioidosis (63).

*S. maltophilia* can cause nosocomial infections; however, the sources of hospital-acquired infection are poorly understood. Inappropriate use of hand-moisturizing lotion instead of soap by a health care worker was associated with infection among bone marrow transplant recipients in one center (64), while in another, contamination of faucet aerators in intensive care unit sinks was implicated as the source of *S. maltophilia* infection (65).

Unlike that of certain *B. cepacia* complex strains, evidence for person-to-person transmission of *B. gladioli*, *B. pseudomallei*, *B. mallei*, *S. maltophilia*, and the other species discussed in this chapter is lacking.

**CLINICAL SIGNIFICANCE**

*B. cepacia* Complex and *B. gladioli*

*B. cepacia* has been long recognized as an occasional opportunistic human pathogen, capable of causing a variety of infections, including bacteremia, urinary tract infection, septic arthritis, peritonitis, and pneumonia in persons with underlying illness. Persons with chronic granulomatous disease (CGD) and CF are particularly susceptible to infection (66). *B. cepacia* also has a history as a nosocomial pathogen, causing infections associated with contaminated hospital equipment, medications, and disinfectants including povidone-iodine and benzalkonium chloride (41). Nosocomial outbreaks of respiratory tract infections in patients on mechanical ventilation in intensive care units have been attributed to contamination of nebulizers or nebulized medications such as albuterol. Contamination of blood culture systems or disinfectants resulting in pseudobacteremia has been described following the isolation of *B. cepacia* from the blood of multiple patients over a short period. Early reports of infection in CF described patients with acute pulmonary deterioration and sepsis (referred to as cepacia syndrome) or chronic respiratory tract infections associated with an accelerated decline in lung function (67). Clinical outcome studies consistently identified *B. cepacia* infection as a significant independent risk factor for morbidity and mortality in CF (68).

The recognition that several closely related species can be distinguished from among organisms previously identified as *B. cepacia* has stimulated interest in the clinical significance of each of these species (69). Approximately 3% of CF patients in the United States are infected with *B. cepacia* complex species, although rates of infection vary from 0 to 20% among CF treatment centers (70). Rates of infection increase with increasing patient age; approximately 5 to 7% of adults with CF are infected (70). Many strains exhibit broad-spectrum antimicrobial resistance (see below), and pulmonary infection is generally refractory to therapy. Furthermore, due to the poor postoperative prognosis associated with *B. cepacia* complex, most CF treatment centers consider infection to be an absolute contraindication for lung transplantation, which at present offers the only therapeutic option for successful intermediate-term survival of persons with end-stage pulmonary disease (71). Thus, respiratory tract infection by these species is a cause of great concern to CF patients and their caregivers.

Although 17 of the 18 species of the *B. cepacia* complex have been recovered from persons with CF (the exception is *B. ubonensis*), the distribution of species in this patient population is quite disproportionate. In the United States, *B. multivorans* and *B. cenocepacia* together account for ~80% of *B. cepacia* complex infections, with *B. vietnamiensis*, *B. cepacia*, and *B. dolosa* together accounting for an additional 15% of infections (11, 41). The remaining *B. cepacia* complex species are much less frequently recovered from human sources. These species include *B. stabilis*, *B. ambifaria*, *B. anthina*, *B. pyrocina*, *B. contaminans*, *B. seminalis*, *B. diffusa*, *B. metallica*, *B. arboris*, *B. latens*, *B. lata*, and *B. pseudomultivorans* (10, 41). Some CF patients are infected with bacteria that, based on genetic analyses, are most appropriately included in the *B. cepacia* complex but cannot be assigned to one of the currently named species. These strains most likely represent additional novel species within the complex. Finally, the incidences of *B. multivorans* and *B. cenocepacia* infection in CF appear to have shifted during the last few years. Whereas *B. cenocepacia* previously accounted for the majority of *Burkholderia* infections in CF (11), currently ~3 times as many CF patients in the United States become infected with *B. multivorans* as with *B. cenocepacia* (41). In the United Kingdom, the recovery of *B. multivorans* from CF patients now also exceeds that of *B. cenocepacia* (72).

Available data suggest that *B. cepacia* complex species also vary with respect to their virulence levels and clinical impacts in CF. Studies in lung transplant recipients, for example, indicate that rates of postoperative mortality are greater for persons infected preoperatively with *B. cenocepacia* than for patients infected with other *B. cepacia* complex species (73, 74). Carefully conducted multivariate analyses of posttransplant outcomes are less definitive, however (75). Thus, although it is almost certainly true that *B. cenocepacia* is the species most frequently associated with cepacia syndrome, it remains to be shown whether this species, in general, is disproportionately associated with poor outcome; case reports document fatal infection associated with other *B. cepacia* complex species, including *B. multivorans*, *B. stabilis*, and *B. dolosa* (76, 77). Although a positive correlation between species frequency and poor clinical outcome seems likely, firm conclusions regarding the relative virulence of *B. cepacia* complex species must await more definitive study. Evidence also suggests that certain strains within species are relatively more virulent in human infection. The *B. cenocepacia* ET12 epidemic strain and the *B. dolosa* SLC6 strain, in particular, appear to be relatively more virulent in CF patients (78, 79). Again, however, further comparative outcome studies are needed before firm conclusions about relative virulence of specific strains can be drawn.

*B. gladioli* is most notable as a plant pathogen, but is also well recognized to be capable of causing infection in persons with CGD or CGD and, occasionally, other immunocompromised patients (80). Anecdotal reports describe acute pulmonary deterioration and recurrent soft tissue abscesses, as well as severe post-lung transplantation infections due to *B. gladioli* in CF patients (75, 81). A more complete appreciation of the epidemiology and clinical significance of *B. gladioli* infection in CF has been confounded by difficulty with accurate identification of this species, which typically is capable of growth on selective media used to isolate
B. cepacia complex species and is frequently misidentified as a member of the B. cepacia complex by commercial test systems (82). Genetic and nontype Burkholderia isolates recovered from CF patients indicates that B. gladioli is much more commonly involved in infection in this patient population than are most B. cepacia complex species, with the exception of B. multivorans and B. cenocepacia (41).

**B. pseudomallei** and **B. mallei**

*B. pseudomallei* is the causative agent of the human and animal disease melioidosis, which is endemic in Southeast Asia and tropical northern Australia and is being increasingly recognized on the Indian subcontinent and in Central and South America (60, 61, 83, 84). In locations where the disease is endemic, infection is seasonal, with up to 85% of cases occurring during the monsoon wet season. Severe weather events and environmental disturbances have been associated with melioidosis clusters in Australia (85), and the Asian tsunami of 2004 resulted in cases across the affected region (86, 87). As travel to Southeast Asia and northern Australia has become more frequent, reports of melioidosis in travelers returning to Europe and the United States are becoming more common (83). Melioidosis is an especially important potential travel-related illness for those with CF, and persistent colonization of airways with *B. pseudomallei* can occur in CF despite prolonged therapy, with repeated disease flares and deteriorating lung function (88, 89). Infection with this organism should be considered in the differential diagnosis of any individual with a fever of unknown origin or a tuberculosis-like illness who has a history of travel to a region where *B. pseudomallei* infection is endemic.

*B. pseudomallei* is acquired from the environment by inoculation through cut or abraded skin, inhalation, aspiration, or ingestion (90). Zoonotic disease is described but is exceedingly uncommon, as are person-to-person transmission and laboratory-acquired infection (83). The association of severe weather events with respiratory infection and high mortality rates has been attributed to a shift from percutaneous inoculation to inhalation (91). This idea supports the potential of *B. pseudomallei* as a bioterrorist agent; its isolation in individuals who do not have a history of travel to an area where melioidosis is endemic should be immediately reported to local or state public health authorities. For further details, see chapter 14 or [http://www.bt.cdc.gov](http://www.bt.cdc.gov).

The majority of persons exposed to *B. pseudomallei* do not develop clinical infection, with rates of seropositivity in the general population as high as 80% in some locations (92). Latent infection with subsequent reactivation is well recognized, with a recent description of disease onset in a biodefense scientist (101). Like melioidosis, human glanders can be acute or chronic, with the clinical presentation and course depending on the mode of infection, the inoculation dose, and host risk factors. Respiratory inoculation can result in pneumonia with potential for dissemination to internal organs and septicemia. Cutaneous inoculation can result in skin nodules and regional lymphadenitis, also with potential for disseminated disease. Involvement of nodes, both mediastinal and peripheral, is much more common in glanders than in melioidosis, often with supplicative abscesses in untreated cases.

**S. maltophilia**

*S. maltophilia*, although typically not pathogenic for healthy persons, is a well-known opportunistic human pathogen. It is among the most common causes of wound infection due to trauma involving agricultural machinery (102). It is also an important nosocomial pathogen associated with substantial morbidity and mortality, particularly in debilitated or immunocompromised patients and patients requiring ventilatory support in intensive care units (103). The incidence of human infection appears to have increased in recent years, and a variety of clinical syndromes have been described, including bacteremia, pneumonia, urinary tract infection, ocular infection, endocarditis, meningitis, soft tissue and wound infection, mastoiditis, epididymitis, cholangitis, osteochondritis, bursitis, and peritonitis (104, 105). Septicemia can be accompanied by erythema gangrenosum, a skin lesion more commonly associated with *P. aeruginosa* and *Vibrio* spp.

The incidence of *S. maltophilia* respiratory tract infection in persons with CF also appears to be increasing (106); however, the unreliability of historical data limits firm conclusions. Approximately 14% of CF patients included in the
Cystic Fibrosis Foundation’s patient registry was reported to be culture positive for *S. maltophilia* in 2011 (72). In large, multicenter clinical trials, however, *S. maltophilia* was found in a larger proportion of CF patients, being second only to *P. aeruginosa* in frequency of isolation from study subjects. Infection or colonization was most frequently transient, with 30% of subjects having at least one sputum culture positive for *S. maltophilia* during the course of 6 months (107). Several case-control studies have drawn conflicting conclusions regarding the role that *S. maltophilia* plays in contributing to pulmonary decline in CF (108).

**Ralstonia and Cupriavidus spp.**

As described above, several former Ralstonia species are now assigned to the genus *Cupriavidus* (5). Among the species in these two genera, *R. picketti* is best known with respect to human infection. Older reports describe this species as being recovered from a variety of clinical specimens and as causing various infections including bacteremia, meningitis, endocarditis, and osteomyelitis (109). *R. picketti* also has been identified in pseudobacteremias and nosocomial outbreaks due to contamination of intravenous medications, “wet” sterile water, saline, chlorhexidine solutions, respiratory therapy solutions, and intravenous catheters (110, 111). This species has also been recovered from the respiratory tract of persons with CF. However, *R. picketti* is easily confused with *Pseudomonas fluorescens* and members of the *B. cepacia* complex based on phenotype (17, 112). Furthermore, several *R. picketti*-like species are also now known to be involved in human infection, particularly in CF (113). Thus, the role of *R. picketti* as a human pathogen is difficult to assess based on historical data.

*R. maminolityltica* (formerly known as *R. picketti* biovar 3/‘thomasi’) was recently described as causing nosocomial outbreaks and a case of recurrent meningitis (17). This species accounts for the majority of *Ralstonia* infections in CF patients, being found in more than twice as many CF patients as those infected with *R. picketti* (113). *R. insidiosa* and *C. respiraci* are species that are also recovered from persons with CF (18, 21). *C. gigardii* has been recovered from cerebrospinal fluid (20), and cases of *C. pauculus* bacteremia, peritonitis, and tenosynovitis have been reported (19). Both of these species may be found in sputa from patients with CF (113). Although *Cupriavidus metallidurans* and *Cupriavidus basilensis* are not known to cause other human infection, they too have been recovered recently from sputum cultures from patients with CF (113). Despite these observations, the roles of *Ralstonia* and *Cupriavidus* species in human infection, particularly in persons with CF, require further elucidation.

**Other Genera**

In general, *Brevundimonas, Comamonas, Delftia, Acidovorax,* and *Pandoraea* spp. infrequently cause human infection. Interest in these species focuses primarily on their roles as plant pathogens or in studies of microbial biodiversity and biodegradation. *Brevundimonas* spp. are occasionally recovered from clinical specimens (114). *B. vesicularis* bacteremia in patients with various underlying illnesses has been reported (115), and the organism has been recognized in cervical specimens because of its ability to produce bright orange colonies on ThayerMartin agar. *B. diminuta* has been recovered from blood, urine, and pleural fluid from patients with cancer (116).

Among the *Comamonas* species, *C. testosteroni* has been implicated most often in human infection, with reports describing endocarditis, meningitis, and catheter-associated bacteremia due to this species (117–119). *D. acidovorax* has similarly been reported to cause infection, being identified in cases of bacteremia, endocarditis, ocular infection, and suppurative arthritis (120). *Acidovorax* spp. have been isolated from a variety of clinical sources, including blood from a patient with hematological malignancy (121). *Acidovorax* spp., *C. testosteroni*, and *D. acidovorax* have also been recovered from sputa of persons with CF (122; J. J. LiPuma, unpublished data); however, the roles of these species in contributing to lung disease in CF have not been established.

In addition to causing infection in CF patients (123, 124), *Pandoraea* spp. have been recovered from blood and from patients with chronic obstructive pulmonary disease or CGD (125). Although the roles of these species in contributing to poor outcomes in persons with underlying diseases are unclear, a recent report describes sepsis, multiple organ failure, and death in a patient who underwent lung transplantation for sarcoidosis (126).

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

The genera described in this chapter include organisms that can survive in a variety of hostile environments and at temperatures found in clinical settings. Therefore, standard collection, transport, and storage techniques as outlined in chapter 18 are sufficient to ensure the recovery of these organisms from clinical specimens. Recovery of *B. pseudomallei* for the diagnosis of melioidosis is increased by the additional collection of throat and rectal swabs into selective media (see “Isolation Procedures” below) and by collecting larger-than-standard volumes of cerebrospinal fluid for culture in suspected neurological melioidosis (127).

**DIRECT EXAMINATION**

Members of these genera have similar morphologies and, with the exception of *B. pseudomallei*, are not easily distinguished from each other on the basis of Gram staining. *B. pseudomallei* may appear as small, Gram-negative bacilli with bipolar staining, making the cells resemble safety pins (Fig. 1). This may increase the index of suspicion for the presence of *B. pseudomallei*, but the sensitivity and specificity of this appearance are not high enough to be relied on for a presumptive clinical diagnosis.

Although PCR-based assays have been described for the identification of *B. cepacia* complex species, *B. pseudomallei*, *B. gladioli*, several *Ralstonia* and *Cupriavidus* species, *Pandora* species, and *S. maltophilia* following culture and isolation (see “Identification” below), the use of PCR for direct detection of these species in clinical specimens remains a research tool (128, 129). Studies of CF sputum samples have indicated that some specimens may be PCR positive but culture negative for certain *B. cepacia* complex species, raising important questions about the natural history of infection in CF. However, the sensitivities and specificities of such PCR assays for the intended target species are difficult to determine in the absence of reliable gold standards. Assays employing real-time PCR or culture-independent strategies employing next-generation bacterial genome sequencing are likely to provide alternative approaches to direct detection of these species in clinical specimens in the near future.

Because septicemia with *B. pseudomallei* is frequently fatal and death often occurs in the first few days after presentation to hospital prior to the availability of culture results, several rapid direct-detection methods have been developed, including urinary antigen detection using latex agglutination and enzyme immunoassay as well as direct fluorescent-antibody
tem (TTS) genes have been developed and been shown to

have high sensitivities and specificities with pure bacterial cultures (135–137). Two clinical evaluations of real-time PCR have met with mixed results, with a sensitivity of 91% in one study using an assay targeting a gene in the TSS1 cluster (129) and a considerably lower sensitivity of 61% in a second study that used an assay targeting the 16S rRNA gene (138). Sensitivity of PCR is highest for pus and other body fluids but is low for blood, most likely reflecting a bacterial copy number effect. Various methods have been assessed for optimal DNA extraction from clinical samples (139), and comparisons have been made between the published real-time PCR targets, with the TTS1-orf2 assay found to be superior in detecting B. pseudomallei directly from clinical specimens (140). Loop-mediated isothermal amplification is easy and quick to perform and needs mini-
mal equipment, with amplification being achieved at a fixed temperature in a water bath or heating block. This procedure has been developed and evaluated for the detection of B. pseudomallei and diagnosis of melioidosis (141). The assay was sensitive and specific for the laboratory detection of B. pseudomallei and had 100% specificity when applied to clinical samples but had a very low diagnostic sensitivity (44%). At present, molecular assays are not sufficiently sensitive to replace conventional culture.

**ISOLATION PROCEDURES**

The species discussed in this chapter grow well on standard laboratory media such as 5% sheep blood and chocolate agars. Such media can be used to recover the organisms from sterile fluid or tissue where a mixed biota is not anticipated (see chapter 18). All species that have been reported to be recovered from blood, including B. pseudomallei, grow in broth-based blood culture systems within the standard 5-day incubation period, so that special blood culture techniques such as lysis-centrifugation and extended incubation periods are not required. The use of selective media facilitates the isolation of these organisms from specimens with mixed microbiota. With the exception of B. pseudomallei, MacConkey agar can be used to isolate most species of these genera. B. pseudomallei is preferred for the isolation of B. pseudomallei and B. pseudomallei. Several selective media have been described, and some are commercially available. A multicenter comparison of three media, PC (for Pseudomonas cepacia) agar (BD Diagnostics, Franklin Lakes, NJ) (142), OFPBL (for oxidation-fermentation base-polymyxin B–bacitracin–lactose) agar (BD Diagnostics) (143), and BCSA (for B. cepacia selective agar; Hardy Diagnostics, Santa Maria, CA) (25), showed that BCSA was superior, being both more sensitive (more B. cepacia isolates were recovered) and more specific (fewer other types of organisms grew) than PC or OFPBL agar (25,144). The sensitivities of TB-T (for trypan blue-tetracycline), PC-AT (for Pseu-
monas cepacia azelaic acid), and BCSA (25, 144) were also compared with those of three commercial media, i.e., B. cepacia media from MAST Diagnostics (Bootle, United Kingdom), Lab M Ltd. (Heywood, United Kingdom), and Oxoid Ltd. (Basingstoke, United Kingdom), through the analysis of 142 clinical and environmental isolates representing all species within the B. cepacia complex (145). BCSA and MAST B. cepacia medium supported the growth of B. cepacia complex isolates most efficiently. The latter two media were also compared in a study to evaluate the sensitivities and specificities for the isolation of B. cepacia complex species from sputum specimens from CF patients

![FIGURE 1 (a) Gram stain of B. pseudomallei in a blood culture; (b) Gram stain of B. pseudomallei from a colony on blood agar. doi:10.1128/9781555817381.ch43.f1](image-url)
agar but more selective. (146). BCSA was reported as being as sensitive as MAST colonies on Ashdown medium agar. (b) FIGURE 2 (a) B. pseudomallei colonies on MacConkey agar; (b) B. pseudomallei colonies on blood agar; (c) B. pseudomallei colonies on Ashdown medium agar. doi:10.1128/9781555817381.ch43.f2

not available. An enrichment broth consisting of Ashdown medium supplemented with 50 mg of colistin is superior to standard enrichment broth such as tryptic soy broth and increases recovery of B. pseudomallei from clinical specimens taken from colonized sites compared with plating on Ashdown medium alone (127). Selective broth cultures should be subcultured to Ashdown medium after 48 h of incubation in air at 37°C, and all inoculated plates should be incubated at 37°C in air and examined daily for 4 days before being discarded, since some colonies become apparent to the naked eye only after extended incubation.

The use of selective media increases the isolation rates of S. maltophilia from clinical and environmental samples (150). Denton et al. (150) studied the sensitivity of a selective medium incorporating vancomycin, imipenem, and amphotericin B as selective agents (VIA medium) for isolating S. maltophilia from sputum samples collected from children with CF. This study compared the use of VIA medium to an existing in-house method that utilized an imipenem disk placed upon bacitracin-chocolate agar (BC medium) and reported an improved detection using VIA as a selective medium.

IDENTIFICATION

B. cepacia Complex and B. gladioli

Accurate identification of B. cepacia complex species can present a challenge (151). Historically, many commercial bacterial identification systems have not been able to reliably distinguish among the 18 species of the B. cepacia complex and often failed to differentiate these species from other closely related species such as B. gladioli and Ralstonia, Cupriavidus, and Pandoraea spp. (82, 112, 152). This has presented a significant problem for CF patients and their caregivers, as detailed in “Clinical Significance” above. The identification of B. cepacia complex species from CF sputum culture has a dramatic impact on patient management and is a cause of considerable anxiety for patients with CF (71, 153). Consequently, when Burkholderia, Ralstonia, Cupriavidus, or Pandoraea species are tentatively identified in a patient with CF by using a commercial system, the identity of the isolate should be confirmed by molecular techniques. To aid clinical microbiologists in the United States, the CF Foundation has established a B. cepacia reference laboratory, which uses a combination of phenotypic and genotypic methods (described below) to confirm the identity of suspected B. cepacia complex isolates (154). Further information concerning this and other reference laboratories with special expertise in Burkholderia can be found on the CF Foundation website (http://www.cff.org).

B. cepacia complex species may require 3 days of incubation before colonies are seen on selective media. On MacConkey or Mueller-Hinton agar, these colonies may be punctate and tenacious, and on blood agar or selective medium such as BCSA, PC agar, or OFPBL agar, the colonies are smooth and slightly raised; occasional isolates are mucoid. On MacConkey agar, colonies of the B. cepacia complex frequently become dark pink to red due to oxidation of lactose after extended incubation (4 to 7 days). Most clinical isolates are nonpigmented, but on iron-containing media such as a triple sugar iron slant, many strains produce a bright yellow pigment. B. cepacia complex species have a characteristic dirt-like odor.

The species of the B. cepacia complex are phenotypically very similar, making their differentiation, even with an extended panel of biochemical tests, rather difficult (Table 1)
Further, isolates within these species show considerable phenotypic variability, which is likely due to their unusually large genomes rich in insertion sequences and mobile elements such as plasmids, transposons, and bacteriophages (155). These features can contribute to genetic plasticity and diversity, which, when differentially expressed in isolates, result in variable biochemical phenotypic profiles. Most strains are weakly oxidase positive, although some strains of B. contaminans, B. lata, and B. pyrrocinia are oxidase negative. B. multivorans, B. pseudomultivorans, B. stabilis, and B. dolosa rarely oxidize sucrose. B. stabilis is ornithine decarboxylase positive, as are most B. cenocepacia strains, but is distinctive in that more than half of strains are β-nitrophenyl-β-D-galactopyranoside (ONPG) negative. B. stabilis, B. lata, and most B. ambifaria strains show poor growth at 42°C. B. dolosa is usually lysine decarboxylase negative, whereas only approximately half of B. multivorans strains are negative. Other B. cepacia complex species are usually lysine decarboxylase positive. B. vietnamiensis and most B. anthina strains do not oxidize adonitol. B. anthina strains show a distinctive creamy morphology on BCSA, which also turns pink (i.e., alkaline) despite the ability of this species to utilize sucrose (156).

Phenotypic differentiation of B. cepacia complex species from B. gladioli and Pandoraea spp. is also difficult (Table 1). Cellular fatty acid analysis is unable to differentiate B. cepacia complex species from B. gladioli (157). However, in contrast to B. cepacia complex species, most B. gladioli strains are oxidase negative, and whereas most B. cepacia complex strains oxidize maltose and lactose, B. gladioli typically oxidizes neither. Pandoraea spp. do not oxidize maltose, lactose, xylose, sucrose, or adonitol, and most are ONPG negative. B. cepacia complex species also may be difficult to differentiate from Ralstonia and Cupriavidus species. However, several of the latter species show a fast and strong oxidase reaction, whereas B. cepacia complex species produce a slow, weak-positive oxidase test. Further, in contrast to most B. cepacia complex species, Ralstonia and Cupriavidus are lysine decarboxylase negative and most often ONPG negative.

The challenge in differentiating B. cepacia complex species prompted the development of molecular genetic diagnostic tests capable of identifying these species individually and distinguishing them (as a group) from biochemically similar species. DNA sequence differences in 16S and 23S rRNA genes have been used to develop species-specific PCR

assays for the identification of several B. cepacia complex species (154, 158), as well as B. gladioli (159). B. multivorans, B. vietnamiensis, and B. dolosa can be reliably identified with 16S rRNA-targeted assays, but insufficient sequence variation in rRNA genes exists to enable reliable separation of the remaining B. cepacia complex species. Fortunately, species-specific sequence variation does exist in the recA gene, and PCR assays targeting this locus enable the reliable identification of the B. cepacia complex species most commonly recovered from human specimens (160–164). Other 16S rRNA- and recA-based PCR assays identify all Burkholderia spp. (i.e., at the genus level) or all species within the B. cepacia complex (i.e., as a group) (154, 161, 165).

Another molecular genetic approach to identifying B. cepacia complex species involves restriction fragment length polymorphism (RFLP) analysis of either 16S rRNA or recA genes (161). Again, insufficient sequence variation in the 16S rRNA gene limits the use of RFLP analysis of this locus, even when multiple restriction enzymes are used (166). In contrast, recA RFLP analysis has proved quite useful in reliably distinguishing all species within the B. cepacia complex (161–165).

Although a multilocus sequence typing (MLST) scheme for the B. cepacia complex was developed primarily as a tool to study the epidemiology and population genetic structure of these species (167), it offers another approach to differentiate species within this group. This scheme was subsequently modified to allow typing of all species within the genus Burkholderia (168). Other genomic approaches, including amplified fragment length polymorphism typing, ribotyping, and whole-cell protein profiling, have been proposed for the differentiation of B. cepacia complex species (169–171). However, these methods are time-consuming and expensive and require an extensive validated database before isolates can be reliably identified. These limitations render them impractical for use in a routine diagnostic laboratory. Cellular fatty acid methyl ester analysis is useful for identification of Burkholderia strains at the genus level but is not reliable for identification of individual B. cepacia complex species and does not differentiate B. gladioli (19).

More recently, several studies have reported good results in using matrix-assisted laser desorption ionization–time-of-flight mass spectrometry (MALDI-TOF MS) for the identification of Burkholderia spp. (172–181). This method relies on a comparison between the mass spectrum of an isolate and the mass spectra in available databases. The discriminatory power of MALDI-TOF MS varies depending on the species and the breadth of the database used (i.e., some bacterial taxa are underrepresented in databases). In general, studies of MALDI-TOF MS for identification of Burkholderia (and the other species discussed in this chapter) have examined relatively small numbers of isolates, and/or not all species in the B. cepacia complex have been included. For example, Desai et al. (180) found that when compared with genotype-based methods, MALDI-TOF MS correctly identified to the genus level 29 isolates belonging to six B. cepacia complex species; 24 of these were correctly identified to the species level. As MALDI-TOF MS spectra library databases are enhanced with additional species reference strains and greater numbers of isolates, it is expected that this method will provide a reliable alternative to genotype-based analyses. The seemingly ever-expanding number of novel Burkholderia species identified among “B. cepacia-like” isolates recovered from human specimens (e.g., the recent description of B. pseudomultivorans) will continue to challenge phenotype-based analyses, however.

### B. pseudomallei and B. mallei

B. pseudomallei colonies on blood agar are typically small, smooth, and creamy in the first 48 h. On further incubation, this appearance may change to dry, wrinkled colonies. B. pseudomallei on Ashdown agar grows as very small (pinpoint) colonies by 18 h, which are usually purple, flat, dry, and wrinkled (“cornflower head”) after 48 h of incubation (Fig. 2c). The organism is motile, indole negative, oxidase positive, and resistant to colistin and gentamicin, features that aid identification. Other typical biochemical reactions are shown in Table 2. B. pseudomallei produces a distinctive musty or earthy odor, but sniffing of open plates should never be undertaken on safety grounds. B. thailandensis may be indistinguishable from B. pseudomallei by these simple criteria but can be distinguished based on arabinose assimilation, since B. thailandensis can utilize l-arabinose as the sole carbon source but neither B. pseudomallei nor B. mallei can do so (182). B. thailandensis is found in clinical samples extremely rarely, and cases reported of human B. thailandensis infection in which the bacterial species was fully verified amount to a single patient (183). B. mallei is also an extreme rarity in clinical specimens from humans but could be confused with B. pseudomallei and B. thailandensis. Two differentiating tests in the event that B. mallei is suspected or needs to be ruled out are (i) that B. mallei is nonmotile and B. pseudomallei and B. thailandensis are motile and (ii) that B. mallei is susceptible to gentamicin while the other two species are inherently resistant. The latter represents a catch for the inexperienced microbiologist, since Ashdown medium normally contains gentamicin and thus fails to support the growth of B. mallei. Cellular fatty acid profiles may be useful for differentiating B. pseudomallei from other genera, but reports vary on its utility in differentiating B. thailandensis and B. pseudomallei (184) or other pathogenic Burkholderia species including B. mallei, B. cepacia complex species, and B. gladioli.

Multiple evaluations have been performed to determine the accuracy of API 20NE for the identification of B. pseudomallei, with the reported percentage of isolates identified ranging from 37 to 99% (183, 185–189). One possible reason for this interstudy variability is that B. pseudomallei is phenotypically distinct in different geographic areas and/or between clinical isolates and those from the environment. A study using a large collection (n = 800) of B. pseudomallei isolates obtained from clinical cases, the environment, and animals from seven Asian countries and northern Australia reported that the API 20NE correctly identified 99% of B. pseudomallei isolates (185). This supports the use of API 20NE for the identification of B. pseudomallei. API 20NE is unable to identify B. mallei or B. thailandensis (185). The automated VITEK 1 system provides accurate identification of B. pseudomallei (189). Two evaluations of the VITEK 2 colorimetric GN card system have reported an accuracy of ~80% for B. pseudomallei, the most common incorrect identification being the B. cepacia group (186, 190). The accuracy of VITEK 2 has been reported to be affected by the medium on which B. pseudomallei is grown prior to testing, with culture on Columbia horse blood agar being associated with the highest rate of accuracy (190). A recent study has also shown geographic variation in the accuracy of VITEK 2 (191). An evaluation of MALDI-TOF MS for the identification of Burkholderia spp. reported accurate identification of B. pseudomallei but misidentification of B. thailandensis as B. pseudomallei (176). This was considered to be due to limitations of the reference spectra

B. pseudomallei must be differentiated from Pseudomonas stutzeri and B. cepacia complex species in clinical specimens. P. stutzeri appears very similar to B. pseudomallei after a few days of incubation, and both B. pseudomallei and B. cepacia complex species may be isolated from persons with CF (88, 89). Whereas B. pseudomallei produces gas from nitrate and is arginine dihydrolase positive, most B. cepacia complex isolates are negative for both characteristics. P. stutzeri is negative for arginine dihydrolase, oxidation-fermentation glucose, and gelatin hydrolysis. P. stutzeri also has only one flagellum, and B. pseudomallei has more than one.

Ralstonia and Cupriavidus spp.

Although R. pickettii was considered to be the Ralstonia species most frequently isolated from clinical specimens, the recent recognition that several other Ralstonia and Cupriavidus species can be identified from among R. pickettii-like isolates limits previous observations. As is the case with B. cepacia complex species, Ralstonia and Cupriavidus species are phenotypically similar, requiring rather extensive biochemical testing to reliably differentiate them; species-level identification with standard biochemical testing is difficult (Table 3). These species may grow slowly on primary isolation media, requiring ≥72 h of incubation before colonies are visible. They are lysine decarboxylase negative and generally catalase positive, although catalase-negative R. pickettii strains have been described (19, 20). Most species show a fast and strong oxidase reaction; however, the intensity of the oxidase reaction varies for R. mannitolyltyica, R. pickettii, and C. gilardii, with some strains showing a weakly positive reaction (19, 20; LiPuma, unpublished). R. pickettii, R. mannitolyltyica, and R. insidiosa grow on BCSA; most Cupriavidus strains do not, but growth is strain dependent. These species do not produce acid from sucrose. Most R. mannitolyltyica strains acidify lactose, whereas most strains from other species do not. R. insidiosa, C. respiraculi, C. gilardii, and C. paucula are differentiated from R. pickettii and R. mannitolyltyica in failing to acidify glucose. Cupriavidus species have a characteristic cellular fatty acid profile different from that of other Ralstonia species (17, 20). The main fatty acid components of these species are C16:0, C16:1w7c, and C18:1w7c (each accounting for ≥20% of the overall fatty acid content); in addition, C14:0, C14:0 3OH, and C17:0 cyclo are always present (each accounting for ≥5 to 10% of the overall fatty acid content) (21, 192).

Molecular genetic tests have proved quite helpful in differentiating these species. A 16S rRNA-directed PCR assay reliably identifies all Ralstonia and Cupriavidus species (as a group), allowing their differentiation from the phenotypically similar species in the genera Burkholderia and Pandoraea (113). Species-specific 16S rRNA-based PCR assays have also been developed; these enable the accurate identification of R. pickettii, R. mannitolyltyica, R. insidiosa, and C. respiracul...

(21, 113, 193). MALDI-TOF MS has been reported to provide accurate identification of small numbers of certain \textit{Ralstonia} species (172, 194).

\textbf{Pandoraea} spp.

Overall, the biochemical profiles of \textit{Pandoraea} strains are similar to those of \textit{Burkholderia} and \textit{Ralstonia} strains isolated from clinical specimens (Table 1) (3, 112, 125). The lack of saccharolytic activity is indicative of \textit{Pandoraea} but is also seen with some \textit{Ralstonia} species. Definitive identification of putative \textit{Pandoraea} isolates requires molecular confirmation. Coenye et al. (195) described 16S rDNA-based PCR assays for the identification of these bacteria. A PCR assay was developed for the identification of \textit{Pandoraea} isolates to the genus level. PCR assays for the identification of \textit{P. apista} and \textit{P. pammonsea} (as a group), \textit{P. pneumoniae}, \textit{P. putorum}, and \textit{P. normiberigenesi} were also developed. \textit{Pandoraea} strains can be differentiated from \textit{Burkholderia} and \textit{Ralstonia} strains by their specific 16S rRNA gene restriction profile (112, 196) and can be identified at the species level through MspI restriction analysis of the \textit{gyrB} gene (197). A quantitative comparison of the whole-cell fatty acid profiles of the members of these three genera allows the differentiation of \textit{Pandoraea} strains from the others (20, 125). However, with the use of the commercially available microbial identification system database (Microbial ID, Inc., Newark, DE), these organisms are mostly identified with low identification scores as \textit{Burkholderia} or \textit{Ralstonia} species (20, 112) due to a lack of discriminatory fatty acids. Individual strains of \textit{Pandoraea} species have been reported to be accurately identified by MALDI-TOF MS (172, 194).

\textbf{S. maltophilia}

Key features for identifying \textit{S. maltophilia} include oxidation of glucose and maltose with a more intense reaction with the latter, positive reactions for DNase and lysine decarboxylase, and a tuft of polar flagella (Table 4) (198). Although most strains were previously believed to be oxidase negative, testing of large numbers of isolates recovered from human specimens and referred to a reference laboratory indicates that as many as 20% may be oxidase positive (199). This proportion may be higher than expected since strains with an “atypical” phenotype may be preferentially referred for analysis. Detection of extracellular DNase activity by \textit{S. maltophilia} is a key to differentiating this species from most other glucose-oxidizing, Gram-negative bacilli. It can be detected on tube-based or plated DNase medium with a methyl green indicator. Care must be taken when interpreting the DNase reaction, since one report documented the misidentification of \textit{S. maltophilia} as \textit{B. cepacia} partially based on false-negative DNase reactions that were finalized with 48 h of incubation rather than 72 h (200). Selected isolates of \textit{Flavobacterium} and \textit{Shewanella} spp. may also be DNase positive (see chapter 44). On sheep blood agar, colonies appear rough and lavender-green and have an ammonia-like odor. \textit{S. maltophilia} has a characteristic cellular fatty acid profile with large amounts (>30%) of 13-methyl tetradecanoic acid (C15:0 iso) and lesser amounts (>10%) of 12-methyl tetradecanoic acid (C15:0 anteiso) and cis-9-hexadecenoic acid (C16:1 cis9) (198). To overcome the problems associated with definitive identification of \textit{S. maltophilia}, Whitby et al. (201) developed a species-specific PCR assay targeting the 23S rRNA gene and reported sensitivity and specificity of 100%. This PCR test was used as a standard to evaluate the identification of \textit{S. maltophilia} using the API 20NE strip and the VITEK 2 ID-GNB card (202). Both systems showed good reliability compared to PCR. A multiplex PCR assay to identify \textit{P. aeruginosa}, \textit{B. cepacia} complex species, and \textit{S. maltophilia} directly in sputum and oropharyngeal specimens from CF patients has been reported, but only a very limited number of \textit{S. maltophilia} isolates were examined. MALDI-TOF MS appears to be an acceptable alternative for identification of \textit{S. maltophilia} (172, 194); however, Desai et al. (180) found...
that some strains were incorrectly identified as *Pseudomonas* species by MALDI-TOF MS. As is the case with several nonfermenting opportunistic species, an incomplete understanding of *Stenotrophomonas* taxonomy challenges accurate identification of clinical and environmental isolates.

**Acidovorax, Brevundimonas, Delftia, and Comamonas spp.**

Characteristics of *Acidovorax, Brevundimonas, Delftia, and Comamonas* are given in Table 4.

*Acidovorax* species, rarely encountered in clinical and environmental samples, are straight to slightly curved, Gram-negative bacilli that occur either singly or in short chains. They are oxidase positive and nonpigmented and have a single polar flagellum. Urease activity varies among strains (198).

*B. diminuta* and *B. vesiculans* are more so than *B. diminuta*, and the vast majority fail to reduce nitrate to nitrite. The most reliable method for differentiating these two species is the test for esculin hydrolysis. Almost all strains of *B. vesiculans* (88%) are reported to hydrolyze this substrate, while *B. diminuta* strains rarely do (5%) (Table 4) (198).

*Comamonas* spp. are straight to slightly curved, Gram-negative bacilli that occur singly or in pairs. The organisms are catalase and oxidase positive and have a single tuft of polar flagella. All human clinical *Comamonas* species reduce nitrate to nitrite. Phenotypic differentiation of *C. testosteroni* is difficult, and as a result, isolates are typically reported as *Comamonas* spp. (Table 4).

*Acidovorax* is phenotypically similar to *D. acidovorans* and the vast majority fail to reduce nitrate to nitrite. Phenotypic differentiation of *C. terrigena* is difficult, and as a result, isolates are typically reported as *Comamonas* spp. (Table 4).
TYPING SYSTEMS
Several molecular genetic methods are available to assess the relatedness of isolates of these genera during nosocomial or community outbreak investigations. These methods are preferred over phenotypically based systems, which are less discriminatory and reproducible. Analysis of whole-genome macrorestriction profiles with pulsed-field gel electrophoresis (PFGE) has gained acceptance as a preferred genotyping method and has proved useful in numerous studies of Burkholderia, Ralstonia, and S. maltophilia (111, 203). The endonucleases XbaI and SpeI are most frequently used and typically yield a dozen or more DNA fragments for analysis. Care must be taken in interpreting PFGE profiles of Burkholderia species, however. These species have unusually large and dynamic multichromosome genomes that are prone to large-scale alterations in content and arrangement (204). Consequently, epidemiologically irrelevant genomic polymorphisms may arise in the short term and confound outbreak investigations (203). Ribotyping, which relies on polymorphisms in and around rRNA operons, has been used to investigate the epidemiology of B. cepacia complex and B. pseudomallei (205–207). Both PFGE and ribotyping are relatively time-consuming and expensive to perform and are therefore not particularly well suited for routine analysis by clinical microbiology laboratories. A variety of PCR-based methods, including randomly amplified polymorphic DNA typing and repetitive-sequence PCR typing, offer attractive alternatives for genotyping S. maltophilia and Burkholderia, Ralstonia, and Pandoraea spp. (50, 122, 196, 208, 209). These methods are inexpensive and can provide rapid, reliable results. MLST, which assesses DNA sequence variation at several chromosomal loci, has been developed for numerous species, including the B. cepacia complex, B. pseudomallei, and B. mallei (167, 210, 211). A modification of the scheme developed for the B. cepacia complex enables MLST analysis of all species within the genus (168). This genotyping strategy provides robust, reproducible, and portable results and is quickly becoming the preferred method for investigating bacterial epidemiology, evolution, and population structure. Both repetitive-sequence PCR using a BOX A1R primer and multilocus variable-number tandem repeat analysis have been developed for B. pseudomallei to exclude a clonal outbreak (212, 213). Typing methods have not been reported for Breundimonas, Delftia, Comamonas, or Acidovorax spp.

SEROLOGIC TESTS
Of the organisms discussed in this chapter, B. pseudomallei is the only one for which serologic tests have been used clinically to diagnose the infection. The indirect hemagglutination assay, although not available commercially, is the most widely used test. It is performed by using a prepared antigen from strains of B. pseudomallei sensitized to sheep cells and includes unsensitized cells as a control. This assay can be adapted to a microtiter plate test system. The serologic tests currently in use have limited value for the diagnosis of melioidosis in persons who have lived in regions where melioidosis is endemic because the healthy indigenous population is often seropositive (56, 92, 214). Serologic testing is potentially useful in persons who do not normally reside in regions endemic for melioidosis, including returning travelers and laboratory workers following accidental laboratory exposure to B. pseudomallei (215). The interpretation of the indirect hemagglutination assay or other serologic assays is complicated by the fact that there are no validated guide-lines, and different cutoff points have been used to define seroconversion following exposure and acute infection. Testing should be performed whenever possible on paired samples. Seroconversion with the development of detectable antibodies to B. pseudomallei in the second sample is supportive of exposure. A 4-fold rise in titer is commonly used to diagnose a range of infectious diseases, but this has not been validated for melioidosis and any reproducible rise between two samples should be viewed as possible evidence of exposure. A single high titer in persons from a nonendemic region with a relevant travel history who presents late after a putative exposure event and for whom paired sera may be less relevant is also suggestive of exposure. Some individuals with culture-proven melioidosis do not have detectable antibodies (216), and so a negative serologic test does not rule out exposure or melioidosis. Given the complexity of this situation, experts in the field should be consulted when serology is used to diagnose melioidosis. Several evaluations of a commercial rapid immunochromatographic test kit (Pan-Bio, Windsor, Queensland, Australia) for the detection of IgG and IgM antibodies to B. pseudomallei have been performed (217–219), but this test is not currently available.

ANTIMICROBIAL SUSCEPTIBILITIES
Specific susceptibility testing interpretative criteria are not available for all of the species discussed in this chapter. For some species, such as the B. cepacia complex and S. maltophilia, interpretative criteria for disk diffusion testing are available for only a limited number of antibiotics. In general, MIC microbroth microdilution tests or Etests are preferred for this group of organisms. B. cepacia complex species are among the most antimicrobial-resistant bacteria encountered in the clinical laboratory. These species are intrinsically resistant to aminoglycoside and polymyxin antibiotics and are often resistant to β-lactam antibiotics due to inducible chromosomal β-lactamases and altered penicillin-binding proteins (220). Antibiotic efflux pumps may mediate resistance to chloramphenicol, fluoroquinolones, and trimethoprim (221). Clinical strains may be susceptible to only a handful of agents, including trimethoprim-sulfamethoxazole (TMP-SMX), cefazidime, chloramphenicol, minocycline, imipenem, meropenem, and some fluoroquinolones (222, 223). The glycolcycline antibiotic tigecycline shows highly variable activity in vitro (224). The relatively high MIC observed for some strains and the potential for discoloration of permanent teeth in children younger than 7 years of age limit the use of tigecycline in CF patients. Clinical and Laboratory Standards Institute (CLSI) interpretative criteria for disk diffusion susceptibility testing are available for ceftazidime, meropenem, minocycline, and TMP-SMX (225). Because isolates that are initially susceptible may become resistant during the course of therapy, susceptibility testing of repeat isolates may be warranted. Furthermore, strains recovered from patients with CF who have received repeated courses of antibiotic therapy are frequently resistant to all currently available antimicrobial agents (222). Combinations of antimicrobial agents may provide synergistic activity against resistant strains; however, antagonism with combinations is also observed in vitro (222).

B. pseudomallei is intrinsically resistant to penicillins, aminoglycosides, and macrolides. Susceptibility testing should be performed to the antimicrobial agents commonly used to treat melioidosis, which are ceftazidime, imipenem or meropenem, amoxicillin-clavulinate, doxycycline, and...
TMP-SMX (226). B. pseudomallei is usually susceptible to all of these agents with the exception of TMP-SMX, reported rates of resistance for which are in the order of 2% in Australia (227, 228) and 13 to 16% in northeast Thailand (229, 230). Disk diffusion testing of TMP-SMX overestimates resistance and is unreliable (228–230); acceptable alternatives include Etest, broth microdilution, and agar dilution (226). Fluoroquinolones are associated with a high rate of therapeutic failure (231) and should not be included in the test panel. Recent studies indicate that tigecycline has good activity against B. pseudomallei in vitro and is effective when combined with other agents in an animal model of B. pseudomallei infection (232, 233), but there are no clinical trial data to support its use.

Current trends in the management of melioidosis involve an initial 10- to 14-day intensive therapy phase with cefazidime or meropenem, followed by eradication therapy with TMP-SMX for at least 3 months (83, 84, 234, 235). A recent trial from Thailand supported dropping the traditional practice of adding doxycycline to TMP-SMX for the eradication phase of therapy (236). In Australia, TMP-SMX is added to cefazidime or meropenem during the intensive phase for neurological, prostatic, cutaneous, and bone and joint melioidosis. Amoxicillin-clavulanate is recommended for eradication therapy in pregnancy and is an alternative to TMP-SMX in children (237). In critically ill patients requiring intensive care, meropenem or imipenem may be superior to cefazidime, and granulocyte colony-stimulating factor is being used in some centers, although a study from Thailand showed no benefit (227, 238–240). From a molecular genotyping study of cases of recurrent melioidosis, relapse following antimicrobial therapy occurred in 9.7% of patients and a new infection occurred in 3.4% (95).

