Several species of the genus *Atopobium* are isolated from various infections (Table 2). Although *A. vaginae* is a prominent member of the commensal microbiota of the healthy vagina (158, 159), it has been increasingly reported to be involved in infections of the genital tract. A strong association between *A. vaginae* and bacterial vaginosis has been reported in several studies. The presence of this organism or *Gardnerella vaginalis* combined with the depletion of *Lactobacillus* spp. is being proposed as an accurate predictor of bacterial vaginosis (131, 132, 160–164). *A. minuta* has been isolated from various infections of the lower part of the body, and *A. parvulum* has been isolated from respiratory specimens (165). Although *A. parvulum* and *A. rimae* have been detected in the pockets formed as a result of periodontitis (142, 165), in a comprehensive study of the microbiota of the subgingival region, these species were found to be associated with oral health rather than disease (140). Among *Eubacterium*-like isolates from severe odontogenic infections, *A. rimae* was the most frequently isolated (134).

**Olsenella**

Olsenella species show disease associations similar to those observed for lactobacilli in the oral cavity and have been found in root caries (166), with *O. profusa* specifically detected in dental caries lesions (68), and *O. ali*, in particular, in endodontic infections (118, 167–169) and acute dental abscesses (169). Both species can also be found in subgingival sites of periodontitis patients (15, 165). In addition, *O. ali* has been reported as one of the causative organisms in clinically significant bacteremia (104).

**Bifidobacterium and Related Bacteria**

Culture-independent analyses have shown that although members of the phyla *Bacteroidetes* and *Firmicutes* dominate the gut microbiota numerically, bifidobacteria appear to be functionally of great importance to intestinal health (170). Because of this, they are generally considered to be nonpathogenic but nevertheless are isolated from infections of polymicrobial etiology (Table 2). Dental caries is the most common clinical entity in which *Bifidobacterium*, mainly *B. lentum*, and the related species *Parabifidobacterium denticolens*, *Scardovia inopinata*, and *Scardovia wiggsiae* (formerly known as *Scardovia* species Cl) may have a pathogenic role (118, 171–174). *B. adolescentis*, *B. dentium*, *B. breve*, and *B. longum* are occasionally isolated from other infections, mainly in immunocompromised individuals (94, 100, 119, 175). Although *B. scardovii* has been isolated from human clinical samples, including blood, urine, and hip (176), its clinical relevance is not known. In addition, a novel species related to *Bifidobacterium*, *Alloscardovia omnicolens*, has been detected in infections at various body sites, including urine and the genitourinary tract, in particular, and the oral cavity, tonsils, lung and aortic abscesses, abdominal wounds, and blood (175).

**Mobuluncus**

The presence of vibrio-like *Mobuluncus* species in smears of vaginal fluid has been widely used as one of the indicators of bacterial vaginosis (177). Indeed, *M. curtisi* is seldom present in the vaginas of healthy women but, instead, is highly associated with bacterial vaginosis and its treatment failure due to persistence of the organism (178, 179). The altered vaginal microbial ecology seen in bacterial vaginosis can be a risk for adverse pregnancy outcome when ascending to the upper genital tract (180). In addition to bacterial vaginosis, *M. curtisi* has been isolated occasionally from endometrial smears and pus specimens of the female genital tract (181) and from blood (182, 183).

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

Many of the organisms described in this chapter are part of the human commensal microbiota and cause disease as opportunistic pathogens. This makes specimen collection difficult because at most sites of infection, the local commensal microbiota is close by. Thus, appropriate and careful specimen collection is critical to avoid contamination of the specimen with the commensal microbiota. Anaerobic transport techniques are also essential for the successful recovery of clinically significant anaerobic bacteria (see chapters 18 and 50). Specimens suitable for the isolation of non-spore-forming, Gram-positive, anaerobic rods include aseptically collected peripheral blood, tissue biopsy specimens, aspirates (e.g., cerebrospinal fluid, joint fluids, and pus), root canal exudates, and subgingival plaque. Mucosal or cutaneous swabs are not recommended for the reasons mentioned above. Instead of collecting periosthetic tissue, sonication of the removed implant followed by sonicate fluid culture has proven to be useful for microbiologic diagnosis of prosthetic joint infection (114, 184).

**DIRECT EXAMINATION**

Direct examination is of unequivocal value in the confirmation of a diagnosis of actinomycosis. The macroscopic presence of “sulfur granules” in pus, which when crushed, Gram stained, and viewed under the microscope reveal a mass of Gram-positive, branching filaments, is characteristic of this disease. Similarly, in cervical smears of women with an intrauterine contraceptive device, the presence of branching, Gram-positive organisms suggests an infection with *Actinomyces* (91, 185). Gram stains of vaginal smears have been considered more useful than culture for laboratory confirmation of bacterial vaginosis, and the diagnostic crite-
ria for this common infection have been based on the standardized Nugent scoring system (177).

In cases in which there is no typical microbiota associated with a particular infection, care should be taken in determining appropriate empiric antimicrobial treatment on the basis of the Gram stain. For example, branching/fastidious rods can be tentatively identified as facultatively anaerobic Actinomyces or strictly anaerobic E. nodatum (152), and the coccoid cells of A. radicidentis are atypical for the genus Actinomyces (65), while easily decolorizing species (e.g., Eubacterium-like species) can yield a false Gram-negative reaction (134). The misinterpretation can lead to antimicrobial coverage targeted against facultative organisms instead of anaerobes and/or Gram-negative bacteria.

**ISOLATION PROCEDURES**

Specimens should be processed without delay using appropriate culture media, including standard anaerobic blood agar enriched with hemin and vitamin K$_1$ and a variety of selective media based on the expected microbiota at the collection site or, in the case of bite wounds, on the oral microbiota of the attacker (human or animal). Fresh or prereduced culture media, including phenylethanol alcohol blood agar and/or colistin-nalidixic acid blood agar, can be useful for enhanced recovery rates of Gram-positive organisms (186). The growth of many acascharyotic species on solid media is enhanced by the addition of 0.5% arginine (187). In general, members of the aciduric genera Bifidobacterium and Lactobacillus can be selectively cultured using agar media with an acidic pH, such as Rogosa or de Man, Rogosa Sharpe agar. However, some nutritionally fastidious Lactobacillus strains fail to grow on these agar media. Lactobacilli isolated from dental caries were recovered equally well on nonselective blood-containing media and on Rogosa agar, and it was concluded that acidic-pH medium is not required for their detection (167). Notably, L. iners, one of the predominant lactobacilli in the vagina, can grow only on blood agar and not on typical solid media used for Lactobacillus (188).

Although some members of this group, particularly Actinomyces species, are facultative anaerobes and can grow well on aerobically incubated culture media, anaerobic incubation is recommended for optimal recovery. If anaerobic jars are used for incubation, anaerobic growth should not be exposed to oxygen by opening the jar before 48 h of incubation, in order to facilitate the detection of slow-growing, oxygen-sensitive organisms (186). The availability of an anaerobic chamber may enable examination of the culture whenever necessary. For reliable detection of slow-growing organisms, the incubation time should be sufficient; for instance, an extended incubation period may be needed for some clinically relevant Actinomyces spp. and Eubacterium-like species (21, 33, 133, 134, 133). In heart tissue specimens from endocarditis patients, grinding the tissue can improve the detection of anaerobic bacteria (77, 99). A lytic anaerobic medium can increase the recovery rate of anaerobes and facultative bacteria in automated blood culture systems (189).

Growth of S. wittigae on Fastidious Anaerobe Agar (Oxoid Ltd., Basingstoke, United Kingdom) may be enhanced by close proximity to other organisms such as Staphylococcus aureus (V. Hall, unpublished data). The viability of T. sanguinis is extremely difficult to maintain in vitro in solid or liquid media and under usually adequate freezing regimens (32; Hall, unpublished).

**IDENTIFICATION**

Traditionally, the identification of bacterial isolates in clinical microbiology laboratories is performed by phenotypic tests. For organisms inert in most conventional biochemical tests or with unusual biochemical profiles, as is the case for many Eubacterium and related species, or in cases where fastidious organisms require specific nutrients or temperatures, identification strategies based on phenotypic characteristics can be challenging. Some Actinobacteria are poorly differentiated in phenotypic tests available to clinical laboratories. In these cases, additional testing is required to achieve identification to the species level. This may include gas-liquid chromatography (GLC), a technique that has now been largely superseded by DNA sequence analysis and/or matrix-assisted laser desorption ionization-time-of-flight mass spectrometry (MALDI-TOF MS).