Because of the potential role of B. mallei as a bioterrorism agent, studies have been done recently to determine the activities of a variety of agents against this species. B. mallei has a susceptibility profile similar to that of B. pseudomallei, except that B. mallei is susceptible to aminoglycosides and newer macrolides such as clarithromycin and azithromycin, whereas B. pseudomallei is resistant (241). Current recommended treatment and duration of therapy for glanders are the same as those for melioidosis.

Guidelines on the management of accidental laboratory exposure to B. pseudomallei and B. mallei have been published (215, 242).

S. maltophilia is intrinsically resistant to many classes of antibiotics. Resistance can also develop rapidly during infection (243). Resistance to β-lactam agents is mediated by at least two β-lactamases, one of which is zinc dependent and resistant to β-lactamase inhibitors and confers resistance to imipenem. Aminoglycoside and quinolone resistance results from mutations in outer membrane proteins. In a study of isolates recovered from patients with CF, doxycycline was the most active agent in vitro (244). TMP-SMX is usually active and is often used in combination with ticarcillin-clavulanate, minocycline, or piperacillin-tazobactam (244). Other combinations that may be effective include ciprofloxacin paired with ticarcillin-clavulanate, ciprofloxacin and piperacillin-tazobactam, or doxycycline and ticarcillin-clavulanate. Tigecycline is reported to have good activity in vitro (224). CLSI interpretive criteria for disk diffusion susceptibility testing are available for minocycline, levofloxacin, and TMP-SMX (225). Many U.S. laboratories comment only on the activity of TMP-SMX but will test additional antibiotics such as minocycline, cefazidime, ticarcillin-clavulanate, and ciprofloxacin or levofloxacin upon request.

In general, C. testosteroni is susceptible to extended- and broad-spectrum cephalosporins, carbapenems, quinolones, and TMP-SMX (245). D. acidovorans is frequently resistant to the aminoglycosides.

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

The species discussed in this chapter are found in the natural environment and may occasionally contaminate clinical specimens. Nevertheless, they are increasingly recognized as nosocomial and opportunistic pathogens, especially in certain patient populations, such as persons with CF. They are also frequently misidentified by commercial microbial identification systems. Therefore, their recovery in the clinical laboratory must be given careful consideration. In particular, species of the B. cepacia complex are not reliably differentiated by phenotypic analyses, and their recovery from persons with CF has serious consequences with respect to patient management and psychosocial well-being (69). Identification of these species should be confirmed by genotypic analyses at a reference laboratory and should be reported to the CF caregiver. Recovery of B. pseudomallei and B. mallei in any context should always be considered to reflect clinical disease. Identification of these species should be confirmed by a reference laboratory with experience with these species. Care must be given to ensure that culture handling and shipping comply with current biosafety regulations (see chapter 18). Identification of these species must be reported to public health officials due to the potential of these species as agents of bioterrorism (see chapter 14). The relevance of the recovery of the other genera described in this chapter, outside the context of CF, is less clear and should be interpreted with caution.

Interpretive criteria for disk diffusion antimicrobial susceptibility testing of most of these species are lacking; MIC broth microdilution and the Etest are therefore the preferred methodologies for susceptibility testing. For multiresistant strains, consideration could be given to testing in reference laboratories for synergy with double or triple combinations of antimicrobial agents (222). It is important to note, however, that neither checkerboard MIC broth microdilution testing nor multiple combination bactericidal antibiotic testing is standardized at present.

Acinetobacter, Chryseobacterium, Moraxella, and Other Nonfermentative Gram-Negative Rods*

MARIO VANEECHOUTTE, ALEXANDR NEMEC, PETER KÄMPFER, PIET COOLS, AND GEORGES WAUTERS

TAXONOMY
The organisms covered in this chapter belong to a group of taxonomically and phylogenetically diverse, Gram-negative, nonfermentative rods and coccobacilli. Still, several of the genera dealt with belong to the same family; i.e., Acinetobacter, Moraxella, Oligella, and Psychrobacter belong to the family Moraxellaceae (Gammaproteobacteria) (1), and Bacteroides, Bergeyella, Chryseobacterium, Elizabethkingia, Empedobacter, Myroides, Sphingobacterium, Wautersiella, and Weekella belong to the family Flavobacteriaceae (Bacteroidetes) (2).

DESCRIPTION OF THE AGENTS
The species dealt with in this chapter all share the common phenotypic features of being catalase positive and failing to acidify the butt of Kligler iron agar (KIA) or triple sugar iron (TSI) agar or of oxidative-fermentative media, indicating their inability to metabolize carbohydrates by the fermentative pathway. These organisms grow significantly better under aerobic than under anaerobic conditions, and many, i.e., those species that can use only oxygen as the final electron acceptor in the respiratory pathway, fail to grow anaerobically at all.

EPIDEMIOLOGY AND TRANSMISSION
Most of the organisms described in this chapter are found in the environment, i.e., soil and water. For methylbacteria, tap water has been implicated as a possible agent of transmission in hospital environments, and methods for monitoring water systems for methylbacteria have been described previously (3). No person-to-person spread has been documented for the species covered in this chapter, except for Acinetobacter and Moraxella catarrhalis.

CLINICAL SIGNIFICANCE
Although for almost all of the species in this chapter, case reports, e.g., of meningitis and endocarditis, can be found, their clinical importance is mostly restricted to that of opportunistic pathogens, except, e.g., for Elizabethkingia meningoseptica, Moraxella lacunata (eye infections), M. catarrhalis (respiratory tract infections), and species of the Acinetobacter calcoaceticus-Acinetobacter baumannii complex.

A. baumannii ventilator-associated pneumonia and bloodstream infections have been documented to be associated with a high degree of mortality and morbidity (4). Particular manifestations of A. baumannii are its implication in severely war-wounded soldiers (5), from which stems its popular designation “Iraqibacter,” and in victims of natural disasters (6).

The clinical impact of infections with A. baumannii is a continuous source of debate (7, 8). Indeed, although severe infections with A. baumannii have been documented, colonization is much more frequent than infection, and differentiation between these conditions can be difficult. Still, although uncommon, community-acquired infections with A. baumannii occur. In particular, community-acquired pneumonia with A. baumannii is increasingly reported from tropical areas, like Southeast Asia and tropical Australia (9, 10).

The clinical role of the closely related species Acinetobacter pittii and Acinetobacter nosocomialis resembles that of A. baumannii, although, compared to these two species, A. baumannii is more often associated with multidrug resistance and epidemic spread in hospitals and possibly also with higher mortality among patients with systemic infections (11, 12).

Other Acinetobacter species occasionally associated with human infections are listed in Table 1. A. johnsonii, A. lwoffii, and A. radiorestitus seem to be common inhabitants of human skin (13). A. lwoffii was a frequent species in clinical specimens during an 8-year study in a university hospital, where it was isolated mainly from blood or intravascular lines (14). Several species, A. irsinii in particular, have been found to cause bloodstream infections in hospitalized patients (15–18), while A. johnii and A. soli have also been implicated in outbreaks of neonatal infections (19, 20). A. parvus is regularly isolated from blood cultures (18, 21), but is often overlooked because of its small colonies and misidentification by API 20NE as A. lwoffii (our unpublished data). Many of the infections with these species are related to intravascular catheters or have another iatrogenic origin.

bNumbers in parentheses after organism names are numbers of strains tested.
cSpecies of the A. caucasicus–A. baumannii complex (65).
dThe numbers are percentages of strains positive in a given test. Carbon assimilation tests were evaluated after 6 days of incubation at 30°C.
eGrowth tested at 38 instead of 37°C.
fWeak growth of most strains with positive reactions.
gUnreproducible or delayed growth of most strains.

origin (15, 22), and their course is generally benign. For various other named or yet-unnamed Acinetobacter species, although recovered from clinical specimens (23, 24), a possible role in infection has not been documented.

Moraxella species are rare agents of infections (conjunctivitis, keratitis, meningitis, septicemia, endocarditis, arthritis, and otolaryngologic infections) (25–27), but M. catarrhalis has been reported to cause sinusitis and otitis media by contiguous spread of the organisms from a colonizing focus in the respiratory tract (25). However, isolation of M. catarrhalis from the upper respiratory tract (i.e., a throat culture) of children with otitis media or sinusitis does not provide evidence that the isolate is the cause of these infections, because M. catarrhalis is present frequently as a commensal of the upper respiratory tract in children (28). Isolates from sinus aspirates and middle ear specimens obtained by tympanocentesis should be identified and reported. Similarly, little is known about the pathogenesis of lower respiratory tract infection in adults with chronic lung diseases, although a clear pathogenic role may be assigned to this species because M. catarrhalis is not a frequent commensal of the upper respiratory tract in adults (28) and because examination of Gram-stained smears of sputum specimens from patients with exacerbations of bronchitis and pneumonia due to M. catarrhalis usually reveals an abundance of leukocytes, the presence of many Gram-negative diplococci as the exclusive or predominant bacterial cell type, and the

presence of intracellular Gram-negative diplococci. Such specimens may yield M. catarrhalis in virtually pure culture, and the organism should be identified and reported. Furthermore, M. nonliquefaciens (29, 30) and M. osloensis (31, 32) are the two species most frequently isolated, approximately in equal numbers, from nonrespiratory clinical material, especially blood cultures from patients at risk. M. canis has been isolated from dog bite wounds (33) and from debilitated patients (27). M. lacunata has been involved in eye infections and in infective endocarditis (34, 35).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Standard methods for collection, transport, and storage of specimens as detailed in chapters 11 and 18 are satisfactory for this group of organisms. The only fastidious species handled in this chapter are Asaia species, Granulibacter bethesdensis, Methylobacterium species, and some Moraxella species; these should be cultured on media containing blood.

DIRECT EXAMINATION

There are no characteristics available that can help to recognize the species dealt with in this chapter by means of direct microscopic examination of the samples. On Gram stain, organisms appear as Gram-negative rods, cocacobacilli, or
diplococci. Neither direct antigen tests nor molecular genetic tests to use directly on clinical materials have been developed.

**ISOLATION PROCEDURES**

Initial incubation should be at 35 to 37°C, although some strains, among them many of the pink-pigmented species, grow better at or below 30°C and may be detected only on plates left at room temperature. In such cases, all tests should be carried out at room temperature. In fact, some of the commercial kits, such as the API 20NE, are designed to be incubated at 30°C.

Growth on certain selective primary media, e.g., MacConkey agar, is variable and may be influenced by lot-to-lot variations in the composition of media. Gram-negative, nonfermentative bacteria (GNF) that grow on MacConkey agar generally form colorless colonies, although some form lavender or purple colonies due to uptake of crystal violet contained in the agar medium. Selective media have been described for *Acinetobacter* spp. (36) and for *Moraxella* spp. (37).

**IDENTIFICATION**

This chapter provides an overview in Fig. 1, which provides a key to the five large groups that can be distinguished among the species described in this chapter. This key is based only on colony color (pink or not) and the presence or absence of oxidase, of benzyl arginine aminopeptidase (trypsin) activity, and of the production of indole. Figure 1 refers to Tables 1 and 3 to 6, which provide further keys to identify the species of these five groups on the basis of biochemical reactions. Results for enzymatic reactions can be read within hours or up to 2 days of incubation, whereas results of carbon source assimilation tests (*Acinetobacter*) and acid production from carbohydrates are read after up to 6 and 7 days, respectively.

For each group of closely related species, we present their taxonomic history (explaining the use of other names in the past and the taxonomic changes introduced since the previous edition), address the clinical importance of the species, and describe the phenotypic data that are useful to differentiate this group from other groups and to differentiate the species within this group. When relevant, antibiotic susceptibility characteristics and treatment options are discussed immediately; otherwise, they are discussed at the end of each section for the five large groups in this chapter.

Although several of the genera discussed in this chapter comprise many more species than the ones addressed here, we focus on those species that can be isolated from clinical samples.

**Classical Biochemical Identification Schemes Presented in This Chapter**

For all the species in this chapter, except those of the genus *Acinetobacter*, the biochemical tests listed have been carried...
out by one of us (G. Wauters), according to standardized protocols, described in detail in chapter 33. The limited number of tests that have been used to discriminate between the species dealt with in this chapter have been selected because they can be carried out easily and quickly, because they mostly yield uniform results per group or species, and because they are highly discriminatory. For the genus Acinetobacter, data based on standardized physiological and nutritional tests were provided by one of the authors (A. Nemec) (see footnotes to Table 1).

**Automated, Commercially Available Phenotypic Identification Systems**

Traditional diagnostic systems, e.g., those based on oxidation-fermentation media, aerobic low-peptone media, or buffered single substrates, have now been replaced in many laboratories by commercial kits or automated systems like the VITEK 2 (bioMérieux, Marcy l’Etoile, France) and the Phoenix (BD Diagnostic Systems, Sparks, MD). The ability of commercial kits to identify this group of GNF is variable and often results in identification to the genus or group level only, necessitating the use of supplemental biochemical testing for species identification. O’Hara and Miller (38), using the VITEK 2 ID-GNB identification card, reported that of 103 glucose-fermenting and nonfermenting, non-fermenter strains, 88 (85.4%) were correctly identified at probability levels ranging from excellent to good and that 10 (9.7%) were correctly identified at a low level of discrimination, for a total of 95.1% accuracy within this group. Bossard et al. (39) compared 16S rRNA gene sequencing for the identification of clinically relevant isolates of GNF (non-Pseudomonas aeruginosa) with two commercially available identification systems (API 20NE and VITEK 2 fluorescent card; bioMérieux). By 16S rRNA gene sequence analysis, 92% of the isolates were assigned to species level and 8% to genus level. Using API 20NE, 54% of the isolates were assigned to species level, 7% were assigned to genus level, and 39% of the isolates could not be discriminated at any taxonomic level. The respective numbers for VITEK 2 were 53, 1, and 46%. Fifteen percent and 43% of the isolates corresponded to species not included in the API 20NE and VITEK 2 databases, respectively. Altogether, commercial identification systems can be useful for identification of organisms commonly found in clinical specimens, like Enterobacteriaceae. However, for rare organisms the performance of these systems can be poor.

**Chemotaxonomic Methods**

The fatty acid profiles for the most common species of GNF have been published (40).

**Matrix-Assisted Laser Desorption Ionization–Time-of-Flight Mass Spectrometry**

Few developments in clinical bacteriology have had as rapid and profound an impact on identification of microorganisms as matrix-assisted laser desorption ionization–time-of-flight mass spectrometry (MALDI-TOF MS) (41, 42). Conventional identification methods rely on biochemical properties and require sometimes lengthy incubation procedures, whereas MALDI-TOF MS can identify bacteria within minutes directly from colonies grown on culture plates. Two commercial platforms, Bruker Biotyper (Bruker Daltonics, Billerica, MA) and VITEK MS (bioMérieux), are available, and although the initial cost of mass spectrometry equipment and maintenance costs are relatively high, the additional identification costs per isolate are minimal.

Studies on the reliability and accuracy of MALDI-TOF MS in identifying species dealt with in this chapter are summarized in Table 2. MALDI-TOF MS appears to be a promising tool for identification of these species, with a reported 80.4% correct species identifications and 92.3% correct genus identifications (43, 44), with most difficulties in obtaining a correct identification due to a missing spectrum in the database at that time. These problems can be overcome by creating new databases or by adding missing spectra (43, 44).

The accuracy of both MALDI-TOF MS systems was found to be similar for identifying GNF (45), and both systems demonstrated performance superior to that of conventional methods (45). Mellmann and coworkers (46) reported 98.75% interlaboratory reproducibility among eight laboratories in a study of MALDI-TOF MS for identifying 480 GNF isolates. Sedo et al. (47) successfully applied MALDI-TOF MS for identification of selected Acinetobacter species, but could not differentiate between different strains belonging to the same species. Besides bacterial identification, MALDI-TOF MS is also being explored for the phenotypic detection of certain antibiotic resistance mechanisms, e.g., the detection of carbapenemase enzymatic activity in A. baumannii strains (48), and for typing.

Schaller and coworkers (49) found MALDI-TOF MS to be a rapid and robust tool for typing the two subpopulations and three 16S rRNA types of M. catarrhalis described previously. Menecacci and coworkers (50) explored the potential utility of MALDI-TOF MS to detect nosocomial spread of multidrug-resistant A. baumannii outbreaks in comparison with the repetitive sequence-based PCR DiversiLab system (bioMérieux) and suggested that it shows promise in routine clinical microbiology.

**DNA Sequence-Based Methods**

Sequence-based methods involving rRNA (16S, 16S-23S spacer, or 23S) and housekeeping genes, such as those encoding RNA polymerase subunit B (rpoB), gyrase subunit B (gyrB), or the recombination A protein (recA), have become standard techniques to identify bacteria in general (51) and have contributed to the better delineation of several of these groups and the discovery and description of new species. Because these are generally applicable methods, their application for species of this chapter is not outlined in detail. Other sequence-based methods, based on DNA array hybridization, have been used for some species of these groups (52). DNA sequence-based fingerprinting methods like amplified ribosomal DNA (rRNA gene) restriction analysis (ARDRA) (53, 54) and tDNA PCR (55, 56) have been applied for the identification of species of several groups as well. These fingerprinting approaches are also generally applicable, but they require reference fingerprint libraries and are often poorly exchangeable between different electrophoresis platforms and laboratories.

**IDENTIFICATION OF THE FIVE GENOTYPIC GROUPS**

**Oxidase-Negative GNF**

Acinetobacter

Members of the genus Acinetobacter are strictly aerobic, oxidase-negative, catalase-positive, coccobacillary bacteria.
They are Gram negative but may be difficult to stain. Most strains do not reduce nitrate to nitrite in a laboratory test, owing to the lack of a dissimilative nitrate reductase. Tween 80 esterase activity is frequently present, while hemolysis and gelatinase production varies. Swimming motility is negative, but “twisting motility” on soft agar may occur. Individual cell sizes are 0.9 to 1.6 μm in diameter and 1.5 to 2.5 μm in length. In the stationary phase, the cells are usually coccolid and occur in pairs. Most strains grow at between 20 and 35°C. Medically relevant species commonly grow well at 37°C, although some of them (A. johnsonii and A. guillouiae) show reduced or no in vitro growth at this temperature.

The organisms can form a pellicle (biofilm) on the surface of fluid media. They grow well on complex media, including blood agar, nutrient agar, and mostly on MacConkey agar. After 24 h of incubation, colonies are 1 to 2 mm in diameter (except for A. parvus, with markedly smaller colonies), colorless to beige, domed, and smooth to mucoid (Fig. 2). Colonies on MacConkey agar can become pink. Many strains can use a wide variety of organic compounds as single sources of carbon and energy. Selective enrichment can be

*Identification by HoxA-51 PCR and/or rpoB gene sequencing.

*Identification by 16S rRNA gene sequencing.

*Direct transfer method.

*Identification also taking into account the rule of thumb that the difference between the first two species listed is larger than 0.2 if the first log score is <1.7.

*Identification by pheA gene sequencing.

*OXA-51 PCR and/or rpoB gene sequencing.

*misidentification in vitro growth.
obtained in mineral media with acetate as the carbon source and ammonium salt as the nitrogen source with shaking incubation at 30°C (36). General features of Acinetobacter have been reviewed previously (57, 58).

Members of the genus Acinetobacter are widespread in nature and have been found in soil, water, sewage, and food, as well as in human and animal specimens. Some of the Acinetobacter species have been predominantly cultured from humans (e.g., A. baumannii, A. nosocomialis, and A. ursingii), while others inhabit diverse ecosystems (A. johnsonii and A. guillouiae) or are confined to specific niches (A. nectaris and A. boissieri) (59).

The ecology of most clinically relevant Acinetobacter species is still poorly resolved. A. baumannii, A. pittii, A. nosocomialis, and A. ursingii have been mainly recovered from clinical specimens in hospitals. Human skin carrier rates of A. baumannii outside hospitals are low (13), but higher rates (also for A. pittii and A. nosocomialis) have been found in tropical areas (60). A. baumannii, including multidrug-resistant strains, has been isolated from sick animals (61) and from hospitalized horses (62), but an animal or environmental reservoir has not been found. A. baumannii is, due to its role as a prominent nosocomial pathogen, the species for which the epidemiology has been studied most intensively. Epidemic strains of this species can survive well in the environment, as they have been found on equipment and on environmental surfaces and materials (63), usually in the vicinity of colonized patients. Multiple sites of the skin and mucosae of patients can be colonized, and colonization may last days to weeks (64).

Species Diversity and Identification

The taxonomy of the genus Acinetobacter has recently been updated with valid names for several medically relevant genomic species known previously under provisional designations, i.e., A. pittii (65), A. berezniae (66), A. guillouiae (60), and A. nosocomialis (65) (former genomic species 3, 10, 11, and 13TU, respectively), and with new medically relevant species, i.e., A. beiyinckii (67), A. gyllenbergi (67), A. parvus (21), and A. soli (20, 68). Some of the recently proposed species names have been shown to be synonymous with already existing ones: A. grimontii with A. junii (69) and “A. septicus” with A. ursingii (70).

At present, the genus Acinetobacter comprises 31 distinct species with valid names (http://www.bacterio.net/acinetobacter.html) and a number of taxa that include either genomic species delineated by DNA-DNA hybridization (7, 57) or species with effectively (but not validly) published names. Recent studies have shown that nearly all Acinetobacter isolates from colonized or infected patients belong to one of these species (14, 17, 18). This indicates that the species diversity of acinetobacters found in the human body environment is well covered by the current classification. Validly named species found in human clinical specimens are listed in Table 1.

Surprisingly, and in spite of its name (derived from the Greek akineto, meaning “motionless” or “nonmotile”) and its lack of flagella, A. baumannii spreads rapidly over certain surfaces. This is likely the result of twitching motility, a form of surface translocation described before for the genus Acinetobacter (71). As shown for A. baumannii ATCC 17978, cultured at 24°C, white (low-intensity) light, and in particular its blue component, is a stimulus governing several metabolic processes, inhibiting motility and the formation of biofilms and pellicles (72). Light regulation is lost at 37°C in A. baumannii (72).

Further studies showed that light regulation is not restricted to A. baumannii, but widespread within the genus Acinetobacter (73). In fact, blue light modulates motility and biofilm formation in many species of the genus. In the Acinetobacter species studied thus far, except A. baumannii, blue light contributes to the decision between motility and sessility and also may facilitate acclimation to different environments. For A. baumannii, both motility and sessility (biofilm formation) were inhibited by blue light and only at low temperature (72).

Identification of Acinetobacter species by commercial identification systems based on biochemical and physiological properties is problematic. This stems from the small number of relevant characters included in these systems and/or from the insufficient quality of reference data in the identification matrices. A. baumannii and the other species of the A. calcoaceticus-A. baumannii complex (i.e., A. pittii, A. nosocomialis, and A. calcoaceticus, the latter a primarily soil-dwelling organism) are generally not differentiated by these systems, while non-glucose-oxidizing species such as A. ursingii and A. schindleri can be misidentified (15). We compared VITEK 2 and Phoenix for the ability to identify

FIGURE 2 Differences in the size of the colonies formed by different Acinetobacter species isolated from human clinical specimens. The strains were grown on TSA (Oxoid) at 30°C for 24 h. (a) A. parvus NIPH 3841; (b) A. ursingii NIPH 1371; (c) A. schindleri NIPH 1034; (d) A. baumannii ATCC 19606. doi:10.1128/9781555817581.ch44.f2
76 isolates of 16 clinical Acinetobacter species and found that only 19 isolates were correctly identified by VITEK 2 and 5 by Phoenix (M. Vanechoute, unpublished data). Nonetheless, the diagnostic systems can be useful for genus-level identification and, when supplemented with testing growth ability at 44°C, also for presumptive differentiation between A. baumannii and A. nosocomialis (Table 1).

More reliable phenotypic identification of Acinetobacter species can be achieved using physiological and nutritional (mainly carbon source assimilation) tests based on the modified system of Bouvet and Grimont (67). Table 1 presents an update of this system aimed to differentiate validly named species of clinical relevance. Assimilation tests were carried out using a basal liquid medium supplemented with 0.1% (wt/vol) carbon source (67). Growth was evaluated after 4, 6, and 10 days of culture at 30°C by means of visual comparison between inoculated tubes containing carbon sources and control tubes containing only inoculated basal medium. However, the species of the A. calcoaceticus-A. baumannii complex are not clearly distinguished from each other by this approach. In addition, the need for in-house preparation of most of the tests precludes the use of this identification scheme for routine diagnostic purposes.

The most precise identification of Acinetobacter species can be achieved by a number of genotypic methods (57), with those based on sequencing particular genes being the current standard. Common targets for this purpose are the rpoB gene (67), currently the best-studied single-gene taxonomic marker for Acinetobacter; the 16S rRNA gene sequence (74); and the 16S-23S rRNA gene spacer region (75). PCR detection of the blaOXA-51-like gene, which is intrinsic to A. baumannii, enables rapid identification of this species (76). The whole-genome sequences of >100 Acinetobacter strains reflecting the currently known breadth of Acinetobacter diversity have been recently published at the NCBI website (http://www.ncbi.nlm.nih.gov/bioproject/183623), and the availability of such a comprehensive set of genomic data may further facilitate efficacious identification.

Genotyping and Epidemiology

A number of molecular methods have been described for differentiation between isolates of the same species and study of the epidemiology of acinetobacters, in particular that of A. baumannii. Standardized random amplification PCR fingerprinting was useful for typing within one laboratory, and its (interlaboratory) reproducibility has been evaluated (77). Macrorestriction analysis with pulsed-field gel electrophoresis allowed for 95% intra- and 89% interlaboratory reproducibility (78). Amplified fragment length polymorphism fingerprinting also enables genotyping of strains (57, 63), and its robustness makes it suited for setting up a local database for longitudinal studies. Typing based on the variable number of tandem repeats has allowed for discrimination between genotypically related but epidemiologically distinct strains, i.e., those belonging to a single type based on several typing methods including macrorestriction analysis and PCR fingerprinting (79, 80). Sequence analysis of the OXA-51-like gene has been proposed as a useful typing method, based on the correlation between particular OXA-51-like enzymes and epidemic clones of A. baumannii (81).

Multilocus sequence typing (MLST) is the standard for global and long-term epidemiological and population studies. Two MLST schemes are currently available for A. baumannii: the scheme proposed by Burtault et al. (82) (http://pubmlst.org/abaumannii/) and that proposed by Diancourt et al. (83) (http://www.pasteur.fr/recherche/genopole/PF8/mlst/). Both schemes are based on the internal fragments of seven housekeeping genes, and they share three genes. The two schemes yield compatible results, although a higher resolution has been reported for the scheme of Burtault et al. (82) by Karah et al. (84).

Resistance to multiple antimicrobials and hospital outbreaks have been associated with several international lineages of A. baumannii, particularly with the so-called European (or international) clones I and II (7, 83, 85). The earliest known strain of clone I was isolated in 1977 (86), and this lineage prevailed among outbreak and multidrug-resistant Acinetobacter strains in some European countries in the 1980s and 1990s (87). Currently, strains belonging to or related to clone I seem to dominate in the current global population of multidrug-resistant A. baumannii, although clone I and other lineages can be common or even prevail in some regions (84, 88–90). Allocation of isolates to international lineages or the identification of novel clones can be achieved by both MLST schemes. European clones I and II correspond, respectively, to MLST-based clonal complexes CC1 and CC2 in the scheme of Diancourt et al. (83) and to CC109 and CC92 in that of Burtault et al. (82), according to Karah et al. (84). Multiplex PCR, targeting the ampC, cseE, and blaOXA-51-like gene sequences, provides rapid assignment to the main clonal lineages (91).

Antimicrobial Susceptibilities

A. baumannii has an extraordinary capacity to acquire or develop resistance to virtually all antibiotics used in the treatment of Acinetobacter infections (7, 8). With the growing proportion of A. baumannii strains resistant to carbapenems, a last therapeutic option is disappearing, although these strains mostly remain susceptible to colistin. Even though multidrug resistance is mainly confined to A. baumannii, strains of other clinically relevant species, such as A. pittii, A. nosocomialis, and A. ursingii, can also be resistant to multiple antibiotics, including carbapenems (92, 93). Resistance mechanisms in A. baumannii comprise all currently known mechanisms, including enzymatic breakdown, modification of target sites, active efflux, and decreased influx of antibiotics. The known resistance mechanisms have been reviewed previously (94). Recent genomic studies have also shed light on the genetic organization of resistance determinants in multidrug-resistant A. baumannii. Large clusters of horizontally transferred genes, conferring resistance to multiple antibiotics and interspersed with mobile genetic elements (resistance islands), were found to be integrated at a specific genomic site in a number of strains (87, 95). Despite the high intraclonal variability of the resistance islands, these structures seem to have evolved independently in two main A. baumannii clones (87, 96).

In vitro determination of antimicrobial susceptibility can be achieved by disk diffusion, agar dilution, or broth microdilution, as recommended by the Clinical and Laboratory Standards Institute (CLSI) (97), or by Etest. The panel of tested antibiotics should cover the spectrum of agents with potential against A. baumannii, including third- or fourth-generation cephalosporins, sulbactam, antipseudomonal penicillins combined with ß-lactamase inhibitors, carbapenems, aminoglycosides, fluoroquinolones, polymyxins, and tetracyclines (98). Of note, susceptibility to colistin should not be tested by disk diffusion due to poor diffusion of this compound in agar. Etest and broth microdilution for determination of the MIC for this drug have been compared and showed a good concordance in the MIC range of 0.25 to 1 mg/liter (99).
Granulibacter bethesdensis

G. bethesdensis (Acetobacteraceae, Alphaproteobacteria) (100) is a Gram-negative, aerobic, coccobacillary to rod-shaped bacterium, the only species of a new sublineage within the acetic acid bacteria in the family Acetobacteraceae. This fastidious organism grows poorly and slowly on sheep blood agar (SBA) at an optimum temperature of 35 to 37°C and an optimum pH of 5.0 to 6.5. It produces a yellow pigment, oxidizes lactate and weakly acetate to carbon dioxide and water, acidifies ethanol and can use methanol as a sole carbon source, all characteristics that distinguish it from other acetic acid bacteria. The DNA base composition is 59.1 mol% G+C. It was isolated first from three patients with chronic granulomatous disease (100) and more recently from an additional patient with chronic granulomatous disease (101).

Oxidase-Positive, Indole-Negative, Trypsin-Negative GNF

Haematobacter

Three Haematobacter species (Rhodobacteraceae, Alphaproteobacteria) have been described, i.e., H. massiliensis (formerly Rhodobacter massiliensis), H. missouriensis, and Haematobacter genomic organism 1 (Table 3) (102). These species cannot easily be differentiated phenotypically, and even the 16S rRNA gene sequences are closely related. Haematobacter species were described as asaccharolytic, but when low-potency phenol red agar is used (see chapter 33), H. missouriensis is clearly saccharolytic, producing acid from glucose and xylose and sometimes from mannitol, whereas H. massiliensis strains do not acidify carbohydrates. Acid is produced from ethylene glycol by all species. All the species are strongly urease and phenylalanine deaminase positive. Arginine dihydrolase is also positive but sometimes delayed. Asaccharolytic Haematobacter strains resemble Psychrobacter phenylpyruvicus but can be differentiated by the lack of tributyrine esterase, the lack of growth improvement by TWEEN 80, and the presence of arginine dihydrolase. Differences from Psychrobacter facalis, Psychrobacter palminus, and related species are the lack of tributyrine and TWEEN 80 esterase, the lack of nitrate reductase, and a positive arginine dihydrolase test.

Strains received at the Centers for Disease Control and Prevention (CDC) have been mainly isolated from patients with septicemia.

Haematobacter strains have low MICs for amoxicillin, fluoroquinolones, aminoglycosides, and carbapenems but variable MICs for cephalosporins, monobactams, and piperacillin.

Moraxella

The genus Moraxella comprises ~20 species that have been validly named. M. catarrhae, M. osloensis, M. nonliquefaciens, and M. lincolnii are part of the normal microbiome of the human respiratory tract. Animal species include M. bovis, isolated from healthy cattle and other animals, including horses; M. boevrei and M. caprae (goats); M. canis (dogs, cats). Numbers in parentheses after organism names are numbers of strains tested. Values are percentages; those in parentheses represent delayed positivity. Abbreviations: Pt, peritrichous; W, weakly positive.

</table>

*Numbers in parentheses after organism names are numbers of strains tested. Values are percentages; those in parentheses represent delayed positivity. Abbreviations: Pt, peritrichous; W, weakly positive.

*Growth markedly promoted by Tween 80. P. phenylpyruvicus grows in 12% NaCl tryptic soy broth supplemented with 0.1% Tween 80, in contrast to P. sanguinis.
Both M. catarrhalis and M. canis grow well on SBA and even on tryptic soy agar (TSA), and their colonies may reach >1 mm in diameter after 24 h of incubation. Colonies of M. catarrhalis grow well on both blood and chocolate agars, and some strains also grow well on modified Thayer-Martin and other selective media. Colonies are generally gray to white, opaque, and smooth and measure about 1 to 3 mm after 24 h of incubation. Characteristically, the colonies may be nudged intact across the plate with a bacteriological loop like a “hockey puck” and can be removed from the agar actively, being very consistent. Most M. canis colonies resemble those of the Enterobacteriaceae (large, smooth colonies) and may produce a brown pigment when grown on starch-containing Mueller-Hinton agar (33). Some strains may also produce very slimy colonies resembling colonies of Klebsiella pneumoniae (large, smooth colonies) and may produce a brown pigment when grown on chocolate agar. The colonial morphologies of M. lynchnii, M. osloensis, and P. phenylpyruvaticus (formerly M. phenylpyruvaticus) are similar, but pitting is rare. On the other hand, pitting is common with M. lacunata, whose colonies are smaller and form dark haloes on chocolate agar. Rod-shaped Moraxella species, especially M. atlantae, are much fasteridious and display smaller colonies on SBA, <1 mm in diameter after 24 h. Colonies of M. atlantae are small (usually 0.5 mm in diameter) and show pitting and spreading (104). The growth of M. atlantae is stimulated by bile salts, which explains its growth on MacConkey agar. M. nonliquefaciens and M. osloensis produce colonies that are somewhat larger than those of M. atlantae and that are rarely pitting. Colonies of M. nonliquefaciens may be mucoid. A selective medium, acetalaminde agar, inhibiting growth of neisseriae when incubated in ambient atmosphere, has been described for M. catarrhalis (37).

Moraxella species are coccoid or cocccobacillary organisms (plump rods), occurring predominantly in pairs and sometimes in short chains, that tend to resist decolorization in the Gram stain (104). M. canis and M. catarrhalis are Neisseria-like diplococci, and they can easily be distinguished from other moraxellae or other cocccoid species by performing a Gram stain on cells cultured in the vicinity of a penicillin disk: cells of M. canis and M. catarrhalis remain spherical diplococci of 0.5 to 1.5 μm in diameter, although of irregular size, whereas cocccobacilli show obviously rod-shaped and filamentous cells.

Moraxella species are asaccharolytic and strongly oxidase positive. M. catarrhalis and M. canis are also strongly catalase positive, and most strains reduce nitrate and nitrite. M. catarrhalis and M. canis may be easily distinguished from the commensal Neisseria species, which are also frequently isolated from respiratory clinical specimens, by the ability of the former to produce DNase and butyrate esterase (tributyryl tetrazolium) (105), and the indoxyl-butyrate hydrolysis spot test is commercially available (Remel, Inc., Lenexa, KS). Butyrate esterase is, however, also present in some other Moraxella species. M. canis acidifies ethylene glycol and alkalizes acetate, in contrast to M. catarrhalis. There are few biochemical differences between M. catarrhalis and M. nonliquefaciens, which are differentiated from each other mainly on the basis of morphological characteristics and by nitrite reductase and DNase activity of M. catarrhalis.

M. atlantae is the only Moraxella species to be positive for pyrrolidonyl aminopeptidase (106). M. lacunata is the only proteolytic species with gelatinase activity. Using the plate method (see chapter 33), gelatin hydrolysis occurs usually within 2 to 4 days. A more rapid and almost equally specific test to differentiate M. lacunata from other moraxellae is the detection of Tween 80 esterase activity, which is often positive within 2 days, whereas all other species, except for very rare M. osloensis strains, remain negative. This species should also be distinguished from Psychrobacter species, which are also Tween 80 esterase positive, but P. phenylpyruvicus and P. sanguinis are urease positive and other Psychrobacter species exhibit luxuriant growth on plain agar, like TSA, even at 25°C.

M. lincnui is biochemically quite inactive. M. osloensis alkalizes acetate, acidifies ethylene glycol, and is resistant to desferrioxamine (250-μg disk). M. nonliquefaciens has opposite properties to those of M. osloensis and is, in addition, always nitrate reductase positive.

Most Moraxella species are susceptible to penicillin and its derivatives, cephalosporins, tetracyclines, quinolones, and aminoglycosides (107, 108). Production of β-lactamase has been only rarely reported for Moraxella species other than M. catarrhalis, of which most isolates produce an inducible, cell-associated β-lactamase (37). Isolates of M. catarrhalis are generally susceptible to amoxicillin-clavulanate, expanded-spectrum and broad-spectrum cephalosporins (i.e., cefotaxime, cefotaxime, ceftriaxone, cefepoxide, cephaloridine, and the oral agents cefixime and cefaclor), macrolides (e.g., azithromycin, clarithromycin, and erythromycin), tetracyclines, rifampin, and fluoroquinolones.

Oligella urethralis and Oligella ureolytica

The genus Oligella comprises two species, O. ureolytica (formerly CDC group IVe) and O. urethralis (formerly Moraxella urethralis and CDC group M-4) (109), which have both been isolated chiefly from the human urinary tract and have been reported to cause urosepsis (110).

Colonies of O. urethralis are smaller than those of M. osloensis and are opaque to whitish. Colonies of O. ureolytica are slow growing on blood agar, appearing as pinpoint colonies after 24 h but large colonies after 3 days of incubation. Colonies are white and opaque, with entire borders, and are nonhemolytic.

O. ureolytica and O. urethralis are small, asaccharolytic cocccobacilli that rapidly acidify ethylene glycol and are susceptible to desferrioxamine. Most strains of O. ureolytica are motile by peritrichous flagella, and all are strongly urease positive (with the urease reaction often turning positive within minutes after inoculation) and reduce nitrate. O. urethralis strains are nonmotile and urease and nitrate reductase negative, but they reduce nitrite and are weakly phenylalanine deaminase positive. Bordetella bronchiseptica and Cupriavidus paradoxus are also rapidly urease positive but are desferrioxamine resistant.

O. urethralis and M. osloensis have biochemical similarities, e.g., accumulation of poly-β-hydroxybutyric acid and failure to hydrolyze urea, but can be differentiated on the basis of nitrite reduction and alkalinization of formate, itaconate, proline, and threonine, all positive for O. urethralis (111). Moreover, O. urethralis is susceptible to desferrioxamine and tributyrate esterase is negative, in contrast to M. osloensis.

O. urethralis is generally susceptible to most antibiotics, including penicillin, while O. ureolytica exhibits variable susceptibility patterns (107).
Paracoccus yeei
The genus Paracoccus (Rhodobacteraceae, Alphaproteobacteria) comprises ~25 species, of which only P. yeei is of some clinical importance. Daneshvar et al. (112) proposed the name P. yeei, later changed to P. yeei, for the former CDC group EQ-2.

Colonies are large and mucoid, with a pale yellow pigmentation. P. yeei organisms are coccoid cells, showing many diplococci and a few very short rods. Microscopically, P. yeei is characterized by distinctive O-shaped cells (Fig. 3) upon Gram stain examination due to the presence of vacuolated or peripherally stained cells. The species is saccharolytic and urease positive.

P. yeei has been isolated from various human wound infections (112).

Psychrobacter
The genus Psychrobacter (113) comprises 34 species, of which only a few are clinically important. Apart from P. phenylpyruvicus, the Psychrobacter strains isolated from clinical material were considered until recently as belonging to the species Psychrobacter immobillis. In a recent study (114), it was shown that almost all the strains formerly identified as P. immobillis belong in fact to the species P. faecalis and P. pulmonis, isolated first from pigeons and lambs, respectively (115, 116). P. immobillis itself is apparently rarely isolated, if at all, from humans.

P. faecalis and P. pulmonis are coccoid, Gram-negative rods growing on TSA with large, creamy colonies. P. faecalis is saccharolytic and acidifies glucose and xylose, while P. pulmonis is asaccharolytic. Both species produce acid from ethylene glycol. They are Tween 80 esterase, tributyrate is acidified. Both species produce acid from Pulmonis, while P. sanguinis does not. Phenylalanine deaminase is always positive in P. phenylpyruvicus but only in one-third of P. sanguinis strains.

Most Psychrobacter species are resistant to penicillin but susceptible to most other antibiotics (107).

Wohlfarttiimonas chitiniclastica
W. chitiniclastica is a Gram-negative, nonfermentative rod living in the larvae of some parasitic flies. It is closely related to the "Gilardi rod group 1" and to Ignatzenschineria larva (118, 119). The type strain of W. chitiniclastica was first classified as "Gilardi rod group 1." W. chitiniclastica may be associated with human myiasis, sometimes resulting in bacteremia (120) or sepsis (118). Fifteen human strains of "Gilardi rod group 1" were isolated from wounds and blood (121).

The organisms are short, coccoid rods, growing on current media with flat, slightly spreading colonies. Some carbohydrates, like glucose, xylose, and fructose, are weakly acidified. This species exhibits a very strong phenylalanine deaminase reaction. Chitinase activity is present as in I. larva, which is, however, urease positive. W. chitiniclastica is resistant to penicillin and susceptible to many other antibiotics.

Oxidase-Positive, Indole-Negative, Trypsin-Positive GNF
Alishewanella fetalis (Alteromonadaceae, Gammaproteobacteria) (Table 4) is a Gram-negative rod that grows at temperatures between 25 and 41°C, with optimum growth at 37°C. A. fetalis can withstand NaCl concentrations of up to 8% but not 10%, which helps differentiate this species from Shewanella algae, which can grow in 10% NaCl (122). Also, in contrast to Shewanella species, it does not produce H₂S in the butt of TSI and KIA. The type strain tested by us acidifies glucose and does not hydrolyze esculin.

A. fetalis has been isolated from a human fetus at autopsy, although its association with clinical infection is unknown (122).

Inquilinus limosus
I. limosus is a rod-shaped, Gram-negative bacterium that measures 1.5 to 2 μm in width by 3.5 μm in length and grows at 35 and 41°C but poorly at 25°C. Colonies are nonpigmented and very mucoid and grow on ordinary media such as TSA. Some strains are motile by one or two polar flagella, but motility is difficult to demonstrate due to the mucoid character of the colonies. In opposition to the original description (123), the species is saccharolytic, acidifying glucose, mannitol, xylose, and other carbohydrates. In contrast, ethylene glycol is not acidified. β-Galactosidase, pyrrolidonyl aminopeptidase, and trypsin are positive, but alkaline phosphatase is negative. Esculin is hydrolyzed. All strains are positive for catalase, β-glucosidase, proline

FIGURE 3 Gram stain of P. yeei, showing characteristic doughnut-shaped morphology.
doi:10.1128/9781555817381.ch44.f3
aminopeptidase, and pyrrolidonyl aminopeptidase and negative for lysine, arginine, ornithine, denitrification, and in-dole production (123).

*I. limosus* can be distinguished from *Sphingobacterium* spp. by its lack of alkaline phosphatase activity and by its acidification of mannitol. Unlike most of the *P. putrefaciens* strains) and by the lack of nitrate reductase.

Identifying the species is difficult because it is not contained in the databases of commercial identification kits and its mucoid appearance may lead to confusion with mucoid *P. aeruginosa* strains (124). Isolates can be recovered on colistin-containing *Burkholderia cepacia* selective media but are inhibited on *B. cepacia* selective agar, which also contains gentamicin (125).

All isolates are reported to be resistant to penicillins and cephalosporins, kanamycin, tobramycin, colistin, doxycycin, and trimethoprim-sulfamethoxazole and susceptible to imipenem and ciprofloxacin (124, 125).

*I. limosus* has been isolated from soil samples and from respiratory secretions of cystic fibrosis patients (124, 125, 127, 128). The clinical impact of chronic colonization with *I. limosus* remains unclear. Chiron et al. (125) reported that for one patient, *I. limosus* was the only potential pathogen recovered from the sputum, whereby acquisition of this bacterium was followed by a worsening of his lung function.

**Myroides odoratimimus** and **Myroides odoratus**

The genus *Myroides* includes two species, *M. odoratimimus* and *M. odoratus*, formerly *Flavobacterium odoratum* (129), which can be isolated from clinical samples. Cells are thin, middle-sized (0.5 μm in diameter and 1 to 2 μm long), nonmotile rods, but both species display a gliding motility. The spreading colonies develop a typical fruity smell, similar to the odor of *Alcaligenes faecalis*. The yellow pigment, al-

at 41°C. *Myroides* species are asaccharolytic, urease positive, and nitrate reductase negative, but nitrite is reduced. *M. odoratus* can be differentiated by its susceptibility to desferrioxamine, while *M. odoratimimus* is resistant. The species also differ by their cellular fatty acid patterns, with *M. odoratimimus* having significant amounts of C13:0 and C15:0 (129).

Organisms identified as *M. odoratus* have been reported mostly from urine but have also been found in wound, sputum, blood, and ear specimens (130, 131). Clinical infection with *Myroides* species is exceedingly rare. In our experience, based on 25 clinical isolates, *M. odoratimimus* is 4 to 5 times more frequently isolated from clinical material than *M. odoratus*.

Most strains are resistant to penicillins, cephalosporins, aminoglycosides, aztreonam, and carbapenems (131).

**Ochrobactrum anthropi and Ochrobactrum intermedium**

*Ochrobactrum*, *Pseudoochrobactrum*, *Rhizobium*, and *Pannobacter* have many morphological and biochemical characteristics in common, and therefore additional characteristics for these taxa are provided in Table 4.

The genus *Ochrobactrum* comprises at present 17 species. Two species, i.e., *O. anthropi* (132) and *O. intermedium* (133), are currently isolated from humans, but recently new species, i.e., *O. haematophilum* (134), *O. pseudogregensis* (134), and *O. pseudintermedium* (135), have been recovered from clinical samples. *O. anthropi* (132) comprises the so-called urease-positive *Achromobacter* species, formerly designated CDC group Vd (biotypes 1 and 2), and *Achromobacter* groups A, C, and D.

Colonies on SBA are small, ~1 mm after overnight incubation, but grow large and creamy after 2 days and appear smooth, circular, and clearly delineated. *Ochrobactrum* species are medium-length, Gram-negative rods and motile by peritrichous flagella, although most cells have only one or two very long lateral flagella.

*Ochrobactrum* species are strongly tryptin and pyrrolidonyl aminopeptidase positive and are saccharolytic, with rapid acidification of glucose and xylose. Acidification of mannitol is irregular and often delayed positive. Ethylene glycol is acidified. Urease is positive in most species; phenylalanine deaminase is always positive. Nitrate reduction and nitrite reduction are positive, except in *O. haematophilum*. *O. intermedium* can be distinguished from *O. anthropi* by colistin resistance and growth at 41°C. Urease is often negative or delayed in this species. *O. pseudintermedium* composes the only species growing at 45°C. Resistance to colistin, tetracycline, and aminoglycosides may have diagnostic value for distinction between *O. intermedium* and *O. pseudintermedium*. Among aminoglycosides, netilmicin provides the most clear-cut results.

*Ochrobactrum* species (Brucellaceae, Alphaproteobacteria) are closely related to *Brucella* species, with *O. intermedium* occupying a phylogenetic position that is intermediate between *O. anthropi* and *Brucella* (133).

*O. anthropi* has been isolated from various environmental and human sources, predominantly from patients with catheter-related bacteremia (132, 136) and rarely with other infections (137). One hospital outbreak in transplant patients has been described (138). A few cases of *O. intermedium* infections have been reported (see, e.g., reference 139), but because of the close phenotypic similarity of *O. anthropi* and *O. intermedium*, it is possible that certain infections considered to be caused by *O. anthropi* were actually caused by *O. intermedium*.

*O. anthropi* strains are usually resistant to β-lactams, such as broad-spectrum penicillins, broad-spectrum cephalosporins, aminoglycosides, and amoxicillin-clavulanate, but are usually susceptible to aminoglycosides, fluoroquinolones, imipenem, tetracycline, and trimethoprim-sulfamethoxazole (136).

**Pannobacter phragmitetus**

*P. phragmitetous*, of the family Rhodobacteraceae (Alphaproteobacteria), has been shown to be identical to the strains formerly designated *Achromobacter* groups B and E (140). The species resembles most strongly *R. radiobacter*, but saccharolytic activity is somewhat weaker and not as extended. Unlike *Rhizobium*, *Ochrobactrum*, and *Pseudochrobactrum*, which all have a strong phenylalanine deaminase activity, *P. phragmitetous* does not produce phenylpyruvic acid from phenylalanine. Another easy and reliable differential test is the hydrolysis of tributyrin, which is positive within 30 min for *P. phragmitetous*, whereas *R. radiobacter* strains are positive only after several hours or overnight incubation or remain negative. *Ochrobactrum* species and *Pseudochrobactrum* species do not hydrolyze tributyrin. Moreover, *P. phragmitetous* grows at 41°C while *R. radiobacter* does not. Cases of septicemia due to *Achromobacter* group B have been reported (141).

**Pseudochrobactrum**

The genus *Pseudochrobactrum* was described in 2006 (142) and comprises two species, i.e., *P. saccharolyticum* and *P. asaccharolyticum*. The type strain of *P. asaccharolyticum* was isolated from a knee aspirate. Two more human strains were isolated from Belgian clinical samples: a wound and an eye swab (our unpublished data). Both species are very similar to *Ochrobactrum* species, but cells are nonmotile. *P. asaccharolyticum* slowly acidifies glucose and xylose, while *P. saccharolyticum* is more saccharolytic. Both species are susceptible to desferrioxamine and do not produce urease. Nitrate reduction and nitrite reduction are negative. The clinical significance of *Pseudochrobactrum* species remains to be assessed.

**Rhizobium radiobacter**

The former genus *Agrobacterium* contained several species of plant pathogens occurring worldwide in soils. Four distinct species of *Agrobacterium* were recognized: *A. radiobacter* (formerly *A. tumefaciens* and CDC group Vd-3), *A. rhizogenes* (subsequently transferred to the genus *Sphingomonas* as *Sphingomonas rosa*), *A. vitis*, and *A. rubi*. More recently, an emended description of the genus *Rhizobium* (Rhizobiaceae, Alphaproteobacteria) was proposed to include all species of *Agrobacterium* (143), of which only *R. radiobacter* is clinically important.

Colonies of *R. radiobacter* are circular, convex, smooth, and nonpigmented to light beige on SBA, with a diameter of 2 mm at 48 h. Colonies may appear wet and become extremely mucoid and pink on MacConkey agar with prolonged incubation. *R. radiobacter* cells measure 0.6 to 1.0 by 1.5 to 3.0 μm and occur singly and in pairs.

*R. radiobacter* grows optimally at 25 to 28°C. It grows at 35°C as well, but not at 41°C. *R. radiobacter* is phenotypically very similar to the *Ochrobactrum* species, although phylogenetically separate. *R. radiobacter* differs clearly from *Ochrobactrum* species by a positive β-galactosidase test and by the production of ketolactonate, which is, however, not routinely tested. *R. radiobacter* has broad saccharolytic activity, including mannitol and raffinose.

*R. radiobacter* has been most frequently isolated from blood, followed by peritoneal dialysate, urine, and ascitic fluid.
Fluid (144). The species has also been isolated from the airways of patients with cystic fibrosis (123). The few cases are from patients with transcutaneous catheters or implanted biomedical prostheses, and effective treatment often requires removal of the device. Most strains are susceptible to broad-spectrum cephalosporins, carbapenems, tetracyclines, and gentamicin but not to tobramycin (144, 145). Testing of individual isolates is recommended for clinically significant cases.

Shewanella algae and Shewanella putrefaciens
The organisms formerly called Pseudomonas putrefaciens, Alteromonas putrefaciens, Achromobacter putrefaciens, and CDC group Ib have been placed in the genus Shewanella, which comprises >50 species. S. putrefaciens was described with two CDC biotypes. CDC biotype 1 was later described as S. putrefaciens sensu stricto, whereas CDC biotype 2 was subsequently assigned to a new species, S. alga (146), later corrected to S. algae.

Colonies of Shewanella species on SBA are convex, circular, smooth, and occasionally mucoid; produce a brown to tan soluble pigment; and cause green discoloration of the medium. Cells are long, short, or filamentous, reminiscent of Myroides. Motility is due to a single polar flagellum.

Most strains of both Shewanella species produce H$_2$S in KIA and TSI agar, a unique feature among clinically relevant GNF. Both are also ornithine decarboxylase positive and have strong alkaline phosphatase, strong trypsin, and strong pyrrolidonyl aminopeptidase activities. S. algae is halophilic, asaccharolytic, and requires NaCl for growth, with growth occurring already on TSA plus 0.5% NaCl. S. putrefaciens does not require NaCl for growth and is saccharolytic, producing acid from maltose and sucrose, and irregularly and weakly from glucose.

Khashe and Janda (147) have reported that S. alga is the predominant human clinical isolate (77%), while S. putrefaciens represents the majority of nonhuman isolates (89%). Although infrequently isolated in the clinical laboratory, S. putrefaciens and S. algae have been recovered from a wide variety of clinical specimens and are associated with a broad range of human infections (148), including skin and soft tissue infections, otitis media, ocular infection, osteomyelitis, peritonitis, and septicaemia. The habitat for S. algae is saline, whereas S. putrefaciens has been isolated mostly from fish, poultry, and meats as well as from freshwater and marine samples.

Shewanella species are generally susceptible to most antimicrobial agents effective against Gram-negative rods, except penicillin and cephalothin (107, 145). The mean MICs of S. algae for penicillin, ampicillin, and tetracycline are higher than the corresponding MICs of S. putrefaciens (147).

Sphingobacterium, Indole-Negative Species
A total of 15 species have been described as belonging to the genus Sphingobacterium. Based on 16S rRNA gene sequence data, the indole-producing Sphingobacterium mizutaii also belongs to this genus, and as a consequence, the description of the genus Sphingobacterium as indole negative was emended to indole variable (149).

In summary, most species of this genus do not produce indole, but S. mizutaii is indole positive and is therefore dealt with among the indole-positive GNF in Table 5.

The species of the genus Sphingobacterium encountered in clinical material include S. multivorans (formerly Flavobacterium multivorans and CDC group IIk-2), S. spiritivorum (including the species formerly designated as Flavobacterium spiritivorum, Flavobacterium yabuuchiae, and CDC group IIk-3), S. thalpophilum, and S. mizutaii (150, 151).

Colonies are yellowish. Sphingobacterium species are middle-sized, nonmotile, Gram-negative rods. All species are strongly saccharolytic; i.e., glucose, xylose, and other sugars are acidified. No acid is produced from mannitol, except by S. spiritivorum, which is also the only species to produce acid from ethylene glycol. S. thalpophilum can be distinguished from other Sphingobacterium species by its nitrate reductase and its growth at 41°C.

S. multivorans and S. spiritivorum can be distinguished from Sphingomonas paucimobilis (formerly CDC group IIk-1) because they are nonmotile, urease positive, and resistant to polymyxin. Many strains of other Sphingomonas species are also colistin resistant.

S. multivorans is the most common human species. It has been isolated from various clinical specimens but has only rarely been associated with serious infections (peritonitis and sepsis) (152, 153). Blood and urine have been the most common sources for the isolation of S. spiritivorum (154). S. thalpophilum has been recovered from wounds, blood, eyes, abscesses, and an abdominal incision (40).

Sphingobacterium species are generally resistant to aminoglycosides and polymyxin B while susceptible in vitro to the quinolones and trimethoprim-sulfamethoxazole. Susceptibility to β-lactam antibiotics is variable, requiring testing of individual isolates (108).

Sphingomonas Species
On the basis of 16S rRNA gene sequence and the presence of unique sphingoglycolipid and ubiquinone types, the genus Sphingomonas (Sphingomonadaceae, Alphaproteobacteria) was created for organisms formerly known as Pseudomonas paucimobilis and CDC group IIk-1 (155, 156). The original genus Sphingomonas can be divided into four phylogenetic groups, each representing a different genus (157), whereby the emended genus Sphingomonas contains at least 12 species, of which only S. paucimobilis and S. parapaucimobilis are thought to be clinically important. However, recent 16S rRNA gene sequencing of 12 strains of clinical origin (Wauters, unpublished) revealed that several named and unnamed Sphingomonas species were present, but no S. paucimobilis and only two S. parapaucimobilis isolates. Because many phenotypic characteristics are shared by these species, routine laboratories最好 report them as Sphingomonas species.

Sphingomonas colonies are slow growing on blood agar medium, with small colonies appearing after 24 h of incubation. Growth occurs at 37°C but not at 41°C, with optimum growth at 30°C. Almost all strains produce a yellow, insoluble pigment, different from flexirubin pigments, as can be established by the KOH test (2). Few strains are nonpigmented or develop a pale yellow color after several days. Older colonies demonstrate a deep yellow (mustard color) pigment.

Sphingomonas species are medium to long, motile rods with a single polar flagellum. Motility occurs at 18 to 22°C but not at 37°C. However, few cells are actively motile in broth culture, thus making motility a difficult characteristic to demonstrate.

Oxidase is only weakly positive or even absent. All the strains are saccharolytic, but some acidify glucose only weakly and slowly. Urease is always negative, and nitrate reduction is only very rarely positive. Esculin is hydrolyzed, and β-galactosidase and alkaline phosphatase are positive. The yellow pigment of some strains may hamper a correct
reading of the yellow color shift when nitrophenyl compounds of the latter substrates are used.

Members of this genus are known as decomposers of aromatic compounds and are being developed for use in bioremediation.

Sphingomonas species are widely distributed in the environment, including water. S. paucimobilis has been isolated from a variety of clinical specimens, including blood, cerebrospinal fluid (CSF), peritoneal fluid, urine, wounds, the vagina, and the cervix, as well as from the hospital environment, including water.

Most strains are resistant to vancomycin, which is exceptional for Gram-negative, nonfermenting rods. This is elsewhere only found in Elizabethkingia and related genera like Elizbethkingia and Empedobacter. Most Sphingomonas species are susceptible to tetracycline, chloramphenicol, trimethoprim-sulfamethoxazole, and aminoglycosides. Susceptibility to other antimicrobial agents, including fluoroquinolones, varies (107, 158).

Oxidase-Positive, Indole-Positive GNF

The natural habitats of most oxidase-positive, indole-positive GNF (Table 5) are soil, plants, and food and water sources, including those in hospitals. Clinically relevant species include Balneatrichis alpica, Bergeyella zoohelcum, Chryseobacterium species, E. meningoseptica, Empedobacter brevis, S. mizutaii, Wautersiella falsenii, and Weeksella virosa. All are indole, trypsin, pyrrolidonyl aminopeptidase, and alkaline phosphatase positive, except for B. zoohelcum, which is pyrrolidonyl aminopeptidase negative, and B. alpica, which is both trypsin and pyrrolidonyl aminopeptidase negative. Table 5 presents an overview of the characteristics useful to differentiate among these species.

\end{table}

\textsuperscript{a}Numbers in parentheses after organism names are numbers of strains tested. Values are percentages; those in parentheses represent delayed positivity.

\textsuperscript{b}Alkalization of acetate is positive for C. anthropl and C. homini and negative for C. treverense.

\textsuperscript{c}Numbers in parentheses after organism names are numbers of strains tested. Values are percentages; those in parentheses represent delayed positivity.

\textsuperscript{d}E. miricola is urease positive (data from reference 170).

\textsuperscript{e}ONPG, o-nitrophenyl-β-D-galactopyranoside.
The species is strictly aerobic and saccharolytic. Both trypsin and pyrrolidonyl aminopeptidase are negative, unlike with other indole-positive GNF. Growth occurs at 20 to 46°C on ordinary media such as TSA but not on MacConkey agar. It acidifies fructose, glucose, glycerol, inositol, maltose, mannitol, mannose, sorbitol, and xylose. B. alpica is nitrate reductase and weakly gelatinase positive. It is similar to E. meningoseptica but can be differentiated from this species by its motility and nitrate reductase and by the absence of β-galactosidase.

B. alpica was first isolated in 1987 during an outbreak of pneumonia and meningitis among persons who attended a hot (37°C) spring spa in southern France (160). Isolates from eight patients were recovered from blood, CSF, and sputum, and one was recovered from water. This species is only rarely isolated from human clinical specimens.

Bergeyella zoohecum

B. zoohecum comprises former CDC group IIj strains (161). B. zoohecum and W. virosa are morphologically and biochemically similar organisms with cells measuring 0.6 by 2 to 3 μm, with parallel sides and rounded ends. B. zoohecum colonies are sticky and tan to yellow.

Both species fail to grow on MacConkey agar and are nonsaccharolytic. Both species are susceptible to desferrioxamine and have the unusual feature of being susceptible to penicillin, a feature that allows them to be easily differentiated from the related genera Chryseobacterium and Sphingobacterium. B. zoohecum can be differentiated from W. virosa because it is pyrrolidonyl aminopeptidase negative, strongly urease positive, and resistant to colistin.

B. zoohecum is isolated mainly from wounds caused by animal (mostly dog) bites and can lead to meningitis and septicaemia (161, 162). Both B. zoohecum and W. virosa are susceptible to most antibiotics. However, at present no specific antibiotic treatment is recommended, and antimicrobial susceptibility testing should be performed on significant clinical isolates.

Chryseobacterium

CDC group IIb comprises the species Chryseobacterium indologenes, Chryseobacterium gleum, and other strains, which probably represent several unnamed taxa.

Strains included in CDC group IIb are nonmotile rods. Cells of C. indologenes are similar to those of Chryseobacterium anthropi, Chryseobacterium hominis, E. meningoseptica, and S. miyutai; i.e., they are thinner in their central than in their peripheral portions and include filamentous forms.

CDC group IIb strains are oxidase and catalase positive, produce flexirubin pigments (2), are moderately saccharolytic, and are esculin and gelatin hydrolysis positive. C. indologenes and C. gleum can easily be differentiated from each other by four characteristics: C. indologenes displays a broad beta-hemolysis area within 3 days of incubation at 37°C on SBA, is always arabinose negative, does not acidify ethylene glycol, and does not grow at 41°C. C. gleum exhibits pronounced alpha-hemolysis, resembling viridans discolouration; always acidifies ethylene glycol; is arabinose positive or delayed positive; and grows at 41°C.

Beta-hemolysis is absent or very rare in other strains of CDC group IIb and is therefore almost specific for the

*Numbers in parentheses after organism names are numbers of strains tested. Values are percentages; those in parentheses represent delayed positivity. Abbreviation: W, weakly positive reaction.

aONPG, o-nitrophenyl-β-D-galactopyranoside.
identification of *C. indologenes*, while the profile of *C. gleum* may be shared by other strains of this group. It should be noted that some *C. indologenes* strains do not produce flexirubin.

Among CDC group IIb species, *C. indologenes* is usually considered most frequently isolated from clinical samples, although it rarely has clinical significance (145). Nosocomial infections due to *C. indologenes* have been linked to the use of indwelling devices during hospital stays (163). More recently, *C. indologenes* has also been associated with the cause of neonatal meningitis (164, 165). Still, the frequency of *C. indologenes* as reported in the literature should be interpreted with caution, because until recently and without molecular biology, *C. indologenes* could almost not be distinguished routinely from other CDC group IIb strains. We have recently examined 21 CDC group IIb strains both phenotypically and by 16S rRNA gene sequencing and found 9 *C. indologenes* isolates, 5 *C. gleum* isolates, and 7 isolates belonging to unnamed *Chryseobacterium* species.

The production of novel types of metallo-β-lactamases from *C. indologenes* has been studied in detail (166). *C. anthrophi* represents part of the strains formerly designated as CDC group Ile (167). Most strains display very sticky colonies, which are nonpigmented but may develop a slightly salmon-pinkish, rarely yellowish color after a few days. In contrast to *C. hominis*, the species is negative for esculin hydrolysis and acidification of ethylene glycol. In addition, many strains are susceptible to desferrioxamine. Most clinical isolates used for the description of the species were from wounds and blood cultures (167).

*C. hominis* includes the strains formerly included in CDC group Iic and most of the strains of CDC group IIh (168). This species does not produce flexirubin pigments, but some strains exhibit a slightly yellowish pigmentation. Colonies are often mucoid. *C. hominis* can be differentiated from *C. gleum* by the absence of flexirubin pigments and the lack of acid production from arabinose. *C. indologenes* strains lacking flexirubin pigments may resemble *C. hominis*, but the latter is never beta-hemolytic and always acidifies ethylene glycol.

Many strains have been isolated from blood. Others have been isolated from dialysis fluid, pus, the eye, intraorbital drain, and aortic valve, but their clinical significance remains to be assessed (168). *Chryseobacterium treverense* has been described recently (169). Part of the strains formerly designated CDC group Ile belong to this species. Although described as indole negative, *C. treverense* strains produce indole that should be detected using the method recommended for GNF (see chapter 33). The species is phenotypically related to *C. anthrophi* and *C. hominis* but can be distinguished by a negative (or very weak) gelatin hydrolysis and the absence of acetate accumulation.

### Elizabethkingia meningoseptica and Elizabethkingia miricola

Colonies of *E. meningoseptica*, formerly *Chryseobacterium meningosepticum* (170), are smooth and fairly large, either nonpigmented or producing a pale yellow or slightly salmon-pinkish pigment after 2 or 3 days. Characteristic features are acid production from mannitol and β-galactosidase activity. Gelatin and esculin hydrolysis are positive. *Elizabethkingia* and *Chryseobacterium* species can be differentiated as well on the basis of 16S rRNA gene sequence analysis (167, 170).

*Elizabethkingia meningoseptica* has been reported to be associated with (neonatal) meningitis (171), nosocomial outbreaks (see, e.g., references 172 and 173), and different types of infection (e.g., adult pneumonia and septicemia [145, 172] and infections reported in dialysis units [174]). A clinical case (sepsis) of *E. miricola* was reported only once.

### Empedobacter brevis

*E. brevis* (175) colonies are yellowish pigmented but do not produce flexirubin. *E. brevis* can be differentiated from *C. indologenes*, *C. gleum*, other CDC group IIb strains, and *C. hominis* by its lack of esculin hydrolysis. Growth on MacConkey agar and stronger gelatinase activity are useful to distinguish it from *C. anthrophi*. The species is rarely recovered from clinical material.

### Sphingobacterium mizutaii

*S. mizutaii*, previously known as *Flavobacterium mizutaii* (151), but originally described as *Sphingobacterium mizutae* (176), is the only indole-positive *Sphingobacterium* species (149). It is saccharolytic—producing acid from a large number of carbohydrates, including xylose—similar to other *Sphingobacterium* species, from which it can be distinguished by its indole production, its failure to grow on MacConkey agar, and its usual lack of urease activity (40).

*S. mizutaii* can be distinguished from *Chryseobacterium* and *Empedobacter* species by its lack of gelatin hydrolysis and no flexirubin production. *S. mizutaii* produces acid from xylose but not from ethylene glycol, allowing differentiation from other indole-positive species. The phenotypic profile of *S. mizutaii* is similar to that of the strains described as *Chryseobacterium* CDC group IIi. Furthermore, 16S rRNA gene sequencing confirms that most CDC group IIi strains actually belong to the species *S. mizutaii* (149).

*S. mizutaii* has been described as an indole-negative species (151), but in our hands all strains tested, including the type strain, produce as much indole as the *Chryseobacterium* strains, using the method recommended for GNF (see chapter 33). *S. mizutaii* has been isolated from blood, CSF, and wound specimens (40).

### Wautersiella falsenii

*W. falsenii* is closely related to *E. brevis*, from which it differs by its urease activity. Two genomovars have been described (177): genomovar 1 is always esculin positive and β-galactosidase negative, whereas 90% of the genomovar 2 strains are esculin negative and 63% are β-galactosidase positive.

*W. falsenii* was described as belonging to a separate genus from *Empedobacter*, based on comparison of its 16S rRNA gene sequence with an *E. brevis* EMBL sequence of poor quality (our unpublished data). A high-quality sequence of the rRNA gene of the type strain of *E. brevis* indicates that *W. falsenii* probably has to be renamed as *Empedobacter falsenii*.

*W. falsenii* is much more frequently isolated from clinical samples than *E. brevis* (177, 178). Its clinical significance remains to be assessed.

### Weeksella virosa

*W. virosa* colonies are mucoid and adherent to the agar, reminiscent of the sticky colonies of *B. zoohelcum*. Colonies are not pigmented after 24 h of incubation but may become yellowish tan to brown after 2 or 3 days. The cellular morphology of *W. virosa* is dealt with above in the discussion of *B. zoohelcum*. *W. virosa* can be differentiated from *B. zoohelcum* because it is urease negative and polymyxin B
and colistin susceptible, whereas B. zoohelcum is rapid urease positive and polymyxin B and colistin resistant. W. virosa comprises former CDC group II strains (179). W. virosa is isolated mainly from urine and vaginal samples (179), in contrast to B. zoohelcum, which is isolated mostly from animal bites.

The appropriate choice of effective antimicrobial agents for the treatment of chryseobacterial infections is difficult (173). Chryseobacterium species and E. meningoseptica are inherently resistant to many antimicrobial agents commonly used to treat infections caused by Gram-negative bacteria (aminoglycosides, β-lactam antibiotics, tetracyclines, and chloramphenicol) but are often susceptible to agents generally used for treating infections caused by Gram-positive bacteria (rifampin, clindamycin, erythromycin, trimethoprim-sulfamethoxazole, and vancomycin) (107, 108, 145). Although early investigators recommended vancomycin for treating serious infection with E. meningoseptica, subsequent studies showed greater in vitro activity of minocycline, rifampin, trimethoprim-sulfamethoxazole, and quinolones (108, 172). Among the quinolones, levofloxacin is more active than ciprofloxacin and ofloxacin (108). C. indologenes is reported to be uniformly resistant to cephalothin, cefotaxime, ceftriaxone, aztreonam, aminoglycosides, erythromycin, clindamycin, vancomycin, and teicoplanin, while susceptibility to pipercillin, ceftazidime, imipenem, quinolones, minocycline, and trimethoprim-sulfamethoxazole is variable, requiring testing of individual isolates (108). Several studies reported that administration of quinolone, minocycline, trimethoprim-sulfamethoxazole, or rifampin and treatment of local infection improve the clinical outcome of patients with E. meningoseptica infections. The choice of appropriate antimicrobial therapy is further complicated by the fact that MIC breakpoints for resistance and susceptibility of chryseobacteria have not been established by the CLSI and the results of disk diffusion testing are unreliable in predicting antimicrobial susceptibility of Chryseobacterium species (180). The Etest is a possible alternative to the standard agar dilution method for testing cefotaxime, ceftazidime, amikacin, minocycline, ofloxacin, and ciprofloxacin but not pipercillin (181). Definitive therapy for clinical samples.

**Azospirillum**

The former Roseomonas genomic species 3 (Roseomonas fauriae) and genomic species 6 have been transferred to the genus Azospirillum (Rhodospirillaceae, Alphaproteobacteria), a genus of nitrogen-fixing plant symbionts that is in a different order of bacteria (188). Some strains of this genus may occasionally be isolated from clinical material (189).

Colonies are pale pink and resemble those of Roseomonas. Cells are somewhat more rod shaped than Roseomonas and are motile by one or two polar flagella. Oxidase is positive and urea is strongly positive, as in Roseomonas species. β-Galactosidase activity and esculin hydrolysis allow differentiation of Azospirillum from other pink-pigmented species.

**Methyllobacterium**

The genus Methyllobacterium, of the family Methyllobacteriaceae (Alphaproteobacteria), currently consists of 20 named species plus additional unassigned biovars, recognized on the basis of carbon assimilation type, electrophoretic type, and DNA-DNA homology grouping (190). Methyllobacterium species are isolated mostly from vegetation but may also occasionally be found in the hospital environment. M. mesophilicum (formerly Pseudomonas mesophilica, Pseudomonas extorquens, and Vibrio extorquens) and M. zatmanii have been the two most commonly reported species isolated from clinical samples.

Colonies of Methyllobacterium species are small, dry, and coral pink. Under UV light, Methyllobacterium colonies appear dark due to absorption of UV light (189). Growth is fastidious on ordinary media such as TSA, producing 1-mm-diameter colonies after 4 to 5 days on SBA, modified Thayer-Martin, buffered charcoal-yeast extract, and Middlebrook 7H11 agars, with the best growth occurring on Sabouraud agar and usually no growth on MacConkey agar. Optimum growth occurs between 25 and 30°C. They are able to utilize methanol as a sole source of carbon and energy, although this characteristic may be lost on subculture. Cells are pleomorphic, vacuolated rods that stain poorly and may resist decolorization (Fig 4). Motility by one polar flagellum is difficult to demonstrate. In the description of the genus (191), methyllobacteria were reported to be oxidase positive, but the strains tested by us with the dimethyl-paraphenyleneediamine reagent were all oxidase negative. Saccharolytic activity is weaker than in Asaia spp., no acid is produced from mannitol, and acid is produced irregularly from glucose.
Arabinose, xylose, and ethylene glycol are acidified. Urea and starch are hydrolyzed.

*Methylobacterium* species have been reported to cause septicemia, continuous ambulatory peritoneal dialysis-related peritonitis, skin ulcers, sepsis, and other infections often in immunocompromised patients (192–195). Tap water has been implicated as a possible agent of transmission in hospital environments, and methods for monitoring water systems for methyllobacteria have been described previously (3).

Active drugs include aminoglycosides and trimethoprim-sulfamethoxazole, whereas β-lactam drugs show variable activity (196). These species are best tested for susceptibility by agar or broth dilution at 30°C for 48 h (30).

*Roseomonas*

The original description of the genus *Roseomonas* (*Acetobacteraceae, Alphaproteobacteria*) included three named species, *R. gilardii* (genomic species 1), *R. cervicalis* (genomic species 2), and *R. fujiae* (genomic species 3), and three unnamed species, *Roseomonas* genomic species 4, 5, and 6 (189). *Roseomonas* genomic species 3 and 6 have been transferred to the genus *Azospirillum*. More recently, Han et al. (188) proposed a new species, *R. mucosa*, and a new subspecies, *R. gilardii* subsp. *rosea* (to differentiate from *R. gilardii* subsp. *gilardii*).

The following *Roseomonas* species can be isolated from clinical samples: *R. gilardii* subsp. *gilardii*, *R. gilardii* subsp. *rosea*, *R. mucosa*, *R. cervicalis*, *Roseomonas* genomic species 4, and *Roseomonas* genomic species 5.

Colonies are mucoid and runny and grow larger than those of *Asaia* and *Methylobacterium*. Pigmentation varies from pale pink to coral pink. *Roseomonas* cells are nonvacuolated, coccoid, plump rods, mostly in pairs and short chains (Fig. 5) and usually motile by one or two polar flagella, but motility is often difficult to demonstrate. Genomic species 5 is nonmotile. Growth occurs at 37°C on ordinary media like SBA, and mostly on MacConkey agar, but the best growth is observed on Sabouraud agar. Oxidase is dependent on the species and often weak. Saccharolytic activity is also species dependent. All *Roseomonas* species strongly hydrolyze urea but not esculin. They are trypsin and β-galactosidase negative. Phenotypic distinction among the different species is based on oxidase, acid production from carbohydrates, and pyrrolidonyl aminopeptidase and nitrate reductase activities.

ANTIMICROBIAL SUSCEPTIBILITIES

Decisions about performing susceptibility testing are complicated by the fact that the CLSI interpretive guidelines for disk diffusion testing of GNF are limited to *Pseudomonas*.
species, B. cepacia, Stenotrophomonas maltophilia, and Acinetobacter species and therefore, except for Acinetobacter species, do not include the organisms covered in this chapter. Furthermore, results obtained with, e.g., Acinetobacter species by using disk diffusion do not correlate with results obtained by conventional MIC methods. In general, laboratories should try to avoid performing susceptibility testing on the organisms included in this chapter. When clinical necessity dictates that susceptibility testing be performed, an overnight MIC method, e.g., Etest (bioMérieux) on Mueller-Hinton agar (181), is recommended.

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

Although certain GNF can on occasion be frank pathogens, e.g., Burkholderia pseudomallei, E. meningoseptica, and P. aegyptiaca, they are generally considered to be of low virulence and often occur in mixed infections, making it difficult to determine when to work up cultures and when to perform susceptibility studies. E. meningoseptica in neonatal meningitis, M. lacunata in eye infections, and M. catarrhalis in respiratory tract infections should be reported as significant pathogens. Direct Gram stain interpretation of clinical specimens may be of limited importance, because these organisms often occur in mixed infections and because their clinical importance has to be interpreted taking into account the considerations discussed below. Decisions regarding the significance of GNF in a clinical specimen must take into account the clinical condition of the patient and the source of the specimen submitted for culture. In general, the recovery of a GNF in pure culture from a normally sterile site warrants identification and susceptibility testing, whereas predominant growth of a GNF from a nonsterile specimen, such as an endotracheal culture from a patient with no clinical signs or symptoms of pneumonia, would not be worked up further. Identification of GNF may also be important to document nosocomial outbreaks linked to hospital environment or medical devices. Because many GNF exhibit multiple-antibiotic resistance, patients who are on antibiotics often become colonized with GNF. GNF species isolated in mixed cultures can usually be reported by descriptive identification, e.g., “growth of P. aegyptiaca and two varieties of GNF not further identified.”

**TAXONOMY**

The genera *Bordetella*, *Achromobacter*, *Alcaligenes*, *Kerstersia*, *Advenella*, and *Paenalcaligenes* belong to the family *Alcaligenaceae* (order *Burkholderiales* in the β-subclass of the Proteobacteria) (1). Other members of this family include *Azohydromonas*, *Brackiella*, *Candidimonas*, *Castellaniella*, *Deroxia*, *Oligella*, *Parapasilimonas*, *Pelistega*, *Pigmentiphaga*, *Pseudimonas*, and *Tayorella* (List of Prokaryotic names with Standing in Nomenclature [http://www.bacterio.net/]).

The genus *Bordetella* contains eight species: *Bordetella avium*, *B. bronchiseptica*, *B. hinzii*, *B. holmesii*, *B. parapertussis*, *B. pertussis* (the type species), *B. petrii*, and *B. trematum* (2–7). Other putative species, such as “*B. ansorpii*” and other strains similar to *B. trematum* (8, 9), have been described but not validly named. *B. pertussis*, *B. parapertussis*, and *B. bronchiseptica* could be considered a single species, but chemotaxonomic differences and differences in host range and pathogenesis (3, 10) support the status as separate species. Analysis of their genome sequences revealed that *B. parapertussis* and *B. pertussis* are independent derivatives of a *B. bronchiseptica*-like ancestor (10). The taxonomy of the genus *Achromobacter* is closely intertwined with the genus *Alcaligenes*. The genus *Alcaligenes* is now limited to *Alcaligenes aquatilis* and *A. faecalis* (the type species) (11, 12), while the genus *Achromobacter* consists of 16 species: *Achromobacter aegrificans*, *A. animicus*, *A. anxifer*, *A. dentirificans*, *A. dolens*, *A. insolitus*, *A. insuavis*, *A. marplatensis*, *A. mucicola*, *A. piechaudii*, *A. pulmonis*, *A. ruhlandii*, *A. sediminum*, *A. spanius*, *A. spiritinus*, *A. suebicus*, and *A. xylosoxidans* (the type species) (5, 11, 13–17, 153). In addition, this genus contains six yet-unnamed genogroups (designated genogroups 1, 3, 8, 9, 12, and 13) (18). The genus *Kerstersia* was proposed for a set of strains phenotypically resembling *A. faecalis*; this genus contains two species (*Kerstersia gyiorum* and *K. similis*) (5, 11). Similarly, the genus *Advenella* was created to harbor a number of *Advenella*-like strains; these strains either belong to *Advenella incenata* or one of several unnamed genomic species (19) or were previously described as *Tetrahobiobacter* species (20). Finally, the genus *Paenalcaligenes* (with the species *Paenalcaligenes hominis* and *P. suwonensis*) was created for single strains isolated from human blood (21) and spent mushroom compost (154), respectively.

**DESCRIPTION OF THE GENERA**

*Bordetella*

*Bordetella* are small (1- to 2-μm) Gram-negative, nonsporulating coccoid rods (22). *B. pertussis* and *B. parapertussis* have smaller genomes than many of the other members of the genus (4,086 Mbp for *B. pertussis*, 4,774 Mbp for *B. parapertussis*, 5,338 Mbp for *B. bronchiseptica*, and 5,287 Mbp for *B. petrii*, but 3,732 Mbp for *B. avium* and around 3.8 Mbp for *B. holmesii*). Insertion sequences are mainly found in the genomes of *B. pertussis* (e.g., IS481 and IS1002), *B. parapertussis* (e.g., IS1001), and *B. holmesii* (e.g., IS481 and IS1001-like) and less so in *B. bronchiseptica* (10, 23, 24). A comparison between the species also revealed that only around 50% of the genome is conserved in all species and that multiple mechanisms, such as gain or loss of genes, point mutations, and horizontal gene transfer, may play a role in the development of the species (25).

*Bordetella* are catalase positive and oxidize amino acids, but no carbohydrates can be fermented. Some species possess peritrichous flagella and are motile. *Bordetella* are able to grow in simple synthetic media under aerobic conditions (except *B. petrii*; see below). However, *B. pertussis* and *B. parapertussis* are sensitive to toxic substances and metabolites present in many microbiological media and need special transport conditions, special culture media, and prolonged incubation. The other species are less sensitive and can be isolated by routine microbiological procedures.

*B. petrii* is the most versatile *Bordetella* species; it can grow aerobically and anaerobically and was initially found as a free-living environmental bacterium (24). All other *Bordetella* are found only in warm-blooded animal and humans. *B. avium* is a pathogen for poultry and has only once been isolated from humans (8). *B. bronchiseptica* can cause respiratory infections in many animal species and, infrequently, also in humans. *B. holmesii* has recently been recognized as a relevant pathogen mostly in immunosuppressed but also in immunocompetent patients and may cause a variety of systemic diseases in various organ systems. "*B. ansorpii*,” *B. hinzii*, *B. petrii*, and *B. trematum* are rarely found in human infections and mainly cause symptomatic diseases in immunocompromised patients. *B. parapertussis* is found in sheep and humans, and *B. pertussis* is thought to be a strictly human pathogen (Table 1).

*Bordetella* express many virulence factors that are controlled by a complex virulence expression system operating...
A. pulmonis small bacilli. Most species are motile, but motility is weak.

media, and on nutrient agar colonies are flat or slightly convex with smooth margins and range from white to light brown. Under laboratory conditions growth occurs between 30 and 37°C and in the presence of 0% to 1.5% NaCl. Several Achromobacter species contain the Q-8 ubiquinone system. Predominant fatty acids are C16:0, C17:0 cyc, and C18:0 anteiso (13, 15, 16). Several Achromobacter species contain the Q-8 ubiquinone system. Predominant fatty acids are C16:0, C17:0 cyc, and C18:0 anteiso (13, 15, 16).

**Achromobacter**

Achromobacter species are Gram-negative, nonsporulating, small bacilli. Most species are motile, but motility is weak or absent in A. pulmonis and is strain dependent in A. insutaeis. Achromobacter species are strictly aerobic and nonfermentative, although strains of some species are able to grow anaerobically with nitrate as an electron acceptor (15, 17). All Achromobacter species are oxidase and catalase positive, but none of them exhibit urease, DNase, lysine decarboxylase, ornithine decarboxylase, arginine dihydrolase, or gelatinase activity (13, 15–17). They grow well on simple media, and on nutrient agar colonies are flat or slightly convex with smooth margins and range from white to light brown (13). Under laboratory conditions growth occurs between 30 and 37°C and in the presence of 0% to 1.5% NaCl (13, 15, 32, 33).

**Bordetella**

Bordetella species are oxidase and catalase positive, but none of them exhibit urease, DNase, lysine decarboxylase, arginine dihydrolase, or gelatinase activity (13, 15–17). They grow well on simple media, and on nutrient agar colonies are flat or slightly convex with smooth margins and range from white to light brown.

**Alcaligenes, Kerstersia, Advenella, and Paenalcaligenes**

Following many taxonomic revisions, the genus Alcaligenes is now limited to A. faecalis and A. aquatilis. Within A. faecalis, three subspecies (A. faecalis subsp. faecalis, A. faecalis subsp. parafaecalis, and A. faecalis subsp. phenolicus) have been described (34, 35). A. faecalis subsp. parafaecalis and A. faecalis subsp. phenolicus are represented by a single environmental isolate each, and A. aquatilis strains have been recovered only from lake sediments (12). Some A. faecalis strains produce a characteristic fruity odor and/or cause a greenish discoloration of blood agar medium; these strains were previously referred to as “A. odorans” (36). Alcaligenes species are Gram-negative, strictly aerobic rods or coccobacilli that possess oxidase and catalase activities (1). Cells are motile by means of 1 to 12 peritrichous flagella. The optimum growth temperature is between 20 and 37°C. They grow well on simple media, and colonies on nutrient agar are generally nonpigmented. Predominant fatty acids in Alcaligenes species are C16:0 and C17:0 cyc (12, 36).

Cells of Kerstersia and Advenella species are Gram-negative, small (1- to 2-μm), and rod-shaped or coccoid and occur alone, in pairs, or in short chains. Motility is strain dependent. They grow well on simple media. On nutrient agar, colonies are flat or slightly convex with smooth margins and range from white to light brown. They are strictly aerobic and nonfermentative. All isolates studied so far are catalase positive, while none of them exhibit β-galactosidase activity (11, 19). Kerstersia strains can grow between 28 and 42°C; growth also occurs with up to 4.5% NaCl. Predominant fatty acids in Kerstersia species are C16:0 and C17:0 cyc (11). Advenella strains can grow between 30 and 37°C and at NaCl concentrations between 0 and 3%. Predominant...
fatty acids in Advenella species are C\textsubscript{18:1} \textomega 7c, C\textsubscript{16:0}, and C\textsubscript{16:1} \textomega 7c (19).

P. hominis cells are Gram-negative, small (1- to 2-\mu m) rods. They grow well on nutrient agar at 25 to 30\degree C and are oxidase positive. Sugars and sugar-related compounds are not utilized. Predominant fatty acids are C\textsubscript{16:0}, summed feature 3 (containing C\textsubscript{16:1} \textomega 7c and/or iso-C\textsubscript{15:0} 2-OH), C\textsubscript{17:0} cyc, and C\textsubscript{18:0} \textomega 7c (21).

### EPIDEMIOLOGY AND TRANSMISSION

**B. pertussis and B. parapertussis**

B. pertussis and B. parapertussis are transmitted by droplets; for B. pertussis in susceptible contacts the transmission rate may be close to 90\%, and the infectious dose is only around 100 CFU (3). The bacteria attach to the ciliated cells of the nasopharynx and then colonize the upper respiratory tract. B. pertussis and B. parapertussis are the causes of pertussis, or whooping cough. Infections by B. parapertussis tend to take a milder clinical course with a shorter duration of coughing and less vomiting and whooping (3, 37–40).

Worldwide in 2012, around 200,000 cases and 90,000 deaths were notified to WHO (http://www.who.int/immunization_monitoring/diseases/pertussis/en/index.html), and it is assumed that the disease is grossly underreported. B. pertussis also continues to circulate in populations where high vaccination coverage of infants and children is achieved (40, 41), because the protection after natural infection and vaccination wanes after several years (38, 41). In vaccinating countries, cases of pertussis are now mainly observed in neonates, unvaccinated young infants, older schoolchildren, adolescents, and adults (38, 40–43). A permanent carrier state is not found with pertussis, although in outbreak situations asymptomatic transient carriage of Bordetella DNA detected by PCR has been observed (3, 39).

In vaccinated European populations, the basic reproduction number was estimated to be around 6 (44); transmission mainly occurs from adolescents and adults to infants or among older vaccinated children, adolescents, and adults (3, 40). Neonates and young infants are at greatest risk of being infected by their parents, although casual contacts may be important (45). In various countries, such as Australia, Brazil, the United States, and the United Kingdom, significant increases in notified cases have occurred in recent years, and various factors, e.g., insufficient vaccine coverage, changes in vaccination calendar, more effective diagnostics, changes in circulating strains, decreased longevity of protection after vaccination, and differences in priming, have been hypothesized to be responsible for the outbreaks (46).

**Other Bordetella Species, Achromobacter, Alcaligenes, Kersteria, and Advenella**

Among the bordetellae, B. holmesii (7) is increasingly found mainly by PCRs primarily using IS\textsubscript{481} as a target, which shows homogeneity in B. pertussis, B. holmesii, and other bordetellae (Tables 2 and 3) (47, 48).

Data on epidemiology and transmission are limited to Achromobacter infections in cystic fibrosis (CF) patients. Persistent infections with A. xylosoxidans can occur, as genetically identical isolates are recovered from the respiratory tract over prolonged periods (49, 50). There have been several reports of multiple CF patients being colonized or infected by the same A. xylosoxidans isolate (50–52). However, no large-scale outbreaks caused by the same strain and involving multiple treatment centers have been identified, and epidemiological studies revealed that there are many different A. xylosoxidans strains infecting CF patients. The “Danish epidemic strain” was identified as A. ruhlandii (53). This strain has infected multiple patients in two Danish CF centers, and cross-infection was documented to also occur by indirect patient-to-patient contact (54).

CLINICAL SIGNIFICANCE

B. pertussis and B. parapertussis
After an incubation period of 7 to 10 days (range, 4 to 28 days), the primary infection starts with rhinorrhea, sneezing, and nonspecific coughs (coryza or catarrhal phase). The typical clinical symptoms of pertussis are found in primary infections of nonvaccinated children, with coughing spasms, whooping, and vomiting (paroxysmal phase) (38, 55). Cases in neonates and unvaccinated young infants often present with apnea as the only symptom (3, 41, 56). In older schoolchildren, adolescents, and adults, the symptoms can vary widely. Adult pertussis is associated with a long illness, and the persistent cough is often paroxysmal and has a mean duration of approximately 6 weeks. It is frequently accompanied by chok ing, vomiting, and whooping (40). The CDC clinical case definition for pertussis (http://www.cdc.gov/vaccines/pubs/surv-manual/chpt10-pertussis.html) requires 14 days of coughing with paroxysms, whooping, or vomiting. The disease is most dangerous in infants, and most hospitalizations and deaths occur in this age group. Fatal cases of the disease may go undetected in young infants (41, 57).

Pertussis-like symptoms may also be caused by adenoviruses, respiratory syncytial virus, human parainfluenza viruses, influenza viruses, Mycoplasma pneumoniae, and other agents (41, 58).

Other Bordetella species
Due to its more frequent diagnosis, B. holmesii (7) is suspected to be a pathogen that may cause respiratory symptoms in adolescents and adults (47, 48) and inflammation in various organs in immunocompromised patients. B. bronchiseptica (59, 60), B. petrii, B. avium, “B. anserinii,” and B. hinzii (61–64) are rarely isolated from respiratory materials from patients with respiratory symptoms. In many cases, patients are systemically or locally immunocompromised. As with other Gram-negative nonfermentative bacilli, cases of bacteremia, septicemia, and other manifestations have been described.

B. trematum (4, 65) has been isolated from people working with poultry, and “B. anserinii” (9, 66) is another rare course of septicemia. B. petrii (67, 68) and possibly other environmental bordetellae (69) are rarely found in clinical material, and B. avium has so far been isolated from respiratory material from humans only once (8) (Table 1).