**Presumptive Identification**

The initial differentiation is based on aerotolerance (growth in air or in air plus 5% CO$_2$), colonial morphology, pigmentation, fluorescence under long-wave UV illumination (365-nm wavelength), and presence of hemolysis. Colony morphology may provide clues regarding the organism involved; for instance, a "molar tooth" appearance is typical for A. israelii, A. gerencseriae, A. nasoV, A. oris, P. propionicum, S. wittigae, and E. nodatum. A. graevenitzii may produce both molar-toothed and smooth, entire colonies (186). However, the majority of species discussed in this chapter produce small, relatively nondescript colonies. Other rapidly recognizable features are fluorescence and/or pigment production: A. graevenitzii, P. propionicum, and E. lentum show orange or red fluorescence under UV light (117, 190); Hall, unpublished), and pink/red pigmentation of colonies is typical for A. odontolyticus, but some other Actinomyces spp. can also produce pigment, especially on rabbit blood agar, with A. graevenitzii appearing as nearly black, A. radicidentis as brown, and A. urogenitalis as reddish colonies (53, 191).

Gram stain morphology can contribute to a presumptive identification; it can show whether organisms are Gram-positive, anaerobic rods, which can be very short (e.g., C. cartum and E. lentum), long (e.g., many Lactobacillus spp.), pleomorphic (e.g., Bifidobacterium), branching (e.g., many Actinomyces spp.), or curved and motile (e.g., Mobiluncus spp.); sometimes a specific cell morphology can be seen, such as "flying birds" (e.g., P. alactolyticus) and the almost ring-shaped V. cambriense (5). The morphology may vary when cells are grown on different culture media. The two Mobiluncus species can be tentatively separated based on the length of the curved, motile cells: in contrast to the short, Gram-variable cells of M. curtum, M. mulleri is reveals clearly longer cells, which often appear as Gram negative (192). Although Actinomyces organisms have been traditionally described as branching rods, many new species within the genus are nonbranching, and some have very short or even coccolid cells (65, 193). Staining of cells can vary with different culture conditions. Certain Gram-positive anaerobes, e.g., F. alocis and M. mulleri, routinely stain Gram negative, whereas older cultures (>3 days) of Actinobaculum and some Eubacterium species and species of related genera are Gram variable (4, 21, 34). Decolorization of Gram-positive organisms may be due to exposure to oxygen or to damage from fixatives and reagents causing a breakdown of the physical integrity of the cell wall; therefore, anaerobic working conditions or, if not available, limited exposure time to oxygen between incubation and staining improves the reliability of the Gram stain for anaerobic bacteria (194). For rapid confirmation of the Gram reaction,
a simple test based on dissolution of the Gram-negative cell wall and cytoplasmic membrane with a solution of 3% potassium hydroxide (195) can be used: when suspended in the solution, Gram-negative cells display increased viscosity and stringing within 30 s, whereas the absence of stringing, i.e., a negative reaction, suggests that the isolate is Gram-positive. Routine screening of special-potency antibiotic susceptibility disk patterns is valuable in confirming the accuracy of the Gram stain reaction (196): Gram-positive species are generally resistant to colistin (10 μg) and susceptible to vancomycin (5 μg) and often to kanamycin (1 mg). However, the intrinsic resistance of some Lactobacillus species/strains, e.g., *L. rhamnosus*, to glycopeptides should be considered (121, 122, 130), in addition to the intrinsic resistance of *Bifidobacterium* to aminoglycosides (197). *H. filiformis* has been reported to be resistant to vancomycin (31).

Additional rapid tests for initial grouping of non-spore-forming, Gram-positive anaerobes include testing for production of catalase (H₂O₂) at a concentration of 15% and indole, nitrate reduction, and motility (186). If presumptive identification to the genus level has been made correctly, this may give valuable information to clinicians in deciding the initial treatment. However, differentiating members of the “normal flora” or normal microbiota of human skin and mucous membranes from pathogenic, non-spore-forming, Gram-positive rods can be difficult. Identification of non-spore-forming, Gram-positive rods to the species level should be performed whenever they are present in pure cultures in clinical specimens or as the predominant organism from normally sterile sites; otherwise, the potential pathogenicity of these less often suspected species may remain undetected.

### Biochemical Testing

For a more advanced phenotypic classification of anaerobic organisms and distinguishing of individual species, sugar fermentation reactions, preferably using preduced, anaerobically sterilized carbohydrates, and enzyme profiles with individual diagnostic tablets, fluorogenic substrate tests, or preformed enzyme kits must be determined. Insufficient growth or poor reproducibility of reactions can cause difficulties in interpretation of results obtained with biochemical tests; therefore, young cultures and heavy inoculum should be used (198).

A well-designed selection of key tests provides a tentative identification of various isolates to the species level prior to confirming their identifications by more definitive methods. Table 3 presents some biochemical characteristics of *Actinomyces* and related organisms. Since the description of many novel species, such as *A. dentalis*, *A. hongkongensis*, *A. massiliensis*, *A. nasicola*, *A. oricola*, *A. urinale*, and “*Actinobaculum massilae*,” is based on a single strain (2, 3, 66, 67, 79, 199, 200), discrepancies in test reactions may appear. In addition, the clarification of the taxonomy of the *A. naeslundii/Actinomyces viscosus* group, while taxonomically valuable and consistent with their ecology, has resulted in a group of species that cannot be differentiated by phenotypic tests alone. Housekeeping gene sequence analysis is required but may be beyond the scope of routine laboratories. Table 4 presents simple enzymatic reactions useful in distinguishing propionibacteria encountered in human infections, and Table 5 shows tests for *Atopobium* and *Olsenella* species. Although the cultivation and identification of *Eubacterium*-like species can be very laborious, not only because of their oxygen sensitivity and slow growth but also due to their nonreactivity in conventional biochemical testing, some simple reactions are helpful for grouping these organisms (Table 6).

In culture-based identification of anaerobic, non-spore-forming, Gram-positive rods, the determination of major volatile fatty acid end products of glucose metabolism, as detected by GLC, is useful for assigning isolates to the genus level (Table 1). Typically, *Actinomyces* strains produce succinic and lactic acids as their major metabolic end products, but *A. dentalis* is reported not to produce succinic acid (67). The *Actinomyces*-like *Propionibacterium* species, *P. propionicum*, is easily separated from *Actinomyces* based on its production of propionic acid (201). For *Lactobacillus* spp., defining characteristics are their ability to grow in acid media and ferment carbohydrates to produce lactic acid as the major end product with acetate production, whereas *Bifidobacterium* spp. produce acetic acid as a major product.

Preformed enzyme and carbohydrate fermentation profiles can be obtained using commercially available identification test kits, such as the API Rapid ID 32A (bioMérieux, Marcy-l’Etoile, France), RapID (Remel, Lenexa, KS), and BBL Crystal (Becton Dickinson Diagnostic Systems, Sparks, MD) systems, according to manufacturers’ instructions. Although this approach is often hindered by similarities in fermentation profiles of separate species within a genus, kits serve as a widely used adjunct to anaerobe diagnostics in most hospital laboratories (202), since they are easy to use and much faster than conventional anaerobic procedures. The main problem with these kits is their incomplete or inaccurate databases (203, 204). Recently, the semiautomated VITEK 2 ANC card (bioMérieux) has been evaluated as a rapid, less subjective method that utilizes colorimetric enzymatic tests. However, this too appears limited by its database, particularly with identification of *Actinomyces* spp. (205).

In addition, the same test performed by different methodologies may give conflicting results; this is particularly true for the commercial identification kits in which the tests are “poised,” to give a definitive positive or negative reaction to aid interpretation. This can have the effect of making the test insufficiently sensitive, giving false negatives compared to conventional tests, or oversensitive, giving rise to false positives (198, 204). Isolates of *A. vaginalis* have been misidentified as *Gemella morbillorum* by the API Rapid ID 32A and RapID ANA II (Remel) test kits (161, 162). In contrast, a clinically relevant *Bifidobacterium* species, *B. scardovii*, was readily separated from other bifidobacteria by using the Rapid ID 32A kit (176). The carbohydrate fermentation test kit API 50 CH (bioMérieux), which is specifically designed for lactobacilli, can be valuable in identification to the genus level but fail at the species level (203). Despite the potential issues, commercial test kits can be useful for the detection of positive reactions and identification of many organisms from clinical sources to the genus level.

A combination of phenotypic tests, specifically the determination of metabolic end products by GLC together with sugar fermentation of carbohydrates and enzyme profiles generated by commercial kits, have successfully been used to identify a number of oral *Eubacterium*-like isolates to the genus and species level (134). For example, the lack of enzyme activity and formation of caproic acid or phenylacetic acid distinguish *P. lactofermentus* or *Mogibacterium* spp., respectively, from other related taxa. However, as already mentioned, phenotypic criteria are particularly unreliable for identification of many *Actinomyces* species (192) and members of the *L. acidophilus* complex and related species (206). In addition, gas chromatographic analysis of cellular fatty acids (196) and examination of protein patterns by polyacrylamide gel electrophoresis have been used taxonom-

Identification by DNA Sequence Analysis

As discussed above, the use of conventional and biochemical tests for the identification of this group carries a significant risk of misidentification. Far-more-precise identifications can be obtained by 16S rRNA gene sequence analysis (207). DNA can be rapidly and reliably purified from members of this group by using commercially available kits, such as GenElute (Sigma-Aldrich, St. Louis, MO), and the 16S rRNA gene can be amplified using "universal" primers that amplify all members of the domain Bacteria (208, 209). Amplicons can be sequenced in-house or submitted to commercial sequencing facilities. The 5’ region of the gene is the most informative for identification purposes; the use of primer 519R for sequencing is recommended (209). Sequences are identified by comparison with those held in the DNA sequence databases, such as GenBank. BLAST interrogation (210) is useful, but care needs to be taken when using the nr/nt database, as a small number of sequences are mislabeled and some nomenclature is inconsistent with current taxonomy. Alternatively, the RefSeq RNA database, which includes only type strains, can be utilized; however, this database is less comprehensive. Also, pairs or even groups of species may have virtually identical 16S rRNA gene sequences and so may require additional tests for identification to the species level. Sequencing of an alternative housekeeping gene (metG or atpA) or a modified technique such as multilocus sequence typing is necessary to differentiate A. naeslundii, A. johnsonii, and A. oris to the species level (1, 211).

Identification by MALDI-TOF MS

Recently, MALDI-TOF MS has been applied to a wide range of organisms; however, relatively few studies have

*Biochemical data compiled from references 14, 15, 17, 152, and 159. Abbreviations and symbols: +, positive; −, negative; v, variable; ND, no data; β-Gal, β-galactosidase.

*In the original description, A. vaginae is facultatively anaerobic.
focused specifically on the organisms included in this chapter. The majority of published studies have utilized the Microflex MALDI-TOF MS analyzer (Bruker Daltonik GmbH, Bremen, Germany) or the VITEK MS MALDI-TOF (bioMérieux). Direct inoculation of organism onto a MALDI-TOF MS plate has been found to generate good identification of common anaerobic organisms. However, some authors found identification rates of only 61.5 to 67.2% using this method (216, 217). Fedorko et al. found that pretreatment was beneficial in the identification of Gram-positive organisms (218). The off-plate method involving a 70% ethanol extraction may be used, but in other studies, simpler and more rapid on-plate extraction methods have been found to give equivalent results (216, 219). Identification is then performed by comparison of spectra generated from extracted samples, and the Andromas database (Paris, France), comprising data from the direct colony method (220).

In a comprehensive study employing partial (~500 bp) 16S rRNA sequencing as the gold standard for identification, MALDI-TOF MS of 290 isolates representing 24 Actinomyces species yielded correct identification rates to the genus and species level of 60 and 50%, respectively, using the Microflex MALDI-TOF MS and the Flex Control version 4613 database (221). Identification rates for Actinobaculum and Varibaculum species were 47 and 0%, respectively. In the same study, some genera yielded higher identification rates: Propionibacterium species, 71% (n = 51); Eggerthella, 92% (n = 12); Atopobium, 71% (n = 17); and Bifidobacterium, 81% (n = 16). However, genera such as Lactobacillus, Eubacterium, and Scardovia were not identified well to the species level, with rates of 0 to 36% (221). Other studies have reported good identification of Actinomyces spp. to the genus level, although identification of some species such as A. neuii remains poor (222).

A number of clinically significant genera and species, e.g., Mogibacterium species and Actinobaculum massiliense, are not included in the current database, which potentially results in either no reliable identification or incorrect identification: M. timidum was identified as Clostridium species in a study by Schmitt et al. (219). Furthermore, for some species, e.g., V. camibrense and P. propionicum, the database comprises few or poorly representative strains, and poor scores may result from intraspecies variation within clinical isolates. This includes P. acnes, within which several phylogroups have been identified. Recently MALDI-TOF MS has been utilized to discriminate between these phylotypes, which may aid in differentiating between clinically significant P. acnes isolates and possible contaminants (223). Changes in nomenclature may also result in distorted identification rates, as E. catenaformis is listed as L. catenaformis in the current database.

In summary, MALDI-TOF MS shows great promise for the future provided that the databases are further developed and regularly updated.
SEROLOGIC TESTS
Serologic tests are of little diagnostic value for this group of organisms.

ANTIMICROBIAL SUSCEPTIBILITIES
In the clinical setting, empirical information is used for the initial diagnosis of infection and choice of antimicrobial therapy, while awaiting culture and susceptibility test results. This is particularly important for this group of organisms because many of them are slow growing, and if they are isolated as part of a mixed infection, it may take some time to obtain pure cultures for testing.

Published data regarding antimicrobial susceptibilities of nonsporing, Gram-positive anaerobes can be difficult to interpret. Changes in bacterial taxonomy, e.g., among the species of the former Eubacterium genus, and more precise classification of tested isolates may result in antimicrobial resistance patterns different from those given in previously published surveys (224). In general, penicillin and other β-lactams are active against Gram-positive bacteria, together with parenteral carbenapens, including meropenem (197, 224–228). Metronidazole has been considered a drug of choice for treatment of anaerobic infections; however, the facultative anaerobes among the genera Propionibacterium, Actinobaculum, Actinomyces, Bifidobacterium, and Lactobacillus are intrinsically resistant, and resistant strains can also be found among the strictly anaerobic genera Actinobium, Eggerthella, Eubacterium, and Mobiluncus (161, 162, 227, 229, 230). Failures or relapses are common in the treatment of bacterial vaginosis, but whether metronidazole-resistant A. vaginae or M. curtisi (161, 162, 181) plays a role is not known. Occasional strains among various genera of nonspore-forming, Gram-positive, anaerobic rods show resistance to clindamycin (224, 225, 229, 231–234). Although vancomycin and teicoplanin are considered active against most Gram-positive bacteria, species-related resistance to glycopeptides is frequent among species of the genus Lactobacillus. Less than one-quarter of the isolates from 80 cases of Lactobacillus infections were reported as susceptible to vancomycin (120). Notably, the vancomycin-resistant L. rhamnosus is the most common Lactobacillus species in clinical specimens (121, 123). In contrast to vancomycin and teicoplanin, rapamycin showed good activity against lactobacilli (229, 235). A novel glycopeptide, telavancin, has been shown to be active against lactobacilli, including L. casei, and Actinomyces species (236). Oxazolidinones have relatively good in vitro activities against Gram-positive cocci but also against anaerobes, and vancomycin may have lower MICs than linezolid (225, 237). Also, streptogramin antimicrobial agents, such as pristinamycin and quinupristin-dalfopristin, have considerable activities against non-spore-forming, Gram-positive rods (197, 225, 232). Fluoroquinolones have a broad spectrum of antibacterial activity and good absorption from the gastrointestinal tract. Novel quinolones, such as garenxonacin, gatifloxacin (topical application), and moxifloxacin, exhibit better antianaerobic activity than the older quinolone compounds levofloxacin and ciprofloxacin (225, 230, 231, 233), suggesting their potential in treating mixed-organism infections.

The testing of anaerobic isolates for susceptibility to antimicrobials by clinical laboratories remains problematic (see chapter 75). The Clinical and Laboratory Standards Institute (CLSI) defines the agar dilution method as the gold standard but recommends it only for reference laboratories (238). Specific guidance is available for lactobacilli (239). broth microdilution is recommended for clinical laboratories but is currently limited to fragilis group Bacteroides. There are a number of reasons for the current lack of susceptibility testing for this group of organisms. Firstly, anaerobic, Gram-positive rods are frequently isolated from polymicrobial infections from which 10 or more species may be cultivated. The relevance of individual susceptibility testing and its interpretation in this scenario are unclear. Secondly, as has been described in this chapter, there are a large number of species that may be found in clinical material, but each laboratory may encounter them relatively rarely. There are therefore insufficient reference data on the susceptibility profile of each species, but even if appropriate data were available, quality control procedures and strains would be required for each species. The most commonly used method for testing anaerobes is the gradient strip (202), which has been found to be useful and reliable (240, 241). Tests should be performed on brucella blood agar and autoclaved read after 48 h, to allow sufficient bacterial growth. Some slow-growing species may require longer incubation.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS
The primary considerations when interpreting laboratory data are the site from which the sample was collected, the collection method, and the likelihood of contamination by the commensal biota. Culture plates from samples from mucosal and cutaneous sites should be interpreted with reference to the normal commensal biota expected for that site and any recent or current antimicrobial therapy. It is important that incubation times are sufficiently long to allow growth of the slow-growing members of this group. Premature reporting of only the fastest-growing species can be misleading since growth rates in vivo and in vitro may be very different. Incubation should be continued for at least 7 days before the final report is issued. The finding of a culture from a specimen dominated by a restricted number of organisms is normally suggestive of infection, particularly if suspected clinically, although recent administration of broad-spectrum antimicrobials may also reduce the diversity of the commensal microbiota.

All isolations of members of this group from normally sterile sites are significant, and the organism should be identified. Members of the group are generally of low-grade pathogenicity and do not produce classical virulence factors, such as protein toxins. All isolates should be regarded as equally important and reported with susceptibility to antimicrobials appropriate to the clinical diagnosis and the site of the infection. Obtaining pure cultures of all of the organisms present in a polymicrobial infection can be difficult and time-consuming but should be attempted. Collation of data regarding the identity and antimicrobial susceptibility profiles of isolates causing confirmed infections will be invaluable in formulating recommendations for empirical treatment, which are lacking at present, and in allowing associations between particular species and diseases to be made.