Achromobacter
All Achromobacter species have been recovered from clinical samples or from the hospital environment. A. xylosoxidans (previously known as A. xylosoxidans subsp. xylosoxidans) is an opportunistic human pathogen capable of causing a wide range of infections, such as bacteremia, meningitis, pneumonia, and peritonitis (70–74). It has also been involved in nosocomial infections attributed to contaminated disinfectants, dialysis fluids, saline solution, and water (75). A. piechaudii has been isolated from various clinical samples, including pharyngeal swabs, nose, wound, blood, and chronic ear discharge samples (76). There is a single report of recurrent A. piechaudii bacteremia associated with an intravenous catheter in an immunocompromised patient (77). A. denitrificans (previously known as A. xylosoxidans subsp. denitrificans) has been recovered from many clinical specimens, such as urine, proctoscopy specimens, prostate secretions, the buccal cavity, pleural fluid, and eye swabs (36), but there are no detailed reports about its clinical significance. A. insolitus (in a leg wound and in urine) and A. spanius (in blood) have been found in clinical material, but their significance is unclear (11). Strains from the recently described species A. anfractuans, A. anfractus, A. anxifer, A. dolens, A. insuavis, A. marplatensis, A. muscolens, A. pulmonis, and A. spirititus have mainly been recovered from sputum of CF patients, but their clinical significance also remains unclear (15, 16).

Achromobacter spp. are frequently associated with CF. A. xylosoxidans has been reported from CF patients since 1985, and prevalence rates in CF vary from 3 to 18% (67, 78–80). However, recent studies based on multilocus sequence analysis indicate that patients with CF are often infected with Achromobacter species other than A. xylosoxidans (53, 81, 82). For example, among 341 Achromobacter-infected CF patients in the United States, 42% were infected with A. xylosoxidans, 23.5% with A. ruhlandii, and 17% with A. dolens (16, 82). A similar prevalence of A. xylosoxidans (38%) was reported for Danish Achromobacter-infected CF patients (83). A. xylosoxidans infections in CF patients do not seem to have a significant impact on lung function (51, 79, 84). Infection with the A. ruhlandii Danish epidemic strain can lead to deterioration of lung function (34).

Alcaligenes, Kersteria, Advenella, and Paealcaligenes
A. faecalis strains have been isolated from a wide range of clinical samples (36), but the accuracy of the identification (especially in older reports) is difficult to assess. A. faecalis was found in cases of bacteremia following surgery or cancer treatment, from ocular infections, from a pancreatic abscess, from infections following bone fractures, from urine, and from ear discharge (73, 85, 86). There are sporadic reports on the recovery of A. faecalis in sputum of CF patients (87). K. gyiorum was isolated from human feces, leg wounds, sputum, and chronic ear infections (11, 88, 89), while K. similis was isolated from leg wounds and a neck abscess (11, 32). A. incenata has been recovered from human sputum (including sputum from CF patients) and blood, and several unnamed Advenella species were isolated from similar sources (19). The sole P. hominis strain described so far was recovered from the blood of an 85-year-old man in Sweden (21).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

B. pertussis and B. parapertussis
Sampling for culture and PCR is difficult, and it influences the sensitivity markedly. Nasopharyngeal aspirates are adequate for infants and young children; for culture, they are more sensitive than swabs. Nasopharyngeal swabs taken from older children, adolescents, and adults by trained personnel provide valid specimens from these age groups and are better than throat swabs. Nasopharyngeal swabs should be taken by gently inserting the swab into the nasopharynx under the inferior nasal choana, and the nose of the patient should be slightly bent upwards (http://www.pasteur.fr/recherche/unites/film_cnr/predlev.swf). If possible, two nasopharyngeal swabs should be taken, one from each nostril. Swabs should be small and made of Dacron or rayon. Flocked nylon swabs, which are more convenient for the patient, may also be used, but they have not been validated for B. pertussis PCR or culture. Calcium alginate swabs and swabs with aluminum shafts should not be used for PCR. Samples should be taken before antibiotic treatment is started (90).
For nasopharyngeal aspirates or swabs, transport time is critical, and a transport medium protecting the bacteria from drying is required. Usual bacteriological transport media, such as Casamino Acids or Amies medium with charcoal, may be used, but transport time should not exceed 48 h. Half-strength Regan-Lowe (RL) charcoal-blood medium may also be used for transport, and it serves as enrichment for B. pertussis (41).

For PCR, swabs can be transported dry at ambient temperature. The use of microbiological transport media, such as Amies medium with charcoal, did not interfere with PCR (90). Other respiratory samples, such as sputum samples or throat washes, are less suitable and have not been validated (3).

Other Bordetella species, Achromobacter, Alcaligenes, Kersteria, Advenella, and Paenicaligenes

For other bordetellae, normal microbiological transport media seem suitable for transport. Similarly, Alcaligenes, Kersteria, Advenella, and Paenicaligenes species can survive in a wide range of environments and at various temperatures. Standard collection, transport, and storage techniques are sufficient to ensure recovery of these organisms from clinical specimens, contaminated nosocomial sources, and the environment.

DIRECT DETECTION METHODS

PCR

PCR is 2- to 6-fold more sensitive than culture depending on age, vaccination status, and duration of symptoms of the patients, and real-time PCR formats offer a result within several hours instead of several days (90–92). Block-based and real-time PCRs seem to have comparable sensitivities (90, 93, 94). The sensitivity of PCR decreases with the duration of cough; however, due to its higher sensitivity, it may be a useful tool for diagnosis up to 4 to 6 weeks of coughing (90, 92). In outbreak situations and after household contacts, a positive PCR may also be obtained for patients with very mild or no symptoms (95). DNA extraction is necessary to limit inhibition of PCR (90). Commercially available extraction kits seem to be comparable and appropriate (90), but no head-to-head comparison has been done. Some of these kits are FDA cleared and/or CE marked for this purpose. Multiplex targets for detection are IS481 (copy number, ∼200 per cell in B. pertussis) (90, 92), which is present in B. pertussis, B. holmesii, and some B. bronchiseptica strains; IS1001 (copy number, ∼20 per cell in B. parapertussis) (96), which is present in B. parapertussis and IS1002, which is present in B. pertussis and B. parapertussis. The combined use of the three ISs has been suggested to distinguish clinically relevant Bordetella spp. (97) and to distinguish B. holmesii (98). In current isolates, the number of ISs remained stable compared to those of the sequenced type strains (96). Monogenic targets include the PT promoter (ptxA-Fr), the PT gene, the recA gene from B. holmesii, and the FHA and porin genes. Targets are summarized in Table 2 (90, 91, 92, 97–100).

Tests detecting single-copy genes were, however, consistently less sensitive than IS481-based PCRs. Sequence-specific detection can be done by fluorescence resonance energy transfer hybridization probes, TaqMan probes, and molecular beacons and also by non-sequence-specific formats using SYBR green I (90). For specificity reasons, most laboratories use sequence-specific formats, and duplex or triplex PCRs for clinically relevant Bordetella spp. have been developed. Multiplex PCRs for the detection of various respiratory agents, including Bordetella spp., are also available but are mostly based on IS481 as the sole target. External quality control programs have been implemented in the United States and in European countries (93). Apart from contamination problems in laboratories, pseudo-outbreaks of pertussis have also been reported on the basis of swabs contaminated with Bordetella DNA from clinic surfaces (101).

Direct Fluorescent-Antibody Staining

Direct fluorescent-antibody staining on nasopharyngeal swabs or nasopharyngeal aspirates is rapid and simple, but it lacks sensitivity and specificity and is not recommended (3). Other stains have no role in pertussis diagnosis.

ISOLATION PROCEDURES

B. pertussis and B. parapertussis

Although culture is thought to be almost 100% specific, PCR has mostly replaced it in routine diagnosis (90). Detailed information on cultural procedures is contained in previous editions of this Manual (102). In brief, various culture media, such as RL medium, Bordet-Gengou (BG) medium, and Stainer-Scholte medium, can be used for culturing B. pertussis and B. parapertussis. Most media are supplemented with cephalexin to suppress concomitant bacteria. Incubation time should be at least 1 week at 35 to 37°C or ambient atmosphere (Table 4). The sensitivity of culture depends on the duration of symptoms, the age, and the vaccination status, and it varies between ∼60% in young unvaccinated infants with few days’ duration of symptoms and <1% in adolescents and adults with more than 3 weeks of coughing (102).

Other Bordetella species, Achromobacter, Alcaligenes, Kersteria, Advenella, and Paenicaligenes

Bordetella spp. other than B. pertussis or B. parapertussis from clinical material are encountered as Gram-negative nonfermentative bacilli in the laboratory. Table 4 gives some information about their growth characteristics and some biochemical reactions that may be used.

Achromobacter species can be isolated from clinical samples by the use of simple media and a selective enteric medium such as MacConkey agar (36). It has been reported that a minority of A. xylosoxidans isolates grow on B. cepacia selective oxidative-fermentative-polymyxin B-bacitracin-

*Pos, positive; Neg, negative.*
lactose agar or Pseudomonas cepacia agar (30% and 20%, respectively) but do not grow on Burkholderia cepacia selective agar (103). Data from the Cystic Fibrosis Foundation Burkholderia cepacia Research Laboratory and Repository (J. J. LiPuma, unpublished data) and a previous study (33) indicate that the majority of A. xylosoxidans strains (~60%) grow on Burkholderia cepacia selective agar. Results obtained in a small-scale study suggest that particular selective media, such as Gram-negative selective agar, may increase the recovery of A. xylosoxidans from the sputa of CF patients (104).

IDENTIFICATION

**B. pertussis** and **B. parapertussis**

*B. pertussis* colonies become visible after 3 to 7 days of incubation, and *B. parapertussis* colonies are visible already after 2 to 3 days. On RL medium colonies are very small, round, and domed, and they appear silvery. *B. parapertussis* colonies are larger and less shiny. The minute colonies on Bordet-Gengou medium have a small zone of beta-hemolysis. *B. pertussis* is a small coccoïd Gram-negative rod which is catalase and oxidase positive (*B. parapertussis* is oxidase negative). Their identity can best be confirmed by agglutination with specific antibodies. Basic biochemical characteristics are given in Table 4. Due to the fastidious growth of *B. pertussis* and *B. parapertussis*, commercial systems for Gram-negative rods are not reliable for identifying these species. 16S rRNA sequencing (59) and matrix-assisted laser desorption ionization—time of flight mass spectrometry (MALDI-TOF MS) (80) can effectively be applied for identification.

Isolates of *B. pertussis* and, less so, *B. parapertussis* should not be subcultured because they undergo a phase change as described above. If strains have to be stored, this should be done from primary clinical isolates, and these should be frozen in glycerol at −70°C or in a sucrose-bovine serum albumin medium. Biosafety level 2 is strongly recommended or obligatory.

**Other Bordetellae**

Colony morphology is not discriminatory, and the bacteria are small coccoïd rods that are catalase positive. In most instances, a biochemical system for identification of Gram-negative bacilli is used, such as API20-NE, Vitek (bioMérieux, Marcy-l’Etoile, France), MicroScan (Siemens, Eschborn, Germany), or Phoenix (Becton Dickinson, Franklin Lakes, NJ) (105). These systems were validated for nonfermentative rods, among which also a few *Bordetella* spp. were evaluated. Overall, the specificity of these biochemical systems for these bacteria is not very high, and for the API20-NE and Vitek II systems, it has been proposed that 16S rRNA gene sequencing be performed if the results of the biochemical identification are not reported as “excellent” or “very good” (105). 16S rRNA gene sequencing or ribotyping offers more reliable identification results, as does MALDI-TOF MS, and either method is available in many reference laboratories (80, 106–108). Apart from *B. bronchiseptica*, isolation of other bordetellae from clinical material is a rare event, and their identification should be confirmed by a reference laboratory to avoid misidentification (109).

**Achromobacter**

*Achromobacter* species typically show very limited action on carbohydrates (15, 16), which hampers the accurate identification at the genus level based on biochemical characteristics, and 16S rRNA gene sequence analysis is recommended for this purpose. Likewise, the increased taxonomic diversity and considerable intraspecies diversity observed in this genus make species-level differentiation based on phenotypic characteristics virtually impossible. A PCR assay (based on the 16S rRNA gene) was developed for *A. xylosoxidans*, but positive results may also be obtained with strains of other *Achromobacter* species as well as with some *Bordetella* species (82, 110). MALDI-TOF MS has successfully been used to identify *A. xylosoxidans* (80, 111) and reportedly allows the separation of *A. xylosoxidans*, *A. ruhlandii*, *A. insolitus*, and *A. spanius* (112), although in another study species-level identification of *Achromobacter* spp. with MALDI-TOF MS turned out to be not straightforward (113). In addition, Desai et al. (114) noted that strains identified as *A. xylosoxidans* by a phenotypic test were commonly identified as *A. ruhlandii* by MALDI-TOF MS. It should be noted that the studies referenced above were published prior to the recent description of additional diversity within the genus *Achromobacter*, and their applicability to differentiate all *Achromobacter* species will need to be reinvestigated. All established *Achromobacter* species can be separated using the concatenated nusA, eno, rpoB, gbd, lepA, nuoL, and nrdA sequences (15, 16, 18). A recent study on a large number of *Achromobacter* strains indicated that most species can even be distinguished based on sequence analysis of the nrdA gene alone (115). An alternative multilocus sequence analysis scheme using atpD, icd, recA, rpoB, and tyrB sequences has also been described previously (116).

**Alcaligenes, Kersteria, Advenella, and Paenalcaligenes**

Also for *Alcaligenes*, *Advenella*, *Kersteria*, and *Paenalcaligenes*, 16S rRNA gene sequence analysis is recommended for accurate identification at the genus level. Members of the genus *Advenella* can be separated from related species by their inability to assimilate phenyl acetate. *Kersteria* strains are oxidase negative. *K. gyiorum* and *K. similis* can be distinguished based on oxidation of D-galacturonic acid and D-glucuronic acid (positive in *K. gyiorum* and negative in *K. similis*) and D-serine (negative in *K. gyiorum* and positive in *K. similis*). A distinguishing characteristic of *A. facalis* isolates is that they reduce nitrite but not nitrate. *P. hominis* cannot assimilate citrate.

**Typing SYSTEMS**

*B. pertussis* and *B. parapertussis* show limited genomic heterogeneity (37), but some polymorphic regions, such as the toxin gene (*ptx*), the toxin promoter (*ptxP*), and the pertactin gene (*prn*), have undergone changes the cause of which is not totally clear (117, 118). The expression of fimbrae undergoes temporal changes, possibly influenced by vaccine coverage (118). Nucleic acids of circulating isolates of *B. pertussis* have been typed by a vast array of methods, such as conventional and next-generation sequencing (31, 118), pulsed-field gel electrophoresis, variable number of tandem repeats (also called multilocus variable-number tandem repeat analysis [MLVA]) (119, 120), restriction fragment length polymorphism (90), single nucleotide polymorphism typing (121), real-time PCR (122), and others (106). Other methods use the proteome as the distinguishing parameter (123). Depending on the problem in question, different typing methods may be employed, and the results can mostly not be compared directly. Similar typing methods have also been used for isolates of *B. holmesii* (124, 125).

Typing of *A. xylosoxidans* isolates with pulsed-field gel electrophoresis of fragments obtained after digestion with
**SEROLOGICAL TESTS**

**B. pertussis and B. parapertussis**

Pertussis in older vaccinated children, in adolescents, and in adults is mostly diagnosed by serological tests. Enzyme-linked immunosorbent assays or bead-based assays to quantify anti-PT antibody levels are recommended diagnostic techniques (128–130) and can be performed with paired (acute and convalescent phase) or single serum samples (128, 129). Paired-sample serology is an optimal method of diagnosis (131), but single-sample serology also provides good sensitivity and specificity to determine cases in older children, adolescents, and adults (128, 132, 133). A WHO reference preparation for human pertussis serology is available (134), and quantitative results in pertussis serology should be reported in international units per milliliter. For single-sample serology, IgG anti-PT antibodies below 40 IU/ml are not indicative of recent contact, whereas levels above >100 IU/ml can be used as an indicator of recent contact with the bacteria (129, 135–137). IgG anti-PT antibodies are primarily measured, and IgA anti-PT may serve as an additional test for equivocal results (>40 IU/ml and <100 IU/ml). Measuring IgM antibodies is not recommended (129), nor are other methods such as immunoblotting, complement fixation, or agglutination (129). Serology is unable to detect infection with B. parapertussis, and it cannot distinguish between vaccine- and infection-induced immunological responses (symptomatic or asymptomatic infection) (129, 135). Commercial assays are of very variable quality and are in need of further standardization (138). Pertussis serology cannot be reliably interpreted for 1 year after vaccination with acellular vaccines (129). External quality control programs for pertussis serology are available (139).

**B. pertussis and B. parapertussis are susceptible in vitro to a range of antibiotics, including some penicillins, macrolides, ketolides, quinolones, tetracyclines, chloramphenicol, and trimethoprim-sulfamethoxazole, whereas they are resistant to most oral cephalosporins (3).** However, in contrast to the case with other bacterial diseases, the exact relationship between the pharmacokinetics and pharmacodynamics of these antibiotics and the in vitro susceptibility of the organism is unknown. Furthermore, the effect on the symptoms of pertussis is not well documented (41, 140).

Methods for antibiotic susceptibility testing of B. pertussis and B. parapertussis are not standardized. If testing is done, the methods include broth macro- and microdilution, agar dilution methods, breakpoint methods, and the Etest, whereas the disk diffusion method is mostly not feasible (41). Erythromycin resistance may be evaluated by disk diffusion method, using charcoal-horse blood (RL) medium without antibiotics and employing a 15-μg erythromycin disk. Few isolates with erythromycin resistance have been found in the United States and in other countries; they have existed in strain collections from the 1960s, and no data so far suggest that this resistance is spreading (41), although it may increase in some countries (141). Erythromycin resistance is mediated by a mutation in the macrolide binding domain of the 23S rRNA. Routine antibiotic susceptibility testing of B. pertussis isolates is not recommended and should be done only when special clinical or epidemiological circumstances are found (41). Continued surveillance of B. pertussis isolates should also include antimicrobial susceptibility testing.

**Other Bordetellae**

*B. bronchiseptica* possesses a β-lactamase (142) and is resistant to many penicillins and cephalosporins, and mostly to trimethoprim-sulfamethoxazole (143). A study of canine and feline isolates (144) showed that most isolates are susceptible to amoxicillin-clavulanic acid, to tetracycline, to gentamicin, and to a quinolone. *B. avium* was resistant to cefuroxime, trimethoprim-sulfamethoxazole, and tetracycline and sensitive to ampicillin, mezlocillin, and gentamicin (143). A human *B. hinzii* isolate was susceptible to amoxicillin, gentamicin, and meropenem but resistant to cefuroxime, ceftriaxone, and ciprofloxacin (62). A human "*B. anosomal*" isolate was resistant to aztreonam, cefuroxime, and ceftriaxone and susceptible to amoxicillin, gentamicin, and ciprofloxacin (69). Antimicrobial susceptibility testing of these Bordetella isolates should be reported in accordance to other infrequently isolated and fastidious nonfermentative Gram-negative rods, and in vitro resistance does not necessarily reflect clinical ineffectiveness.

**Achromobacter**

*A. xylosoxidans* isolates (145) were sensitive only to imipenem, piperacillin, ticarcillin-clavulanic acid, ceftazidime, and trimethoprim-sulfamethoxazole. Aminoglycosides, expanded-spectrum cephalosporins other than ceftazidime, and quinolones showed no activity. The majority of the strains were resistant to conventional tobramycin concentrations, but 41% of the strains were inhibited by the higher tobramycin concentrations achievable by aerosol delivery of the antibiotic. Similarly, 92% of strains were inhibited by high doses of colistin (100 μg/ml). Little synergistic activity was measured for combinations of antibiotics, and additive activity was noted with chloramphenicol-minocycline, ciprofloxacin-imipenem, and ciprofloxacin-meropenem (146). A. *xylosoxidans* was resistant against azithromycin and clarithromycin, and only modest synergistic and/or additive activities were observed when azithromycin was combined with clarithromycin, and ciprofloxacin-imipenem, and ciprofloxacin-meropenem (197). These data correlate well with those obtained in many smaller clinical studies and case reports (49, 51, 52, 148). Antimicrobial susceptibility data for other Achromobacter species are rare, but *A. spanius* and *A. insolitus* are resistant to most quinolones, macrolides, and cephalosporins tested (19), while a blood isolate of *A. piechaudii* was resistant to ampicillin, cefpodoxime, and gentamicin but susceptible to all other antibiotics tested (199). More than 90% of Achromobacter isolates recovered from Danish CF patients were resistant to amikacin, ciprofloxacin, and tobramycin, and particularly high MICs were recorded for aztreonam (>256 μg/ml) and fosfomycin (>1,024 μg/ml) (150). The lowest MICs were observed for meropenem (94% of isolates without antibiotics and employing a 15-μg erythromycin disk. Few isolates with erythromycin resistance have been found in the United States and in other countries; they have existed in strain collections from the 1960s, and no data so far suggest that this resistance is spreading (41), although it may increase in some countries (141). Erythromycin resistance is mediated by a mutation in the macrolide binding domain of the 23S rRNA. Routine antibiotic susceptibility testing of B. pertussis isolates is not recommended and should be done only when special clinical or epidemiological circumstances are found (41). Continued surveillance of B. pertussis isolates should also include antimicrobial susceptibility testing.

**Other Bordetellae**

*B. bronchiseptica* possesses a β-lactamase (142) and is resistant to many penicillins and cephalosporins, and mostly to trimethoprim-sulfamethoxazole (143). A study of canine and feline isolates (144) showed that most isolates are susceptible to amoxicillin-clavulanic acid, to tetracycline, to gentamicin, and to a quinolone. *B. avium* was resistant to cefuroxime, trimethoprim-sulfamethoxazole, and tetracycline and sensitive to ampicillin, mezlocillin, and gentamicin (143). A human *B. hinzii* isolate was susceptible to amoxicillin, gentamicin, and meropenem but resistant to cefuroxime, ceftriaxone, and ciprofloxacin (62). A human "*B. anosomal*" isolate was resistant to aztreonam, cefuroxime, and ceftriaxone and susceptible to amoxicillin, gentamicin, and ciprofloxacin (69). Antimicrobial susceptibility testing of these Bordetella isolates should be reported in accordance to other infrequently isolated and fastidious nonfermentative Gram-negative rods, and in vitro resistance does not necessarily reflect clinical ineffectiveness.

**Achromobacter**

*A. xylosoxidans* isolates (145) were sensitive only to imipenem, piperacillin, ticarcillin-clavulanic acid, ceftazidime, and trimethoprim-sulfamethoxazole. Aminoglycosides, expanded-spectrum cephalosporins other than ceftazidime, and quinolones showed no activity. The majority of the strains were resistant to conventional tobramycin concentrations, but 41% of the strains were inhibited by the higher tobramycin concentrations achievable by aerosol delivery of the antibiotic. Similarly, 92% of strains were inhibited by high doses of colistin (100 μg/ml). Little synergistic activity was measured for combinations of antibiotics, and additive activity was noted with chloramphenicol-minocycline, ciprofloxacin-imipenem, and ciprofloxacin-meropenem (146). A. *xylosoxidans* was resistant against azithromycin and clarithromycin, and only modest synergistic and/or additive activities were observed when azithromycin was combined with clarithromycin, and ciprofloxacin-imipenem, and ciprofloxacin-meropenem (197). These data correlate well with those obtained in many smaller clinical studies and case reports (49, 51, 52, 148). Antimicrobial susceptibility data for other Achromobacter species are rare, but *A. spanius* and *A. insolitus* are resistant to most quinolones, macrolides, and cephalosporins tested (19), while a blood isolate of *A. piechaudii* was resistant to ampicillin, cefpodoxime, and gentamicin but susceptible to all other antibiotics tested (199). More than 90% of Achromobacter isolates recovered from Danish CF patients were resistant to amikacin, ciprofloxacin, and tobramycin, and particularly high MICs were recorded for aztreonam (>256 μg/ml) and fosfomycin (>1,024 μg/ml) (150). The lowest MICs were observed for meropenem (94% of isolates...
were susceptible), piperacillin-tazobactam (all isolates were susceptible), and trimethoprim-sulfamethoxazole. Colistin (MIC₉₀ = 8 µg/ml) and ceftazidime (MIC₉₀ = 24 µg/ml), two antibiotics commonly used for inhalation therapy, exhibited good activity (150).

**Alcaligenes, Kerstersia, Advenella, and Paenalcaligenes**

A. faecalis is more susceptible to antibiotics than A. xylosoxidans. Most A. faecalis strains are resistant to amoxicillin, ticarcillin, aztreonam, kanamycin, gentamicin, and nalidixic acid while being susceptible to the combination of amoxicillin or ticarcillin with clavulanic acid, to various cephalosporins, and to ciprofloxacin (151). Most Kerstersia isolates are susceptible to ciprofloxacin and cefotaxime (11), although two recently described isolates were ciprofloxacin resistant (89). Recent clinical isolates were found to be susceptible to cefepime, gentamicin, and trimethoprim-sulfamethoxazole (88, 89). Antimicrobial susceptibility in Advenella spp. and P. hominis has not yet been studied.

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

The usefulness of diagnostic methods in pertussis and parapertussis cases is dependent on the duration of symptoms (Fig. 1). Due to its sensitivity and speed, real-time PCR is the preferred method for the direct detection of B. pertussis and B. parapertussis in the United States (152) and elsewhere. Suggestions for the interpretation and reporting of real-time PCR results are given in Table 3.

If culture is performed, the isolation of B. pertussis and B. parapertussis implies an infection, although the sensitivity is sufficiently high only for neonates and unvaccinated infants. Routine antimicrobial sensitivity testing of isolates is not necessary. Culture remains necessary, especially for surveillance of circulating B. pertussis and B. parapertussis isolates.

Serological diagnosis of pertussis is usually based on single-sample serology. Results cannot be correctly interpreted for about 1 year after vaccination with acellular pertussis vaccines. IgG anti-PT levels of ≥100 are indicative of recent contact. In adolescent and adult populations, IgG anti-PT levels of <40 IU/ml may be interpreted as not indicative of recent infection (129). Except in Massachusetts, serology is not accepted as a confirmation of cases in the United States. Many European countries with statutory notification and laboratory confirmation accept serology as a proof of infection.

Similar to the case with other rarely isolated Gram-negative nonenteric rods, the clinical relevance of isolates of *Achromobacter* sp., *Alcaligenes* sp., *Kerstersia* sp., *Advenella* sp., and *P. hominis* from clinical material should be discussed on a case-by-case basis between the microbiology laboratory and the clinician. Antimicrobial testing of these species should be performed and can be helpful in guiding therapeutic decisions.

Francisella tularensis is the causative agent of tularemia, an acute and fatal illness in animals and humans. Human infections caused by F. tularensis occur via arthropod bite, handling of infected animals, inhalation of infectious aerosols, and ingestion of contaminated food or water. F. tularensis is highly infectious, with only 10 organisms sufficient to cause illness, and has a notorious reputation for causing laboratory-acquired infections. Within the Francisella genus, F. tularensis is joined by six lesser-known Francisella species which are largely considered environmental species and nonpathogenic or opportunistic pathogens of humans. Whereas F. tularensis causes tularemia in animals and humans, F. noatunensis and F. halioticida infect and cause death in fish and abalone, respectively. F. novicida and F. philomiragia are associated with salt or brackish water and are only infrequent causes of opportunistic infections in compromised individuals. F. tularensis was examined by multiple countries for its possible use as both an offensive and retaliatory biological weapon in the years leading up to and following World War II. In 2012, F. tularensis was classified as a Tier 1 agent, one of six bacterial species which are recognized, with ≥99.8% and ≥99.2% shared identities between their 16S rRNA genes and 1.1 Mb of genome sequence, respectively (1, 4).

F. novicida and F. philomiragia, both originally isolated from saltwater sources (5–8), have been classified as species distinct from F. tularensis on the basis of serologic, virulence, and biochemical differences (7, 9). Between F. philomiragia and F. tularensis, genome reassociation studies show 39% average DNA relatedness, while sequencing indicates >98.3% shared identity in their 16S rRNA gene sequences (5, 10). A high degree of genetic similarity exists between F. novicida and F. tularensis as evidenced by DNA hybridization studies (>70% DNA relatedness) (5, 11), and on this basis F. novicida was proposed as a fourth subspecies of F. tularensis (5, 11). Recent whole-genome comparisons, however, provide evidence that F. novicida and F. tularensis evolved as two distinct population lineages, consistent with F. novicida and F. tularensis being two separate species (4, 12). Clinical and ecological differences between F. tularensis and F. novicida also indicate the two represent distinct species (12) (see “Epidemiology and Transmission” and “Clinical Significance” below).

Only one isolate of F. hispanensis has been described to date (11, 13). In DNA hybridization experiments, F. hispanensis showed 52%, 57 to 61%, and 39% identities with F. novicida, F. tularensis, and F. philomiragia, respectively (11). F. noatunensis, F. halioticida, and F. guangzhouensis have been linked only to environmental sources, recovered from a number of saltwater fish species, giant abalone, and air-conditioning systems, respectively (14–17). Mean reassociation values of 68% between F. noatunensis and F. philomiragia (16), 49.2 to 59.6% between F. noatunensis and F. halioticida, and 61% between F. philomiragia and F. halioticida are observed by DNA hybridization (16, 18).

Additional Francisellaceae members, isolated in culture, including Francisella spp. recovered from seawater (18) and a Francisella sp. isolated from two different patients in the United States in 2005 and 2006, have been described (19). Preliminary characterization data indicate that these Francisella spp. are distinct from F. tularensis, F. novicida, and F. philomiragia but await final assignment into the genus. The genome of the tick endosymbiont Wolbachia persica, has recently been sequenced, thereby confirming its placement in the Francisella genus (1, 3). Putative Francisellaceae family members identified on the basis of 16S rRNA gene sequencing include Francissella-like endosymbionts (PLEs) in Amblyomma maculatum and multiple Dermacentor and Ornithodoros tick species (1, 20).

Francisella

46
DESCRIPTION OF THE AGENTS

The genus Francisella comprises tiny Gram-negative cocco-bacilli, which range in size from 0.2 to 1.7 µm and can be distinguished from similar genera by several features (Table 1). Members of the genus take up Gram-positive bacteria, and they are strict aerobes, weakly catalase positive, urease negative, nonmotile, and non-spore forming, and they metabolize limited number of carbohydrates (Table 2). Only a few sugars (glucose, maltose, sucrose, and glycerol) are utilized by most members of the genus. Acid is produced without gas. Unique cellular fatty acids are associated with the genus (Table 1) (1, 5, 21).

A few key differences separate species of the Francisella genus, including oxidase production, growth in nutrient broth with 6% NaCl, optimum growth temperatures, and sugar utilization (Table 2). Additionally, levels of virulence differ in mammals, with F. tularensis being the most virulent. In laboratory mice, a 100% lethal dose (LD₉₀) of only 1 to 10 cells is observed for F. tularensis, compared to an LD₉₀ of >10⁶ for F. novicida (9, 22). Levels of virulence also differ between F. tularensis subspecies; F. tularensis subsp. novaensis displays an LD₉₀ of <10 when inoculated subcutaneously into rabbits, compared to an LD₉₀ of ∼10³ for F. tularensis subsp. holarctica (23). No mortality occurs in mice inoculated with 10⁸ cells of F. philomiragia (23) or 10⁹ cells of F. novicida (24). Similarly, F. guangzhouensis was found to be avirulent in mice (17).

In the last 15 years, >40 whole-genome sequences have been completed for Francisella species, including F. tularensis subsp. tularensis, F. tularensis subsp. holarctica, F. tularensis subsp. mediasiatica, F. novicida, F. philomiragia, F. hispaniensis, F. noatunensis, and Wolbachia persica (3). The size of Francisella genomes is ~1.9 Mb, with a G+C content of ~32% (http://www.ncbi.nlm.nih.gov/genome/?term=Francisella). All Francisella genomes are comprised of a single chromosome. Plasmids are unique to some environmental Francisella spp., including F. novicida and F. philomiragia, and are not conserved across all members of a given species (http://www.ncbi.nlm.nih.gov/genome/?term=Francisella). Whole-genome analyses indicate that F. tularensis, the causative agent of tularemia, contains only seven unique genes in comparison to other members of the Francisella genus (3). These genes encode proteins predicted to be involved in exopolysaccharide and lipopolysaccharide synthesis as well as a hypothetical membrane protein (3).

EPIDEMIOLOGY AND TRANSMISSION

F. tularensis has been recovered only from the Northern Hemisphere, with the distribution of the subspecies varying throughout this region (1, 2, 25) (Table 3). Infections caused by F. tularensis subsp. tularensis occur only in North America, whereas F. tularensis subsp. holarctica has a much wider distribution, causing disease throughout the Northern Hemi-

\(^{a}\)V, variable or slow reaction; NT, not tested; NB, nutrient broth.

\(^{b}\)Delayed or variable reaction. F. tularensis subsp. mediasiatica does not ferment glucose (1).
F. tularensis is a zoonotic pathogen, capable of infecting a large variety of animal species. The bacterium has been isolated from vertebrates, including mammals, amphibians, and birds, as well as from invertebrate arthropods (39–41). However, F. tularensis is most commonly associated with rodents and other mammals, particularly hares and rabbits. In both vertebrates and invertebrates, infection with F. tularensis can be lethal.

In contrast to F. tularensis, F. novicida and F. philomiragia do not appear to circulate in animal or arthropod hosts. Only a single isolation of F. philomiragia from an animal host (musk rat) has been documented (6). Arthropods infected with F. novicida or F. philomiragia have never been identified. Transmission of F. novicida and F. philomiragia to humans appears to be associated with proximity to or contact with near-drowning in saltwater sources (8, 42).

Most isolates of F. novicida are from North America, with a report of F. novicida-like organisms in Thailand and Australia (43, 44). Similarly, most isolates of F. philomiragia have been from North America, with two single incidences reported from Central and Eastern Europe and one from the Southern Hemisphere (Australia) (5, 8, 44–46).

F. noatunensis was isolated from both the Northern and Southern Hemispheres (14, 15), whereas F. hispanensis, F. haliotica, and F. guangzhouensis have been recovered only in Spain, Japan, and China, respectively (11, 13, 16, 17).

## CLINICAL SIGNIFICANCE

### F. tularensis

Globally, tularemia is caused by two F. tularensis subspecies, F. tularensis subsp. tularensis (type A) and F. tularensis subsp. holarctica (type B). The disease has been known historically by a number of synonyms, such as rabbit fever, deerfly fever, market men’s disease, glandular type of tick fever, Ohara’s or yato-byo disease, and water rat trappers’ disease, attesting to the variety of clinical presentations, the infectious agent’s ubiquitous presence in nature, and the means by which humans may acquire the infection.

The clinical spectrum of tularemia depends on the mode of transmission, the virulence of the infecting strain, the immune status of the host, and timely diagnosis and treatment (47). Tularemia can be misdiagnosed since the disease is rare and its symptoms are not unique; a sudden onset of

*Human infections documented in the published literature.*
chills, fever, headache, and generalized malaise characterize the onset of illness. The differential diagnosis includes a wide range of infectious diseases, such as cat scratch fever, mycobacterial infections, anthrax, brucellosis, legionellosis, and plague (47).

Patients may present with any one of the clinical forms of tularemia: ulceroglandular, glandular, ocular, oropharyngeal, typhoidal, and pneumonic (47). Upon infection, the period for disease onset is typically 3 to 5 days but can range from 1 to 21 days (28, 47). Disease presentation (i.e., signs and symptoms) correlates with the route of bacterial entry, with all forms of tularemia accompanied by fever (47). The most common form is ulceroglandular disease (45 to 80% of the reported cases), where the portal of entry is via an infective arthropod bite or other inoculation through the skin barrier. Glandular tularemia is similar to ulceroglandular disease but lacks the ulcerated site of infection. Ocular tularemia occurs when the conjunctiva is the initial site of infection, usually as a result of the mechanical transfer of organisms from an infectious source to the eye by the fingers. Oropharyngeal tularemia occurs from ingestion of contaminated water or food and is associated with pharyngeal lymphadenopathy. Pneumonic tularemia occurs by direct inhalation of the organism and is considered the most severe form of the disease. Typhoidal tularemia is the most difficult form to recognize because there is no identified portal of entry and localized signs are absent. If untreated, bacterial dissemination from the primary site of infection can lead to secondary clinical presentations, such as sepsis.

The severity of infection can range from mild and self-limiting to fatal and is largely dependent on the infecting strain. Little to no tularemia-related mortality is reported in Europe and Asia, where only F. tularensis subsp. holarctica causes tularemia. In comparison, mortality in the United States ranges between 2.3% (those diagnosed by culture and serology) and 9% (culture-confirmed cases only) (38, 48), with tularemia caused by the more virulent F. tularensis subsp. tularensis as well as F. tularensis subsp. holarctica. In the last decade, molecular epidemiologic studies have demonstrated that among culture-confirmed human cases in the United States, infections due to A1b strains of F. tularensis subsp. tularensis result in a significantly higher rate of mortality (24%) than infections caused by F. tularensis subsp. tularensis A1a (4%) and A2 (0%) strains or F. tularensis subsp. holarctica (7%) (27). Virulence comparisons in mice corroborate these findings and show that A1b strains are more virulent than other F. tularensis subsp. tularensis strains (49).

The third subspecies of F. tularensis, F. tularensis subsp. mediasiatica, has only been isolated from regions of Central Asia, and a description of human illness due to this subspecies is lacking in the literature. Experimental studies with rabbits indicate virulence comparable to that of F. tularensis subsp. holarctica (25).

F. novicida and F. philomiragia

Human infections caused by F. novicida and F. philomiragia are very rare, and the extent of these organisms primarily infecting patients with underlying compromising conditions. Fewer than 20 cases of F. philomiragia infection have been described since the discovery of this species in 1974 (5, 8, 44–46). All but one case have involved a host with an impaired physical barrier to infection (near drowning) or an impaired immunologic defense system (chronic granulomatous disease or myeloproliferative disease). The drowning and water exposure cases were associated with salt water and brackish water, in contrast to F. tularensis infections, which are associated with freshwater sources. Fewer than 10 cases of F. novicida infections have been reported worldwide (5, 8, 42–44, 50, 51). Healthy individuals presented with mild illness (regional lymphadenopathy without fever), whereas patients with compromising conditions, primarily underlying liver disease, presented with fevers; in the latter cases, F. novicida was isolated from patient blood samples.

F. hispanensis

Only one human case due to infection with F. hispanensis has been reported in the literature (11, 13). A previously healthy, immunocompetent patient presented with fever, myalgia, diarrhea, and lower left back pain; the organism was isolated from both blood and urine of this patient.

F. noatunensis and F. halioticida

F. noatunensis and F. halioticida have never been associated with human infection, and the risk of human infection is considered very low. F. noatunensis is the significant cause of disease in farmed and wild fish, whereas F. halioticida has been associated with mortality in shellfish (giant farmed abalone) (52).

Another Francisella species

An unclassified Francisella sp. was isolated from the blood and cerebrospinal fluid of two different patients in the United States in 2005 and 2006 (19). No other cases with this species have been reported.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

In the United States, F. tularensis is classified as a Tier 1 select agent. To receive or possess F. tularensis strains, laboratories must be registered with the Federal Select Agent Program (http://www.selectagents.gov). Clinical laboratories are exempt from the registration requirement with the Select Agent Program as pertains to conducting diagnostic testing for select agents. Both Tier 1 and non-Tier testing for select agents may be performed by clinical laboratories as long as the laboratory destroys or transfers any confirmed select agent (including clinical samples the isolate was derived from) with 7 days of identification. Laboratories identifying an organism as F. tularensis are required to report this finding immediately; laboratories need to complete Form 2 and submit it to the Select Agent Program. If the organism is to be transferred following identification, then the laboratory must also complete Form 2 and obtain transfer approval from the Select Agent Program. Select agent report forms, contact information, laboratory registration information, and pertinent citations of the U.S. Federal Code may be found at http://www.selectagents.gov.

Personnel handling diagnostic cultures of F. tularensis are at considerable risk for infection. Due to the extremely low infectious dose for F. tularensis, tularemia has been one of the most commonly reported laboratory-associated bacterial infections (53, 54). Even though the use of biological safety cabinets and prophylactic antibiotic therapy (as well as vaccination, where available) provides safeguards for laboratory workers, these precautions have not fully eliminated laboratory exposures or modified practices in the clinical laboratory to minimize risks (55).
Arthropods may be stored intact in 2% NaCl for culture and saline are inadequate for keeping \textit{F. tularensis} viable until processed in the laboratory. Freezing of samples, unless the proportion of organisms might be expected to be high can be directly examined by microscopy by Gram staining, direct fluorescent-antibody (DFA) binding, or immunohistochemistry (IHC). Under microscopic examination of Gram-stained specimens, Francisella cells (single and pleomorphic) appear tiny and counterstain so faintly with safranin that they can easily be missed (Fig. 1). Basic fuchsin counterstains \textit{F. tularen}si better than safranin. Due to the small size of \textit{F. tularensis}, Gram staining of clinical specimens is usually of little diagnostic value. \textit{F. tularensis} should be included in the clinical laboratory differential if very small, faintly staining Gram-negative cocco-bacilli are seen. \textit{F. tularensis} cells are smaller than \textit{Haemophilus}

**DIRECT EXAMINATION**

**Microscopy**
Fresh clinical specimens (ulcer and wound swabs, tissues, and aspirates) where the concentration of organisms might be expected to be high can be directly examined by microscopy by Gram staining, direct fluorescent-antibody (DFA) binding, or immunohistochemistry (IHC). Under microscopic examination of Gram-stained specimens, Francisella cells (single and pleomorphic) appear tiny and counterstain so faintly with safranin that they can easily be missed (Fig. 1). Basic fuchsin counterstains \textit{F. tularen}si better than safranin. Due to the small size of \textit{F. tularensis}, Gram staining of clinical specimens is usually of little diagnostic value. \textit{F. tularensis} should be included in the clinical laboratory differential if very small, faintly staining Gram-negative cocco-bacilli are seen. \textit{F. tularensis} cells are smaller than \textit{Haemophilus}

**Antigen Detection**
A rapid and specific staining method (DFA) for detection of \textit{F. tularensis} in specimens includes the use of a fluorescein isothiocyanate-labeled hyperimmune rabbit polyclonal antibody directed against whole, killed \textit{F. tularensis} cells. This staining method can be used to presumptively identify \textit{F. tularemia} subsp. \textit{tularemia} and \textit{F. tularensis} subsp. \textit{holarctica} in clinical specimens (47). Cultures, lesions, tissues, or aspirates may be rapidly assessed by this approach. This DFA reagent does not work well or at all with \textit{F. novicida} or \textit{F. philomiragia}. IHC staining using a monoclonal antibody directed against the lipopolysaccharide has been successfully used to visualize \textit{F. tularemia} in formalin-fixed tissues (58). Neither the DFA reagent nor the IHC reagent is commercially available. DFA testing of specimens is provided by reference laboratories (Laboratory Response Network [LRN]) in the United States.

**Nucleic Acid Detection**
Because of the relative rarity of human tularemia, evaluation of molecular diagnostics with clinical specimens has been challenging. PCR-based diagnostic methods have been used most commonly for diagnosis of ulceroglandular tularemia, the most prevalent clinical form. DNA detection by conventional PCR directed at the \textit{tul4} gene (unique to \textit{Francisella}

FIGURE 1  Gram stain of \textit{F. tularensis}. Magnification, ×810. doi:10.1128/9781555817381.ch46.fl
FIGURE 2  

**F. tularensis** on CA (A) and CHAB (B) after 72 and 48 h of growth, respectively. (Panel A is courtesy of the CDC Public Health Image Library [Larry Stauffer, Oregon State Public Health Laboratory].) doi:10.1128/9781555817381.ch46.f2
on blood agar, and no growth on MacConkey agar should raise suspicion for *F. tularensis*. *F. tularensis* is oxidase negative, weakly catalase positive, β-lactamase positive, X and V or satellite growth negative, and urease negative. Gram stain, oxidase, XV or satellite, and urease tests can help differentiate *F. tularensis* from other similar Gram-negative organisms, including *Brucella* spp., *Haemophilus influenzae*, *Bartonella* spp., *Pasteurella multocida*, and *Acinetobacter*. (Table 1). If *F. tularensis* is suspected based on these results, the isolate should be sent to a reference laboratory that can confirm (or rule out) its identification as *F. tularensis*. In the United States, all states have at least one reference laboratory that is part of the LRN. LRN laboratories are able to confirm the identification of bacterial select agents, including *F. tularensis*. See also http://www.bt.cdc.gov/lrn.

The colony morphology of *F. tularensis* is most distinctive when the organism is grown on CHAB; after 48 h at 37°C, *F. tularensis* colonies are 1 to 2 mm, raised, shiny, green, and opalescent (Fig. 2B). On CA, BCYE, and Thayer-Martin agar after 48 h at 37°C, *F. tularensis* colonies are ~1 mm, white to gray, and smooth and opaque and have an entire margin (Fig. 2A). *F. novicida* and *F. philomiragia* grow more robustly than *F. tularensis* (Table 2), and colonies of *F. philomiragia* are mucoid.

Isolates can be identified as *F. tularensis* using antigen or molecular detection methods, including slide agglutination, DFA staining (Fig. 3), PCR, or sequencing. The slide agglutination test identifies a suspicious culture by mixing commercially available (Becton, Dickinson and Company) polyclonal rabbit anti-*F. tularensis* antibody with suspicious cultures. DFA staining can also be used to identify *F. tularensis* subsp. *tularensis* and *F. tularensis* subsp. *holarctica* isolates (47). Care should be taken to ensure that prepared smears are not too thick, as this can interfere with the performance and interpretation of the test. In general, antigen-based identification methods work optimally when fresh cultures (24 h) are tested. If a culture older than 24 h is to be tested by antigen detection methods, a fresh subculture should be prepared. Polyclonal antibodies to whole killed *F. tularensis*, used in both the DFA and slide agglutination tests, generally react poorly or not at all with *F. novicida* due to differences in the O antigens of the lipopolysaccharides of the two organisms (47, 69). Thus, this method for identification of *F. tularensis* isolates is preferred, due to this specificity.