One specific disease caused by Gram-positive, nonsporing anaerobes is actinomycosis. Pus collected from suspected lesions should be examined macro- and microscopically for the presence of sulfur granules; if present, this should be reported as confirmation of a clinical history consistent
with actinomycosis. Culture of Actinomyces or related genera alone from a site where the specimen is likely to have been contaminated with the commensal microbiota should be interpreted with caution. This is particularly the case for the head and neck regions since Actinomyces is one of the predominant genera among the normal oral microbiota.

Clostridium*

DENNIS L. STEVENS, AMY E. BRYANT, AND KAREN CARROLL

TAXONOMY

The genus Clostridium comprises obligately anaerobic (or occasionally aerotolerant), Gram-positive rods. Currently, >200 clostridial species and subspecies are validly published (http://www.dsmz.de); however, the number of clinically significant clostridia from human infections is limited (Table 1).

Phylogenetically, the genus Clostridium is heterogeneous, with many species intermixed with other spore-forming and non-spore-forming genera. Traditionally, the different species have been defined based on morphological, ultrastructural, and physiological features. During the past 2 decades, analyses of 16S rRNA gene sequences indicated that the “clostridia” could be divided into 19 clusters (1). Cluster I forms the basis of the genus Clostridium and is analogous to group I proposed by Johnson and Francis almost 40 years ago (2). The type species, C. butyricum, and most of the clinically relevant Clostridium species cluster within rRNA homology group I (reviewed in reference 3). The heterogeneous non-group I clostridia require reclassification; however, 16S rRNA gene sequences may not be adequate alone in distinguishing genera, and it is necessary to find genetic and phenotypic characteristics that enable rapid discrimination among genera within this group.

Two new species clustering within the C. coccoides rRNA group, C. hathewayi (4) and C. bolteae (5), were described from human feces. Phenotypically, C. clostridioforme is a relatively heterogeneous anaerobic species. Sequencing analyses of 16S rRNA genes from 107 strains that were previously identified phenotypically as C. clostridioforme in various clinical laboratories revealed that “C. clostridioforme” in fact represents three distinct species: C. bolteae, C. clostridioforme, and C. hathewayi (6). C. barletti is another new Clostridium species described from human feces (7); the clinical significance of this organism remains unknown. “C. neonatale” was proposed as a novel species recovered from bacteremia in patients with necrotizing enterocolitis (NEC) (8). Anaerotruncus colihominis is a new genus and species within the C. leptum rRNA cluster of organisms originally described from human feces (9) and subsequently found in patients with bacteremia (10). Though it was originally described as a non-spore-forming organism, further studies have revealed that sporulation occurs under some conditions (10) and should therefore be considered in Clostridium identification schemes. On the basis of biochemical properties, phylogenetic position, DNA G+C content, and DNA-DNA hybridization, the unification of Clostridium orbiscindens and Eubacterium plautii into the new species Flavonifractor plautii has been proposed (11).

DESCRIPTION OF THE GENUS

Clostridia belong to the phylum Firmicutes and comprise a heterogeneous (paraphyletic) group consisting of at least 12 lineages. Clostridia have a wide range of G+C contents, from 22 to 55 mol%, while the toxigenic species have a much narrower range of G+C contents, 24 to 29 mol% (3). Morphological and phenotypic properties that have traditionally been used to define the genus include (i) the formation of endospores, (ii) anaerobic energy metabolism, (iii) an inability to reduce sulfate to sulfide, and (iv) a Gram-positive cell wall structure.

Vegetative cells of Clostridium species are pleomorphic, rod shaped, and arranged in pairs or short chains; the cells have rounded or sometimes pointed ends (12,13). Rods may join to form tight coils or spiral configurations in species such as C. cocleatum and C. spiroforme. Clostridia stain Gram positive in early stages of growth, although some species, such as C. clostridioforme, C. hathewayi, C. innocuum, and C. ramosum, may appear Gram negative. Several species (e.g., C. tetani) appear Gram negative by the time that spores have formed. Endospores are often wider than the vegetative organisms, imparting characteristic spindle shapes to clostridia. Most strains are motile by means of peritrichous flagella. Nonmotile species include C. perfringens, C. ramosum, and C. innocuum (12).

Clostridium species are metabolically diverse. As currently designated (1), most species are chemoorganotrophic; some species may be chemolithotrophic and chemoheterotrophic. They can be saccharolytic, proteolytic, neither, or both; they do not carry out dissimilatory sulfate reduction. They usually produce mixtures of organic acids and alcohols from carbohydrates, proteins and peptides, or purines and pyrimidines.

Most species are obligately anaerobic, although the tolerance to oxygen varies widely; some species (e.g., C. tertium) grow but do not sporulate in the presence of air, and a few aerotolerant species, such as C. carnis, C. histolyticum, and occasional strains of C. perfringens, give scant growth on...
solid media incubated under 5 to 10% CO₂. Aerotolerant clostridia and certain Bacillus species may be distinguished by several means: (i) clostridia usually form spores only under anaerobic conditions, (ii) they grow better anaerobically than in air, (iii) they usually do not produce catalase, and (iv) they have straight-chain, saturated, and monounsaturated cellular fatty acid (CFA) compositions, whereas Bacillus species have branched-chained CFAs. Although Clostridium species are usually catalase and superoxide dismutase negative, trace amounts of these enzyme activities may be detected in some strains, such as C. perfringens. In addition, clostridia lack a cytochrome system and are thus oxidase negative. Clostridia often occur in nature and in infections as consortia of mixed species, wherein aerobic and facultative organisms utilize oxygen, provide nutrients or other factors, and create an environment favorable for clostridial growth.

Clostridia produce more kinds of protein toxins than any other bacterial genus, and >25 toxins lethal to mice have been identified (reviewed in reference 14). At least 15 species of cluster I Clostridium produce protein toxins, and new toxins and virulence proteins have been discovered through traditional isolation techniques and genomic analyses (15, 16). These proteins include neurotoxins, enterotoxins, cytotoxins, collagenases, permeases, necrotizing toxins, lipases, lecithinases, hemolysins, proteinases, hyaluronidases, DNases, ADP-ribosyltransferases, neuraminidases, and some others that are simply known as lethal toxins. Botulinum neurotoxin and tetanus neurotoxin (BoNT and TeNT) are the most potent toxins known, with lethal doses of 0.2 to 10 ng per kg of body weight for various animals, including humans (17). Epsilon toxin is a 33-kDa protein produced by C. perfringens type B and D strains, and in animals it causes edema and hemorrhage in the brain, heart, spinal cord, and kidneys. It is among the most lethal of clostridial toxins and is considered a potential bioterrorism agent (17, 18).

Many genomic sequences of pathogenic clostridia are now available and should facilitate a comprehensive approach for understanding virulence factors involved in clostridial pathogenesis:

EPIDEMIOLOGY AND TRANSMISSION

Clostridium species are widespread in nature due to their ability to form resistant endospores. They are commonly found in soil, feces, sewage, and marine sediments. The ecology of C. perfringens in soil is greatly influenced by the degree and duration of animal husbandry (reviewed in reference 19), and this has relevance to the incidence of gas gangrene caused by contamination of war wounds with soil. For example, the incidence of clostridial gas gangrene was higher in agricultural lands in Europe than in the Sahara Desert of Africa (19). Similarly, the incidences of tetanus and foodborne botulism are also clearly related to the presence of clostridial spores in soil, water, and many foods (19). Outbreaks of hospital-acquired enteric C. difficile infections (CDIs) are often traceable to environmental sources and other typical background factors for nosocomial infection (20). Clostridia are present in large numbers in the indigenous microbiota of the intestinal tracts of humans and animals, in the female genital tract, and in the oral mucosa as well.

CLINICAL SIGNIFICANCE

Although exogenous clostridial infections or intoxications, such as tetanus, foodborne botulism, and gas gangrene, have been feared for centuries, severe cases of hospital-acquired and community-acquired C. difficile colitis have recently emerged. Endogenous clostridia, in association with non-spore-forming anaerobes and facultative or aerobic organisms, also cause severe infections in diabetic patients and in patients in whom the mucosal integrity of the bowel or respiratory system has been compromised. Head and neck infections, brain abscesses, sinusitis, otitis, aspiration pneumonia, lung abscesses, pleural empyemas, cholecystitis, intra-abdominal infections, gynecologic and obstetric infections, soft tissue infections, myonecrosis, and septic arthritis and bone infections all may involve clostridia. Common predisposing factors are surgical procedures, trauma, vascular stasis, bowel obstruction, malignancy, immunosuppressive agents, diabetes mellitus, prior aerobic infection, and use of antimicrobial agents with poor activity against clostridia (see the section on C. difficile below).

Clostridial Bacteremia

Clostridium species are important causes of bloodstream infections (21–23). C. septicum is isolated only rarely from the feces of healthy individuals but may be found in the appendices of normal individuals. More than 50% of patients whose blood cultures are positive for this organism have some gastrointestinal anomaly, such as diverticular disease, or an underlying malignancy, such as carcinoma of the colon. Another clinically important association has been observed between C. septicum bacteremia and neutropenia of any origin (24) and, more specifically, neutropenic enterocolitis involving the terminal ileum or cecum (13, 25, 26). Patients with diabetes mellitus, severe atherosclerotic cardiovascular disease, or anaerobic myonecrosis (gas gangrene) may also develop C. septicum bacteremia (27). The clinical importance of recognizing C. septicum bacteremia and starting appropriate treatment immediately cannot be overemphasized. Patients with this condition are usually gravely ill and may have metastatic spread to distant anatomic sites, resulting in spontaneous myonecrosis (13). Mortality rates are very high. C. septicum has also been recovered from cirrhotic patients with bacteremia, as have C. perfringens, C. bifermans, and other clostridia (28). Some of these patients have demonstrated septic shock (26).

Another clostridial species of importance in patients with serious underlying disease, such as malignancy and acute pancreatitis, is C. tertium. This organism, as well as C. septicum and C. perfringens, may be seen among the bacteria in the blood of such patients, with or without neutropenic enterocolitis (29). C. tertium may present special problems in terms of both identification and treatment. This organism may appear to be Gram negative, and it is aerotolerant and resistant to metronidazole, clindamycin, and cephalosporins. C. sordelli and C. perfringens have been associated with toxic shock syndrome and abortion (30, 31).

Studies of anaerobic bacteremia by Woo et al. (32) and Simmon et al. (22) identified clostridia based on sequencing of genes encoding 16S rRNA. C. perfringens and C. tertium
the food vehicle is typically improperly cooked meat or a meat product, such as gravy, that has cooled slowly after being cooked or may have been inadequately reheated. Spores surviving the initial cooking germinate, and vegetative cells proliferate during slow cooling or insufficient reheating. Illness results from the ingestion of food containing about 10⁸ or more viable vegetative cells, which sporulate in the alkaline environment of the small intestine, producing an enterotoxin (C. perfringens enterotoxin [CPE]) in the process. Diarrhea develops within 7 to 30 h of ingestion of such food and is generally mild and self-limiting (18); however, in the very young, the elderly, and the immunocompromised, symptoms are more severe, occasionally resulting in death (39). Enterotoxin-producing C. perfringens has been implicated as an etiologic agent of persistent diarrheal disease (33).

**Enteric Infections**

**Food Poisoning**

C. *perfringens* is one of the most common bacterial causes of foodborne illness in the United States and Canada (35–37), and virtually all cases have been due to type A strains (18, 35, 38). In C. *perfringens* type A foodborne disease, were the two most frequently identified species, causing up to 79% and 5%, respectively, of clostridial bacteremias. The mortality rate of clinically relevant clostridial bacteremia ranged from 29 to 35%, and risk factors for mortality (33) were liver disease and older age. The C. *clostridioides* group (including C. *clostridioides*, C. *hathewayi*, and C. *botulicae*) has also caused bacteremia (6, 34).

*Abbreviations and symbols: +, positive reaction; −, negative reaction; v, variable reaction; w, weakly positive reaction; ST, subterminal; T, terminal. A superscript indicates rare variability. Boldface type indicates key reaction results. Capital letters indicate major metabolic products from peptone-yeast-glucose (PYG), lowercase letters indicate minor products, and parentheses indicate a variable reaction for fatty acids as follows: A, acetic; B, butyric; IB, isobutyric; IC, isocaproic; IV, isovaleric; L, lactate; P, propionate; PA, phenylacetate; S, succinate; and V, valerate.

C. *botulinum* is urease negative, and C. *sordellii* is urease positive. C. *botulinum* usually forms chalk-white colonies on egg yolk agar.

A toxin neutralization test is required for identification. Send suspected isolates or C. *botulinum*-containing material to the appropriate local or state public health agency.

4Nonproteolytic.
5Porous amino peptidase differentiates C. difficile and C. innocuum. C. difficile is positive, and C. innocuum is negative.
6Swarming.
7Cigar shaped. C. bolteae is lactose and β-NAG negative, C. clostridiiforme is lactose positive and β-NAG negative, and C. hathewayi is lactose and β-NAG positive.
8C. tertium, C. carnis, and most C. histolyticum isolates grow aerobically.

In elderly patients in nursing homes and tertiary-care institutions and has been considered to play a role in antibiotic-associated diarrhea (AAD) without pseudomembranous colitis. C. perfringens strains associated with food poisoning produce the CPE, which generally acts by forming pores in membranes of host cells (18). C. perfringens strains isolated from nonfoodborne diseases, such as AAD and sporadic diarrhea, carry cpe on a plasmid (40, 41), which may be transmitted to other strains.

Enteritis Necroticans (Pigbel and Darmbrand), Necrotizing Enteritis, and NEC
Enteritis necroticans is caused by alpha-toxin- and beta-toxin-producing strains of C. perfringens type C. Beta toxin is located on a plasmid (41) and is mainly responsible for pathogenesis (18, 42, 43). Enteritis necroticans is a life-threatening infection causing ischemic necrosis of the jejunum. In Papua New Guinea during the 1960s, it was found to be the most frequent cause of death in children; it has been associated with pig feasts and occurs both sporadically and in outbreaks. Immunization against the beta toxin decreased the incidence of the disease in New Guinea (44). Enteritis necroticans has also been recognized in the United States, the United Kingdom, Germany, and other developed nations, especially involving adults who are malnourished or who have diabetes, alcoholic liver disease (45, 46), or neutropenia (47). It should be noted that NEC, a disease resembling enteritis necroticans but associated with C. perfringens type A, has been found in North America in previously healthy adults (48).
NEC is a serious gastrointestinal disease affecting low-birth-weight (premature) infants hospitalized in neonatal intensive care units. The etiology and pathogenesis of this disease have remained an enigma for more than 4 decades (49). Pathological similarities between NEC and enteritis necroticans include their patterns of bowel necrosis and degrees of inflammation (50). Both diseases may manifest intestinal gas cysts (50). The sources of the gas, which contains hydrogen, methane, and carbon dioxide, are probably the fermentative activities of intestinal bacteria, including clostridia. Epidemiological data support an important role for C. perfringens or other gas-producing microorganisms (e.g., "C. neonatale," certain other clostridia, or Klebsiella spp.) in the pathogenesis of NEC.

**C. difficile Infection**

Prevalence of CDIs

*C. difficile*, the major cause of antibiotic-associated pseudomembranous colitis, is also the most frequently identified cause of hospital-acquired diarrhea and is responsible for >250,000 cases of diarrheal disease per year in the United States, with a cost exceeding $1 billion annually (51). *C. difficile* has been isolated from feces of 3 to 5% of the healthy population, 30% of healthy neonates, and 20 to 30% of sedentary patients (52). McFarland et al. (53) reported that 21% of 399 patients with negative cultures on admission to a hospital with a high prevalence of *C. difficile*-associated disease (CDAD) acquired *C. difficile* during hospitalization. Of these patients, 63% remained asymptomatic, while 37% developed diarrhea.

Role of the PaLoc in CDI

Only strains that carry the pathogenicity locus (PaLoc) (54) possess the genetic information for the *C. difficile* enterotoxin, TcdA, and the cytotoxin, TcdB (tcdA and tcdB, respectively). Only strains producing TcdA and/or TcdB cause CDI. A limited number of cases of CDI or pseudomembranous colitis are caused by TcdA- TcdB- strains (55–58). Results with a hamster model indicate that TcdB may be more important for disease induction than TcdA (59). Strains that carry only the genes for the binary toxin CdtA/B do not cause CDI or pseudomembranous colitis. The role of toxins in the pathogenesis of CDI is reviewed in reference 60.

TcdA and TcdB, together with toxins from *C. sordellii*, *C. perfringens*, and *C. novyi* (61), belong to the family of large clostridial cytotoxins (LCCs). The molecular masses of TcdA and TcdB are 308 kDa and 270 kDa, respectively. Such LCC toxins glycosylate small GTP-binding signal proteins of the Ras family, leading to a breakdown of the cell’s cytoskeleton and thus causing apoptosis (62). Both TcdA and TcdB are autoactivated once inside the cell. However, in contrast to A and B toxins of the diphtheria type, they are single chained.

Two accessory proteins, TcdR and TcdC, of the PaLoc (54) are regulatory elements that control toxin expression (56, 63). The tcdC gene has gained diagnostic attention since it is shortened in endemic hypervirulent ribotype 027/NAP1 (North American pulsotype 1) isolates (herein called ribotype 027 isolates) (64). Some studies suggest that such strains overproduce toxins and may lead to more severe cases of CDI (65, 66), although this is controversial (60).

Risk Factors and Course of CDI

Acquisition of *C. difficile* alone does not induce CDI. Several other risk factors, like age, hospitalization, severe bowel surgery, treatment with proton pump inhibitors plus a change in colonization resistance due to such treatments plus colonization with a TcdA/TcdB-producing *C. difficile* strain, are necessary for development of CDI.