PCR methods targeting *F. tularensis*-specific genes can also be used for the identification of suspicious cultures (59, 61). As described earlier in this chapter, it is important to consider that many *F. tularensis* PCR assays cross-react with *F. novicida*. Therefore, it may be important to rule out *F. novicida* as the cause of infection, particularly in areas where *tularemia* has not been previously reported. 16S rRNA gene sequencing, using universal 16S rRNA gene primers or Francisella-specific 16S rRNA gene primers, can identify the organism as a Francisella species (10, 29, 70). Due to the high degree of genetic relatedness between *F. tularensis* and *F. novicida*, 16S rRNA PCR and sequencing do not readily distinguish these two species. *F. novicida* isolates have been misidentified as *F. tularensis* in clinical laboratories by 16S sequencing (42).

Members of the Francisella genus have a unique fatty acid composition, high in saturated even-chain acids (C10:0, C12:0, and C16:0) and two long-chain hydroxyl acids (3-OH-C16:0 and 3-OH-C18:0) (71), which can be used to identify the organism as belonging to the Francisella genus (Table 1) (1, 5, 21). Bacterial identification systems that rely on fatty acid profiles have been used to identify *F. tularensis*; however, it is important to note that commercial systems do not include *F. novicida* or many other Francisella spp. in their databases. Indeed, misidentification of *F. novicida* as *F. tularensis* in a clinical laboratory setting, using these systems has been described (42).

Commercial biochemical identification systems available in clinical laboratories are not recommended for the diagnosis of *F. tularensis* because of the high probability of misidentification and the potential for generating infectious aerosols (47). Misidentification is largely due to a lack of biochemical reactivity by *F. tularensis* and a limited number of strains used in the development of databases. Because of the limitations in identifying *F. tularensis* isolates using automated systems in clinical laboratories, a high level of suspicion by clinical microbiologists is essential for accurate and timely diagnosis of tularemia. Results from automated identification systems should be analyzed critically in the clinical laboratory, taking into consideration the reliability of these systems for accurate identification of slow-growing and/or rare organisms. Potential indications of misidentification by automated systems include a low probability or confidence value and/or an identification of a pathogen inconsistent with the clinical or microbiology picture.

The utility of matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) mass spectrometry (MS) combined with dedicated bioinformatics and statistical methods for identification and differentiation of Francisella strains was recently demonstrated (72). Forty-four strains of *F. tularensis* were accurately identified to the subspecies level as well as differentiated from six strains of *F. philomiragia* (72). Thus, this method shows promise as a method for future identification of *F. tularensis* in the clinical laboratory. At the current time, however, documented use of MALDI-TOF MS with commercially available databases in clinical laboratory settings is lacking.

**FIGURE 3** DFA staining of a culture of *F. tularensis*. Magnification, ×490. doi:10.1128/9781555817381.ch46.f3

**TYPING SYSTEMS**

Once an isolate has been identified as a Francisella sp., supplemental tests can be used for additional characterization, including typing of species, subspecies, and strain. Oxidase can be used to differentiate *F. philomiragia* from *F. novicida* and *F. tularensis* (Table 2). Glycerol fermentation and citrulline ureidase activity distinguish *F. tularensis* subsp. *tularensis* from *F. tularensis* subsp. *holarctica* (Table 2); conventional assays for these biochemical tests have been described (73). The 96-well automated MicroLog MicroStation system with GN2 microplates (Biolog Inc., Hayward, CA) can also be used to...
assess the glycerol fermentation of \( F. \) \( \text{tularensis} \) (47). The genus can be typed by sequence analysis of the 16S rRNA gene (10, 70). PCR methods (both conventional and real-time) can type isolates at the level of genus, species, subspecies (\( F. \) \( \text{tularensis} \) subsp. \( \text{tularensis} \) or \( F. \) \( \text{tularensis} \) subsp. \( \text{holarctica} \)), and subclade (\( F. \) \( \text{tularensis} \) subsp. \( \text{tularensis} \) subclades A1 and A2) (47, 74). Pulsed-field gel electrophoresis can differentiate the three \( F. \) \( \text{tularensis} \) subsp. \( \text{tularensis} \) subpopulations, A1a, A1b, and A2 (27). For discrimination of individual strains, an optimized, multiplex multilocus variable-number tandem-repeat assay for \( F. \) \( \text{tularensis} \), based on 11 different repeats in the genome, can be used (75, 76).

**SEROLOGIC TESTS**

A confirmatory diagnosis of tularemia can be established serologically by demonstrating a 4-fold or significant change in specific antibody titers to or response between acute- and convalescent-phase sera to \( F. \) \( \text{tularensis} \) antigen (47). A single positive antibody titer for a patient with no history of tularemia vaccination is a presumptive diagnosis of tularemia. As antibody responses to \( F. \) \( \text{tularensis} \) generally require 10 to 20 days to develop postinfection, serologic testing is of limited use in clinical management of patients with acute illness. IgM, IgA, and IgG antibodies may appear simultaneously (77, 78), and antibodies to \( F. \) \( \text{tularensis} \) can persist for more than 10 years (79, 80). IgM responses have been shown to be sustained for long periods and are therefore not indicative of early or recent infection (77, 79).

Agglutination testing, either by the tube agglutination (TA) or the microagglutination (MA) method, is a standard serologic test for determining the presence of antibodies in patients with tularemia (47, 79, 81). Formalin-killed antigen (prepared from \( F. \) \( \text{vulpes} \) subsp. \( \text{holarctica} \) strain LVS) is commercially available from Becton, Dickinson, and is also prepared within reference laboratories worldwide. In the United States, a single specimen with a TA titer of \( \geq 1:160 \) or an MA titer of \( \geq 1:128 \) is considered positive. Formalin-killed \( F. \) \( \text{tularensis} \) whole-cell antigen may display low-level cross-reactivity with \( Brucella \) antibodies (82, 83). No cross-reactivity of \( F. \) \( \text{novicida} \) or \( F. \) \( \text{philomiragia} \) sera has been observed with \( F. \) \( \text{tularensis} \)-killed cells (9). Enzyme-linked immunosorbent assays (ELISAs) have been adopted for use in the parts of Europe where tularemia is endemic (47, 79, 84, 85). The lipopolysaccharide and/or outer membrane fraction remains the primary ELISA antigen used in test applications. Antigenic differences between \( F. \) \( \text{tularensis} \) subsp. \( \text{tularensis} \) and \( F. \) \( \text{tularensis} \) subsp. \( \text{holarctica} \) have not been identified for use in serology assays. Thus, serology assays do not distinguish the infecting subspecies. This is of the most importance in North America, where both \( F. \) \( \text{tularensis} \) subsp. \( \text{tularensis} \) and \( F. \) \( \text{tularensis} \) subsp. \( \text{holarctica} \) cause tularemia.

\( F. \) \( \text{tularensis} \) organisms are intracellular bacteria and are capable of elicting both humoral and cell-mediated immunity (77). The latter response has been known to remain strong 25 years after infection (86). Host T cells retain proliferative responses to unique \( F. \) \( \text{tularensis} \) membrane proteins, with concomitant increases in interferon and interleukin-2 levels (77, 86–88). Tests for measuring the cell-mediated immune response are specialized and are not routinely used for diagnosis of tularemia (89).

**ANTIMICROBIAL SUSCEPTIBILITIES**

\( F. \) \( \text{tularensis} \) infections are treatable with narrow-spectrum antibiotics. Naturally occurring resistance in \( F. \) \( \text{tularensis} \) to aminoglycosides, tetracyclines, and fluoroquinolones has never been shown (47, 90–92). The risk for development of antibiotic resistance in clinical disease is low, as tularemia is an end-stage disease and also is not transmitted from person to person (47). Treatment failures in tularemia patients correlate with a delay in the initiation of antibiotics with respect to symptom onset, as opposed to development of resistance (60, 93, 94). Lymph node suppuration, which is nonresponsive to all classes of antibiotics and requires surgical drainage, can develop in these cases. Considerably longer recovery times are observed in these cases and can be greater than 70 days (94).

\( \beta \)-Lactam antibiotics are not used for treatment of tularemia, as \( F. \) \( \text{tularensis} \) strains encode a class A \( \beta \)-lactamase, FTU-1 (95). \( \beta \)-Lactamase resistance appears to be limited to penicillins; \( \text{in vitro} \) MIC determinations indicate that FTU-1 does not confer resistance to other \( \beta \)-lactams, including first- and second-generation cephalosporins (95). Although third-generation cephalosporins have been shown to be active against \( F. \) \( \text{tularensis} \) \( \text{in vitro} \), clinical experience indicates that cettrioxone is not effective for treatment of tularemia (96). Macrolides are also not recommended for treatment of tularemia, as type B strains from Central and Eastern Europe and Asia are naturally resistant to erythromycin and other macrolides (97).

Antimicrobial susceptibility testing of \( F. \) \( \text{tularensis} \) is not performed in clinical microbiology laboratories because of safety concerns in working with this organism and because resistance to antibiotics used for clinical treatment of tularemia has never been reported (90). The Clinical and Laboratory Standards Institute (CLSI) has published interpretative criteria and quality control limits for broth microdilution of \( F. \) \( \text{tularensis} \) using Mueller-Hinton medium supplemented with 2% IsoVitaleX (98, 99).

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

Serology is a common method for laboratory confirmation of \( F. \) \( \text{tularensis} \) infection, due largely the organism’s slow growth and fastidious nature. Nonetheless, culture provides a conclusive diagnosis of infection and whenever possible should be attempted using appropriate biosafety measures. A very tiny Gram-negative bacterium that grows slowly, shows fastidious growth characteristics, and is oxidase negative, weakly catalase positive, urease negative, \( NV \) or satellite negative, and \( \beta \)-lactamase positive should be strongly suspected as \( F. \) \( \text{tularensis} \) and referred to a reference laboratory. Confirmation of \( F. \) \( \text{tularensis} \) infections includes (i) identification of a culture as \( F. \) \( \text{tularensis} \) and/or (ii) a 4-fold difference in titers in acute- and convalescent-phase serum samples, with one of the paired samples having a positive titer. A positive test result for a primary clinical specimen using antigen or molecular detection methods, including DFA staining, IHC staining, or PCR, provides only a presumptive diagnosis of \( F. \) \( \text{tularensis} \). A single positive serum sample is also considered presumptive for tularemia. For all cases presumed to be tularemia, it is necessary to verify that the patients’ symptoms are compatible with tularemia.

In the United States, tularemia is a nationally notifiable disease and \( F. \) \( \text{tularensis} \) is also classified as a select agent. Identification of a bacterial select agent requires isolation of the organism in culture and confirmation. Laboratories identifying an organism as \( F. \) \( \text{tularensis} \) are required to report this finding immediately; laboratories need to complete Form 4 and submit it to the Select Agent Program. Report forms, contact information, laboratory registration information, and pertinent citations of the U.S. Federal Code may be found at [http://www.selectagents.gov](http://www.selectagents.gov).
REFERENCES

**Brucella***

GEORGE F. ARAJ

Brucella spp. are common zoonoses among domestic animals and among wildlife, including novel species of marine mammals. Brucella spp. also cause infections in humans and can mimic other infectious and noninfectious diseases, posing challenges to physicians in reaching a diagnosis. The remittent/undulant fever of brucellosis was first confused with other diseases, such as malaria and typhoid fever, and has had many synonyms pertaining mainly to the geographic locations where the disease occurred: Mediterranean fever, Malta fever, Gibraltar fever, and Cyprus fever (1, 2). Over the last decade, there has been renewed interest in this organism due to its inclusion in the potential biological weapons lists of most authorities (3, 4).

**TAXONOMY AND GENOME**

*Brucellaceae* is a family of phylogenetically closely related free-living soil organisms composed of *Brucella*, *Ochrobactrum*, and *Mycoplasma* spp. The *Brucellaceae* are part of the order *Rhizobiales*, which includes other genera involved in human disease: *Bartonella*, *Afibia*, *Methyl bacterium*, and *Roseomonas* (5, 6).

The taxonomy of *Brucella* spp. remains to be clarified. Studies indicate that terrestrial *Brucella* spp. are homogeneous species harboring >90% interspecies homology by DNA-DNA hybridization studies, identical 16S rRNA gene sequences, and >98% sequence homology by comparative genomics. Because of these findings, a suggestion was made to consider *Brucella* a monospecific genus and the different species as biovars of *Brucella melitensis* (7).

The average size of the genome is $2.37 \times 10^6$ Da, with a DNA G+C content of 58 to 59 mol%. Currently, the genus *Brucella* encompasses 10 recognized species: 6 terrestrial, 3 marine, and 1 proposed species of unknown origin (*Brucella inopinata* sp. nov.) from a breast implant (8–11). The six terrestrial *Brucella* species are *B. melitensis* (three biovars) (preferred hosts are goats, sheep, and camels), *B. abortus* (seven biovars) (cattle and buffalo), *B. suis* (five biovars) (swine and a range of wild animals), *B. canis* (dogs), *B. ovis* (rams), and *B. neotomae* (desert and wood rats). The three identified marine species, *B. delphini*, *B. pinnipedialis*, and *B. ceti*, were recovered from marine mammals (e.g., seals, whales, and dolphins) and were found to differ phenotypically from the six terrestrial species by their patterns of substrate-mediated metabolic activity. Though preferred or predominant hosts are recognized for *Brucella* spp., cross-infection of other mammalian species, including humans, may occur (12).

**DESCRIPTION OF THE GENUS**

*Brucella* spp. are facultative, intracellular, small (0.5- to 1.5-mm), Gram-negative cocobacilli that lack capsules, flagella, endospores, or native plasmids. They are aerobic (some prefer CO$_2$ for their growth), do not ferment sugars, and are positive in a few oxidative metabolic tests. *Brucella* spp. can grow on a wide range of culture media, and colonies appear after 24 to 48 h of incubation as mostly smooth colonies, but rough variants can occur (12, 13).

**ANTIGENIC COMPONENTS**

Several antigenic determinants of *Brucella*, related mainly to lipopolysaccharide (LPS) and protein antigens, have been characterized. The LPS is the major antigen that dominates the antibody response. LPS of rough strains is very similar to LPS of smooth strains. Based on their O side chain, smooth strains were reported to be composed of two antigenic epitopes: A (B. abortus) and M (B. melitensis). The smooth-strain LPS has been reported to be responsible for observed cross-reactions in both the agglutination and complement fixation tests between smooth species of *Brucella* and *Yersinia enterocolitica* (O:9, *Escherichia hermanii*, *Escherichia coli* O:157, *Salmonella enterica* serovar O:30, *Stenotrophomonas maltophilia*, *Vibrio cholera* O:1, and *Francisella tularensis*). Cross-reaction has been attributed to the similarities of the O-specific side chains of the LPS molecules of these organisms (reference 14; refer also to chapter 46 in this Manual).

The characterized protein antigens include outer and inner membrane, cytoplasmic, and periplasmic antigens. Some are recognized by the immune system during infection and are potentially useful in diagnostic tests (15). For example, Omp25 is an outer membrane structural protein that is highly conserved in all *brucellae* and is associated with both LPS and peptidoglycan. In addition, some proteins, such as ribosomal proteins (e.g., L7/L12) and fusion proteins, demonstrate a protective effect against *Brucella* based on antibody and cell-mediated responses (16). These molecules may be useful in potential vaccines.

---

*This chapter contains information presented in chapter 44 by Jeannine M. Petersen, Martin E. Schriever, and George F. Araj in the 10th edition of this Manual.*
VIRULENCE FACTORS, PATHOGENIC MECHANISMS, AND IMMUNE RESPONSE

The exact pathophysiological aspects of infection remain to be defined, especially since this “stealth pathogen” can infect and survive without inducing a massive inflammatory response (17–20). The incubation period is variable but generally is 1 to 4 weeks. The intracellular location and survival of the organism contribute to its virulence and pathogenesis. Virulence determinants include urease to avoid stomach stress through oral passage and Brucella-containing vacuoles (BCV), which enable escape from immune system recognition and provide an acidic environment to hamper antibiotic activity. A Brucella LPS cell component (containing a poly N-formyl perosamine O chain and a Cu/Zn superoxide dismutase) and outer membrane protein 25 (OMP25) help the bacteria survive within mononuclear phagocytes (21). Also, Brucella LPS poorly induces gamma interferon and tumor necrosis factor alpha (TNF-α), both of which are essential for T-helper 1 (Th1)-type-cell-mediated immunity for the elimination of the organism (22).

Briefly, once the brucellae enter the body via various routes, they are encountered by polymorphonuclear and mononuclear phagocytes, to which lectin facilitates attachment, and lipid rafts help in avoidance of defense mechanisms. After entry into the cell, the first step entails the establishment of an intracellular replication niche, and Brucella LPS and a periplasmic cyclic β-glucan are essential for this step. Brucella spp. escape from phagocytic killing by inhibiting the phagosome-lysosome fusion and hence evade the immune system. These factors together with the BCV aid in its survival, propagation, and persistence within macrophages and other cells. As brucellae remain within macrophages, they are transported through regional lymph nodes into the circulatory system and subsequently seeded throughout the body, with tropism for the reticuloendothelial system, resulting in different clinical phases of disease (18).

The overall inflammatory process results in a slow degradation of Brucella cell wall components by the polymorphonuclear leukocytes and can lead to granuloma formation, which is more often associated with B. abortus than B. melitensis (18).

Protective immunity, though not long term, is conferred by antibodies to LPS and T-cell-mediated macrophage activation, triggered by protein antigens. Lymphocytes are the main stimulant of the immune response. The Th1 response stimulates IgG2a production, which is involved mostly in protection against intracellular pathogens through cell-mediated immunity, and is critical for the clearance of Brucella infection. The Th2 response stimulates the production of IgG1 and is mainly responsible for protection against extracellular pathogens through the humoral immune response (23, 24).

Recently, the production of cytokines, chemokines, and matrix-metalloproteinases has been associated with induced osteoclastogenesis in brucella arthritis and osteomyelitis, and the OMP19 lipoprotein, together with TNF-α, were reported to be associated with astrocyte apoptosis in neurobrucellosis (23). Though receiving close attention, the exact nature of the immune response and the protective antigens/factors involved in this disease are still being investigated, and the pathogenic mechanisms of reinfection remain unknown (25).

EPIDEMIOLOGY AND TRANSMISSION

Animals are generally asymptomatic carriers of Brucella spp. The major symptoms appear during infectious abortion of the animal placenta and fetus. Invaded fetal tissue may contain up to $10^{10}$ infectious bacteria per gram of tissue and fluid (12). Although Brucella can be killed by pasteurization, exposure to UV light, acidity, or many antibiotics and disinfectants, it can survive for long periods under various conditions, e.g., 10 weeks in soil, 11 weeks in aborted fetuses, 17 weeks in bovine stool, around 3 weeks in milk and ice cream, and several months in fresh goat cheese (12, 26). Brucella can infect both humans and animals. In terms of the total numbers of infected human cases, B. melitensis dominates the world arena (especially in the Mediterranean and Arabian Gulf countries). However, B. abortus and B. suis supersede it in certain geographic locations in Europe. B. canis has also been reported to cause human diseases, while B. ovis and B. neotomae have not (12, 27–29). Brucella spp. associated with marine animals have been reported to cause disease in humans (30, 31). The epidemiologies of human brucellosis differ between areas of endemcity and nonendemcity in terms of age, sex, season, and risk factors. In regions of endemcity, such as the eastern Mediterranean Basin, Middle East, the Arabian Peninsula, Mexico, Central and South America, Southern Europe, Central Asia, and the Indian subcontinent, the disease occurs among the general population. In the general population, levels of infection are almost equal among adults and children of both sexes and mostly due to ingestion of unpasteurized goat, sheep, cow, and camel milk or its products (e.g., soft cheese, ice cream) (2, 27–29, 32–34).

In areas where the disease is not endemic, infection is seen predominantly among adult males, acquired occupationally by transmission through direct skin contact (e.g., through cuts and abrasions) with infected animal parts, inhalation of aerosolized infected particles, and accidental inoculation (e.g., sprays or aerosols inoculated into the eye, mouth, and nose). These infections occur mostly among dairy industry professionals, veterinarians, abattoir workers, and clinical and research microbiology staff (35, 36). Human-to-human transmission may occur, although very rarely. Few cases of neonatal brucellosis have been reported, and the isolation of Brucella from human milk may explain its pathogenesis (37, 38).

Laboratory-acquired infection (LAI) is an important source of transmission. Brucella has a very low infectious dose ($\leq 10^2$ organisms), and personnel should adhere to strict safety precautions, especially when handling cultures suspected of containing the organisms in clinical, research, and production laboratories (36, 39, 40). Most cases of laboratory-acquired disease result from mishandling and misidentification of the organism (40). The frequent failure of clinical laboratories to correctly identify isolates as Brucella species is particularly worrisome from the perspective of laboratory safety and potential use as a bioweapon. B. melitensis, B. abortus, and B. suis are category B Select agents (4).

CLINICAL CATEGORIES OF HUMAN BRUCELLOSIS

The clinical categories of human brucellosis are based on arbitrary criteria. In 1956, Spink based them on the duration of symptoms (acute, <2 months; subacute, 2 to 12 months; chronic, >12 months) (41). Subsequently, others based them primarily on extent of clinical manifestations (e.g., subclinical, localized, chronic, and active, with or without localized disease, including bacteremic and serological classifications) (29, 42). To date, no uniform definition has been adopted.
The incubation period is variable but usually ranges between 1 and 4 weeks. The disease onset is insidious and can present with a wide and diverse range of nonspecific clinical signs and symptoms, such as fever, sweats, arthralgias, myalgia, fatigue, loss of appetite, weight loss, hepatomegaly, and splenomegaly. Complications can involve many organs and tissues with signs of focal disease. The routine hematological and biochemical profiles are usually within normal limits, with some elevation in erythrocyte sedimentation rate and liver function tests. Thus, to the unaware physician, the diagnosis of brucellosis can be a dilemma and may protract for weeks and, in some complicated cases, for years (27, 29, 43–47). Increased business and leisure travel to countries where the disease is endemic has led to diagnostic challenges in areas where brucellosis is uncommon, especially when the presentation is unusual (29, 48). Overall, the mortality is very low, but morbidity is high. Previously thought to be uncommon, brucellosis in childhood now seems to be as prevalent as and presents in a manner similar to that in adults in areas of endemicity (33, 49).

Because of these nonspecific clinical features, human brucellosis can imitate a variety of diseases and, thus, has been labeled “the disease of mistakes.” For example, it can be misdiagnosed and confused with other diseases, such as typhoid fever, rheumatic fever, tuberculosis, malaria, infectious mononucleosis, endocarditis, histoplasmosis, ankylosing spondylitis, pyelitis, cholecystitis, thrombophlebitis, chronic fatigue syndrome, collagen vascular diseases, autoimmune diseases, and tumors (27, 29, 46, 47, 50).

COMPLICATIONS
The most commonly encountered focal complications are osteoarticular (10 to 70%) (mostly joints), genital in both males (6 to 8%) and females (2 to 5%), neurological (3 to 5%), cardiac (1 to 3%), pulmonary (1 to 2%), and renal (<1%). Mortality is very low (<1%) and is almost exclusively due to cardiac complications (27, 29, 42, 43, 45, 47, 50–53).

Osteoarticular complications occur mostly as arthritis (10 to 70%) and rarely as osteomyelitis (<1%). The joints most frequently involved are, in descending order, sacroiliac, knee, hip, vertebra, ankle, and multiple other joints. Generally, Brucella arthritis can be misdiagnosed as rheumatoid arthritis, rheumatic fever, tuberculosis, and systemic lupus erythematosus.

Neurobrucellosis (3 to 5% of cases) can affect both adults and children with diverse presentations, including fever, headache, meningeal signs, coma, or paresis. Depression, psychosis, and mental fatigue are not uncommon complaints (33, 54–58). Cerebrospinal fluid (CSF) analysis, both of adults and children, is nonspecific, and results can overlap those of other central nervous system diseases (such as mycobacterial, viral, syphilitic, or fungal infections) or noninfectious diseases (such as psychiatric problems, multiple sclerosis, and cancer) (55, 56, 59). The yield of Brucella culture from CSF is low (5% to 10%). Therefore, the use of Brucella serology tests, especially indirect Coombs’ test, Brucellacapt, or enzyme-linked immunosorbent assay (ELISA), on CSF specimens is essential to diagnose neurobrucellosis (56, 60).

With appropriate treatment, the prognosis is usually good for acute presentations and varies in settings of chronic disease.

Genital complications in males (6 to 8% of cases) are mostly orchitis or epididymo-orchitis (27, 43). In females, rare complications reported include abortion, cervicitis, salpinx, tubo-ovarian abscess, and ovarian dermoid cyst (27, 43, 61–63).

Relapse is considered one of the most important features of brucellosis and its complications. The exact factors associated with relapse remain to be determined, but some were noted to include the use of less-effective antibiotic therapy, a positive blood culture during the initial presentation, and ≤10 days’ duration of symptoms before initiation of treatment (27, 43, 45, 64, 65).

COLLECTION, HANDLING, STORAGE, AND TRANSPORT OF SPECIMENS
Specimens for the laboratory investigation of cases of brucellosis may be sent for culture, serology, and/or molecular testing. Culture can be performed on a wide range of specimen types, including blood (at least two sets), bone marrow, CSF, pleural and synovial fluids, urine, abscess specimens, and tissue specimens. Adequate volumes should be secured prior to initiation of antimicrobial therapy.

Blood (serum) and, when relevant, CSF samples are used for serologic testing. Molecular testing, though usually for research purposes, can be performed on blood (serum or whole blood), CSF, and bone marrow specimens.

The guidelines for proper specimen collection, handling, transport, and processing are generally similar to those reported for blood cultures and other specimens submitted for bacterial culture (refer to chapter 18 in this Manual). If delay in delivery to the lab is anticipated, specimens can be held in the refrigerator. To avoid/minimize laboratory exposures to the pathogen, specimens from patients suspected of having the disease should be labeled appropriately and referred to a reference laboratory, with the label specifying that the laboratory should rule out brucellosis (66).

DIRECT DETECTION
To circumvent the limitations of routine culture and serodiagnostic tests for human brucellosis, in-house-developed conventional PCR and reverse transcription (RT)-PCR assays can directly detect Brucella from clinical specimens. Several Brucella-specific gene targets have been used, including BCS P31 (encodes a 31-kDa cell surface protein) and BP26 (encodes a 26-kDa periplasmic protein), 16S rRNA, and the insertion sequence IS711. The sensitivities of these assays are quite varied, ranging from 50% to 100%. This variation might be related to different DNA extraction methods, detection formats, and different types of specimens (67–74). The ribosomal 16S-23S ITS region constitutes a suitable target in clinical specimens and in formalin-fixed, paraffin-embedded, archived tissue, as well as for identification of isolates from culture to the species level (69).

Molecular assays constitute a useful adjunct and have promising potential for the diagnosis of human brucellosis in a clinical laboratory setting. Their routine incorporation in the diagnosis of human brucellosis remains in need of further optimization, standardization, and improvement (69, 74, 75).

CULTURE
Culture is considered the gold standard in the laboratory diagnosis of brucellosis. Recovery of isolates can also be helpful for epidemiologic tracing and antimicrobial susceptibility testing. Conventional methods require long incubation times (6 weeks) and generally have varied yields, being higher among patients with acute brucellosis (40% to 90%)
than among patients in the chronic, focal, and complicated stages (5% to 20%) (67, 68, 76). When positive, culture provides the definitive diagnosis. Bone marrow cultures result in a 15- to 20%-higher yield than peripheral blood cultures. The conventional standard medium for the nonautomated blood culture broth has been the biphasic Ruiz-Castañeda bottle. The growth of the pathogen takes between 7 and 35 days to become positive, and the bottles should be held for 6 weeks, with frequent visual inspection (every 3 days) and terminal subculture before the specimen is discarded as negative.

Automated continuously monitored blood culture systems, such as Bactec (BD Diagnostics, Sparks, MD) and BacT/Alert (bioMérieux, Durham, NC), result in higher yields than the conventional culture method and expedite the detection of bacterial growth (the majority of bacteria are recovered within 1 week). There is no need to incubate bottles longer than 10 to 14 days (68). The lysis centrifugation system showed improved and faster yields than nonautomated blood culture systems. However, due to the need for centrifugation and manipulation before direct plating, the system may entail exposure and contamination hazards. Rarely, some patients with brucellosis have a positive blood culture in the absence of positive serology (29, 76).

Recovery of Brucella from other clinical material, such as bone marrow, CSF, joint fluid, homogenate of tissues, and bones, in addition to blood specimens, can be achieved by inoculation of specimens into broth media (such as those used for blood cultures) in addition to plated media (blood and chocolate agar). Plated media are incubated at 37°C, preferably under 5 to 10% CO₂, for up to 10 days prior to being reported as negative (67, 68).

**IDENTIFICATION**

Clinical microbiology laboratories should identify colonies suspected of being Brucella spp. on the basis of a few morphologic, biochemical, and serologic tests. All manipulations of Brucella cultures should be done in a biological safety cabinet. In these setups, the colonies are generally recovered directly from inoculated clinical specimens or as a result of subculture from broth media (e.g., biphasic Ruiz-Castañeda medium and blood culture medium showing signs of growth) on blood (Fig. 1A) and chocolate agar. Colonies can grow on other media as well (e.g., Mueller-Hinton agar [Fig. 1B] and MacConkey agar [can show variable growth]). Thayer-Martin or Martin-Lewis medium can be used to isolate Brucella spp. from contaminated specimens. Generally, colonies are visible after 24 to 48 h of aerobic incubation or incubation with 5 to 10% CO₂ at 37°C, and there is no need to keep the plates more than 72 to 96 h before discarding them as negative. The colonies are 1 to 2 mm in diameter, entire, smooth, and glistening. Rough variants can occur with Brucella canis colonies. The presumptive identification of Brucella spp. from these colonies entails demonstrating small Gram-negative cocobacilli (0.5 to 0.7 mm in diameter and 0.6 to 1.5 mm in length) (Fig. 2). Biochemical reactions show positive oxidase, catalase, and urease tests, as well as a positive slide agglutination reaction with specific B. abortus and/or B. melitensis antisera (12, 13).

Once these tests are performed and completed, the clinical laboratory may report the organism as presumptively Brucella spp. Further characterization and identification to the species level of the pathogen involve extensive testing not routinely performed in most clinical laboratories (13, 14). In the United States, Laboratory Response Network (LRN) reference laboratories are able to confirm and identify Brucella to the species level, and these laboratories can provide guidance and additional pertinent information. See also [http://www.bt.cdc.gov/lrn/](http://www.bt.cdc.gov/lrn/).

When definitive identification is indicated, conventional and molecular characterizations (e.g., based on DNA target sequencing) can be helpful. Conventional classification/identification to the species level of Brucella spp. can be determined from results of certain reactions, such as dye inhibition (thionine, fuchsin, safranin), CO₂ requirement,

**SEROLOGIC TESTS**

Serologic assays are the most commonly relied upon tests in the laboratory diagnosis of brucellosis (68). Serological results are optimally interpreted in the context of the evolution of antibody responses after infection with *Brucella* spp. IgM first appears, followed by the appearance of IgG within 10 to 14 days. The general evolution of these and other immunoglobulins depends on the response to treatment; in recovery, a gradual and slow decline in titers is observed, while persistent titers alert the clinician to a poor response to treatment due to focal complications, chronic infections, or relapse (83–85). Persistence, (i.e., detection of antibodies, mostly IgG and some IgM, for a very prolonged time [months and sometime years]) is observed in 15 to 20% of asymptomatic patients who have undergone treatment and cure. The explanation for this remains elusive (27).

Several antigens are used for serologic diagnostic assays, generally obtained from *B. melitensis* and *B. abortus*. Whole-cell preparations are the antigens used in the agglutination and the indirect fluorescent-antibody (IFA) tests, while sonic extracts, purified LPS, or protein extracts of *Brucella* are used mainly in ELISAs (13, 67, 68). Detection of antibodies against infections due to *B. canis* and *B. ovis* require using major outer membrane protein antigens because these strains exist in a rough colony form and do not share cross-reacting antigens with the other *Brucella* spp. (86). Since there is no standardized reference antigen, it is important to note that the source of the antigen, commercial or otherwise, can influence the test results (68).

A wide range of in-house serologic tests and formats have been used for investigating patients with brucellosis (Table 1). These include direct agglutination tests in tubes, e.g., the serum agglutination test (SAT), and on slides, e.g., the Rose Bengal test, indirect Coombs’ test, Brucellacapt.
tests, IFA, and ELISA for detection of immunoglobulin classes and subclasses (68, 87). Generally, agglutination-based tests cannot differentiate the types of antibodies involved, while the enzyme immunoassay (ELA) and IFA can. Commercial EIAs detecting *Brucella* IgG and IgM with a high degree of sensitivity and specificity have been available for 10 years and are considered an excellent method for screening sera for *Brucella* antibodies (68, 87).

*Brucellacapt* (Vircell, Granada, Spain) has been introduced as a rapid (18 to 24 h) and easy serologic test to carry out. The test is based on immunocapture agglutination methodology that can detect, in a single step, the nonagglutinating IgG and IgA antibodies and seems to be useful in the follow-up of disease activity. The sensitivity and specificity are similar to those of Coombs’ test. However, since the latter test is cumbersome because of multiple washing steps, centrifugation, and a long turnaround time (48 h), *Brucellacapt* can offer a valuable alternative and can be of help in the follow-up of patients (88). Immunochromatographic lateral-flow dipstick tests have been advocated for screening/zurveillance of patients with brucellosis in areas of endemicity and as outbreak and field tests. They are simple, rapid, and easy to perform and read with high (>90%) sensitivity and specificity (89).

Recently, numerous protein antigens have been evaluated in microarrays aiming to reveal differential antibody responses among sera from patients with brucellosis at different infection stages for future use as reliable antigens in serologic assays (25, 90).

Interpretation of serologic test results in relation to exposure, diagnosis, and prognosis of the disease necessitates an accurate assessment of the clinical histories and current status of patients and an understanding of the usefulness and pitfalls of the laboratory tests (27, 29, 68). Positive cutoff titers in the *Brucella* agglutination test for diagnosis have generally been considered to be ≥160 in symptomatic patients. However, much lower titers with the SAT have been reported for patients with active disease (27). Moreover, one has to be careful when negative serology is encountered when brucellosis is suspected, since this may be due, for example, to infection with *B. canis*, which can be missed by serologic assays using *B. abortus* or *B. melitensis* antigen. In addition, this may be due to very early disease presentation or due to using slide tests or SAT alone, and thus repeat testing after 1 to 2 weeks is warranted (68, 83). A combination of agglutinating (SAT) and nonagglutinating (e.g., Brucellacapt or indirect Coombs) tests are recommended to definitively exclude *Brucella* species infection.

In acute brucellosis, elevations in *Brucella*-specific IgG, IgM, IgA, IgE, IgG1, and IgG3 are shown, while in those patients with chronic brucellosis, elevations in IgG, IgA, IgE, IgG1, and IgG4 are usually seen (27, 68, 87). Monitoring the treatment response requires a sequential follow-up for patients with serologic titers. A decline indicates good prognosis, persistently high titers necessitate continuous monitoring, and a resurgence in antibody titers most likely indicates relapse or reinfection. Slide and tube agglutination (TA) titers fall faster than with Coombs’ test and *Brucellacapt*, and ELA, as the latter titers can stay positive for years, e.g., 2 to 3 years. Persistence of residual positive titers in cured patients has doubtful meaning (68, 83, 85, 91, 92). Relapse has also been diagnosed by a detection of a resurgence in *Brucella*-specific IgG and IgA antibodies, not IgM (83–85). Markers for differentiating active from inactive disease are being sought. For example, anti-Brucella cytoplasmic or perilysin protein antibodies, as determined by ELISA, increased only in patients with active brucellosis and were a better predictor of cure than antilipopolysaccharide antibodies (91, 93, 94). Also, some interleukins show a decrease posttherapy (95).

Though serologic tests are currently of high importance for the investigation of patients with brucellosis, several limitations can be encountered, mainly lack of standardized antigen preparations and assay methodologies, as well as the detection of sustained high antibody titers in some patients, despite treatment and cure (68). False-positive serologic results are rare. However, two cases were recently reported in the United States, a finding which led to initiating not only unnecessary treatment but also a wide range of public health investigations (96). False-negative results are ascribed mainly to direct agglutination, e.g., SAT in cases of focal complications or chronic brucellosis (27, 68). Although very rare, positive cultures have been described in the absence of any positive serologic test.

### ANTIMICROBIAL SUSCEPTIBILITIES

Routine susceptibility testing of *Brucella* species is not indicated for many reasons. These include the rare development of antibiotic resistance against the tetracyclines, rifampin, and aminoglycosides; the lack of plasmids concerning laboratory safety; a poor correlation between high levels of in vitro activity and clinical efficacy for many agents, including β-lactams, quinolones, tigecycline, and etaropenem; and a general lack of well-established testing conditions and interpretative standards (97–101). Recently, the CLSI presented guidelines to determine the MICs of tetracycline and doxycycline against *Brucella* sp. by a Mueller-Hinton broth dilution method (98). The Etest on Mueller-Hinton agar supplemented with sheep blood or horse serum for drug-synergy testing has also been described (102).

### ANTI-BRUCELLA THERAPY

Appropriate antimicrobial therapy for treatment of human brucellosis reduces morbidity, prevents complications, and minimizes relapses. Several anti-*Brucella* agents have been used (e.g., doxycycline, rifampin, co-trimoxazole, streptomycin-gentamicin, some quinolones, and cephalosporins) with various rates of success. Currently, the most effective treatment regimen and the optimal duration of treatment remain unclear (103, 104).

Fewer relapses with combined regimens than with monotherapy have been reported. For adults with uncomplicated infection, the WHO recommends oral doxycycline and rifampin for 6 to 8 weeks, but a regimen of doxycycline and streptomycin or gentamicin showed higher cure rates. Recommendations for children older than 8 years include doxycycline (45 days or 8 weeks) and gentamicin (5 to 7 days) or streptomycin (14 days), doxycycline plus rifampin, or co-trimoxazole (6 weeks). For children younger than 8 years, gentamicin (5 to 7 days) plus co-trimoxazole (6 weeks) or co-trimoxazole plus rifampin (6 weeks) are recommended (33, 49). Triple regimens using doxycycline, rifampin, aminoglycoside, or ceftriaxone for 2 to 3 months are recommended for patients with endocarditis and neurobrucellosis (56, 97, 105, 106).

Treatment regimens with fluoroquinolones and broad-spectrum cephalosporins have been reported. Although these agents have good MICs in vitro against *Brucella* spp., patients treated with these regimens have higher rates of relapses than patients on the standard regimen. The use of fluoroquinolones in combination with rifampin for the treatment of bacteremia and complicated brucellosis has
yielded varied results (104, 106). A systematic review and meta-analysis study covering 30 trials and 77 treatment arms showed that among patients with bacteremia and complicated brucellosis, higher failure and relapse rates and shorter treatment durations (less than 6 weeks) were observed with monotherapy than with multidrug therapy. The preferred treatment should be with dual or triple regimens, including an aminoglycoside (104). A recent study showed that treatment delay beyond 3 months of disease onset resulted in a significantly lower cure rate (107).

The question about postexposure prophylaxis (doxycycline and rifampin therapy for 3 to 6 weeks) after a high-risk exposure in the lab remains debatable. Guidelines for postexposure management are empirical (17, 108). Upon possible exposure, however, recommendations were made to take a baseline blood sample, monitor for symptoms weekly for 6 months, and perform serological surveillance at 0, 2, 4, 6, and 24 weeks (17).}

**PREVENTION**

Vaccines have been successful in the control of livestock infections, which can subsequently reduce infections in humans. Most veterinary vaccines focus on live, attenuated B. abortus (strain S19) and a more stable rough mutant of B. suis (strain RB51) for cows, B. melitensis (strain Rev-1) for sheep and goats, and B. suis 2 for swine. However, the Brucella vaccine developed for humans still suffers from limited efficacy and serious medical reactions (109, 110). Heating of dairy products and related foods has also been limited efficacy and serious medical reactions (109, 110).

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

Brucella is a "stealth" and highly infectious pathogen that can result in a wide range of disease spectra, including focal or complicated presentations. Recognition of Brucella as a plausible diagnosis can expedite appropriate laboratory testing and prompt treatment to avoid serious complications. With proper interpretation and appropriate use of tests, proper clinical decisions can be reached, and serology is the most relied upon for accurate diagnosis. Laboratories should use a combination of two agglutination tests, namely, the SAT and indirect Coombs’ test, the SAT and Brucellacapt, or ELISAs for IgG and IgM. In doing so, one would be able to detect antibodies in different stages of the disease, since in the acute stage, any test can be positive, while in chronic, complicated, or focal disease cases, the SAT can be negative while Coombs’ test, Brucellacapt, and ELISA using IgG can be positive (Table 2). Again, one should keep in mind that any serologic test findings need to be interpreted in the context of the patient’s clinical history (29, 68). Culture is also mandatory in suspected cases, and when positive, it confirms the diagnosis and offers an opportunity for identifying the organism to the species level to help in epidemiologic tracing and for antimicrobial susceptibility testing. In the United States, laboratories that recover a potential Brucella sp. should promptly notify public health authorities and refer the isolate to the nearest LRN reference laboratory for confirmation. Though not yet standardized and still largely research tools, molecular methods may be used in laboratories where optimized assays are available.

TAXONOMY

Taxonomy and Description of Genus

*Bartonella* (including some species formerly known as *Rocha-limaea* and *Grahamella*) is a genus of short, facultative, intracellular, pleomorphic, Gram-negative, cocobacillary or bacillary rods that measure 0.2 to 0.6 μm by 0.3 to 1.0 μm (Fig. 1). Members of this genus can induce persistent bacteremia in healthy people and animals and vascular proliferative infections in immunocompromised people. *Bartonella bacilliformis* is the type species and was formerly classified in the family *Bartonellaceae* in the order *Rickettsiales*. The current taxonomic classification incorporates former members of the *Rocha-limaeae* (*R. quintana*, *R. vinsonii*, and *R. henselae*) and *Grahamella* genera into the *Bartonella* genus, which is now separate from the order *Rickettsiales*, as members of the alpha-2 subgroup of the class alphaproteobacteria within the *Rhizobiales* order. To honor Henrique da Rocha-Lima, who was no longer recognized after the merge of the genera *Rocha-limaeae* into *Bartonella*, a new species isolated from a patient with bacteremia was named "*Bartonella rocha-limaeae"* (1). There are now 32 recognized species or subspecies of *Bartonella* ([http://www.bacterio.net/bartonella.html](http://www.bacterio.net/bartonella.html)), many of which have been associated with human disease (2). Because of the slow growth of these bacteria on agar plates (dividing time, approximately 24 h), standard biochemical methods for identification are not useful for clinical diagnosis of infection. *Bartonella* are oxidase and catalase negative and do not produce acid from carbohydrates. All *Bartonella* species are highly hemin dependent. For primary agar culture of enriched blood-containing media, all members of the genus typically require 8 to 45 days in the presence of 5% CO₂ to form visible colonies (Fig. 1). Optimal growth temperatures for various *Bartonella* species vary from 25 to 30°C for *B. bacilliformis* to 35 to 37°C for *B. henselae*, *B. quintana*, *B. koehlerae*, or *B. elizabethae*. On primary isolation, some *Bartonella* species, such as *B. henselae*, *B. clarridgeiae*, *B. vinsonii*, and *B. elizabethae*, form colonies with a white, rough, dry, raised appearance that create a depression in the agar medium. Colonies are therefore hard to extract or transfer to subsequent plates. Other *Bartonella* species, such as *B. quintana*, form colonies that are usually smaller, gray, translucent, and sometimes viscous or mucoid. A few members of the genus, including *B. bacilliformis*, *B. clarridgeiae*, *B. capreoli*, *B. rochalimae*, and *B. schoenbuchensis*, are motile by means of unipolar flagella.

*B. bacilliformis*, the type species of the genus, is the etiologic agent of Carrion’s disease, which is characterized by either an acute hemolytic bacteremia, known as Oroya fever, or a chronic vasoproliferative form with cutaneous nodular vascular eruptions known as verruga peruana. *Bartonella quintana*, the agent of trench fever, causes a febrile bacteremic illness with symptoms that include myalgia, chills, headache, and severe leg pain. *B. quintana* is also a cause of the disease bacillary angiomatosis (BA), which is characterized by vascular proliferative lesions in immunocompromised individuals, particularly those with AIDS (3). *B. quintana* is a common cause of culture-negative endocarditis and bacteremia in homeless individuals (4). BA can also be caused by *B. henselae*. Although *B. henselae* is historically associated with cat scratch disease (CSD), a self-limiting infection in immunocompetent individuals, CSD can be complicated by neuroretinitis, granulomatous hepatitis, and fever of unknown origin. *B. henselae* is also associated with endocarditis in humans (although much less frequently than *B. quintana*) and in dogs. A fourth human pathogen, *B. elizabethae*, caused a single case of endocarditis in an immunocompetent individual (5). Since the description of infections associated with these 4 initial *Bartonella* species, *Bartonella vinsonii* subsp. *arupensis*, *B. koehlerae*, and *Bartonella alsatica* have been associated with a small number of endocarditis infections in humans (6), and "*Bartonella washoensis"* was described as the cause of human myocarditis in a single patient (7). *Bartonella grahamii* has been associated with a case of human neuroretinitis and bilateral retinal artery branch occlusions (8). *B. vinsonii* subsp. *arupensis* has similarly been isolated from a bacteremic rancher who had fever and mild neurological manifestations (9). More-recent and less-well-studied *Bartonella* species isolated from or detected in humans include *B. rochalimae*, "*B. tamiæ*," *B. tribocorum*, and "*B. melophagii"* (1, 2, 10, 11).

EPIDEMIOLOGY AND TRANSMISSION

*Bartonella* species are transmitted by insect vectors, such as fleas, sand flies, body lice, and, potentially, ticks, biting flies, and wingless flies. Transmission also occurs by animal scratches or possibly bites. Some species are geographically very limited; an example is *B. bacilliformis*, which lives at specific altitudes in the Andes Mountains of South America.

---

*This chapter includes materials prepared by Ricardo G. Maggi, Volkhard A. J. Kempf, Bruno B. Chomel, and Edward B. Breitschwerdt and included in the 10th edition of this Manual.*
due to the limited distribution of its sand fly vector, Lutzomyia verrucarum. Others, such as B. quintana, B. henselae, B. elizabethae, and B. vinsonii subsp. berkholffii, appear to have a worldwide distribution (2). B. quintana outbreaks are associated with populations of homeless individuals living under conditions of poor sanitation and personal hygiene. Infestation by the human body louse, Pediculus humanus, results in inoculation of B. quintana in arthropod excreta through broken skin (12, 13).

Cats are the main reservoir for B. henselae, B. clarridgeiae, and B. koehlerae. CSD, caused by B. henselae infection, is transmitted from cat to cat mainly by the cat flea, Ctenocephalides felis; however, direct cat flea transmission as a cause of human CSD has not been confirmed (6). Stray cats, cats living outdoors, and young cats are more likely to be bacteremic. The prevalence of B. henselae infection is usually highest in warm and humid climates where cat fleas are abundant. B. henselae antibody prevalence in domestic cat populations can range from 14 to 81% (14–16) Genotype I (Houston) is more common in cats in the Far East (Japan, the Philippines), whereas type II (Marseille, France) is predominant in Western Europe, North America, and Australia (6). Coinfection of cats with different Bartonella species or genotypes is reported, as is coinfection in humans and dogs (17–19). Additionally, B. quintana, B. koehlerae, and B. clarridgeiae DNA can be detected in cat fleas, suggesting their possible role as vectors for these organisms. Bartonella species DNA has been amplified from species of Ixodes ticks from numerous sites throughout the world, but vector competency for transmission of Bartonella from ticks to humans has never been confirmed (20, 21).

Twelve Bartonella species and subspecies, including B. bacilliformis, B. tamiia, B. grahamii, B. koehlerae, B. alsatica, B. quintana, B. elizabethae, B. henselae, B. vinsonii subspecies arupensis and berkholffii, “B. washoensis,” and B. rochalimae (22), can infect humans and can elicit a wide spectrum of clinical manifestations, including cutaneous vasculitis, endocarditis, myocarditis, bacillary angiomatosis, peliosis hepatitis, and granulomatous inflammatory disease (Table 1). Other Bartonella species, such as B. vinsonii subsp. vinsonii, B. doshiae, B. taylorii, B. peromysci, B. birtlesi, B. tribocorum, B. talpae, B. bovis, B. chomelii, B. schoenbuchensis, and B. capreoli, have been isolated only from blood from animals, including wild rodents, squirrels, felids, canids, and ruminants, such as cattle, deer, and elk (2, 23, 24). Domestic and wild canids represent the main reservoir of B. vinsonii subsp. berkholffii, with high antibody prevalence in dogs from tropical countries (6) and high prevalence of bacteremia in coyotes (Canis latrans) in California (25).

In addition, a wide range of rodent hosts worldwide are infected with rodent-adapted Bartonella species (2). Finally, several Bartonella species can be isolated from domestic and wild ruminants, for which biting flies may be important vectors for transmission among these animal species (2).

CLINICAL SIGNIFICANCE

Human Pathogens

Oroya Fever and Verruga Peruana (Carrion’s Disease): B. bacilliformis

The disease caused by B. bacilliformis, especially its chronic form known as verruga peruana, has been recognized since pre-Columbian times in populations inhabiting the Andes Mountains. However, the suspected link between the acute form (Oroya fever) and the chronic form was finally confirmed in 1885, when Daniel Carrion, a medical student, died of Oroya fever after inoculating himself with material from a verruga (wart-like lesion). The acute form of disease, usually seen in nonnative populations in the zone of endemicity, is a progressive, severe, febrile anemia with intravascular hemolysis associated with B. bacilliformis-infected erythrocytes. Mortality was reported to range from 40 to 90% of cases prior to the discovery and use of antibiotics (26).

Chronic bacteremia occurs in people from regions of endemicity, although evidence for persistent infection is reported from zones where the disease is not endemic (26, 27). The second stage of infection occurs weeks to months following acute infection and is characterized by cutaneous nodular angioproliferative lesions known as verruga peruana; mucosal and internal lesions are also known to occur (28). These lesions can persist for several months, though prognosis for full recovery is favorable at this stage. A newly emerging pathogen, “Candidatus Bartonella ancashi,” is now also considered an additional etiologic agent of verruga peruana in the Ancash region of Peru (29).

Trench Fever, Bacillary Angiometasis, Endocarditis, and Prolonged Fever: B. quintana

Trench or quintan fever is a recurrent fever characterized by 3 to 5 (or more) febrile episodes lasting 4 to 5 days, with fever occurring after an incubation period of 15 to 25 days. Severe headaches and skin pain, in addition to malaise, anorexia, abdominal pain, restlessness, and insomnia, are common symptoms. Mild forms and asymptomatic carriage are also reported (4, 30). B. quintana endocarditis is one of the most common causes of culture-negative endocarditis (31–33). In HIV-infected individuals, bacteremia caused by B. quintana develops insidiously and is characterized by recurrent fever, headaches, and myalgias. B. quintana and B. henselae are the two Bartonella species that cause bacillary angiomatosis (BA). BA, also called epithelioid angiometasis, is a vasculoproliferative disease of the skin characterized by violaceous, pink, or colorless papular to nodular skin lesions that can clinically suggest Kapost’s sarcoma (KS) but histologically appear quite distinct from the lesions of KS. Fever, weight loss, and malaise can develop in people with disseminated BA. Subcutaneous nodules and lytic bone lesions are also associated with B. quintana infection but not with BA caused by B. henselae (34).

Zoonotic Bartonelae

Cat Scratch Disease

B. henselae is the sole or predominant etiologic agent of cat scratch disease (CSD) in humans (35, 36), whereas B. clarridgeiae (37, 38) and B. grahamii, based on multilocus sequence typing (39), are suspected in a few cases as well. There are now strong arguments against A. felis being an etiologic agent of CSD (31). It is estimated that at least 22,000 human cases of CSD occur yearly in the United States. Between 55% and 80% of CSD patients are <20 years old. There is a seasonal pattern, with most cases occurring in autumn and winter (40).

In classical CSD, 1 to 3 weeks elapse between the cat scratch or bite and onset of clinical signs. In 50% of cases, a small skin lesion, often resembling an insect bite, appears at the inoculation site, usually the hand or forearm. The lesion evolves from a papule to a vesicle and in some instances becomes a partially healed ulcer. These lesions generally resolve within a few days to a few weeks. Lymphadenitis develops approximately 3 weeks after exposure and is generally unilateral. Epithelial, axillary, or cervical lymph nodes are most frequently involved. Lymph nodes are usually swollen and painful, and lymphadenopathy persists for several weeks to several months. In 25% of CSD cases, suppuration occurs. The large majority of cases present with signs of systemic infection: fever, chills, malaise, anorexia, and headache. In general, the disease is benign, and lymphadenopathy resolves spontaneously without sequelae or antibiotic treatment. Atypical manifestations of CSD occur in 5% to 10% of the cases. The most common of these is Parinaud’s ocuuloglandular syndrome (periauricular lymphadenopathy and palpebral conjunctivitis); however, retinitis, meningitis, encephalitis, osteolytic lesions, and thrombocytopenic purpura can occur (41, 42). Encephalopathy is one of the most serious complications of CSD; it usually occurs 2 to 6 weeks after the onset of lymphadenopathy but typically resolves in a complete recovery and few or no sequelae (43).

B. henselae is also a frequent cause of prolonged fever and fever of unknown origin in children. Rheumatic manifestations of B. henselae infection in children, including cases of myositis and arthritis with skin nodules, have been described. However, arthritis is described in a very limited number of cases. Other rheumatic manifestations include erythema nodosum, leukocytoclastic vasculitis, and fever of unknown origin with myalgia, osteolytic lesions, and arthralgia (6).

Fever, weight loss, malaise, and enlargement of internal organs can develop in people with disseminated BA due to B. henselae. When visceral parenchymal organs are involved with B. henselae-induced vascular proliferation, the condition is referred to as bacillary peliosis hepatitis (liver) or splenic peliosis. These lesions are comprised of multiple, blood-filled, partially endothelial-cell-lined cystic structures in the liver or spleen (44). Bacillary peliosis hepatitis does not occur with B. quintana infection. BA patients with B. henselae infection are epidemiologically linked to cat and cat flea exposure (34). B. henselae and B. quintana are implicated rarely in cases of HIV–associated brain lesions, meningoen cephalitis, encephalopathy, dementia, or neuropsychological decline (45). B. henselae infection is also described in adult and pediatric solid organ transplant patients (46, 47).

Zoonotic Bartonella Species Associated with Endocarditis, Myocarditis, Neuroretinitis, Fever, and Neurological Symptoms

Several zoonotic Bartonella species are recognized as causative agents of blood culture-negative endocarditis or myocarditis in humans, including B. henselae (48), B. koehlerae, B. elizabethae, B. alberta (48), B. vinsonii subsp. berkhoffii (48), B. vinsonii subsp. arupensis (49), and B. washoensis (6). Bartonella species account for 3 to 4% of all human cases of endocarditis in France, a percentage similar to that of endocarditis cases caused by Coxiella burnetii, the agent of Q fever (48). Some rodent-borne Bartonella species are also
associated with cases of neuroretinitis (B. elizabethae, B. grahamii) or fever with bacteremia and neurological symptoms (B. vinsonii subsp. arupensis) (9).

Other Bartonella Species or Subspecies
The clinical impact on animals or humans of many Bartonella species is still unknown. Bartonella species are routinely detected in asymptomatic, bacteremic human and animal patients, many of which are detected via blood donor programs (50, 51). Although “Candidatus B. melophagi” was isolated from the blood of two women (11) and B. bovis DNA was amplified from heart valves of cows with endocarditis, no other specific pathology has been associated with Bartonella species infecting domestic and wild ruminants or for many of the rodent-borne Bartonella species.

Canine and Feline Bartonella Species
Several of the 32 identified Bartonella species or subspecies have been detected in or isolated from pet dogs and cats, thereby highlighting the zoonotic potential of these bacteria for persons with extensive domestic animal contact (19, 23, 52–59). B. henselae, B. clarridgeiae, B. koehlerae, B. quintana, B. bovis, B. elizabethae, and B. vinsonii subsp. berkhoftii are pathogenic for dogs (60), and B. henselae, B. clarridgeiae, B. wadsworthii, B. quintana, B. rochei, B. elizabethae, and B. vinsonii subsp. berkhoftii are also known to infect felines (61, 62). A number of manifestations, including endocarditis (63), myocarditis, epistaxis, proliferative vascular disease, and lethargy, can develop in dogs with Bartonella infection (60, 64–66). Bartonella-infected cats are more likely to have kidney disease and urinary tract infections, stomatitis, and lymphadenopathy than noninfected cats (23), but most cats infected with B. henselae appear to be asymptomatic. In experimentally infected cats, fever, lymphadenopathy, mild neurologic signs, and reproductive disorders have been reported (23). The clinical spectra of Bartonella infection in dogs and cats can be highly varied, ranging from no apparent abnormalities to subclinical infections accompanied by lethargy and weight loss.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS
Most specimens used for Bartonella isolation are either blood or tissue. Bartonella species are easier to isolate from blood than tissue. For patients with B. henselae infection, this species is rarely isolated from immunocompetent individuals unless they have endocarditis. CSD patients rarely have bacteremia or cultivable bacilli in CSD lymph nodes. Blood samples can be collected either in Isolator blood lysis tubes (Wampole, Cranbury, NJ), sodium citrate tubes, or plastic EDTA tubes. If storage of specimens prior to culture is necessary, samples should be kept frozen (at least –20°C). Blood collected from B. henselae-infected cats into EDTA and Isolator blood lysis tubes yields good recovery and no loss of sensitivity for EDTA tubes kept at –65°C for 26 days (15). Specimens should be collected prior to antimicrobial therapy. Tissue from enlarged lymph nodes, cutaneous lesions, or various organs can be cultured after homogenization or processed for DNA extraction and PCR. Fresh tissues are preferred for PCR amplification, but paraffin-embedded tissue can be used (67). Fine-needle aspiration has also been successful for detection of Bartonella and is less invasive than biopsy (68). Bartonella species have successfully been cultured from aqueous humor (69, 70).

DIRECT EXAMINATION
Microscopy
With the exception of B. bacilliformis, Bartonella species cannot be visualized in erythrocyte-stained blood smears from animal or human patients (18). In rats experimentally infected with B. hirtzii, there can be up to 8 bacteria per erythrocyte (71). Warthin-Starry silver stain is recommended for microscopic detection of Bartonella organisms in fixed tissue sections but is not highly specific and is relatively insensitive, even when lymph node biopsy specimens from CSD patients are examined. In patients with BA, a larger number of bacilli are usually identifiable by Warthin-Starry silver staining of tissues.

Antigen Detection
Immunocytochemical staining is a specific technique but is not widely available (3). Direct immunofluorescence of blood smears allowed rapid diagnosis of B. quintana in a patient with acute trench fever (52) and in bacteremic homeless patients (31).

Nucleic Acid Detection
Although PCR and agar plate culture are useful tests to document infection with Bartonella species in cats, these traditional techniques are not generally sensitive enough to detect active infection with a Bartonella species in human or dog blood samples. Therefore, PCR amplification directly from blood or other diagnostic samples is of limited value in patients with low levels of bacteremia.

Advances in PCR methodologies and equipment have facilitated an impressive increase in the sensitivity of molecular detection of Bartonella DNA in patient samples. The 16S rRNA gene (rrs) was first used by Relman et al. in 1990 for the identification of the microbial etiology of bacillary angiomatosis (72). However, this gene does not discriminate among all Bartonella species. The most widely targeted genes are those coding for citrate synthase (gltA), heat shock protein (groEL), riboflavin synthase (ribC), a cell division protein (ftsZ), and the 17-kDa antigen (73) (Table 2). Sequences of gltA and rpoB (RNA polymerase beta-subunit) are congruent with DNA-DNA hybridization for Bartonella speciation (73). The intergenic spacer (ITS) region located between the 16S and 23S rRNA genes is a useful diagnostic target for Bartonella detection, speciation, and genotyping (17, 19, 54, 74–78). Inclusion of positive, negative, and processing controls is critical, and confirmatory tests (e.g., PCR followed by sequencing or the use of a second target gene PCR assay) must be performed to avoid potential nonspecific amplification and false-positive results (77).

ISOLATION PROCEDURES
Blood
In immunocompromised patients, including transplant recipients, the level of bacteremia is often higher than in immunocompetent individuals, except in the presence of endocarditis, when blood cultures can be equally sensitive for isolating Bartonella species from immunocompetent and immunocompromised patients (3). However, after inoculation of Bartonella-infected blood into the broth of CO₂ detection-based blood culture systems, Bartonella species do not usually produce turbidity or convert enough oxidizable substrate to CO₂. Thus, these routinely used, automated blood culture systems rarely detect Bartonella species from

(Continued on next page)
patients’ blood. Instead, *Bartonella* species can be recovered from the blood of bacteremic patients if specific blood collection tubes are used in conjunction with centrifugation and plating directly onto special agar. *Bartonella* species can be isolated directly from blood using the lysis centrifugation system (Isolator) or from tubes containing EDTA anticoagulant, followed by plating onto fresh chocolate and heart infusion agars containing 5% fresh rabbit blood in the absence of antibiotics. There is preferential growth of *B. henselae* on heart infusion agar, and they do not pith the *B. quintana* colonies; they are more tan than *B. henselae* colonies are usually smooth, flat, and shiny, and *B. quintana* isolates of *B. henselae* from cutaneous lesions, liver, spleen, or lymph nodes is possible after homogenization in supplemented M199 medium and plating directly onto solid agar. Commercial sheep or horse blood agar plates have also been used but are less sensitive for primary isolation of *Bartonella* species. Plates inoculated with blood should be incubated at 35°C for at least 4 weeks in 5% CO₂ and at high humidity. Incubation in candle jars or sealed, gas-permeable plastic bags aids in preserving moisture and limiting contamination, both of which are critical when incubating these rich, nonselective agars for long periods of time. Colonies usually appear after 5 to 15 days (79). Due to prolonged incubation times, other slow-growing pathogens, including *Mycobacterium tuberculosis* and *Hemophilus capsulatum*, can grow on the plates; therefore, appropriate safety precautions should be taken with all positive cultures. Broth-based or biphasic culture system vials used for blood culture, such as the BACTEC Peds Plus vials (Becton, Dickinson, Sparks, MD) can be used for *Bartonella* isolation (80). DNA staining (e.g., acridine orange staining) and blind subculture from negative bottles before they are discarded at 7 days can increase the likelihood of identifying *Bartonella* (81). In a different assay, samples of heparinized blood are sedimented and plasma is then collected for inoculation into shell vials. Culture is then performed by the centrifugation-shell vial technique using the T84 bladder carcinoma cell line (inaccurately designated ECV304 human endothelial cells) (3).

### Tissue

Recovery of *Bartonella* species from cutaneous lesions, liver, spleen, or lymph nodes is possible after homogenization in supplemented M199 medium and plating directly onto solid agar (3). Cocultivation with an endothelial cell line (3) or use of the shell vial method is laborious but can occasionally yield bacterial growth (3), as with isolation of *Bartonella* from heart valve tissues (31). Various liquid media have been developed for primary isolation of *B. henselae* from blood, serum, and other tissues (10, 11, 17–19, 63, 71, 74, 75, 82–89), but isolation in liquid media is of low sensitivity.

### IDENTIFICATION

Colonies of *B. henselae* have two morphological types that can grow simultaneously from primary culture: (i) irregular, raised, off-white, dry, rough (cauliflower-like) colonies that pit and adhere to the agar and (ii) small, circular, tan, and moist colonies that are more easily scraped from the agar surface. The predominant colony morphologies of primary isolates of *B. henselae* are those described for type i above. *B. quintana* colonies are usually smooth, flat, and shiny, they are more tan than *B. henselae*, and they do not pit the agar (3). Highly passaged and confluent *B. quintana* colonies

Abbreviations: F, forward primer; R, reverse primer; S, sense probe; ITS, 16S rRNA-23S rRNA gene intergenic spacer region (rrs-rrl intergenic spacer); rrs, 16S rRNA gene.
can appear somewhat mucoid. *B. clarridgeiae* produces small, white, raised, indurated, and cohesive colonies which can also appear to spread during primary isolation. Most *Bartonella* species appear uniformly smooth after repeated subcultures. The bacilli are small (2 μm by 0.5 μm) and stain best with Gimenez stain (3). With Gram staining, *Bartonella* species are weakly counterstained with safranin or basic fuchsin. *Bartonella* species appear in Gram stains as small, Gram-negative, slightly curved rods somewhat resembling *Campylobacter*, *Helicobacter*, or *Haemophilus*. Colony morphology, in conjunction with slow growth requiring more than 7 days of incubation, along with negative catalase and oxidase reactions, is often sufficient for a presumptive identification. DNA amplification and sequencing is optimal, however, for confirmation of *Bartonella* genus, species, and strain.

*B. bacilliformis*, *B. clarridgeiae*, *B. capreoli*, *B. rochalimae*, and *B. schoenbuchensis* are the only members of the genus that are motile by means of unipolar flagella. *B. henselae*, as well as several other *Bartonella* species, has a twitching motility on wet mounts, associated with the expression of trimeric autotransporter adhesins (TAAs) (as shown for *B. henselae* [90]). These TAAs are responsible for host cell adherence and may mediate specific interactions with host erythrocytes and endothelial cells (91).

Most species are biochemically inert except for the production of peptidases. None of the various commercially available identification systems contain *Bartonella* species in their databases. However, the MicroScan rapid anaerobe panel (Baxter Diagnostics, Deerfield, IL), the RapID ANA II, and RapID ID 32 A have been used for identification. The MicroScan rapid anaerobe panel is reported to provide species identification (code 10077640 for *B. henselae*, code 10073640 for *B. quintana*, and code 10077240 for *B. bacilliformis*). Overall, these identification kits are of limited use for accurate diagnosis of *Bartonella* infections. Measurements of preformed enzymes and standard testing reveal minor differences between species.

Identification of *Bartonella* isolates is largely based on nucleic acid techniques, some of which allow for species determination, strain determination within a given species, or even genotyping. Methods include Southern blotting, gel and capillary electrophoresis, PCR, DNA hybridization, restriction fragment length polymorphism (RFLP) analysis, and gene sequence analysis (81). As described above, PCR and sequencing of target genes, such as *gltA*, *rpoB*, the internal transcribed spacer (ITS) region, 16S rRNA, *groEL*, or *rbcL*, are the most widely used (Table 2). Matrix-assisted laser desorption–ionization time of flight (MALDI-TOF) mass spectrometry has been applied to the identification of *Bartonella* species as isolated colonies and was able to differentiate 17 distinct species (92). The current Bruker MALDI Biotype CA system library database lacks *Bartonella* species on the “Organisms Claimed List.”

**TYPING SYSTEMS**

Several molecular methods, such as pulsed-field gel electrophoresis (PFGE), multilocus sequence typing (MLST), multispacer repeat analysis (MSLR), and multiple-locus variable-number tandem-repeat analysis (MLVA) (93), can be used to genotype *B. henselae* (and in some cases *B. quintana*) isolates. Also, a genomic fingerprinting technique using infrequent restriction-site PCR (IRS-PCR) can be used to identify pathogenic *Bartonella* species (94). Even when isolation of infecting species is not possible, PCR amplification of ITS DNA directly from diagnostic samples, followed by nucleic acid sequencing, is an invaluable tool for the primary identification at the species, subspecies, and genotype levels (11, 15, 17–19, 54, 71, 74, 75, 77, 78, 84, 87, 95, 96). *B. vinsonii* subsp. *berkhoffii* can be separated into 4 distinct genotypes based upon 16S-23S ITS sequences (78).

**SEROLOGIC TESTS**

Due to difficulties with traditional culture methods for isolation, serologic testing for *Bartonella* infection, including immunofluorescent-antibody assay (IFA), enzyme-linked immunosorbent assay (ELISA), and Western blotting (WB), is the cornerstone for clinical diagnosis. ELISA is the simplest to perform and can easily be automated but has a low sensitivity (17% to 35%) (14). IFAs, using commercial antigen slides for *B. henselae* and *B. quintana*, have become the most frequently used serological tests worldwide. Human infection with *B. henselae* or *B. quintana* is evaluated by detecting the presence of IgM and/or IgG antibodies directed against the *Bartonella* bacteria.

The first IFA for CSD used *B. henselae* bacilli that were cocultivated with Vero cells to inhibit auto-agglutination (35). This test was found to have good sensitivity (84% to 95%) and specificity (94% to 98%) using sera from patients with CSD (35, 36, 97). For this test, titers ranging from 64 to 256 or higher are considered positive and usually indicative of recent or ongoing infection. In cases of endocarditis caused by either *B. henselae* or *B. quintana*, high IgG antibody titers (≥800) are usually detected (98). A titer of IgG antibody to either *B. henselae* or *B. quintana* of ≥800 has positive predictive values of 0.810 for detection of *Bartonella* infection in the general population and 0.955 for detection of *Bartonella* infections among patients with endocarditis (98).

Nevertheless, IFA is time-consuming, requires appropriate equipment and expertise, and is subject to interobserver variation due to difficulty in reading the immunofluorescence (81). In humans, it has been postulated that the sensitivities of different IFAs may range from 14 to 100%, depending on antigen source and cutoff values used by different laboratories (14, 99–104). Antigenic variability among *Bartonella* test strains can result in false-negative serological results for some patients (100–103, 105–108). Cross-reactivity can occur among different *Bartonella* species. Antigen adsorption can be used to reduce cross-reactivity (81). Cross-reactivity to different *Bartonella* species can be present in up to 95% of samples (109). In addition, cross-reactive antibodies to other pathogens, e.g., *Chlamydia pneumoniae*, *Coxiella burnetii*, and spotted fever group Rickettsia, have been reported (74, 75, 104, 110–113). In humans with late-stage AIDS and *Bartonella* coinfection, antibodies were detected in only 75% of culture-positive or tissue PCR-positive patients (114). In addition, several reports describe detection and/or isolation of *Bartonella* species from seronegative patients (4, 74, 75, 99, 105, 106, 115–117). This discrepancy between little or no serological detection of *Bartonella* antibodies despite detection of *Bartonella* DNA and/or bacterial isolation suggests that seronegative infection is more common in humans than currently recognized. Dihydropiroxamiduccinyltransferase, the trimeric autotransporter adhesins (BadA, Vomps), and other proteins of *B. henselae* and *B. quintana* are immunodominant target proteins potentially useful for diagnostic immunoblots (118–120). However, immunoblot-based serological tests do not show clear immunoreactive profiles, which diminishes their utility for routine serological diagnosis of *Bartonella* infections.
ANTIMICROBIAL SUSCEPTIBILITIES AND SUSCEPTIBILITY TESTING

Antimicrobial susceptibility testing can be performed by agar dilution methods using either blood or chocolate agar or by microdilution techniques using various media supplemented with blood (121). There are no current recommendations or guidelines for the interpretation of antimicrobial susceptibility of *Bartonella* species offered by the Clinical and Laboratory Standards Institute (CLSI) or EUCAST. The Etest (AB Biodisk, Solna, Sweden) can also be used to determine antibiotic susceptibility (122). Results of susceptibility testing against *Bartonella* species are summarized in Table 3. Of paramount importance, however, is the observation that there is often not a correlation between demonstrated susceptibility in vitro and clinical response in vivo. Penicillin G provides an excellent example. All five *Bartonella* species tested show good susceptibility in vitro in Table 3, yet patients treated with penicillin G have had progressive *Bartonella* infection and development of new BA lesions (122). In addition, *Bartonella henselae* isolates have various in vitro susceptibilities to trimethoprim-sulfamethoxazole, and *Bartonella henselae* has been isolated from a patient taking this antibiotic (122).

Evaluation of susceptibility to antibiotics has been performed either with cell cultures or with axenic media. Determination of antibiotic susceptibility in axenic medium has been carried out both on solid media enriched with 5 to 10% sheep or horse blood and in liquid media (123, 124). It should be noted that the conditions required to grow *Bartonella* during susceptibility testing do not meet standardized criteria established by the CLSI. Bacteria of the genus *Bartonella* when grown axenically are susceptible to many antibiotics, including β-lactams, aminoglycosides, chloramphenicol, tetracyclines, and macrolide compounds, including telithromycin, rifampin, the fluoroquinolones, and co-trimoxazole–trimethoprim–sulfamethoxazole (121, 123, 125, 126), which may not accurately represent in vitro activity.

In vitro antibiotic susceptibilities can also be examined for Bartonella species cocultivated with eukaryotic cells. As with agar-based susceptibilities, these in vitro studies demonstrate that Bartonella species are susceptible to many antibiotics (127). However, many of the tested antibiotics show solely bacteriostatic activity (127, 128). Only aminoglycosides are bactericidal in vitro when Bartonella species are grown either in liquid medium (121), endothelial cells, or erythrocyte cocultures.

**Choice and Use of Antibiotics In Vivo**

CSD typically does not respond to antibiotic therapy. There is generally only minimal benefit with antibiotic treatment. A randomized, open trial of gentamicin plus doxycycline versus no treatment for immunocompetent patients with B. quintana bacteremia (without endocarditis) established the efficacy of doxycycline plus gentamicin (129). However, addition of gentamicin to doxycycline for treatment of Bartonella endocarditis patients has often been complicated by renal failure. Bartonella endocarditis is a chronic, indolent infection that is often present for months before diagnosis; increasing reports of glomerulonephritis at or shortly after the time of diagnosis prompt caution in the use of gentamicin to treat Bartonella endocarditis patients (130). It may be prudent to treat Bartonella endocarditis patients with doxycycline 100 mg per os (p.o.) or intravenously (i.v.) twice daily plus rifampin (300 mg po) twice daily for 6 weeks, instead of doxycycline plus gentamicin.

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

Diagnosis of Bartonella infection in humans, especially for typical forms of CSD, is based mainly on serologic tests, which is the most cost-effective approach. However, the sensitivities of IFA range from 14 to 100%, depending on selected test antigens, laboratory cutoff, and test procedures used (14). For endocarditis, the best approach is serological testing and performance of nucleic acid amplification methods on cardiac valves. A single-step serological assay against Coxella burnetti and Bartonella species found a sensitivity of 100% and a positive predictive value of 98% for the diagnosis of Bartonella infection in patients with blood culture-negative endocarditis (131), but this test is not readily available.

Special thanks go to Jane E. Koehler for advice and chapter editing.

TAXONOMY

The Legionellaceae are composed of a single genus, Legionella, and 58 validly named species and three subspecies (http://www.bacterio.cict.fr/l/legionella.html) (Table 1). Legionella pneumophila, Legionella micdadei, Legionella longbeachae, and Legionella dumoffii are the most important from a clinical standpoint, with L. pneumophila causing more than 90% of cases of Legionnaires’ disease (LD). The Legionellaceae are most closely related to the Coxiellaceae, and these two families comprise the proposed order “Legionellales,” within the class Gammaproteobacteria and phylum Proteobacteria ph. nov. Coxiella burnetii, the agent of Q fever, shares many characteristics with L. pneumophila, including intracellular parasitism and close homologies with several virulence genes (1). Some investigators proposed the use of Tatlockia and Fluorobacter as additional genera within the Legionellaceae (2), but a subsequent study of 16S rRNA demonstrated that as additional genera within the Legionellaceae (2), but a subsequent study of 16S rRNA demonstrated that Legionellaceae is our aqueous or soil environment and that humans are an accidental host of the bacterium. While almost all Legionella spp. have been isolated from environmental water sources, L. longbeachae appears to be a soil organism equipped with genes that may aid its residence/pathogenesis in soil insects or worms (13). Environmental L. pneumophila is a facultative intracellular parasite of several different free-living amoebae, such as Acanthamoeba and Naegleria, existing in microbial consortia in biofilms and free-flowing water.

L. pneumophila grows optimally at 35 to 37°C and at a temperature range from 20 to 42°C. Other Legionella spp. infecting humans may have more restricted growth temperatures, including one new species that does not grow at temperatures greater than 35°C (14). Growth on solid media is enhanced by increased humidity. Incubation in 2 to 5% CO₂ can enhance the growth of some Legionella spp. Bacterial phenotype, including immunogenicity, cell size, and virulence, can be altered by growth at different temperatures (12).

Amino acids, rather than carbohydrates, are used as energy sources by the Legionellaceae growing in vitro. Primary isolation of all known Legionella spp. requires medium supplementation with L-cysteine, as does successful propagation of all but a few species. Iron supplementation of growth media is required for optimal growth, although many Legionella spp. can grow, albeit poorly, in the absence of the mineral. Growth of L. pneumophila is enhanced by the addition of α-ketoglutarate (0.1%) to media via an unknown, nonnutritive mechanism.

Growth of L. pneumophila in artificial media can be inhibited by a number of factors. These include the presence of high (100 mM, or 0.6%) NaCl concentrations, toxic

*Several other yet-unnamed species probably exist.

*Isolated from humans, yes (Y) or no (N). Severely immunosuppressed patients may acquire infections with Legionella spp. not previously isolated from humans.

*Number of recognized serogroups (SG). NK, not known.

*NC, no color; BW, bright blue-white; YG, pale yellow-green; BW/YG, some strains are BW and some YG; NK, not known; Y/BW, bright-yellow diffusible, with some strains having in addition colony-bound bright blue-white cells; R, dark red; R/YG, the majority of strains are red, with the remainder being yellow-green; wR, weakly red.

*AN, alternative name. The valid genus names Fluoribacter and Tatlockia are not in widespread use.
peroxides, products of other bacteria and fungi, and some lipids (12). In addition, optimal growth occurs over a very narrow pH range from 6.7 to 6.9. Solid growth media contain activated charcoal to inactivate toxic lipids and peroxides, and an organic buffer [morpholinepropanesulfonic acid (MOPS) or N-(2-acetamido)-2-aminoethanesulfonic acid (ACES)] to reduce sodium content and provide the required pH. Preparation of growth media for Legionella spp. can be complex and is usually best left to competent commercial sources or to specialized laboratories.

**EPIDEMIOLOGY, TRANSMISSION, AND PATHOGENESIS**

LD was first recognized as a distinct entity when epidemic pneumonia with a 15% fatality rate developed during and after a convention of Pennsylvania State Legionnaires in Philadelphia, PA, in July 1976 (15, 16). Joseph McDade and colleagues at the CDC determined that a novel Gram-negative bacterium was the cause of the outbreak (17). Neither the disease nor the bacterium was found to be novel, with the first known epidemic of LD occurring in 1957 (18) and the bacterium being isolated multiple times from the 1940s on.

Environmental studies found that the bacterium was widespread in natural bodies of water and occasionally at high concentrations in warm waters found in plumbing systems, water heaters, warm water spas, and cooling towers. Many different Legionella spp. exist in nature within free-living amoebae, and as a result, these otherwise fastidious bacteria can multiply within the amoebae and be protected from biocides (19). Legionella-infected amoebae are often found in complex consortia of microorganisms within biofilms. The bacteria are present in very low concentrations in freely flowing cold water and biocide-treated waters but can multiply in warm, and especially stagnant, water. Devices that aerosolize these contaminated waters serve to disseminate the bacteria. In contrast to this, L. longbeachae infections appear to be acquired mainly through exposure to soil, especially some types of potting soil (20).

Legionella pneumophila serogroup 1 causes 95 to 98% of cases of community-acquired LD. The Pontiac monoclonal antibody (MAb) 3-1 subgroup of L. pneumophila serogroup 1 constitutes about 80 to 90% of clinical isolates of this serogroup. Just a few clonal types of L. pneumophila serogroup 1, Pontiac subgroup, are responsible for about 50% of sporadic community-acquired infection (7, 21, 22). Several L. pneumophila serogroup 1 strains that predominate as clinical isolates are uncommon in the environment, whereas most L. pneumophila strains that are commonly found in the environment are unusual causes of LD (22-24). Infection caused by the L. pneumophila serogroup 1 Pontiac subtype is less common in nosocomial LD, especially that involving immunocompromised patients. Up to 60% of nosocomial LD may be caused by other L. pneumophila serogroup 1 subtypes, other L. pneumophila serogroups, and other Legionella species (25, 26).

Infection is acquired by aerosol inhalation of contaminated water, although microaspiration may also be a mechanism for acquiring the disease (15). The majority of community epidemics of LD are from Legionella-contaminated cooling towers or other aerosol-generating devices. Contaminated potable water systems, such as water heaters and warm water in pipes, can also be a major source of disease, although these sources are not usually the cause of explosive outbreaks of the disease but rather of more prolonged and slower-paced outbreaks. Either source type may cause sporadic cases of LD.

Despite the ubiquity of Legionella spp. in our environment, LD is an unusual cause of pneumonia. About 0.5 to 5% of adults requiring hospitalization for pneumonia have LD. Passive reporting indicates that the disease incidence is from 4 to 20 cases per million people per year, and a prospective study estimated that the disease incidence is about 80 cases per million people per year or between 8,000 and 18,000 LD cases annually in the United States (27). This rate may be an underestimate, as a recent German study found that the annual rate was 180 to 360 cases/million population (28), which was roughly equivalent to 4% of all cases of community-acquired pneumonia, not just patients hospitalized for pneumonia. Underdiagnosis of LD is common in the United States and elsewhere, with only about 3,400 cases being reported to the CDC in 2010; underdiagnosis is due to both the failure to order laboratory tests for the disease and the insensitivity of laboratory diagnostic methods (29). Sporadic community-acquired LD is much more common than epidemic-associated disease, with only about 4% of U.S. cases being associated with known cases of LD. About 20% of LD cases are travel associated, with overnight travel being a risk factor for the disease. LD occurs year-round, with seasonal peaks in the warmer months (from the late spring until early fall); about 60% of reported U.S. and European cases occur between June and October (30, 31).

The incubation period of LD is estimated to be between 2 and 14 days, with a median value of about 4 days. A study of a large outbreak extended the incubation period to as long as 19 days, with a median value of 7 days (32). Epidemiologic case definitions for LD used by public health authorities can be found online (www.cdc.gov/legionella/health-depts/CSTE-position-statement.html, www.ecdc.europa.eu/en/activities/surveillance/ELDSNet/Pages/EU%20case%20definition.aspx).

L. pneumophila causes disease by infecting human mononuclear cells, primarily alveolar macrophages. After the bacterium is inhaled into the lungs, it invades lung macrophages and multiplies in them. The molecular and cellular pathogenesis of L. pneumophila has been studied in detail, but relatively little is known about the pathogenic mechanism of the other Legionella spp., except that of L. longbeachae, which has been the subject of a few studies. L. pneumophila injects hundreds of pathogenicity effectors, via a type IV secretion system, into host macrophages almost as soon as the bacterium makes contact with the phagocytic cell. Bacterial strains lacking this type IV secretion system, termed Dot or Icm, are avirulent. The injected effectors hijack normal cellular host defenses that would ordinarily destroy the bacterium within a fused phagolysosome. Instead, the virulent bacteria reside in a nonfused phagosome that is associated with host ribosomes, and rather than being killed, it derives nutrients from the cell and multiplies within the specialized phagosome. After multiplying many thousandfold within the phagocyte, the bacteria effect cell death. At the same time, the bacteria change their phenotype to become very motile, small, and primed for invading adjacent uninfected phagocytes. The bacteria possess other secretion systems, by which they secrete a number of proteases and other potentially toxic substances, many of which are either proinflammatory or tissue destructive. Intracellular iron acquisition is important for bacterial survival and growth within the cell; a number of bacterial effectors aid in iron acquisition. The host response to the bacterium, as well as secreted toxic substances, produces intense inflammation.
that destroys host tissues in the lung. The bacteria are controlled primarily by the innate immune system and by acquired cellular immunity. Detailed descriptions of pathogenesis can be found elsewhere (15, 33).

**CLINICAL SIGNIFICANCE**

LD is a type of bacterial pneumonia caused by *L. pneumophila* and other *Legionella* spp. The pneumonia ranges in severity from mild to fatal, with an average fatality rate of 12% (34). Major risk factors for the disease include endogenous or exogenous suppression of the cellular immune system, cigarette smoking, overnight travel outside the home, use of well water, chronic heart or lung disease, and chronic renal failure. Patients at particularly high risk of LD are those receiving high-dosage glucocorticosteroids, those with solid organ transplants, and those receiving anti-tumor necrosis factor therapy for a variety of autoimmune diseases (15).

LD cannot be readily distinguished from other forms of community-acquired pneumonia by clinical, roentgenographic, or nonspecific laboratory studies (15). Several attempts at developing a clinical scoring system to distinguish LD from other pneumonias have failed. The severity of pneumonia at presentation, underlying diseases, and promptness of specific antibiotic therapy are important prognostic factors. Promptly treated LD can be cured in 95 to 99% of cases in an otherwise healthy person. Less than half of patients may respond if there is a delay in therapy, immunosuppression, or respiratory failure (15). Untreated disease causes death in about 15% of previously healthy patients and up to 75% of severely immunocompromised ones (15).

Prospective, randomized controlled studies of adequate size have not been performed to determine the optimal therapy for LD, so great reliance is placed on experimental tissue culture and animal model studies, as well as results of nonrandomized studies (15, 35). Erythromycin, clarithromycin, azithromycin, a tetracycline, levofloxacin, and moxifloxacin all appear to have roughly equivalent efficacies for nonimmunocompromised outpatients with mild LD (15). The quinolone antimicrobials, especially levofloxacin, and azithromycin are the drugs of choice for severe disease and for immunocompromised patients (15, 36). Antimicrobial therapy with more than one agent is sometimes used but is of questionable benefit and may be harmful (37).

Pontiac fever is an acute influenza-like illness that has been associated with exposure to *Legionella* spp-containing environmental aerosols (38, 39). The etiology and pathogenesis of this disease are unknown, but it appears that the disease is caused by inhalation of bacterial toxins, such as endotoxin, or perhaps by an acute allergic reaction to a bacterium. Since multiple microorganisms and endotoxin have been found in aerosols causing Pontiac fever, it is unclear if *Legionella* spp. play any role at all in disease causation. Pontiac fever is self-limited, with no reported deaths, little to no need for hospitalization, and no need for antibiotic therapy.

**COLLECTION, STORAGE, AND TRANSPORT**

Expectorated sputum and other lower respiratory tract specimens are the most common sources of *Legionella* spp. Other less common sources include pleural fluid and blood. Rare sources have included pericardial fluid and specimens from kidney, liver, spleen, myocardium, respiratory sinuses, skin and soft tissues, infected wounds, peritoneal fluid, prostatic and native heart valves, joint fluids, bone marrow, and intestine. Culture of available sputum, bronchoscopy specimens, lung biopsy specimens, and pleural fluid should be routine for laboratory diagnosis of LD. Lung biopsy specimens have the highest yield but may be negative. Culture of expectorated sputum or other lower respiratory tract secretions, second in yield to lung biopsy specimens, should always be performed for optimal detection of legionella infection. Pleural fluid has low yield but should be cultured if it is available. Culture of other specimen types for *Legionella* spp. is not indicated unless there is a high clinical suspicion of the disease affecting these sites or specific laboratory evidence of the disease elsewhere.

Sputum microscopic scoring criteria cannot be used to determine which sputum specimens should be cultured for legionella bacteria because of limited purulence and scanty secretions in patients with LD. Up to 80% of specimens culture-positive for *Legionella* spp. may be rejected on the basis of the criterion of the presence of sputum purulence for processing specimens (40, 41).

Urine for antigen detection should be collected in a sterile container (42). Boric acid preserves the antigen, but use of commercial urine transport systems containing boric acid have not been studied for antigen preservation and freedom from interactions. Urine can be transported to the laboratory at room temperature if no more than a several-hour delay is anticipated. Longer transport times require specimen refrigeration; antigen in frozen (−20 to −70°C) urine samples is stable for several months (43).

Blood for serum antibody testing is collected in standard tubes and transported at room temperature (44). Test performance is not adversely affected by storage of the clotted unseparated blood at room temperature for several days. Long-term storage of aliquots to allow parallel testing without freeze-thawing, which can lower antibody levels, is at −20°C. *Legionella* spp. are hardy and generally survive for up to a week in clinical specimens. Sputum and other respiratory tract specimens, including lung biopsy specimens, should be collected in sterile containers and transported to the laboratory promptly at room temperature. Transportation and storage should be at 2 to 5°C if more than a several-hour delay is anticipated before the specimen can be plated. Very long term storage is best at −70°C, although this can reduce bacterial concentration to below the level of detection when the starting concentration is low or the specimen is primarily aqueous. Repeated freeze-thawing is harmful to the bacteria. Some tissues, especially spleen, contain growth-preventing substances and must be plated promptly; even overnight storage at 5°C dramatically reduces culture yield (note that this is not true of lung specimens).

Valid data on the stability of *Legionella* spp DNA in clinical samples have not been published. Regardless, special conditions for the transportation of respiratory materials or serum samples used solely for *Legionella* spp. PCR do not appear to be required. General guidelines for the transport and preanalytical storage of these specimen types are found in chapter 18 of this Manual.

**DIRECT EXAMINATION**

**Microscopy**

The morphology of *L. pneumophila* found in lung and sputum is a small coccobacillus to short rod 3 to 5 μm in length (Fig. 1). This is much different from that observed for the bacterium taken from a culture plate, which is usually a long filamentous bacillus 10 to 25 μm in length. *L. pneumophila* is
very difficult to detect by Gram staining sputum or lung biopsy specimens. Use of 0.1% basic fuchsin, rather than safranin, greatly enhances the staining of the bacterium from culture plates, but even with use of this stain, it is very difficult to visualize the bacterium in sputum and tissues. Less than 0.1% of L. pneumophila cells present in lung tissue or sputum can be visualized by Gram staining using basic fuchsin. The small size of intracellular L. pneumophila, the form present in human tissues, makes visualization difficult with Gram stain, as does stain uptake by the surrounding proteinaceous material found in sputum and tissue.

Enhancement of bacterial staining by silver precipitate stains, such as the Warthin-Starry stain and its modifications and the Dieterle stains (45, 46), was an early approach to the detection of L. pneumophila in embedded tissues as well as sputum. These silver stains are useful for detection of the bacterium in embedded tissues but have no present role in the staining of the bacterium in sputum or other nonembedded specimens. Silver stains are not highly sensitive, can produce artifacts, and require expert use and interpretation for optimal sensitivity and specificity.

Some Legionella spp., in particular L. micdadei, may stain with acid-fast stains, both in fresh specimens and from Formalin-fixed tissues (47, 48). The small coccobacillary morphology of Legionella spp. should be a clue that the acid-fast organism is not a mycobacterium.

Immunofluorescence microscopy is the most sensitive and specific microscopic method for the detection of L. pneumophila in tissues and sputum (Fig. 1) (49, 50). Optimal sensitivity and specificity require exacting staining methods and great expertise by the microscopist. Even when the test is well performed, its sensitivity has been low compared to those of other diagnostic methods (51). For these reasons, this test is now rarely used for direct examination, except perhaps in the examination of autopsy lung specimens. Detailed discussions of this test can be found elsewhere (50).

**Antigen Detection**

LD due to L. pneumophila serogroup 1 can often be diagnosed by detection of bacterial antigenuria (42). Several immunoassays are commercially available for this purpose, the most convenient of which is a rapid single-test immunochromatographic card assay. Immunochromatographic card assays are made by at least six companies, and three are FDA cleared (Alere, BinaxNOW; SA Scientific, SAS Legionella; and Meridian, TRU Legionella); of these, only the BinaxNOW assay has been extensively evaluated. Several other assays utilize a microtube-based enzyme immunoassay. The strength of all these assays is their detection of infections with L. pneumophila serogroup 1 and, in particular, its Pontiac/MAb 2/MAb 3-1 monoclonal subtype (25, 26, 52, 53). The immunochromatographic card assays can be up to 40% less sensitive than the microtube-based immunoassays (54), although prolonged incubation and urine concentration can enhance card test sensitivities (55); neither of these enhancements is in the manufacturer’s directions. The ability to quickly test a single specimen, combined with ease of use and robustness, makes up for a decrease in sensitivity of the immunochromatographic card assays.