The spectrum of symptoms ranges from mild self-limiting diarrhea to bloody-slimy diarrhea (called *C. difficile*-associated diarrhea) to the development of full-scale pseudomembranous colitis (67). The onset of CDI may begin immediately following antibiotic treatment or as long as 4 to 6 weeks after the course of antibiotics has been finished. Antibiotics most commonly associated with CDI are clindamycin, expanded- and broad-spectrum cephalosporins, and fluoroquinolones (68).

Bloody, mucus-filled stools generally indicate greater destruction of the colonic mucosa and hence are associated with more severe disease. Clinical diagnosis may be established by rectoscopy and the identification of pseudomembranes on the colonic mucosa. Severe cases are typically observed among the elderly, in nursing home residents, and in immunocompromised patients (65–67).

Epidemic Outbreaks

Hypervirulent strains (such as those of ribotype 027) have caused outbreaks in Canada, the United States, Europe, and even worldwide (65, 66, 69). These outbreaks have occurred among younger age groups, in patients with no underlying diseases, and even among outpatients. These cases are associated with megacolon and rupture of the large bowel and are often lethal. There is evidence that use of fluoroquinolones may be an essential trigger in the onset of such outbreaks (70).

Particularly vexing complications of CDIs are relapses after antibiotic treatment caused by the initial causative strain or by reinfection with a second *C. difficile* strain (71). Published data report relapse rates of 20 to 50%. Even the first relapse should be treated with a vancomycin step therapy (see below). Fecal transplantation has been shown to be highly effective for treatment of recurrent CDI (reviewed in reference 72), and two newer drugs, fidaxomicin and rifaximin, have been approved for recurrent CDI (73). The use of the probiotic *Saccharomyces boulardii* (74) has also been suggested, but results are not yet definitive. Eradication of *C. difficile* from the hospital environment is a worthy objective but a difficult task for infection control practitioners. Commonly used disinfectants are not sporicidal. Rather, isolation of symptomatic patients has been the main control mechanism. However, recent studies suggest that asymptomatic carriers are an important reservoir for *C. difficile* in both the community and hospital environments (75, 76).

Other Etiologies of AAD

*C. difficile* is responsible for ≤20% of cases of AAD (77, 78). Enterotoxin-producing *C. perfringens* type A has been isolated from AAD patients who are negative for *C. difficile* and who have no other apparent cause of the disease. Coinfection with *C. difficile* and enterotoxigenic *C. perfringens* type A has also been reported for AAD patients (79). Though the incidence of *C. perfringens*-associated AAD has been estimated to be 5 to 20% (80), additional epidemiologic studies are needed to accurately determine the role of this organism in AAD.

**Histotoxic Clostridial Skin and Soft Tissue Infections**

Histotoxic clostridial species such as *C. perfringens*, *C. histolyticum*, *C. septicum*, *C. novyi*, and *C. sordellii* cause aggressive
necrotizing infections of the skin and soft tissues attributable, in part, to the elaboration of bacterial proteases, phospholipases, and cytotoxins (26). Necrotizing clostridial soft tissue infections (gas gangrene) are rapidly progressive and characterized by marked tissue destruction, gas in the tissues, shock, and frequently death (81).

**Clostridial Myonecrosis**

**Traumatic Gas Gangrene due to *C. perfringens***

*C. perfringens* myonecrosis (gas gangrene) is one of the most fulminating Gram-positive infections of humans. Predisposing conditions include crush-type injury, laceration of large- or medium-sized arteries, and open fractures of long bones that are contaminated with soil containing the bacterial spores. Gas gangrene of the abdominal wall and flanks occurs after penetrating injuries, such as knife or gunshot wounds, sufficient to compromise intestinal integrity, with resultant leakage of bowel contents into the soft tissues. Cutaneous gas gangrene caused by *C. perfringens*, *C. novyi* type A, and *C. sordellii* have been described in the United States and northern Europe among drug abusers injecting “black-tar heroin” subcutaneously (26, 82–86).

Clostridial gas gangrene is characterized by the sudden onset of excruciating pain at the infection site (87) and rapid development of a foul-smelling wound containing a thin serosanguinous discharge and gas bubbles. Brawny edema and induration develop and give way to cutaneous blisters containing bluish-to-maroon fluid. Later, such tissue may become liquefied and slough. The margin between healthy and necrotic tissue often advances several inches per hour despite appropriate antibiotic therapy (87), and shock and organ failure frequently accompany gas gangrene, and when patients become bacteremic, the mortality exceeds 50%.

Diagnosis is not difficult because the infection (i) always begins at the site of significant trauma, (ii) is associated with gas in the tissue, and (iii) is rapidly progressive. A Gram stain of drainage or a tissue biopsy specimen is usually definitive, demonstrating large, Gram-positive rods and an absence of inflammatory cells. Using experimental models, Bryant and colleagues have demonstrated that the severe pain, rapid progression, marked tissue destruction, and absence of neutrophils in *C. perfringens* gas gangrene is caused by alpha-toxin-induced occlusion of blood vessels by platelets and neutrophils (26, 88, 89).

**Spontaneous, Nontraumatic Gas Gangrene due to *C. septicum***

The first symptom of spontaneous *C. septicum* gas gangrene may be confusion, followed by the abrupt onset of excruciating pain and rapid progression of tissue destruction, with demonstrable gas in the tissue (13, 19, 87, 90). Swelling increases, and bullae appear filled with clear, cloudy, hemorrhagic, or purplish fluid. The surrounding skin has a purplish hue, perhaps reflecting vascular compromise resulting from bacterial toxins diffusing into surrounding tissues (13). The mortality of patients with spontaneous gangrene ranges from 67 to 100%, with the majority of deaths occurring within 24 h of onset. Predisposing host factors include colonic carcinoma, diverticulitis, gastrointestinal surgery, leukemia, lymphoproliferative disorders, cancer chemotherapy, radiation therapy, and AIDS (13, 26, 90). Cyclic, congenital, or acquired neutropenia is also strongly associated with an increased incidence of spontaneous gas gangrene due to *C. septicum*, and in such cases, NEC, cecitis, or distal ileitis is commonly found. These gastrointestinal pathologies permit bacterial access to the bloodstream; consequently, the aerotolerant *C. septicum* can proliferate in normal tissues (19). Patients surviving bacteremia or spontaneous gangrene due to *C. septicum* should have aggressive diagnostic studies to rule out gastrointestinal pathology.

**Gynecologic Infections due to *C. sordellii***

Gas gangrene of the uterus, especially that due to *C. sordellii*, has historically occurred as a consequence of illegal or self-induced abortions but in modern times also follows spontaneous abortion, normal vaginal delivery, and cesarean section (reviewed in reference 31). *C. sordellii* has also been implicated in medically induced abortions (31). Young, previously healthy women with fatal postpartum *C. sordellii* infections present with a unique clinical picture of little or no fever, a lack of a purulent discharge, refractory hypotension, extensive peripheral edema and effusions, hemoconcentration, and a markedly elevated white blood cell count (31). Death in these cases ensues rapidly, and the infection is almost uniformly fatal (31).

**Other Clostridial Skin and Soft Tissue Infections***

Crepitant cellulitis, also called anaerobic cellulitis, is seen principally in diabetic patients and characteristically involves subcutaneous tissues or retroperitoneal tissues and can progress to fulminant systemic disease; the muscle and fascia are not involved.

Cases of *C. histolyticum* infection with cellulitis, abscess formation, or endocarditis have also been documented in injecting drug users (91). *C. sordellii* was responsible for endophthalmitis after suture removal after a corneal transplant (92). *C. perfringens* endophthalmitis due to penetrating injuries is a fulminating infection (93).

**Exotoxins of the Histotoxic Clostridia**

Our current understanding of the potent toxins produced by these clostridia is based on studies done between World Wars I and II, when gas gangrene was a major complication of battlefield injuries. Investigators of this period designated the major lethal toxins of these bacteria with Greek letters, with the letter “α” always used to designate the most potent or most significant lethal factor. The original monograph by Smith and Williams (19) remains an important compilation of the known exotoxins of the histotoxic clostridia and their roles in pathogenesis. Over the ensuing decades, modern technology has provided a greater understanding of the mechanisms of action of some of these factors (reviewed in references 94 and 95), as described in individual sections that follow.