Clinical test performance for all assays is dependent on the pretest probability of L. pneumophila serogroup 1 and on the probability of Pontiac monoclonal subtype L. pneumophila serogroup 1 infection (25, 52). The assays detect about 60 to 70% of L. pneumophila serogroup 1 Pontiac monoclonal subtype epidemic infections and up to 90% of sporadic cases of pneumonia caused by this subtype. The differences in test sensitivity for the same bacterial subtype are probably due to differences in disease severity, the other major factor determining test sensitivity. Patients with severe L. pneumophila serogroup 1 LD, for example, those requiring intensive-care nursing and ventilator assistance, are the most likely to have positive urine antigen tests; test sensitivity in this population is probably in the range of 90 to 95% of those infected with the Pontiac monoclonal subtype. On the other hand, urine testing may detect only 50% of outpatients with mild epidemic disease caused by the same monoclonal subtype, perhaps 40% of hospitalized patients with other L. pneumophila serogroup 1 subtypes, and fewer than 5 to 40% of those with infections caused by other serogroups and species (26, 56). The test may be negative during the first day of illness, but those with severe disease are likely to be positive on presentation to the hospital. Repeat testing 2 to 3 days after the onset of illness may lead to detection of a small number of patients who had negative tests initially.

Test sensitivity can be enhanced by concentrating the specimen using ultrafiltration devices such as Amicon concentrators (Millipore, Billerica, MA). In some studies, this has increased test sensitivity by about 30%, without affecting specificity (57, 58). Prolonging the incubation time for the BinaxNOW assay to 60 min also increases sensitivity without decreasing specificity (26, 59). Test sensitivity may decrease if specimens are frozen for months before being tested (43).

The urine antigen assays are very specific, i.e., in the range of 99 to 99.9%. False-positive tests can be due to rheumatoid arthritis-like factors in urine, freeze-thawing of urine, and excessive urinary sediment. All together, these causes of false-positive tests account for no more than a few percent of all positive tests. Regardless, all positive tests

---

(C) Direct immunofluorescent staining of L. pneumophila in lung.

doi:10.1128/9781555817381.ch49.f1
Molecular Diagnosis of LD

Nucleic acid-based detection of *Legionella* spp. in sputum, urine, and blood has been successfully used in reference and research laboratories, with detection of *L. pneumophila* being the most extensively studied. The best results show that molecular diagnosis is a more sensitive method of diagnosis than culture (60, 61), although some studies showed rough equivalence (62). Test sensitivities have been estimated to be 80 to 100% and 30 to 50% for lower respiratory tract secretions and serum, respectively; test specificities are estimated to be >90% (60–62). Sputum digestion may be important to increase yield (63). Prior studies indicated that urine is a suitable PCR analyte, but more-recent work shows that urine is not a suitable specimen type for the detection of *Legionella* species DNA (60).

Both conventional and real-time assays have been utilized (62, 64). Most laboratories use the macrophage infectivity protein (*mip*) gene target to detect *L. pneumophila*. *Legionella* spp. are most commonly detected using an *rRNA* gene target (usually the 16S *rRNA* gene, although 23S *rRNA* is claimed to have advantages) (65). Recent work shows that the *wzm* target can be used to specifically detect *L. pneumophila* serogroup 1 (66). A multiplex assay that detects *L. pneumophila* serogroup 1 (*wzm*), *L. pneumophila* (*mip*), and *Legionella* spp. (ssrA) has been described to be a sensitive and specific assay for use with clinical specimens (67). Multiplex assays are most commonly used because they have no disadvantage over uniplex methods, although one study showed the superiority of a nucleic acid sequence-based amplification (NASBA) uniplex assay over a multiplex format (68, 69).

No FDA-cleared commercial PCR assay is marketed in the United States. Several commercial PCR assays are marketed elsewhere for use in testing respiratory specimens. Tests based on reverse hybridization include Gen ID CAP Bac (AID Diagnostika, Germany) and Chlamylege (bioMérieux, France). Examples of non-FDA-cleared commercial real-time PCR assays that detect *L. pneumophila*, *Legionella* spp., or both targets include Duplica real-time assays (EuroClone, Italy), *Legionella pneumophila* plus species (Diagnocode Diagnostics, Belgium), Unyvero (Curetis, Germany), and *Legionella pneumophila* PCR (GeneProof, Czech Republic). Sufficient evaluations of the performances of these commercial assays have not been published, requiring extensive internal and external validation before use. European external quality assessment schemes are available for PCR assays (www.qcmd.org, www.instandev.de).

The added benefit of nucleic acid amplification-based detection of *Legionella* spp. in sputum over that obtained by urine antigen testing appears to be slight, with an 11% greater yield than from urine testing alone. This is likely because of the predominance of *L. pneumophila* serogroup 1, Pontiac subgroup, in community-acquired disease (70). The performance of nucleic acid testing for the detection of nosocomial LD and LD in immunocompromised patients is probably significantly better than urine antigen testing.

A problem with molecular detection of *Legionella* spp. in clinical specimens has been the inability to type detected bacteria for epidemiologic purposes. This is now possible for the majority of PCR-positive specimens using a nested PCR method (60, 71, 72). Descriptions of primers and detailed protocols are available online (http://www.hpa-bioinformatics.org.uk/legionella/legionella_sbt/php/sbt_homepage.php).

Because *Legionella* spp. are commonly found in water, contamination of almost any molecular reagent with *Legionella* species nucleic acid is a concern. False-positive PCR tests for *Legionella* spp. have been attributed to contaminated commercially produced "pure" water and nucleic acid extraction columns (73–75). Since sequencing of false-positive products yielded *Legionella* species sequences, the possibility of contamination cannot be excluded by the ability to sequence the product and assign it to a particular *Legionella* spp. (74). In the case of extraction column contamination, only a few columns of the same lot may be contaminated and not the entire lot. This means that multiple negative controls are required for optimal specificity, including extraction controls as well as no-template controls. Finally, contamination of specimens with tap water containing *Legionella* spp. is a concern and has been reported to result in pseudo-outbreaks of LD related to bronchoscopy, for both culture and DNA detection methods (76, 77).

ISOLATION PROCEDURES

Specimen Plating

Optimal yield of *Legionella* spp. from clinical specimens usually requires (i) that specimens be diluted to reduce inhibition by tissue and serum factors, as well as antibiotics, (ii) that the specimen be pretreated to reduce contaminating microbiota, and (iii) that a variety of selective and nonselective media be used (Table 2). Practically, this entails the inoculation of a nonselective medium and two different selective media, with the specimen diluted in broth or water, and the same three plates should be inoculated with the specimen diluted in an acid buffer, for a total of six inoculated plates. Culture of *Legionella* spp. from normally sterile fluids and tissues, such as pleural fluid, aseptically obtained lung tissue, or blood, is often successful without the use of multiple selective media and specimen decontamination.

Dilution (1:10) in tryptic soy broth or distilled water increases the culture yield of most specimen types, including sputum and other liquid respiratory tract specimens, lung tissue, lymph nodes, spleen, and probably other organs, such as liver and kidney. Sputum and other respiratory tract specimens should first be examined in a petri dish for purulent-appearing material, and this material should be selected for culture. Tissues (about 1 g) are ground in a tissue grinder with a small amount (1 ml) of broth, which adequately dilutes most tissues except for spleen; this tissue requires an additional 1:10 dilution for the best recovery of bacteria. Liquid specimens are roughly diluted by adding about 0.1 ml of vortex-mixed liquid specimens to 0.9 ml of the dilution broth. Pleural fluid, joint fluid, and blood subcultured from blood culture bottles do not require dilution before being plated; in fact, pleural fluid yield may be enhanced by concentration by centrifugation.

Decontamination is required to reduce contaminating microbiota in most sputum and other respiratory tract secretions. This is done by diluting (1:10) the specimen in a low-pH KCl-HCl buffer (pH 2.2) and incubating it at room temperature (4.0 min) before plating the suspension onto culture media. Timing is critical here, with resultant low yield if the timing is off by as little as a minute. The culture

\(^b\)The selectivity scale is from 0 to 4+, where 0 means that the agents do not inhibit these organisms, 1+ means that the agents cause slight inhibition (they allow about 75% growth), 2+ means that about 25 to 50% growth is allowed, 3+ means that about 10% growth is allowed, and 4+ means that less than 1% growth is allowed.

---

The medium is sufficiently buffered so that the acidified specimen is neutralized upon being plated. An alternative to specimen acidification is heating at 50°C for 30 min. Most aseptically collected tissue specimens do not require decontamination, although occasionally lung tissues contain multiple contaminating bacteria and fungi. In this case, heat or acid treatment of tissue ground in sterile distilled water may help; sometimes dilutions of the ground tissues are also required for optimal yield, with or without pretreatment. For specimens critical for epidemiologic purposes, culture yield can sometimes be enhanced by plating multiple 10-fold dilutions of specimens onto a wide variety of media, by using a variety of specimen treatments, such as heat and acid, and by performing coculture with amoebae (78, 79).

**Inoculation of Plates**

Approximately 0.1 ml is inoculated onto each plate, with the bulk of the inoculum applied to the first quadrant. Comparative studies to show whether it is better to streak plates for isolation or to uniformly distribute the inoculum over the entire plate are lacking. The plates must be thoroughly dry before being inoculated to aid in absorption of the relatively large-volume inoculum and to retard spreading of contaminants throughout the plate.

**Culture Media**

Buffered charcoal yeast extract medium supplemented with 0.1% \(\alpha\)-keto glutaric acid (BCYE\(\alpha\)) is used for the isolation and growth of Legionella spp. Use of BCYE without \(\alpha\)-keto glutaric supplementation cannot be recommended for clinical use, as this amino acid greatly enhances the growth of the bacterium (80).

BCYE\(\alpha\) can be made selective by the addition of antimicrobial agents (Table 2). A variety of different antifungal agents are used in the media. Cycloheximide is a poor choice for media used for clinical specimens, as it fails to inhibit *Candida albicans*. Both anisomycin and natamycin inhibit more yeasts than does cycloheximide. An array of media exists because no one selective medium is best for all purposes. Optimal yield of Legionella spp. from clinical specimens requires the use of three different media, one plate with nonselective medium (BCYE\(\alpha\)) and two with selective media (BCYE\(\alpha\) medium with antimicrobial agents [BMPA] and BCYE with polymyxin B, anisomycin, and vancomycin [PAV]). BMPA is an excellent selective medium for the vast majority of *L. pneumophila* strains, but the cefamandole present in the medium inhibits the growth of some other *Legionella* spp. and, rarely, *L. pneumophila* strains. Use of the less selective medium, PAV, is required for optimal growth of some *Legionella* spp. other than *L. pneumophila*. No selective medium inhibits multiresistant Gram-negative bacteria, reducing culture yield in nosocomial disease.

Selective and nonselective media are optimized for the isolation of *L. pneumophila*, and their performance for the isolation of other *Legionella* spp. is not accurately known. One study showed that *L. micdadei* in guinea pig spleen had enhanced recovery on BCYE\(\alpha\) medium prepared with 1% bovine serum albumin; the growth was enhanced because of less growth inhibition by spleen tissue (81). Whether addition of bovine serum albumin to BCYE\(\alpha\) medium enhances *L. micdadei* recovery from human lung or sputum is unknown and probably unlikely. A BCYE\(\alpha\)-based selective medium containing natamycin, aztreonam, and vancomycin has been reported to be useful for the isolation of *L. longbeachae* from soil (82).

The medium shelf life is around 1 year for nonselective plates and slants (83). This long shelf life requires thick plates (25-ml pour), complete drying of plates before storage at 2 to 4°C in sealed plastic bags, and protection from light. Selective media lose selectivity after about 3 months' storage time, but depending on the incorporated antibiotic, the media may last considerably longer.

Quality control testing of media is required before they are put into use. Current CLSI standards are inadequate for proper quality control (QC) testing of these media. About 1% of commercial media fail laboratory QC testing (personal observations). The CLSI QC testing protocol utilizes a heavy inoculum of medium-adapted *Legionella* species strains and a growth/no-growth test. Minor variations in the ways media are manufactured, such as the addition of excess salt, overlong autoclaving, and degradation of buffers, can all seriously affect the ability of the medium to support wild strain growth but not necessarily that of medium-adapted strains. The optimal method for QC medium testing is the inoculation of the test media with several hundred non-artificial-medium-passaged *L. pneumophila* bacteria (obtained from infected guinea pig lung) and quantification of the bacterial colonies after 3 to 4 days of incubation (84).
In the absence of the availability of lung-passaged L. pneumophila bacteria, low-passage-number clinical strains should be used, with care taken to plate only several hundred bacteria per plate. QC testing of selective media for the ability to suppress non-Legionella bacteria can be done by inoculation of the plate with relatively antibiotic-susceptible Escherichia coli and Staphylococcus aureus strains, such as ATCC 25922 and 25923; the growth should be markedly suppressed.

**Medium Incubation**

Inoculated media are incubated at 35 to 37°C in humidified air. Regardless of the humidification method, care must be taken to keep the incubators or jars very clean and to regularly sterilize the containers or incubators. A small amount of CO$_2$ supplementation (2 to 5%) may enhance the growth of some of the more fastidious Legionella spp., such as L. sainthelensi and L. oakridgensis. This low level of CO$_2$ supplementation will not harm the growth of L. pneumophila, but CO$_2$ levels higher than 5% may inhibit growth. Since the more capnophilic species are very rare human isolates, many laboratories do not use CO$_2$ incubation of media for Legionella spp.

**Plate Inspection**

Legionella species colonies begin to appear on culture plates on day 3 of incubation. It is very unusual for the bacterial colonies to appear on plates after 5 incubation days. Some very rarely isolated Legionella spp. may require up to 14 days of incubation before growth appears; this is an extremely rare event. Regardless, it is reasonable to inspect culture plates on days 1 to 5 and then again at day 14.

The late appearance of Legionella spp. on culture plates can be used to great advantage if a careful record is kept of the colonies present on days 1 and 2 postincubation. New colonies appearing after day 2 should be suspected of being Legionella spp. Very rarely, Legionella spp. may grow from heavily infected lung (usually after autopsy of a fatal untreated case) on day 2, so some latitude in growth rate assumptions needs to be applied in the case of autopsy lung cultures. Legionella spp. never grow from clinical specimens on day 1 postincubation, a critical point in the distinction of Pseudomonas aeruginosa colonies from those of Legionella spp., as very early colonies of the latter superficially resemble those of the former.

Proper observation of culture plates requires the use of a dissecting microscope illuminated with direct light aimed at the plate surface at approximately a 30° angle. Failure to use a dissecting microscope, or use of improper lighting, will result in missed positive cultures, especially when there is mixed bacterial growth on the plates. In addition, very young Legionella species colonies are very small and difficult to see with the naked eye. Therefore, use of a dissecting microscope can speed up the time to colony detection by as much as a day. Legionella species growth occurs almost exclusively in the first streak quadrant and sometimes at the edge of the plate.

The size and morphology of Legionella species colonies change with time. Very young colonies (day 3) are flat, entire, and 0.5 to 1 mm in diameter, and when observed using a dissecting microscope and incident visible light, they usually have a speckled blue, blue-green, or red color. Within 6 to 24 h of additional incubation, these colonies become smooth, convex, iridescent, entire, and about 1 to 3 mm in diameter, and they look opal-like when observed with a dissecting microscope (Fig. 2). A thick string may form when a loop is inserted in the colony and then removed from the colony. Unlike with several mimics, the edges of the colonies are of the same consistency as the central portion and are not watery or clear. In another 1 to 2 days, the colonies may increase in size to up to 5 to 7 mm, become umbonate, sometimes with a tuberculated or inhomogeneous texture, and develop spreading edges; their iridescent nature may be lost at this stage. It is these late-stage colonies that are most difficult to distinguish from non-Legionella spp., making daily plate observation crucial for accurate detection. Very rarely, some Legionella species colonies do not change morphology with prolonged incubation.

Biosafety level 2 precautions should be used for the manipulation of Legionella species cultures. It is safe to inspect culture plates, pick typical colonies, and subculture them on an open bench in a properly ventilated laboratory. Making an organism emulsion on microscope slides for the purposes of Gram staining can also be safely carried out on an open bench. However, vortexing suspensions, sonication, tissue grinding, primary plating, and manipulations that may result in generation of a high-concentration aerosol should be performed in a biological safety cabinet. No well-documented case of laboratory-acquired LD has been reported.

**FIGURE 2** Photographs of *L. pneumophila* colonies growing on BCYE$\alpha$ agar. Note the internal speckling and different colors that may be seen, sometimes in the same culture.

doi:10.1128/9781555817381.ch49.f2
Initial Workup of Suspect Colonies and Look-Alike Bacteria

Colonies suspected of being Legionella spp. should first be stained with Gram stain to ascertain that the bacteria are small and sometimes filamentous Gram-negative rods. A small amount of the colony should be emulsified in sterile water or saline on a glass slide. It is important to completely suspend the bacteria in the liquid, as nondispersed clumps may stain as Gram-positive rods. It is also crucial to use 0.1% basic fuchsin counterstain because safranin stains the Gram-negative rod very poorly. Depending on the colony age and on the strain and species, Legionella spp. taken from plates vary in size from short rods that are 0.5 by 5 μm to very long filamentous bacteria that are 1 by 25 μm.

Gram-negative bacteria should then be plated to two different media, BYCExα and either tryptic soy blood agar (TSBA) or BCYEExα made without l-cysteine (BCYEExα-l); in approximately equal amounts in a small (1-cm²) area; eight or more isolates can be plated to each plate if needed (Fig. 3). Rather large amounts of the picked colony should be inoculated into these media to enable growth after 16 to 18 h of incubation, as the small inocula normally used for other bacteria may otherwise take several days to produce visible colonies on plates. If only a single small colony is available, then it can be emulsified in a small amount (~0.5 ml) of sterile distilled water (not saline) and used for staining, plate inoculation, and sero-identification. Legionella spp. should grow in 16 to 36 h on BCYEExα medium but not on TSBA or BCYEExα-l medium; this takes advantage of the l-cysteine-growth dependence of Legionella spp. Sometimes, Legionella spp. will grow poorly on TSBA or BCYEExα-l medium; at most, growth is only about 10% of the growth on BCYEExα. Nutrient carryover from the primary-isolation plate is the explanation for this light growth; this can be proven by making a subculture of growth on BCYEExα-l or TSBA on a second plate of the same medium. Rare Legionella spp. partially lose growth dependence for l-cysteine upon serial passage but, even so, grow more poorly on BCYEExα-l than on BCYEExα; these species include L. nagasakiiensis, L. oaktidensis, and L. jordanis, none of which have been reported to cause more than two cases of LD each. TSBA performs almost as well as does BCYEExα-l for determining l-cysteine dependence for clinical isolates and may be less expensive, depending on the number of isolates tested per plate. If a blood-containing agar medium, rather than BCYEExα-l, is used as the screening plate for l-cysteine dependence, great care must be taken that the medium base is not too rich. For example, Brucella blood agar will support L. pneumophila growth almost as well as BCYEExα medium, and other blood-containing media have been described to do the same (85). The plates are incubated overnight at 35 to 37°C or until there is visible growth on the BCYEExα plate. Compare the relative amounts of growth on the plates to determine if there is l-cysteine dependence. Most Legionella spp. produce a characteristic dank odor that is very specific to the trained nose when they exhibit pure growth.

Common mimics of Legionella species colonies on BCYEExα plates include Eikenella corrodens, P. aeruginosa, Flavobacterium spp., Sphingomonas spp., and some Bacillus spp. All of these bacteria grow equally well on BCYEExα and BCYEExα-l media, but when young, they often grow as speckled colonies on BCYEExα plates. Francisella tularensis can grow well on BCYEExα agar but has no resemblance to Legionella species colonies. However, F. tularensis is the only Gram-negative bacterium other than Legionella spp. that exhibits l-cysteine growth dependence. The colony morphology of F. tularensis is not speckled but rather is opaque and homogeneous. Adding to the confusion is that some serotyping reagents for Legionella spp. may cross-react with F. tularensis.

There is one case report of the misidentification of F. tularensis as L. pneumophila (86). When tularemia is suspected, more-stringent safety precautions are needed. Of note, some Bacillus species mimics can stain as Gram-negative rods, have inapparent sporulation, and do not grow on TSBA (but will grow on BCYEExα-l) (87). With prolonged incubation, colonies of E. corrodens, Sphingomonas spp., and Flavobacterium spp. change color and no longer resemble Legionella spp.; E. corrodens colonies become light to dark green, Flavobacterium spp. bright yellow, and Sphingomonas spp. a grayish yellow. Very young P. aeruginosa and Bacillus species colonies resemble the speckled flat to slightly convex young Legionella species colonies but with prolonged incubation change their morphology, making them easily recognizable as non-Legionella species colonies. Bordetella pertussis colonies may appear late on BCYEExα plates, although this bacterium neither is cysteine dependent nor possesses colony morphology similar to that of Legionella spp. B. pertussis has been reported to be misidentified as Legionella spp., abetted by serological cross-reactivity (88). Because many different bacteria may cross-react with serological reagents used for typing and identifying Legionella spp., it is crucial to become familiar with the morphology and growth characteristics of this genus; relying exclusively on serotyping to identify Legionella spp. could result in mistaken identification.

Microbiologists should know that some pathogenic fungi and higher bacteria grow well on BCYEExα medium, presenting both potential biohazards and the opportunity to diagnose unsuspected infections. Coccioides spp. often grow within a day or two on this medium and can rapidly form arthroconidia; as such, they present a biohazard. Blastomyces dermatitidis also grows well and converts to the mold phase within a few days. It is likely that other pathogenic fungi grow equally well on this very rich medium. Nocardia spp. and rapidly growing mycobacteria often grow quite well on this medium, making BCYEExα medium and its selective variants plating media of choice for the laboratory diagnosis of nocardiosis (89, 90). Bacteremia from Nocardia spp. can sometimes be diagnosed by subculture of blood culture bottles to BCYEExα.

IDENTIFICATION FROM BACTERIAL COLONIES

Basic Identification

Once l-cysteine dependence has been confirmed, further identification of Legionella spp. in a clinical laboratory relies almost exclusively on serotyping the bacteria, using either immunofluorescence or agglutination methods (50, 91). Prior to attempting identification by serotyping, the plate should be illuminated with long-wave UV light in a dark-room; some Legionella spp. other than L. pneumophila fluoresce a brilliant bluish white and some a brilliant red; such bacteria are best identified by a reference laboratory and are not L. pneumophila. L. pneumophila fluoresces a very pale yellow-green, usually with diffusion of the fluorescent pigment into the culture medium; this is not specific for this species, and sometimes young cultures are completely nonfluorescent. An excellent and specific FDA-cleared fluorescein isothiocyanate (FITC)-labeled monoclonal antibody to all serogroups of L. pneumophila is available (Monofluo; Bio-Rad). Also an excellent non-FDA-cleared
FIGURE 3 Identification flow scheme for basic identification of *Legionella* spp. grown from a BCYEα plate. Abbreviations: BCYE, BCYEα; BCYE-L, BCYEα made without L-cysteine; BAP, tryptic soy blood agar; UV light, colony fluorescence and color when illuminated with long-wave (360-nm) UV light. doi:10.1128/9781555817381.ch49.f3
Serotyping of Legionella spp. is carried out using polyclonal antiserum produced by the CDC, other public health agencies, and commercial laboratories (m-TECH, Denka Seiken, Oxoid, and others). Either immunofluorescence or agglutination reactions are used, with no clear evidence of superiority of one technique over the other (95). Some producers make polyvalent serum pools that react with a large number of species or serogroups, which can be useful to reduce the number of monovalent antiserum used. The specificity of the polyvalent antiserum has not been studied in great detail, although at least one product reacted with a number of non-Legionella spp. (96). This makes it important that monovalent typing be performed and that the bacteria meet minimal phenotypic criteria for Legionella spp. Unfortunately, cross-reactions between different species and serogroups occur even when monovalent antiserum are used (4, 97–101). Use of cross-adsorbed polyvalent antiserum has been described as a research tool to avoid this problem of cross-reactions, but these reagents are not available outside some research laboratories (102–104). In addition to intragenus cross-reactions, a large number of cross-reactions of monovalent polyclonal antibodies to non-Legionella spp., including P. aeruginosa, Flavobacterium spp., Bacteroides fragilis, Capnocytophaga ochracea, B. pertussis, Bordetella bronchiseptica, and possibly Burkholderia pseudomallei, have been reported (105–111). Antibody to L. pneumophila serogroup 1 is quite specific, but otherwise enough cross-reactions exist to make serological identification only presumptive. Antiser to newer Legionella spp. are often unavailable.

Monoclonal typing antibodies reduce the number of cross-reactions with Gram-negative bacteria but are commercially available only for the identification of L. pneumophila (112–115). However, great care must be used by experienced microbiologists, as cross-reactions with some non-Legionella spp. have been reported with the L. pneumophila-specific monoclonal antibody, including S. aureus, yeasts, and Bacillus spp. Legionella spp. are relatively inert biochemically and will not be identified using conventional tube or commercial panel biochemical tests. The few biochemical characteristics described for Legionella spp. that can be determined in most laboratories, such as oxidase, catalase, and β-lactamase tests, are unhelpful for identification of these bacteria.

The gold standard for the identification of new Legionella spp. has been DNA-DNA hybridization analysis (116). This method is tedious, expensive, and labor-intensive and requires special expertise as well as a large collection of reference DNA standards. As such, DNA-DNA hybridization analysis is not used to identify already-known species.

Molecular identification of Legionella spp. has replaced other identification techniques in research and specialty laboratories for several reasons. These include the labor cost and time required to serotype a strain, serological cross-reactions, the limited availability of antibodies to newer strains, the lack of specific and easy biochemical characterization methods, and the increasing availability of inexpensive DNA sequencing and matrix-assisted laser desorption ionization–time of flight mass spectrometry (MALDI-TOF MS) instrument systems.

MALDI-TOF MS is a rapid and cost-effective method for the species-level identification of Legionella spp. (117). This technique is currently unable to perform serogroup-level identification. Major disadvantages are a lack of comprehensive databases and the fact that MALDI-TOF can identify only known species. About 80 to 90% of isolates tested by reference laboratories are correctly identified to the species level by this method, with some portion of this low
sensitivity being due to incomplete databases. Almost all isolates not identified by this method are given low reliability scores but correct identifications (117). Once the databases are more complete, MALDI-TOF MS should be able to identify almost all known Legionella spp. present in the databases. If an isolate cannot be identified by MALDI-TOF MS, DNA sequence analysis is used to identify the bacterium.

DNA sequence-based identification methods take advantage of the specific 16S rRNA or mip gene sequences of the different Legionella spp. (3, 118–120). A mip database, procedure instructions, including primer sequences, mip sequence alignment software, and other genomic software tools are all available online (http://webarchive.nationalarchives.gov.uk/20140714084352; http://www.hpa.org.uk/web/HPAweb&HPAwebStandard/HPAweb_C/1195733805138). Sequence analysis of 16S rRNA has been used to identify several new Legionella spp. (121–124). Partial sequencing of 16S rRNA (500 bp) is able to accurately identify all Legionella spp. to the genus level, all L. pneumophila strains, and about 90% of Legionella spp. other than L. pneumophila to the species level; incorrect species-level identification is a problem for the more unusual Legionella spp. (14, 125). The DNA sequence of the rpoB gene has been shown to distinguish between species as well as or better than 16S rRNA or mip gene sequencing (126). Intergeneric 16S-23S ribosomal spacer PCR analysis has been successful for species identification and does not require DNA sequencing (127); the lack of available databases and the paucity of strain data for many species limit the usefulness of these techniques. The relative performances of mip sequencing and full-length 16S rRNA sequencing are not known, but partial 16S rRNA sequencing should not solely be relied on when an unusual Legionella sp. is identified. Limited numbers of reference strains, especially of some unusual species, have been tested by these methods, leaving open the possibility of incorrect classifications.

PCR-based methods can be used to distinguish between L. pneumophila serogroup 1 and other serogroups (66, 128). PCR can also be used to distinguish Pontiac/MAb 1/MAb 3-1 strains of L. pneumophila serogroup 1 from non-Pontiac strains (24, 128).

There are several reports of genotypic discordances for identical serogroups and vice versa (129–131). Sequencing of the L. pneumophila dnaJ gene appeared to be able to distinguish between some, but not all, L. pneumophila serogroups (118); different serogroups that had very similar genotypes had been shown by other methods to have discordant genotypes and serogroups. More-extensive testing of this method needs to be performed before it is put into routine use.

TYPING SYSTEMS

Typing of Legionella spp. is important for public health investigations to help link culture-positive environmental sites with clinical isolates during an epidemic of the disease. Typing cannot be used by itself to determine the environmental source of an outbreak and must be accompanied by an epidemiologic investigation. Otherwise, incorrect conclusions may be made about epidemic sources (132, 133). This problem is due to clonal distributions of environmental and clinical Legionella spp. (134–137) and to the poor specificity of some typing techniques (136, 138).

Monoclonal antibody typing plays a major role in subtyping L. pneumophila serogroup 1 isolates and, when used with molecular methods, can increase typing specificity (136, 139, 140). Used by itself, monoclonal antibody typing may not be specific enough to distinguish between closely related strains, but this method can be very helpful in epidemic situations as a quick screening test of environmental isolates to determine which isolates to genotype.

Sequence-based typing appears to be the most specific and precise molecular subtyping system for both L. pneumophila and L. pneumophila serogroup 1 (141). A standardized pulsed-field gel electrophoresis method yields reproducible results and is used as a reference typing method by one national laboratory (137). As whole-genome sequencing and sequence analysis become less expensive, more automated, and less labor-intensive, it is possible that this method will be used in the future for molecular typing of isolates (142).

ANTIBODY DETERMINATION

LD can be diagnosed by demonstration of an increase in antibodies to killed bacterial cells (44). The immunofluorescent-antibody assay (IFA) is considered the gold standard method. While most patients develop both IgG and IgM responses, some develop IgM-only, IgG-only, or IgA-only responses, making it necessary to test for total immunoglobulin response and not just IgG. In addition, IgM antibodies may persist for as long as a year after infection, making the presence of IgM a poor marker of acute disease (143). About 75% of patients with culture-proven nosocomial L. pneumophila serogroup 1 LD develop seroconversion to the bacterium, whereas the test seems to have higher sensitivity in LD epidemics. Seroconversion requires weeks to months after infection, with only about a 50% seroconversion rate after 2 weeks; for optimal test sensitivity, acute-phase serum should be frozen while convalescent-phase sera are collected at 2, 4, 6, 9, and 12 weeks postinfection. Parallel testing of sera is required for the best specificity. The most specific testing is for seroconversion to L. pneumophila serogroup 1 only, and the least specific is the use of polyvalent antigen preparations, with approximate test specificities of 99 and 90 to 95%, respectively. Serologic diagnosis is best used for epidemiologic studies because of the retrospective nature of serologic diagnosis and limitations of test specificity and sensitivity.

ANTIMICROBIAL SUSCEPTIBILITIES AND SUSCEPTIBILITY TESTING

The antimicrobial susceptibility of L. pneumophila grown in broth or on agar can give results having no clinical correlate. This is because of the intracellular location of the bacterium in human infection, to which not all antimicrobial agents gain access and retain activity (35). In addition, the complex broth and agar media used to grow L. pneumophila inactivate many drugs. There is no indication for performing antimicrobial susceptibility testing against Legionella spp. except in a research setting, where correlative studies of intracellular and experimental animal infection models can be performed. The microbiologist must not assume that a particular drug will be effective for the treatment of LD simply because the drug is active against L. pneumophila in vitro, nor should there be an assumption that drugs having low MICs for the bacterium in vitro will be more clinically effective than will drugs with higher MICs for the organism. Antimicrobial resistance to drugs used for LD treatment has never been documented to be responsible for clinical treatment failures. Low-level ciprofloxacin resistance of a clinical isolate of L. pneumophila was recently described;
whether this had any effect on clinical outcome, or whether the resistance developed during ciprofloxacin treatment, is unknown (144). When antimicrobial susceptibility testing is performed for research purposes, it is best done using buffered yeast extract broth in a microtube dilution format (145). Use of the Etest method has no useful role in the clinical or research testing of Legionella spp.

Antimicrobial agents having good intracellular activity against L. pneumophila include most macrolide, tetracycline, ketolide, and quinolone antimicrobial agents (15, 35). No β-lactam agent or aminoglycoside has acceptable intracellular activity against the bacterium. It is unknown if the intracellular activities of antimicrobial agents against L. pneumophila can be extrapolated to all other Legionella spp. and to treatment of infections caused by Legionella spp. other than L. pneumophila. Some of these other Legionella spp. may reside in subcellular compartments different from those of L. pneumophila and thus may respond differently to antimicrobial agents (146). However, macrolide and quinolone antimicrobials appear to be effective for the treatment of LD caused by L. micdadei, L. longbeachae, L. bozemanae, and L. dumoffii (147).

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

Multiple laboratory methods have to be used for optimal laboratory diagnosis of LD. Culture of Legionella bacteria from sputum, lung, or other respiratory specimens is the most specific (100%) method for diagnosis of the disease; it is very sensitive (~80 to 90%) in cases of severe untreated disease and insensitive (~20%) in those with mild disease. Culture may be the only positive diagnostic test, especially when Legionella bacteria other than L. pneumophila are causing the infection. Because of the technical difficulty of culture diagnosis, its expense, and its low sensitivity for nonsevere disease, several alternative diagnostic methods have been developed. The antigennuria assay is more sensitive than culture for the detection of community-acquired disease and especially epidemic disease. Even so, the antigennuria test is only about 60% sensitive under the best of circumstances, performs poorly for detection of nosocomial infection, and detects almost exclusively L. pneumophila serogroup 1. Antibody detection complements other laboratory diagnostic methods but is retrospective, as it requires seroconversion for greater test specificity and sensitivity. In addition, antibody results obtained using only polyvalent antigens must be viewed with circumspection. Molecular amplification tests are highly sensitive, but in the absence of FDA-cleared and marketed tests in the United States, extensive in-lab validation of homebrew assays is required before implementation. The performance of all laboratory diagnostic tests for non-L. pneumophila serogroup 1 LD is unknown but presumably is not as good as it is for the diagnosis of L. pneumophila serogroup 1 disease.

A major hindrance to the evaluation of all laboratory diagnostic methods is the lack of a good gold standard of LD. Culture diagnosis, while very specific, is known to be imperfect and of limited sensitivity, especially for epidemic LD. The performances of the diagnostic tests are often compared to that of culture diagnosis, which tends to overestimate test sensitivity and underestimate specificity.

Positive cultures for all Legionella spp. are virtually diagnostic of LD, providing there are supportive clinical findings, such as pneumonia. In contrast, single serum specimens showing elevated antibodies to Legionella spp. or to L. pneumophila are often not the result of LD. Only increases in titers of antibody to L. pneumophila serogroup 1, a test not usually commercially available, are specific enough for diagnosis, but even then, the use of appropriate techniques is required for optimal specificity. Detection of L. pneumophila serogroup 1 antigennuria is almost as specific as a positive culture, once heat-labile factors capable of causing false-positive tests are excluded. Positive test results must be reported promptly to the patient’s clinician as well as to infection control and public health authorities.

**REFERENCES**

Anaerobic bacteria must be considered etiological agents in a number of clinical syndromes, including aspiration pneumonia, brain abscess, and intra-abdominal infection (1). Infections of prosthetic shoulder joints and corneal implants often involve Propionibacterium acnes (2, 3). Thus, complete diagnostic microbiology laboratories must have protocols in place to detect anaerobes, identify them, and determine their antimicrobial susceptibilities. New technologies such as pyrosequencing and other metagenomic tools are showing that anaerobes are involved in more types of infectious processes than were previously suspected based on culture methods alone, so future laboratory processing must adapt to include more molecular methods (4). Even autism has been associated with anaerobes in the bowel (5). Clostridium difficile has continued to be one of the most important agents of diarrhea for both outpatients and those in health care settings (6, 7). Lemierre’s disease and its agent, Fusobacterium necrophorum, are still an often overlooked but important cause of chronic sore throat (8). New anaerobic species continue to be identified at an increasing rate due to new molecular tools (see the following chapters). This chapter presents an approach to general diagnostic (not research-oriented) anaerobic bacteriology based on the resources and capabilities of laboratories.

Specimen choice, collection, transport, and handling are important activities leading to clinically relevant results involving anaerobes. Because of the presence of anaerobes in all mucous membranes of mammals, specimen collection requires extreme caution to avoid contamination by the resident microbiota. A recently published guideline document contains syndrome-based specimen collection and handling procedures (9). Thus, aspirates, curetting specimens from deep wound tissue, and tissue biopsy specimens are recommended (also see chapter 18).

Respiratory tract samples must be collected to avoid oral and nasal secretions. For example, chronic sinusitis diagnosis requires an aspirate obtained by needle and syringe through the palate or aspirated endoscopically through a protected collector (10). Because transtracheal aspiration is rarely performed today, protected specimen brush samples obtained during endoscopy are the most common acceptable sample for anaerobic culture of lung abscess or other lung infection (11). They must be cultured quantitatively to determine the clinical relevance of isolates. The surgeon should be provided with a freshly boiled tube containing 1 ml chopped-meat broth or anaerobic broth (thioglycolate), into which the brush is dropped after it is cut off the shaft using sterile scissors. This protocol requires notifying the laboratory in advance so that the broth can be supplied to the operating attendants. Once received in the laboratory, the broth can be vortexted and a 0.01-ml calibrated loop can be used to inoculate anaerobic and aerobic media. Potential pathogens are usually present in numbers >1,000 CFU/ml (>10 colonies per plate). Physicians often obtain a percutaneous needle aspiration (also called fine-needle aspiration) through intact skin overlying an area of infiltration in the lung, using radiological guidance (12). These samples contain only the tiniest volume of material and must be ground up (if solid tissue) and/or diluted in anaerobic broth to stretch the sample for inoculation of all necessary media. This process naturally results in lower recovery of pathogens present in small numbers. Throat swabs for detection of F. necrophorum require special consideration (13).

Because of the relative intolerance of anaerobes to atmospheric oxygen, specimens for anaerobic culture must be transported in containers that exclude air. Some types of flocked swabs have been shown to maintain the viability of anaerobes during transport (<24 h), but due to the predilection of swabs to pick up contaminating biota and the very small volume that they absorb, they should be reserved for special cases where no other specimen type can be obtained, such as in cases of brain abscess (14). Incubation of blood in at least one anaerobic blood culture bottle should be part of the standard blood culture protocol (15). Chapter 18 of this Manual, the Wadsworth-KTL Anaerobic Bacteriology Manual (1), and Clinical and Laboratory Standards Institute (CLSI) Document M56-A, Principles and Procedures for Detection of Anaerobes in Clinical Specimens (16), expand on those sites from which anaerobic bacteriology cultures should be performed. Transport devices include small vials with special media and glass beads to break up clumps designed for dental samples (only laboratories with specific expertise should attempt culturing periodontal and other dental infection samples), larger tubes with anaerobic atmosphere and oxygen-absorbing gel to maintain organism viability (Anaerobe Systems, Morgan Hill, CA), sterile tubes for fluids, citrated or EDTA tubes for serosanguinous fluids in danger of clotting, and plain sterile containers for larger tissue samples (17).

For some anaerobic infections, a Gram stain is a critical step in the diagnosis and allows timely clinical management.
Urinary tract infections caused by anaerobic bacteria can be detected first by Gram staining (18). When urinary tract infections persist and routine aerobic cultures are negative, prolonged incubation in 5% CO₂ or anaerobic-medium inoculation should be considered. Molecular analysis of urine has shown previously unsuspected anaerobes in large numbers; these methods may be standard in the future (19). A sputum Gram stain displaying numerous polymorphonuclear leukocytes (PMNs) or degenerating PMNs, rare or no squamous epithelial cells, and mixed morphologies, including small, Gram-positive cocci in chains; fusiform, Gram-negative rods; and Gram-negative cocobacilli, may be the only laboratory test suggesting aspiration pneumonia, as the culture will yield only normal respiratory biota. For serious necrotizing fasciitis, myonecrosis, or clostridial gas gangrene, Gram stains showing rare degenerative PMNs and anaerobic morphotypes (boxcar-shaped, Gram-positive or variable rods, for example) should be supportive evidence that a patient requires emergent surgery. The special syndrome of bacterial vaginosis, indicated by lack of Lactobacillus morphotypes and numerous Gram-variable cocobacilli (see chapter 18 for more information), is best diagnosed by Gram staining. In fact, culture is not recommended. Newer studies using molecular methods have shown that many organisms implicated in bacterial vaginosis cannot be recovered in culture (20, 21).

Finally, C. difficile infection is best diagnosed by toxigenic culture, but given that this method takes too long for clinical impact, molecular detection of the toxin B gene yields the next-best results (22). Poplar enzyme immunoassays for toxins A and B are now known to be unacceptably insensitive and even nonspecific (23, 24). If culture is being done, such as for epidemiological studies or method comparisons, stool should be inoculated both to selective media and to enrichment broth. Taurocholate-containing enrichment broth promotes the growth of anaerobic spores and yields the best recovery (25). Stool can be pretreated by heating at 80°C for 10 min (to select for spores) or, alternatively, by mixing it 1:1 in 95 to 100% ethanol for 1 h (to kill vegetative cells) and then incubated in broth and plated to selective media (1).

Initial anaerobic culture processing should always include Gram staining and, for most specimens, plating to anaerobic blood agar (containing horse or sheep blood, additional hemin, and vitamin K), Bacteroides bile esculin agar, and kanamycin-vancomycin agar with laked sheep blood and an anaerobic broth. Commercial media prepared totally without oxygen exposure has been shown to enhance recovery of some anaerobes (26). If the plates recover organisms, the broth need not be evaluated. However, the broth should be held for up to 14 days in some circumstances, such as for detection of joint infection. As soon as possible after inoculation, media should be placed into an anaerobic atmosphere. Methods such as nitrogen flushing holding jars have been used. Today, smaller incubation containers, such as plastic envelopes, boxes, and shorter jars, and automated gas flushing instruments, e.g., Anaeromat (Mart Microbiology, Drachten, The Netherlands) and Whitley Jar Gassing System (Microbiology International, Frederick, MD), are used to shorten the exposure of plated samples to air (toxic oxygen). Use of an anaerobic chamber for all sample manipulations and incubation is the best method to ensure viability of fastidious anaerobes. If rapid creation of an anaerobic atmosphere is not possible for inoculated plates, it would be better to wait until enough anaerobic samples have been received to fill up one jar and then plate them all at once, closing and gassing the jar as quickly as possible. Jars and boxes should not be opened until after 48 h of incubation to prevent premature death of some slower-growing microorganisms by exposure to air during their logarithmic growth phase. Clostridium perfringens, the agent of gas gangrene, however, grows very quickly and can be identified after overnight incubation. If the clinical situation or initial Gram stain suggests this microbe, it may be prudent to incubate plates individually in plastic anaerobic envelopes (GasPak EZ Anaerobe Pouch System [Becton Dickinson Microbiology Systems, Cockeysville, MD]; AnaeroPack [Mitsubishi Gas Chemical America, Inc., New York, NY]) so that the plates may be examined early (27).

The initial Gram stain will yield preliminary information about the culture. Clinically important information should be telephoned to the physician or caregiver. For some laboratories, this may be the only anaerobic procedure possible. It is better to interpret Gram stains well and report relevant results quickly than to perform inadequate cultures, which will lead to misleading results. Poor specimen handling or transport, exposure to air, lack of good anaerobic media or atmosphere, early opening of incubation chambers, and other factors will result in growth of only the hardest anaerobes, generating incomplete results. As more information becomes available, the use of newer molecular tools may be necessary for complete anaerobic microbiology. Initial examination of colonies should be performed using a stereomicroscope or at least a strong petri-dish magnifying glass. Colony morphologies that appear similar when observed at a distance can be differentiated when magnified, and the presence of tiny colonies near larger ones can be discerned. For culture methods, use the pointed end of a broken sterile wooden stick, touch the tip of a colony, and then touch the colony paste to an anaerobic blood plate, a chocolate agar plate, and a spot on a glass slide. This ensures that the same colony goes onto both plates and the slide. The blood plate should be streaked in quadrants, and special potency disks of 1,000 μg of kanamycin, 5 μg of vancomycin, and 10 μg of colistin can be arranged on the first quadrant. Susceptibility (≥10-mm zone diameter) of the different antibiotics is used to help with further identification (28, 29). The chocolate agar plate is incubated in 5% CO₂ to test a large number of anaerobes in a pie plate format for aerotolerance. Those that grow are not strict anaerobes and can be identified using routine methods. Some organisms can be identified quickly based on colony and Gram stain morphology and a few spot tests; others will require more-extensive methods. The multiparameter anaerobic (and corynebacteria) identification card for the VITEK system (ANC ID card; bioMérieux, Durham, NC) has acceptable performance for common anaerobic genera and would be a good choice for those laboratories without molecular assessment capability (30).

If more-involved phenotypic methods are necessary, available, and warranted by clinical considerations, and when more advanced methods such as matrix-assisted laser desorption ionization–time-of-flight (MALDI-TOF) mass spectrometry and sequencing are not possible, prereduced anaerobically sterilized biochemical agents, gas chromatography, and some newer technologies may be employed. MALDI-TOF has been used to identify anaerobes quickly and inexpensively (after initial purchase of the instrument) (31–33). Commercial MALDI-TOF instruments (MALDI Biotyper, Bruker Daltonics, Billerica, MA; VITEK MS, bioMérieux) are gaining favor for the diagnostic laboratories (34). Sequencing of genetic markers, such as portions of the 16S rRNA gene and other useful genetic elements, is another method used for anaerobic identification today in clinical laboratories with molecular-assessment capability (34). If the filter "bacteria [ORGN] not uncultured [TITL]" is entered in the BLAST field named "Entry Query," the BLAST database search will not be cluttered with uncultured clones.
Modifications such as pyrosequencing are also expected to be useful for anaerobic identifications (35). Chapters 4 and 6 also discuss general principles and the utility of these and other methods. The following chapters of this book (chapters 51 through 54) contain up-to-date taxonomic information, including changes from the last edition.