**Major Extracellular Toxins of *C. perfringens***

The major *C. perfringens* extracellular toxins implicated in gas gangrene are alpha toxin and theta toxin. Alpha toxin is a lethal lecithinase that has both phospholipase C and sphingomyelinase activities and has been implicated as the major virulence factor based on the observation that immunization of mice with purified recombinant protein consisting of the C-terminal alpha-toxin domain (amino acids 247 to 370) provided protection against lethal challenge with *C. perfringens* (96). In addition, intravascular activation of platelets by alpha toxin leads to platelet aggregation (88, 97) and formation of occlusive thrombi that completely and irreversibly occlude capillaries, venules, and arterioles (88, 89). Without adequate tissue perfusion, the anaerobic niche is extended and rapid destruction of viable tissue, so characteristic of clostridial gas gangrene, ensues.
Theta toxin from *C. perfringens* (also known as perfringolysin) is a member of the thiol-activated cytolsin family, now termed cholesterol-dependent cytolsins, that includes streptolysin O from group A streptococci, pneumolysin from *Streptococcus pneumoniae*, and several others. Upon contact with cholesterol in the host’s cell membranes, theta-toxin monomers oligomerize and insert into the membrane, forming a pore and resulting in cell lysis (98). The signature undecapeptide sequence, ECTGLAWEWW, is highly conserved among all cholesterol-dependent cytolsins and mediates this activity (99). Theta toxin contributes to the pathogenesis of gas gangrene, likely by its ability to modulate the inflammatory response to infection (100, 101).

**Major Extracellular Toxins of *C. septicum***

*C. septicum* produces four main toxins, alpha toxin (α, lethal, hemolytic, necrotizing activity), beta toxin (β, DNase), gamma toxin (γ, hyaluronidase), and delta toxin (δ, septicolsin, an oxygen-labile hemolysin), as well as a protease and a neuraminidase (19). Unlike the alpha toxin from *C. perfringens*, the *C. septicum* alpha toxin does not possess phospholipase activity. Active immunization against alpha toxin significantly protects against challenge with viable *C. septicum* (102).

**Major Extracellular Toxins of *C. sordelli***

Pathogenic strains of *C. sordelli* produce up to seven identified exotoxins. Of these, lethal toxin (LT) and hemorrhagic toxin (HT) are regarded as the major virulence factors. LT and HT are members of the LCC family, all having molecular masses between 250 and 308 kDa. Other members include the *C. difficile* toxins A and B and *C. novyi* alpha toxin. All LCCs possess remarkable amino acid similarity, with identities ranging between 26 and 76%. LT and *C. difficile* toxin B have the highest homology, with amino acid sequences being 76% identical and 90% homologous to one another. All LCCs possess glycosyltransferase activity and modify signaling molecules that control the cell cycle, apoptosis, gene transcription, and the structural functions of actin, such as cell morphology, migration, and polarity. Once modified, these proteins become inactive. Modification of actin cytoskeletal assembly and organization presumably leads to the massive capillary leakage characteristic of *C. sordelli* infection. The *C. sordelli* neuraminidase has been shown to contribute to the leukemoid reaction, in part, by enhancing the proliferation of granulocyte progenitor cells (103). Other exotoxins include an oxygen-labile hemolysin, DNase, collagenase, and lysocleithinase; however, their roles in pathogenesis have not been extensively investigated.

**Botulism**

The **Organism and Its Toxin**

*C. botulinum* is the cause of the rare but frequently fatal illness known as botulism, which is characterized by sudden flaccid paralysis. Spores of *C. botulinum* are widely distributed in soil and aquatic habitats. *C. botulinum*, along with unique strains of *C. butyricum*, *C. baratti*, and *C. argentinense*, produce BoNT, the most lethal poison known. The intravenous lethal dose for BoNT has been estimated as 0.1 to 0.5 ng per kg of body weight, and BoNT is among the most potent protein toxins by oral ingestion, with an estimated oral lethal dose of 0.2 to 1 μg per kg (104). There are seven antigenic serotypes of BoNT (A through G) (105), which serve as useful clinical and epidemiological markers (106). Recently a strain of *C. botulinum* was identified that produced both type B and H toxins (107). Toxin serotypes A, B, and E of *C. botulinum* are the principal causes of botulism in humans (108). Neurotoxicogenic strains of *C. butyricum* (109) and *C. baratti* (110–112) that produce type E and F neurotoxins, respectively, have been implicated mainly in infant botulism. Type E botulin-toxin-producing *C. butyricum* strains were confirmed by sequencing of the 165 rRNA gene (113), leading to the conclusion that neurotoxicogenic *C. butyricum* must be regarded as an emergent foodborne pathogen. *C. argentinense*, which produces type G neurotoxin (108), has been isolated from soil in Argentina. Its reported isolation from autopsy materials from five individuals who died suddenly has not been substantiated, and *C. argentinense* has not been clearly implicated in botulism. *C. botulinum* types C and D are associated primarily with botulism in birds and mammals (114, 115). Strains of *C. botulinum* that produce more than one serotype of BoNTs, generally with one serotype being formed in much higher levels, have been isolated from the environment and human and animal botulism cases (108, 116). The BoNTs are coexpressed with nontoxic proteins of toxin gene clusters (117), and evidence suggests the complexes are much more stable than the labile BoNTs in the gastrointestinal tract. The genes for BoNT complex formation are associated with unstable genetic elements in certain serotypes, enabling toxin gene transfer to nontoxic clostridial species that are closely related to *C. botulinum*, such as *C. sporogenes* and *C. subterminale* (118).

There are four naturally occurring types of botulism: (i) classical foodborne botulism, an intoxication caused by the ingestion of preformed botulinic toxin in contaminated food; (ii) wound botulism, which results from elaboration of botulinic toxin in vivo after the growth of *C. botulinum* in an infected wound; (iii) infant botulism, in which botulinic toxin is elaborated in vivo in the gastrointestinal tract of an infant colonized with *C. botulinum*; and (iv) botulism due to intestinal colonization in children and adults (108, 119). Intestinal colonization in adults has been associated with surgery and administration of antibiotics (108). *C. botulinum* has been isolated from patients colonized with *C. difficile* (109), with viral infections (120), or with Crohn’s disease (121). In 2008, an international outbreak of botulism caused by commercial carrot juice was reported by Sheth et al. (122).

Regardless of the category of botulism, the toxin enters the bloodstream at a peripheral site (e.g., gut, wound, or lung) and is transferred to the neuromuscular junctions of motor neurons, where it binds irreversibly to the presynaptic membranes. The site of action of all serotypes of BoNT is the presynaptic terminal of motor neurons (123–126). Elucidation of the three-dimensional structure of botulinum and tetanus toxins and their constituent domains has provided considerable insights into their mechanisms of action (125–128). BoNT penetrates the plasma membrane by receptor-mediated endocytosis, and the light chain of 50 kDa (the catalytic domain) is internalized into the nerve cell through a protein channel (125, 126). Once internalized, BoNT specifically cleaves proteins involved in vesicle trafficking of neurotransmitters to the membrane (126). Exocytosis of acetylcholine is prevented at the nerve terminal to the neuromuscular junction, with consequent blockade of innervation of muscle activity (126). The clinical hallmark of botulism is an acute flaccid paralysis, which begins with bilateral cranial nerve impairment involving muscles of the eyes, face, head, and pharynx and then descends symmetrically to involve muscles of the thorax and extremities. Botulinum toxin, unlike TeNT, probably does
Infant Botulism Treatment and Prevention Program [www.infantbotulism.org; 24-hr/7-day phone, (510) 231-7600] since 2003 (137, 140). Since 2007, it has been made available to physicians outside the United States on a case-by-case basis. Early treatment has shortened hospital stays and significantly reduced the associated costs of hospitalization (141). A recent Cochrane review substantiated that administration of BIG is more effective than any other medical intervention, though the findings were of moderate quality (141).

Botulinum Toxin as a Bioterrorism Agent

Inhalational botulism, which results from aerosolization and inhalation of botulinum toxin, has been considered a fifth category of botulism (104, 142, 143). Botulism could also result from covert contamination of foods (104, 144). Inhalational botulism has been demonstrated experimentally in monkeys (104, 143), accidentally in three veterinary personnel in Germany who were exposed to reaerosolized BoNT from rabbits and guinea pigs with aerosolized BoNT on their fur (104), and in three researchers who were exposed to an aerosol during BoNT manipulations (145). Terrorists have attempted to use aerosolized botulinum toxin as a bioweapon but were not successful. Although inhalational botulism is possible, the toxin is unstable in aerosols, and the more likely route of intentional intoxication is by food contamination and oral ingestion.

Tetanus

Tetanus, caused by C. tetani, is often associated with puncture wounds that do not appear to be infected. The organism and its spores can be isolated from a variety of sources, including soil and the intestinal contents of numerous animal species. A potent neurotoxin (TeNT), often referred to as tetanospasmin, is elaborated at the site of trauma and rapidly binds to neural tissue, provoking a characteristic paralysis and tonic spasms (146). Tetanus is a totally preventable infection with immunization with tetanus toxoid. However, a 2009 study from the United Kingdom demonstrated that, overall, only 83% of the population had protective levels of anti-tetanus toxin antibody (147) and that the age group with the greatest susceptibility was those >70 years of age (32%), followed by those <1 year of age (29%) and, remarkably, those between 45 and 69 years of age (>20%). Thus, immunization of women during pregnancy is recommended, as is routine immunization of all age groups at roughly 5-year intervals.