Susceptibility testing should be performed for clinically important anaerobes. As outlined by several authors, clinically important isolates include those isolated from blood cultures, brain abscess, heart valve or vascular graft tissue, bone biopsy from patients with osteomyelitis, joint aspirations, and isolates from well-collected prosthetic device infection sources. Others to test include likely pathogens from sterile body sites and those from patients who failed initial therapy. An excellent overview of current antimicrobials for anaerobes and testing methods was recently published (36).

The Etest (bioMérieux) has been a method to test individual organisms for many years, but its correlation to reference broth methods is still imperfect; which result best correlates to patient response is not clear (37). Another similar gradient strip method, the M.I.C. Evaluator Device (Thermo Fisher Scientific, Lenexa, KS), has also been evaluated with inconclusive results (38). Other systems include a spiral gradient endpoint system (36). Broth dilution per-sample gradient strip method, the M.I.C. Evaluator Device (bioMérieux) has been a method to test individual organisms for many years, but its correlation to reference broth methods is still imperfect; which result best correlates to patient response is not clear (37). Another similar gradient strip method, the M.I.C. Evaluator Device (Thermo Fisher Scientific, Lenexa, KS), has also been evaluated with inconclusive results (38). Other systems include a spiral gradient endpoint system (36). Broth dilution performed in an anaerobic chamber is also acceptable, but interpretation of results may be difficult and current guidelines recommend its use only for members of the Bacteroides fragilis group (39). The CLSI standard method (agar dilution) is generally not utilized in clinical laboratories, of which only 21% did anaerobic susceptibilities at all in a 2008 survey (39, 40). A European group (EUCAST Subcommittee on Antimicrobial Susceptibility Testing of Anaerobe Bacteria) is also working on protocols.

It is clear that anaerobic bacterial protocols occupy a separate and distinct place in the clinical microbiology laboratory. Laboratories must determine the extent of effort they can devote to anaerobes and then develop their processes to perform only those protocols that they can guarantee will yield reliable, timely, and accurate results. Organisms of importance can always be sent to a reference laboratory for further studies in anaerobic chopped-meat broth or anaerobic transport vials.

Peptostreptococcus, Finegoldia, Anaerococcus, Peptoniphilus, Veillonella, and Other Anaerobic Cocci

YULI SONG AND SYDNEY M. FINEGOLD

51

TAXONOMY

Gram-positive anaerobic cocci (GPAC) are better known to most bacteriologists as peptococci or peptostreptococci. Peptococcus is only remotely related to other species of GPAC and is rarely cultured from human clinical specimens. Peptococcus niger is now the sole remaining representative of this genus. Until recently, most clinical isolates of GPAC were identified as species in the genus Peptostreptococcus; however, data obtained by molecular methods have led to extensive taxonomic changes during the last decades and also to the identification of new genera and species. Since 1998, the genus Peptostreptococcus has been divided into six novel genera (1–3). The type species, Peptostreptococcus anaerobius, and the recently described species Peptostreptococcus stomatis (4) are the only two species in the genus Peptostreptococcus that have been isolated from human specimens. Peptostreptococcus magnus and Peptostreptococcus micros were assigned to two new genera, Finegoldia and Parvimonas, respectively (3, 5). For the remaining peptostreptococci, three genera were proposed: Anaeroceoccus, Peptoniphilus, and Gallicola (1). Anaerococcus has eight species (Anaerococcus hydrogenalis, A. lactolyticus, A. murdochii, A. octavus, A. prevotii, A. tetradius, A. vaginalis, and a newly described species, A. senegalensis [6]); Peptoniphilus has 14 species (P. asaccharolyticus, P. gorbachii, P. harei, P. indolicus, P. ivorii, P. lactimilis, P. Olsenii, and, more recently, P. methioninivorax [7]; P. tyrelliae and P. coxii [8]; and P. duerdenii and P. koenoeniae [9], with P. grossensis [10] and P. timonensis [11] being effectively but not validly described to date). Gallicola contains only one species, Gallicola barnesae, which has not been reported from human specimens. Most recently, two new GPAC genera were described: Mordochiella (12) and Anaerosphaera (13).

Taxonomy of the other GPAC from human clinical specimens has also been under revision. Streptococcus parvulus has been transferred to the genus Atopobium as Atopobium parvulum. Peptostreptococcus productus was reclassified in a newly proposed genus, Blautia, as Blautia producta (14); Peptostreptococcus saccharolyticus has been transferred to the genus Staphylococcus. Table 1 shows the changes in classification of GPAC species.

The Gram-negative anaerobic cocci (GNAC), including the genera Veillonella, Acidaminococcus, Megasphaera, and Anaeroglobus plus the recently described Negativicoccus, have been classified in a single family, the Acidaminococcaceae (15). The genus Veillonella has 13 species, of which only Veillonella alcalescens, V. atypica, V. denticariosi, V. dispar, V. parvula, V. rogosae, and the newly described species V. tobutsuensis have been isolated from human oral cavities (16–19). Besides Veillonella spp., Acidaminococcus fermentans and A. intestini of the genus Acidaminococcus, M. elsdenii and M. micronuciformis of the genus Megasphaera, and A. geminatus of the genus Anaeroglobus have also been isolated from human clinical samples.

DESCRIPTION OF THE GROUP

The organisms included in this chapter are obligately anaerobic non-spore-forming, sometimes elongated cocci. The genera Anaerococcus, Anaerocephaera, Finegoldia, Gallicola, Murochiiella, Parvimonas, Peptococcus, Peptoniphilus, and Peptostreptococcus are Gram-positive, coccolid or occasionally coccoid cells. In Gram-stained preparations of pure cultures, cells vary in size from 0.3 nm to 2.0 nm and can be arranged in pairs, short chains, tetrads, small clusters, or irregular masses; most species are present as either chains or clumps. The ability to utilize carbohydrates varies greatly; some genera are asaccharolytic, but a few are strongly saccharolytic. For most species, the products of protein digestion appear to be the principal energy source. The genus Staphylococcus contains two species, Staphylococcus saccharolyticus and Staphylococcus aureus subsp. anaerobius, which initially grow under anaerobic conditions and become aerotolerant on subcultures. Strictly anaerobic Staphylococcus epidermidis is reported to be occasionally isolated from clinical specimens (20). The genera Veillonella, Acidaminococcus, Megasphaera, Anaeroglobus, and Negativicoccus are Gram-negative cocci. Cells vary in size from 0.3 μm to 2.5 μm. They characteristically occur in pairs, but single cells, masses, or chains may also occur. Carbohydrates are weakly fermented or not fermented. Gas is produced. The metabolic end products are the principal characteristics by which the genera can be differentiated.

EPIDEMIOLOGY

GPAC are part of the commensal microbiota of human mouth, upper respiratory and gastrointestinal tracts, female genitourinary system, and skin (21). Parvimonas micra is
usually considered to be the predominant species of GPAC in the oral flora. The skin flora contains GPAC, with *Finegoldia magna* as the species identified most frequently, followed by *P. asaccharolyticus*. GPAC are opportunistic pathogens and account for approximately one-third of isolated anaerobic bacteria from clinical specimens (21, 22). They can be isolated from a wide variety of sites, of which the dominating are abscesses and infections of the skin and soft tissue, the mouth, bones, and joints, and the upper respiratory and female genital tracts. With increasing studies of GPAC as pathogens, certain species are being associated with specific types of infection. *F. magna* is most commonly associated with infections of the skin and soft tissue and with bone and joint infections. *P. anaerobius* and *A. prevotii* are most common GPAC associated with infections of the abdominal cavity and female urogenitary tract. *Parvimonas micra* is mainly recognized as an oral pathogen.

GNAC form part of the oral, genital, respiratory, and intestinal floras of humans (21). *Veillonella* species are part of the normal mouth and urogenital floras. They are found in the greatest concentrations in saliva and on the surface of the tongue (23, 24). *Veillonella* can also be found in the upper respiratory tract and intestine. Occasionally, *Veillonella* species have been isolated from sites of infection, where they are typically part of a mixed culture. *Acidaminococcus* and *Megasphaera* are part of the intestinal flora but may also be recovered from certain infections.

### CLINICAL SIGNIFICANCE

GPAC are opportunistic pathogens; they can cause various infections involving all areas of the human body, ranging in severity from mild skin abscesses to more serious and life-threatening infections such as brain abscess, epidural abscess, bacteremia, endocarditis, necrotizing pneumonia, and septic abortion. Of all isolated anaerobic bacteria from clinical specimens, GPAC account for approximately 25 to 30% (21, 25). The incidence of anaerobic cocci in pleuropulmonary infections such as lung abscess, necrotizing pneumonia, aspiration pneumonia, and empyema is about 40% (26, 27). Anaerobic cocci are also often isolated from skin and soft tissue infections and a range of chronic and acute wound infections such as anaerobic streptococcal myonecrosis, progressive bacterial synergistic gangrene, necrotizing fasciitis, crepitant cellulitis, chronic burrowing ulcer, and synergistic necrotizing cellulitis (21, 28, 29). These are severe infections, and the mortality rates may be as high as 75%. Other infections in which anaerobic cocci have been recognized as significant pathogens are oral and dental infections, female genital tract infections, and intra-abdominal infections (30–32). GPAC are also involved as pathogens in ocular infections, ear, nose, and throat infections, head and neck infections (including serious neck space infections), meningitis, pericarditis, bone and joint infections (including prosthetic joints), breast abscess, urinary tract infections, and anorectal sepsis with and without anal fistula (33, 34).
Estimation of the clinical significance of anaerobic cocci isolated from clinical specimens is often difficult, partly due to their fastidiousness and thus difficulty to isolate. The polymicrobial nature of GPAC infections, in addition to inadequate classification, has most likely contributed to the neglect of the clinical significance of individual species of GPAC. Molecular methods have led to improved identification of GPAC within various infections and have led to better acknowledgment of the clinical importance of GPAC. For example, La Scola et al. (35) recently identified GPAC in blood cultures and osteoarticular samples using matrix-assisted laser desorption ionization–time of flight mass spectrometry (MALDI-TOF MS) and 16S rRNA gene sequencing. Furthermore, a case of bacteremia caused by *Finegoldia* was also recently reported by Rosenthal et al. (36). Using pyrosequencing, several studies have demonstrated that besides aerobic species, anaerobes including *Peptostreptococcus*, *Finegoldia*, and *Anaerococcus* are prominent colonizers of wound infections (37–41). Another interesting study indicated that when the microbial flora was identified with pyrosequencing for patients with chronic rhinosinusitis, anaerobic genera like *Peptostreptococcus* predominated, in contrast to *Staphylococcus* species, which were detected using traditional methods (42).

Mostly, GPAC are isolated from polymicrobial infections, but in many cases, the organisms are isolated in pure culture; this is the case mainly for *F. magna*, although other species, like *P. anaerobius*, *P. asaccharolyticus*, *P. indolicus*, *P. micra*, *A. vaginalis*, *A. prevotii*, and *P. harei*, also occur (21, 22, 43) in pure culture.

*F. magna* is the most pathogenic and one of the most frequently isolated GPAC species found in human clinical specimens. It has been isolated in pure culture from a wide variety of infections at various body sites. These include cases of endocarditis, meningitis, and pneumonia, some of which have been fatal (44). *F. magna* is most commonly associated with infections of the skin and soft tissue, with bone and joint infections, and with chronic wounds, including diabetic ulcers and pressure ulcers, but it has also been isolated from cases of septic arthritis, prosthetic implant infections, breast abscess, diabetic foot infections, and upper respiratory tract infections, such as sinusitis and otitis media. Using culture-independent methods, *F. magna* was detected from patients with culture-negative endocarditis and prosthetic joint infections (45, 46). More recently, *F. magna* has been implicated in a case of toxic shock syndrome (36). These reports suggest that the overall significance of *F. magna* as a pathogen is underestimated and that more accurate detection and identification of this bacterium might lead to a changed view of the frequency of *F. magna* in relation to certain clinical conditions. Several virulence factors have been described for *F. magna*, such as protein L, peptostreptococcal albumin binding protein (PAB), SufA, and *F. magna* adhesion factor (FAF), as reviewed by Murphy and Frick (22). Recently, whole-genome sequencing furthered the understanding of the pathogenicity of this organism by elucidating both chromosomally encoded and mobile plasmid-mediated virulence factors (47). In a recent study by Donelli et al. (48), *F. magna* was described to have the ability to form biofilm, which could protect it from host immune defense as well as targeted antibiotic therapies.

*P. anaerobius* is involved in polymicrobial infections, including abscess of the brain, ear, jaw, pleural cavity, pelvis, urogenital tract, external genitalia, abdominal regions, nasal septum, and coverage of acute and chronic wound infections (21, 22). It is one of the most common GPAC associated with infections of the abdominal cavity and female urogenital tract (21). The isolation of *P. anaerobius* from endocarditi-
Direct examination of specimens frequently provides the most rapid indication of microbial infection. A variety of microscopic, immunologic, and molecular techniques have been developed for direct examination of GPAC.

Microscopic morphology of the anaerobic cocci is varied. *P. anaerobius* and *B. producta* are large coccobacilli that form chains, especially in broth cultures. Other anaerobic cocci, such as *A. tetradus*, *A. prevotii*, and *F. magnus*, have cells greater than 0.6 µm in diameter in pairs and clusters and may resemble staphylococcal cells. *P. micra* cells are less than 0.7 µm in diameter and occur in packets and short chains; difference in cell size has been used as one characteristic to distinguish *P. micra* and *F. magnus*. Serologic studies have described an indirect fluorescent-antibody test for *P. anaerobius*, *P. micra*, and *B. producta* (59), but such tests have not been developed or commercialized further. Molecular methods, such as nucleic acid probe hybridization and PCR amplification, are not yet standardized or available commercially for the direct demonstration of medically important GPAC from clinical specimens, but the PCR technique has been applied for detection of anaerobic cocci (60–64) for research purposes. Several studies reported using the checkerboard DNA-DNA hybridization method to directly detect microbes from oral clinical samples, including *P. micra* (65–68). Most recently, high-throughput pyrosequencing analysis of 16S rRNA genes has significantly increased our understanding of the microbiological etiology of an infection. For example, pyrosequencing was used to detect GPAC in various wound types, including diabetic foot ulcers, pressure ulcers, infected root canals, and brain abscesses (37–39, 69).

**ISOLATION PROCEDURES**

Routinely used anaerobic plate media, such as brucella, Columbia, or Schaedler agar base supplemented with 5% sheep blood, vitamin K₁, and hemin, support the growth of these microorganisms. The usual procedures for anaerobes should be followed. Many of these organisms require high moisture content for optimal growth, so fresh media should be used. Laboratories unable to prepare their own media may wish to consider the use of commercially prepared, prereduced, anaerobically sterilized blood agar (Anaerobe Systems, USA; bioMérieux, France; HiMedia, India). These media have an extended shelf life, up to 6 months, and yield results comparable to or better than to those obtained with fresh media.

GPAC are heterogeneous; a single medium is unlikely to support the growth of all representatives and be reasonably selective. Wren (70) showed that nalidixic acid-Tween (NAT) blood agar gave better isolation than neomycin blood agar, possibly due to the particularly inhibitory nature of neomycin against GPAC, but recommended that a combination of different media (the best combinations being NAT and neomycin-vancomycin agar or NAT and neomycin blood agar) be used to maximize recovery rates. Turng et al. (71) described *Parvimonas micra* medium, a selective and differential medium for *P. micra* which contains colistin-nalidixic acid agar (Difco, Detroit, MI), a selective base for Gram-positive cocci supplemented with glutathione and lead acetate. Strains of *P. micra* can use the reduced form of glutathione to form hydrogen sulfide, which reacts with lead acetate to form a black precipitate under the colony. Tween 80 supplementation (0.02%) of media may improve growth of some GPAC.

Gutierrez de Ferro et al. (23) tested different media for recovery of *Veillonella* spp. from saliva samples and concluded that a selective medium for *Veillonella* with vancomycin and laked blood gave the greatest recovery of *Veillonella*.

**IDENTIFICATION**

Some GPAC, particularly strains of *P. asaccharolyticus*, decolorize readily with Gram stain and can be confused with Gram-negative anaerobes such as *veillonellae*. GPAC can be distinguished from GNAC by special potency disks (vancomycin, 5 g; kanamycin, 1,000 g; and colistin, 10 g). The cell morphology of older cultures of GPAC can be very irregular, with many coccobacillary and rod-like forms. It is also important to distinguish GPAC from microaerophilic organisms, such as strains of *Streptococcus* species. A simple and reliable test is to apply a 5-g metronidazole disk to the edge of an inoculum; GPAC show a zone of inhibition of 15 mm or greater, whereas microaerophilic strains show no zones after incubation for 48 h (72).

*P. anaerobius* is the only GPAC that gives a zone of inhibition of ≥12 mm around a 5% sodium polyanethol sulfonate (SPS) disk. *Parvimonas micra* also exhibits a zone of inhibition with SPS; however, the zone is usually <12 mm. Most *P. anaerobius* strains form distinctive colonies on enriched blood agar; they are 1 mm in diameter after 24 h and gray with slightly raised off-white centers and a distinctive sweet odor (72). *Parvimonas micra* and *F. magna* can be readily distinguished by a combination of colonial morphology and proteolytic enzyme profiles, supported by Gram-stained cell morphology to assess the cell size. An anaerobic coccus with a milky halo around the colonies and small cells (<0.6 µm) can be presumptively identified as *Parvimonas micra* (72). *F. magna* cells are larger than those of most peptostreptococci. Published data (3) also indicate that they can be differentiated by enzymatic tests for proteolytic activity such as proline arylamidase, phenylalanine arylamidase, and tyrosine arylamidase.

*P. asaccharolyticus* is another GPAC species that was reported to be frequently isolated from human clinical specimens, but studies indicated that most of the clinical strains identified as *P. asaccharolyticus* in the past are *P. harei* (73), which has the same biochemical features as *P. asaccharolyticus* and can be differentiated from *P. asaccharolyticus* only by its irregular colony and cell morphologies. Therefore, the incidence of *P. asaccharolyticus* in clinical material is potentially highly overestimated. Cells of *P. harei* vary considerably in size (diameter, 0.5 to 1.5 µm) and shape (circular, oval, or elliptical), whereas cells of *P. asaccharolyticus* are more uniform. Colonies of 5-day cultures on enriched blood agar are approximately 1 mm in diameter, entire, flat, and translucent.

Similar observations were made for *A. prevotii* and *A. tetradus*, which were reported as common species of GPAC in human clinical material in early surveys. However, nucleic acid studies indicate that they are very heterogeneous. Again, our study based on 16S rRNA gene sequencing indicated that a large percentage of organisms identified as *A. prevotii* or *A. tetradus* are strains of *A. vaginalis* (74). It is likely that strictly defined strains of *A. prevotii* and *A. tetradus* are only occasionally recovered from most clinical specimens. The activity of pyroglutamic acid arylamidase might be useful for differentiation of *A. prevotii* and *A. tetradus*.
tetradus; however, distinctions cannot be generalized because insufficient numbers of strains of each species have been reliably identified. A. prevotii and A. tetradus can be distinguished from other recognized species of GPAC by production of α-glucosidase and β-glucuronidase. Strains of other saccharolytic GPAC, such as A. vaginalis and A. lactolyticus, can be differentiated by their enzyme profiles.

Table 2 summarizes the differential characteristics of GPAC. Based on published data from our group and others (75), we developed a flowchart for rapid identification of GPAC (Fig. 1). The identification is based on phenotypic tests that can be performed in any diagnostic laboratory. Most of the information presented here relates to the phenotypic characteristics of strains isolated from humans.

Several identification systems, such as the Rapid ID 32A (bioMérieux, Marcy L’Etoile, France) and RapID ANA II (Remel, Inc., Lenexa, KS) systems, are available commercially for the rapid identification of anaerobes. Our most recent evaluation of the Rapid ID 32A kit for identification of GPAC by comparison with 16S rRNA gene sequencing identification showed that the system is good for accurate identification of P. micro, P. anaerobius, F. magna, and P. asaccharolyticus but not the others.

Veillonella, Acidaminococcus, and Megaplasma comprise the principal genera of GNAC. The identification of Veillonella at the species level remains uncertain and inconvenient owing to the lack of conventional phenotypic and biochemical discriminating tests. Moreover, serologic tests are no longer available. Table 3 contains a key for differentiating the genera of GNAC (15).

IDENTIFICATION

Molecular Methods

The introduction of molecular-based methods for bacterial identification enabled a real paradigm shift to take place in the early 1990s. 16S rRNA gene-based methods have been used for identifying clinically important GPAC. Monoplex or multiplex PCR, 16S rRNA gene-based methods were developed for rapid identification of clinically significant GPAC isolates from clinical samples (43, 55, 76–79). Lin et al. (80) developed an oligonucleotide array for clinically important anaerobes, including A. prevotii, A. tetradus, F. magna, P. asaccharolyticus, P. anaerobius, and P. micro. Beighton et al. (18) reported using rpoB gene sequencing for identifying Veillonella strains isolated from tongue samples, and subsequently, a simple two-step PCR procedure was developed for the identification of the recognized oral Veillonella species (77).

MALDI-TOF MS

More recently, a second revolution occurred. MALDI-TOF MS was introduced and broadly accepted as a new diagnostic gold standard for microbial species identification. MALDI-TOF MS is utilized for identification of GPAC isolated from clinical specimens (35). By constructing a database using commonly isolated strains of GPAC as a reference, Veloo et al. (81) could identify clinical isolates by MALDI-TOF MS, and results were then compared with those of other identification methods. This method is a rapid and inexpensive alternative to molecular identification that offers equivalent accuracy. Additionally, complete bacterial identification by MALDI-TOF MS is more cost-effective than by conventional methods.

ANTIMICROBIAL SUSCEPTIBILITIES

New information regarding the antimicrobial susceptibilities of individual GNAC is increasing due to the improvement in classification and identification. For example, in a recent study, the susceptibilities of 14 species of 115 GPAC, which were identified using genetic approaches, were determined for 14 antibiotics (82). However, the new information is sparse compared with the information available for other anaerobic species. And it is difficult to compare the new data to other published data because the previous studies failed to give results for specific species, opting instead to combine data for the group.

Antibiotics such as penicillins, clindamycin, and metronidazole are generally considered to be effective against GPAC. However, studies indicate that the susceptibilities are variable between various species (83–87) and should continue to be studied, to monitor a potential increasing resistance of GPAC to antibiotics. Most evidence suggests that P. asaccharolyticus, F. magna, and P. micro are usually susceptible to penicillins, although Wren (70) reported 16% and 8% resistance among isolates of F. magna and P. micro, respectively. In other studies, F. magna showed lower rates of resistance (10 to 20%) to clindamycin, metronidazole, and penicillin and higher rates of resistance (>20%) to erythromycin and tetracycline (70, 84, 85, 88–91), but two other studies reported a higher prevalence of resistance to clindamycin (86, 92). Brazier et al. (84) suggests that A. prevotii is resistant to tetracycline, erythromycin, and clindamycin; the study also found that the highest percentage of overall resistance detected among GPAC was 41.6% resistance to tetracycline, followed by 27.4% resistance to erythromycin. Among GPAC as a group, 7.1% of isolates were resistant to penicillin and clindamycin and 3.5% of isolates were resistant to amoxicillin-clavulanate. Other studies have shown resistance of A. prevotii, isolated from diabetic foot infections, to clindamycin, levofloxacin, and ceftazidime (93, 94). Clinical isolates of A. mardochii (six strains) were reported to be resistant to colistin sulfate, two strains to kanamycin, one to clindamycin, and three showing intermediate resistance to penicillin; in the same study, P. gorbacchi showed resistance to clindamycin (95).

A recent study reported that P. oxii strains were resistant to doxycycline and 29% were resistant to moxifloxacin and clindamycin, whereas all strains of P. tyrelliae were susceptible to doxycycline but resistant to moxifloxacin and 25% were resistant to clindamycin (8). Clindamycin resistance of strains of P. asaccharolyticus and P. micro has also been reported (85, 94, 96). In general, GPAC are more susceptible to β-lactams and β-lactamase inhibitors, cephalexin, carbenemesis, and chloramphenicol (97). Cephalosporins are usually, but not always, effective. Carbapenememesis are extremely active. Several studies (70, 98, 99) indicated that first-generation quinolones, such as ciprofloxacin, have only moderate activity, but more recently developed agents, such as trovafloxacin, clinafloxacin, and Bay y3118, are extremely active (98). Useful references are available regarding the activity against anaerobes for ceftobiprole (93, 100), oritavancin (96), daptomycin (101), dalbavancin (94), tigecycline (102), and linezolid (103). P. anaerobius has also been shown to be extremely susceptible to a new antibiotic, oritavancin, which is being developed for infections caused by vancomycin-susceptible and -resistant organisms (96).

It is worth noting that the resistance rates for P. stomatis and P. anaerobius are different (86). P. anaerobius sensu lato exhibits some resistance to several drugs: amoxicillin,

<sup>a</sup>Data mainly from the work of Murdoch (21) and Song et al. (75); undescribed strains that cluster in whole-cell composition as assessed by pyrolysis mass spectrometry. Abbreviations and symbols: GLC, gas-liquid chromatography; A/a, acetate; B/b, butyrate; IV, isovalerate; IC, isocaproate; C/c, n-caproate; SPS, sodium polyanethol sulfonate; ALP, alkaline phosphatase; ADH, arginine dihydrolase; α-GAL, α-galactosidase; β-GAL, β-galactosidase; α-GLU, α-glucosidase; β-GUR, β-glucuronidase; ArgA, arginine arylamidase (AMD); ProA, proline AMD; PheA, phenylalanine AMD; Leu, leucine AMD; PyrA, pyroglutamyl AMD; ND, not determined; - , >90% negative; w, weakly positive; + , >90% positive; d, different reactions; w, weak positive.
FIGURE 1 Flowchart with key characteristics for identification and differentiation of GPAC. a, SPS test was done using an SPS disk (5% SPS; Anaerobe Systems, Morgan Hill, CA). All GPAC are sensitive to SPS except for P. anaerobius, which gives a zone of inhibition of ≥12 mm around an SPS disk. P. micra also exhibits a zone of inhibition with SPS; however, the zone is usually <12 mm. R, no zone or zone of inhibition is <12 mm; S, zone of inhibition is ≥12 mm. b, All the enzymatic tests were done using Rapid ID 32A systems (API bioMérieux, Marcy l’Etoile, France) according to the manufacturer’s instructions. β-GAL, β-galactosidase; α-GLU, α-glucosidase; β-GUR, β-glucuronidase; ArgA, arginine arylamidase (AMD); ProA, proline AMD; PheA, phenylalanine AMD; PyrA, pyroglutamyl AMD; GGA, glutamyl glutamic acid AMD; ALP, alkaline phosphatase. c, glucose fermentation tests were performed using prereduced, anaerobically sterilized peptone-yeast-glucose (PYG) broth (Anaerobe Systems). A pH of ≤5.5 in the PYG tubes was interpreted as positive and ≥5.9 as negative fermentation. d, described by D. A. Murdoch (21). doi:10.1128/9781555817381.ch51.f1
amoxicillin-clavulanate (3/30 strains resistant), cefoxitin (2/30 strains resistant), azithromycin, and moxifloxacin (1/30 strains resistant). There was no resistance found in 31 strains of *P. stomatis*.

Veillonellae show resistance to tetracycline, erythromycin, gentamicin, and kanamycin, and they are susceptible to penicillin G, cephalothin, and clindamycin. Their resistance is intermediate for chloramphenicol and lincomycin (104).

### EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Because anaerobic bacteriology is time-consuming, several interim reports are desirable. The initial report should give Gram stain results and bacterial and human cell morphologies. The relative quantities of different organisms seen in the smear give a good overall impression of the specimen quality, the nature of the polymicrobial infection, and the relative importance of each organism. In general, bacterial isolates that are predominant, virulent, and resistant to antimicrobial agents should be given the greatest attention. Bacteria present in pure culture or in large numbers are probably of major importance, as are organisms recovered in multiple cultures and isolated from normally sterile sites. Furthermore, Gram stain results can guide the laboratory in choosing media for optimal recovery of the predicted organisms.

The significance of finding anaerobic Gram-positive and Gram-negative cocci in clinical specimens depends on the specimen and the likelihood that it was contaminated by the microflora of the skin or mucous membranes. Hence, interpretation of culture results is dependent on the nature and quality of the specimen submitted to the laboratory.

**Propionibacterium, Lactobacillus, Actinomyces, and Other Non-Spore-Forming Anaerobic Gram-Positive Rods**

VAL HALL AND SARAH D. COPSEY

**TAXONOMY AND DESCRIPTION OF THE AGENTS**

The anaerobic, Gram-positive, non-spore-forming rods are widely distributed in two Gram-positive phyla: Actinobacteria and Firmicutes (Table 1).

**Phylum Actinobacteria**

The genus Actinomyces and the related clinically relevant genera Actinobaculum, Mobiluncus, and Varibaculum contain anaerobic and aerotolerant, non-acid-fast, Gram-positive organisms with variable morphology, ranging from characteristic branching rods to cocccobacilli. The genus Actinomyces currently comprises 41 species, of which 24 have been isolated from human sources. The species epithet A. naeslundii now applies only to isolates previously termed "A. naeslundii genospecies 1," while the novel species A. oris and A. johnsonii accommodate the former "A. naeslundii genospecies 2" and "genospecies WVA 963," respectively (1). The majority of species produce succinic acid from glucose. The genus Actinobaculum includes the human-associated species A. massiliense, A. schaalii, and A. urealyticum (2–4). The genus Mobiluncus contains two species, M. curtisii and M. mullieri, which are strictly anaerobic, curved bacilli with variable Gram reactions and corkscrew motility. They resemble Actinomyces in that succinic acid is the major metabolic end product from glucose. Varibaculum, currently comprising only V. camerensiense (5), is related to Mobiluncus on the basis of 16S rRNA gene sequence analysis, as is Actinomyces neuii, which is distantely related to Actinomyces sense stricto and would appear to be worthy of proposal as a novel genus (6).

Propionibacterium species are anaerobic and aerotolerant, pleomorphic, Gram-positive rods that produce propionic acid from glucose. Five Propionibacterium species have been isolated from human clinical infections: P. acnes, P. avidum, P. granulosum, P. propionicum, and P. acidipaciens (7). A related species, Propionimicrobium lymphophilum, formerly a member of Propionibacterium, has also been isolated from clinical material, while Propionirox lacus is a member of the normal skin microbiota (8, 9).

Members of the genus Bifidobacterium and the closely related genera Alloccoccus (10), Parascardovia, and Scar- dovia (11) are strictly anaerobic or occasionally microaerobic, Gram-positive, pleomorphic rods, appearing as uniform to branched or club shaped. Typically, bifidobacteria produce fructose-6-phosphate phosphoketolase as well as acetic and lactic acids as major metabolic end products. Bifidobacteria are acidophilic and are nutritionally fastidious. There are currently 41 Bifidobacterium species. Of these, 11 species have been isolated from the human gut and oral cavity. B. longum now includes the former species B. infantis and B. suis as subspecies (12, 13).

Numerous taxa have been misassigned to Lactococcus in the past, including the so-called "anaerobic lactobacilli," which are now recognized to constitute two genera, Atopobium and Olsenella, within the family Coriobacteriaceae (14, 15). The Atopobium species A. minuta and A. rima (both formerly Lactobacillus species), A. parvulum (formerly Streptococcus), and A. lacticum (formerly Eubacterium) produce lactic acid as the major glucose metabolic end product (14, 16). The genus Olsenella is closely related to Atopobium and currently includes two species isolated from the human oral cavity: O. uli (formerly Lactobacillus uli) and O. profusa (15, 17).

The genus Eggerthella (18) includes the human pathogens E. lenta and E. sinensis, while the former E. hongkongensis has been moved to the new genus Parasaccattella (19). Other members of the Coriobacteriaceae found in human infections include the genera Collinsella (20), Slackia (18), and Cryptobacterium (21), while the genera Adlercreutzia and Gordoniobacter have been isolated recently from feces and the colon, respectively (19, 22, 23).

**Phylum Firmicutes**

Lactobacillus, a large and heterogeneous genus, contains microaerobic, catalase-negative, non-spore-forming, Gram-positive rods, which produce lactic acid as their single or major metabolic end product from glucose fermentation. The majority of Lactobacillus species are found within the family Lactobacillaceae and order Lactobacillales. However, Catenbacterium mituokai (24), isolated from human feces, forms a cluster with Kandleria vitulina and Eggertia cate naformis (formerly Lactobacillus vitulinus and Lactobacillus

cataforma, respectively) within the family Erysipelotrichaceae (23, 26).

Organisms assigned to Eubacterium are defined by default; they do not produce propionic acid as a major acid product, lactic acid as the sole major acid product, succinic and lactic acids with small amounts of acetic or formic acids, or acetic and lactic (acetic > lactic) acids, with or without formic acid, as the sole major acid products (27). Due to the number of phylogenetically distinct species within this genus, reclassification of a large number of species is ongoing either to novel genera or to existing ones based on 16S rRNA phylogeny and phenotypic characteristics. It has been proposed that Eubacterium sensu stricto should be restricted to E. limosum, E. callenderi, and E. barkeri (28). Using this definition, the family Eubacteriaceae then includes the genera Eubacterium sensu stricto; Anaerofastis (with one species, A. stercoromininis, isolated from human feces) (29); and Pseudoramibacter alactolyticus, a saccharolytic species found in the oral cavity of humans (28). The Eubacterium species E. biforme, E. cylindroides, and E. dolichum fall within the family Erysipelotrichaceae mentioned above, together with the Eubacterium family Bulleidia extructa, isolated from the human mouth (30), and Holdemania filiformis (31) and Solobacterium moorei (16), isolated from human feces. Turenibacter sanguinis, isolated from a blood culture (32), also belongs to this family (25).

The Eubacterium species E. infravium, E. minutum, E. nodatum, E. sphenenum, and E. sulci (formerly Fusobacterium sulci), together with Mogibacterium, a genus of five species that are difficult to differentiate by phenotypic tests (33, 34), are a group of asaccharolytic taxa isolated from the human mouth. Many Eubacterium species are closely related to clostridia. Phylogenetic analysis indicates that the taxonomic importance of spore formation as a criterion for assignation to the genus Clostridium may have been overemphasized. Numerous phylogenetic clusters contain both sporulating and nonsporulating representatives. The Eubacterium species E. budayi, E. moniliforme, and E. nitrigenes are found in clostridial cluster 1 described by Collins et al. (35), while E. straeum belongs to a group that includes Clostridium leptum and Anaerovorans colligens (36). E. tenue and E. yurii belong to cluster XI. E. tenue is related to Clostridium ghonii and Clostridium sordellii; further work is required to determine whether these species constitute a novel genus. Strains of Eubacterium plautii and Clostridium orbiscindens have been shown to belong to the same taxon and renamed Flavonifractor plautii (37). E. yurii is related to the genus Filifactor, which includes Filifactor alocis (formerly Fusobacterium alocis), isolated from oral infections in humans (38). E. contortum, E. eligens, E. hallii, E. ramulus, E. rectale, E. ventriosum, and Lachnospiraceae clostridium subsp. subterminum (formerly E. saburreum) (39) belong to the family Lachnospiraceae. E. rectale and E. ramulus are related to Roseburia intestinalis (40). This family also includes the recently described formate-requiring species Marvinbryantii (formerly Bryantella) formatexigenes (41, 42), isolated from human feces without any disease association so far, and Oribacterium sinus (43), a highly motile species isolated from pus of a human sinus. E. eligens and Lachnospira pectinoschiza are close phylogenetic neighbors and are both motile rods whose growth in broth culture is stimulated by the presence of fermentable carbohydrates. E. eligens should therefore be transferred to the genus Lachnospira. Anaerostipes cacciae (44) and Anaerostipes hadrus (formerly Eubacterium hadrum) (45) form a loose group with E. hallii and Coprococcus eutactus, all common species in human feces. “Catabacter hongkongensis” is a deep-branching member of the order Clostridiales, isolated from blood cultures and associated with high mortality (46, 47), but as yet has not been validly published.

**EPIDEMIOLOGY AND TRANSMISSION**

The majority of the organisms described in this chapter are part of the commensal microbiota associated with the mucocutaneous surfaces of the human and animal digestive tract, being found in the mouth, small and large intestines, urogenital tract, and skin (48–52). Microbial colonization of an individual occurs in a successive manner during the first weeks and months of life. Actinomyces species are among the initial colonizers of the mouth (53), whereas bifidobacteria and lactobacilli play an important role in the development of the healthy gut and its associated immune defenses (54, 55). Where members of this group cause infections, the host itself is the most likely source, although the commensal microbiota of other humans can be responsible, for example, in the case of infections resulting from human bites or clenched fist injuries from striking the face and mouth (36).

**CLINICAL SIGNIFICANCE**

Non-spore-forming, anaerobic, Gram-positive rods seldom cause infections alone but are typically found in polymicrobial infections associated with mucosal surfaces (Table 2). Many anaerobes involved in infections of the head and neck originate from the oral cavity, whereas most vaginal and bladder pathogens are of fecal origin. In intra-abdominal infections due to organ perforation, the predominant recoveries reflect the microbiota at the site of the leakage (57). For surgical patients, anaerobes are a significant cause of morbidity and mortality (58). Anaerobic bacteria can occasionally spread to adjacent tissues and the bloodstream, with serious consequences. For anaerobic bacteremias, the gastrointestinal tract is the most common source, followed by abscesses, gynecologic infections, and wound infections (59). The incidence and range of anaerobic, Gram-positive rods found in blood cultures may be underestimated because many of them are slow growing and have fastidious nutritional requirements. Anaerobic blood culture methods tend to be targeted at Clostridium species and Bacteroides fragilis, which grow readily and rapidly in commonly used broth media.

**Actinomyces and Related Bacteria**

Actinomyces and related bacteria are associated with a wide range of infections, normally as part of a polymicrobial consortium (Table 2) (60). Actinomycosis is a chronic, granulomatous infection affecting the cervicofacial, pulmonary, and abdominopelvic regions and is caused primarily by Actinomyces species, particularly A. israelii, A. gerencseriae, and A. graevenitzii, and P. propionicum (61, 62). Actinomyces organisms make up a significant proportion of the microbiota in dental plaque in healthy individuals but are also associated with a wide range of dental and oral infections, including dental caries, endodontic infections, odontogenic abscesses, and dental implant-associated infections (63–70). Cervicofacial lesions normally arise as a consequence of untreated dental caries or are associated with dental extractions or trauma. These allow the causative organisms, which are part of the oral commensal biota, to enter the tissues (71). Although actinomycoses are regarded as the primary cause and form the characteristic aggregates of branching rods seen macroscopically as sulfur granules, there are always multiple species present, with Aggregatibacter actino-
Actinomyces species have also been implicated in infected osteoradionecrosis.

</table>

Actinomyces and Mycobacterium tuberculosis or malignancy on initial examination. Actinomyces meyeri has been shown to have a predilection for causing pulmonary actinomycosis, and dissemination to other organs has also been observed (82, 83). In a study in which anaerobic culture methods were used on sputum samples from adult cystic fibrosis patients, Actinomyces species were frequently isolated (84).

The majority of pelvic infections are found in women using intrauterine contraceptive devices (85), and abdominal infection normally arises following perforation of the bowel as a result of disease or surgery (86). A number of Actinomyces species, especially A. israelii and A. turicensis but also A. cardiffensis, A. gercenzeriae, A. naeslundii, A. odontolyticus, and A. uracinalis, as well as V. cameliense, have been isolated from intrauterine device-associated infections (5, 87-90). The most frequently isolated Actinomyces species from clinical infections are A. turicensis, A. radingae, and A. meyeri.
A. timonensis are also isolated from similar soft tissue infections and are found in a range of soft tissue infections. In addition, A. naeslundii and A. israelii have been isolated from infected hip prostheses (92, 93). Pericarditis cases caused by A. israelii and A. meyeri have been reported (94). Due to the small numbers of human clinical isolates reported to date, the natural habitats and clinical associations of A. dentalis, A. hominis, A. hongkongensis, A. nascolia, A. oricola, and A. radicidentis have yet to be determined.

Actinobaculum spp. are strongly associated with complex urinary tract infections. Increasing evidence suggests that A. schaalii is an underestimated emerging uropathogen, which has also been implicated in invasive infections such as bacteremia, endocarditis, cellulitis, and spondylodiscitis (95–98). A. massilense is also associated with soft tissue abscesses (99).

Propionibacterium

Propionibacteria can be found in various systemic or disseminated opportunistic infections (Table 2), such as endocarditis, central nervous system infections, osteomyelitis, osteitis, and arthritis (100–102), and in about 20% of infected dog and cat bite wounds (103).

Because P. acnes is a member of the normal skin microbiota, it is frequently discarded as a contaminant or as clinically insignificant, particularly when isolated from the blood (104). However, the pathogenic potential of P. acnes should not be underestimated when there are predisposing factors present, such as a foreign body, surgery or trauma, diabetes, or immunosuppression (102, 105–109). Recently, mounting evidence has implicated P. acnes as an important pathogen in not only acne vulgaris, but also endocarditis and prosthetic joint infections, and it also has potential roles in prostate cancer and sarcoidosis (110, 111).

One-third of cases of P. acnes endocarditis are complicated by intracardiac abscess formation, potentially as a result of delayed treatment due to the initial isolation of P. acnes being deemed insignificant (112). Prosthetic joints are particularly susceptible to P. acnes infection (113, 114), and biofilm formation appears to be a specific virulence factor associated with invasive strains (115). Controversy remains regarding the optimum incubation time required to recover P. acnes from joint infections with suitable sensitivity and specificity for a confident diagnosis. Extended incubation of aspirates and tissue has been suggested; however, this may also increase the potential for false-positive results (116). P. acnes has also been included as part of the mixed bacterial community found in the sputum of adult cystic fibrosis patients (84).

P. propionicum is part of the normal oral microbiota and causes oral and eye infections (70, 117, 118) as well as actinomycosis, in which it displays a spectrum of pathogenicity similar to those of A. israelii and A. gerencseriae (61). P. acidifaciens is particularly associated with dental caries (7).

Lactobacillus

Despite the reputation of lactobacilli as beneficial organisms, they can be involved in serious infections (Table 2), especially in immunocompromised individuals (100, 119–123). The Lactobacillus species most frequently isolated from various human infections are L. rhamnosus, L. casei, L. fermentum, L. gasseri, L. plantarum, L. acidophilus, and L. ultunensis (120, 123, 124). Lactobacilli are particularly associated with advanced dental caries (68, 118, 124), where they are considered a secondary colonizer because of their preference for low-pH habitats, but probably play a role in exacerbating existing lesions (125). The clinical infections most commonly caused by lactobacilli are bacteremia and endocarditis, with an associated relatively high mortality rate (120), with the mouth the primary route of entry to the bloodstream, either as a result of normal chewing and brushing or following dental procedures (120). Detection of lactobacilli, alone or with other microorganisms, in blood cultures of patients with underlying diseases may be clinically significant. L. rhamnosus was the most frequent species detected in Lactobacillus bacteremia and endocarditis (104, 120, 121, 123, 126). Concern has been expressed that probiotic strains consumed in foodstuffs may cause disease in some individuals. Although such reports are rare (127), there have been reports of sepsis and endocarditis attributed to probiotic Lactobacillus strains (128, 129). In some cases, these have been attributed to inappropriate dosages and routes of administration, and it should be remembered that organisms used as probiotics are defined at the strain level and that, although infections may be caused by other strains within the same species, this does not imply that probiotic strains are unsafe. Vancomycin-resistant lactobacilli have been implicated in dialysis-related peritonitis after extended use of glycopeptides (122, 130).

Pyrosequencing has demonstrated that a limited number of Lactobacillus spp. (L. crispatus, L. gasseri, L. jensenii, and L. iners) are responsible for sustaining the normal vaginal bionetwork (131). The depletion of these Lactobacillus spp. from the vaginal microbiota is considered one of the characteristic features of bacterial vaginosis. In contrast to other Lactobacillus species, L. iners has been associated with an intermediate state of bacterial vaginosis (131, 132).

Eubacterium and Related Bacteria

The genus Eubacterium remains poorly defined, but species belonging to this genus and its relatives in the phylum Firmicutes are commonly isolated from oral infections (Table 2), particularly when nutrient-rich media and extended incubation times are used. For example, careful isolation of tiny-colony-forming anaerobes from periodontal pockets in adult patients with advanced periodontitis showed that “Eubacterium” species (mainly asaccharolytic) dominated (133), suggesting a role in the etiology of chronic periodontitis. When molecular identification methods were applied to a collection of Eubacterium-like strains from oral infections, Mogibacterium timidum was one of the most frequently detected species (134). Mogibacterium vescum, B. extructa, F. alocis, and P. alactolyticus were also found among the isolates from severe (some of them requiring treatment in intensive care units) odontogenic infections. Less frequently isolated were E. sulci, E. yurii, and L. saburreum (134). Many species found in odontogenic infections are also common in endodontic infections (70, 135–137). F. alocis, E. nodatum, E. sphenum, and M. timidum have been associated with periodontal diseases (138–142), and “Eubacterium” species in general with failing dental implants (143). Due to their presence in the oral cavity, various Eubacterium and related species are among the anaerobic findings in human bite wound infections (103). Filifactor villosus, a species of animal origin, has been isolated from infected cat bite wounds in humans (144).

Recently, a number of species have been identified as the etiological agents in nondental infections: Shuttleworthia satelles in a case of endocarditis (145) and B. extructa from a periprosthetic hip infection (146). S. moorei and Robin-
*Eggerthella* and Related Bacteria

Species of the genera *Eggerthella* and *Paraeggerthella* are recovered from a wide range of human infections (Table 2). *E. lenta* (formerly *Eubacterium lentum*) is a well-recognized pathogen particularly of intra- and periabdominal sites (100, 104, 119, 154). *E. lenta*, *E. sinensis*, and *P. hongkongensis* have been found in blood in association with clinically significant infections of relatively high mortality (104, 155). *Cryptobacterium curtum* and *Slackia exigua* have been associated with chronic periodontitis (138, 140). The latter has also been associated with endodontic infections (136) and polymicrobial wound and abscess infections thought to be of intestinal origin (156). An as yet unnamed, *Eggerthella*-like taxon is positively associated with bacterial vaginosis (131, 157).

**Atopobium**