Tetanus is an intoxication analogous to botulism except that it occurs solely through wound infection and production of tetanospasmin (TeNT). TeNT is synthesized as a single, inactive polypeptide chain (150 kDa), which is cleaved by an intrinsic protease to produce an active form, consisting of a heavy chain (100 kDa) and a light chain (50 kDa) linked by a disulfide bond (126). The heavy chain binds to neuronal cells, and the three-dimensional structure of this region has been elucidated (126). The light chain, a zinc endopeptidase, enters the cell cytoplasm and traverses the nervous system to reach the spinal cord and brain stem, where it affects glycnergic and GABA (gamma-aminobutyric acid)-ergic neurotransmission (126, 146). Inhibitory impulses to CNS neurons are blocked, while uninhibited firing of motor nerve transmission continues, resulting in prolonged muscle spasms of both flexor and extensor muscles that can persist for weeks. The mechanism by which excocytosis of neurotransmitter release is inhibited is analogous to that of BoNT; in fact, TeNT

Infant Botulism

Infant botulism is the most frequently recognized form of botulism in the United States (45% of cases in California) and has been reported in at least 15 other countries (119, 134–138). The geographic distribution of toxin types in infant botulism cases has paralleled the spore distribution of C. botulinum toxin types in soils sampled from different locations (119). Type A has been the most frequent BoNT type in cases of infant botulism in states west of the Mississippi River, whereas type B cases have predominated east of the Mississippi River (119, 139). Three cases have been caused by a strain(s) of C. botulinum that produced toxins requiring both type B and F antitoxins for neutralization (108). Type E infant botulism, caused by neurotoxigenic strains of C. butyricum, was initially confirmed in two infants from Italy (138), and later in additional patients. Type F infant botulism has been caused by neurotoxigenic C. baratii (138).

Most infants that contract botulism are 3 weeks to 6 months old (119), and the only clearly defined risk factors have been exposure to soil, dust, and honey (119, 137). Since C. botulinum spores have not been detected in any food or liquid ingested by these infants other than honey (119), it is recommended that honey not be fed to infants <1 year of age. Whatever the sources, the ingested spores of C. botulinum germinate within the intestinal tract, and the vegetative cells multiply and produce the neurotoxin, which is then absorbed into the bloodstream (108, 119). The first sign of illness is usually constipation, which is often overlooked. Infants develop lethargy and mild weakness, with feeding difficulties, pooled oral secretions, and an altered cry (119). They eventually lose head control and may go on to develop ophthalmoplegia, ptosis, flaccid facial expression, dysphagia, other signs of cranial nerve deficits, generalized muscular weakness, and finally respiratory insufficiency and the inability to swallow. There is likely a spectrum of clinical features in infant botulism, ranging from mild illness not requiring hospitalization to severe botulism requiring intensive care. Human immune globulin that neutralizes BoNT (BabyBIG; intravenous BIG-IV) has been licensed to the California Department of Public Health.
cleaves the vesicle-associated membrane protein at the same peptide bond as BoNT B (125). Unlike with the pathophysiology of botulism, TeNT is retrogradely transported in neurons to the CNS and its site of action (126, 146).

The worldwide incidence of tetanus has been estimated to be as many as 500,000 cases per year (146). Neonatal tetanus is endemic in developing countries due to a lack of vaccine programs for infants or adult women. In developed countries, injection of drugs (i.e., skin popping) has become an important risk factor (148, 149). Neonatal mortality is highest in low-birth-weight newborns (150).

### Additional Clostridial Species of Interest

*Clostridium innocuum* is associated with bacteremia in immunocompromised hosts and has also been recovered from patients with recurrent CDAD (151). It is often resistant to multiple drugs used to treat anaerobic infections (151). *C. ramosum* was the second-most-common *Clostridium* species (after *C. perfringens*). From clinical specimens from children, *C. ramosum* was identified more often than the other two species (152). The third-most-common *Clostridium* species in adults is *C. tetani* (21). This species may be resistant to clindamycin and multiple cephalosporins. As noted earlier, *C. tertium* is often isolated from blood cultures from immunocompromised patients and has been reported as a cause of neutropenic enterocolitis and meningitis (29, 153–155). *C. hathewayi* and *C. boeae* have been isolated from a variety of human infections (6, 34), including a fatal case of sepsis (156). Phenotypically similar *C. clostridioforme* is one of the clostridia most commonly isolated from human infections and appears to be associated with human infections that are more serious or invasive than infections with *C. hathewayi* or *C. boeae*.

The emergence of 16S rRNA gene sequencing technology has provided a means of identification of strains that may previously have been misidentified or classified as *Clostridium* without species identification. Examples are from cases of bacteremia caused by *C. hathewayi* (34), *C. intestinalis* (157), and *C. symbiosum* (158); fatal sepsis due to *C. fallax* in a previously healthy 16-year-old (159); and abscesses yielding *C. celercrencens* (160). Microarray analysis of DNA from fecal samples has also been useful in the determination of predominant species in the large bowel (161). It is likely that in this era of molecular identification techniques a more accurate picture of clostridial infections will emerge.

### CLINICAL MICROBIOLOGY OF CLOSTRIDIAL DISEASES

#### General Methods for Collection, Transport, and Storage of Clinical Specimens

The proper selection, collection, and transport of clinical specimens are extremely important for the laboratory diagnosis of clostridial infections. For recommended collection and transport procedures in general, refer to chapter 18.

#### Specific Methods for Collection and Direct Examination of Clinical Specimens

In addition to requiring aspirates and tissues, selected clostridial illnesses require special specimens. The methods for collection and direct examination of these specimens are described below.

Suspected Gas Gangrene or Necrotizing Fasciitis

Gas gangrene and necrotizing fasciitis represent extremely urgent situations requiring rapid clinical diagnoses. Multiple tissue specimens should be sampled from the active sites of infection when gas gangrene is suspected, because clostridia are often not distributed uniformly in pathologic lesions. The direct examination of a Gram-stained smear of the wound is of major importance for the early presumptive diagnosis of gas gangrene (81). Characteristic findings in *C. perfringens* infections include the absence of leukocytic infiltration and the presence of clostridia in smears prepared from central areas of the lesion. Special note should be made of Gram-positive rods, with or without spores, because sporulation in tissue is not common for the two species most frequently encountered in wound and abscess materials, *C. perfringens* and *C. ramosum*. *C. perfringens* usually appears as large, relatively short, fat, Gram-positive rods with blunt ends and often in short chains in tissue smears; the cells of *C. ramosum* are more slender and longer (Fig. 1). *C. perfringens* may or may not be encapsulated in smears from wounds; capsules usually are present in smears of endometrial specimens from postabortion *C. perfringens* infections. Spore stains offer no advantage over Gram stains for demonstration of spores, but examination with a phase-contrast or dark-field microscope may be helpful if the spores are close to maturity. If spores are present, shapes (spherical or oval) and positions (terminal, subterminal, or central) in the cells should be noted.

Suspected *C. perfringens* Foodborne Illness

A freshly passed fecal specimen and the suspected food are the preferred specimens for *C. perfringens* culture and toxin assays. These specimens should be placed into sterile containers, stored at 4°C, and shipped on cold packs as soon as possible. For optimal recovery, stool specimens should be processed within 24 h of collection. Swab specimens are inadequate for the toxin assay because the sample volume is insufficient.

Several methods have been described for the detection of CPE in feces, including cell culture assays, enzyme-linked immunosorbenent assay (ELISA), and reversed passive latex agglutination (RPLA) (162, 163). The cell culture assay using Vero cells is not as sensitive as or as reproducible as other methods (80, 164). The results of the RPLA kit (PET-RPLA; Oxoid Ltd., Basingstoke, United Kingdom, and Remel Inc., Lenexa, KS) are reproducible, and the test is reasonably sensitive; however, nonspecific interference by fecal matter has been reported (163). Similarly, the background bacterial DNA in stool has been reported to interfere with PCR amplification of the enterotoxin gene (163). While an in-house ELISA system developed by the Food Safety Microbiology Laboratory of the Central Public Health Laboratory, London, United Kingdom, has been reported to be the most sensitive assay and is considered the gold standard, the TechLab (Blacksburg, VA) CPE ELISA system has also provided a specific, reliable, and practical tool for detecting CPE in fecal samples (80, 164).

Suspected Enteritis Necroticans (*C. perfringens* Type C)

If enteritis necroticans is suspected, the appropriate specimens include three blood cultures from three different venipuncture sites, stool (at least 25 g, or 25 ml if liquid), and bowel contents or tissue from the involved bowel (e.g., surgical specimen or autopsy material). Specimens should be transported in tightly sealed, leakproof containers for the following: direct Gram staining, culture, isolation, identification, and typing of *C. perfringens*. PCR assays for genotyping *C. perfringens* are being used in certain research
Suspected CDI

Among the risk factors that warrant initiating a detailed microbiologic diagnosis of CDI in patients with diarrhea are (i) antibiotic exposure; (ii) host factors, such as advanced age (>65 years), immunosuppression, or severe underlying...
gastrointestinal disease; (iii) exposure to acute or chronic health care facilities; and (iv) use of proton pump inhibitors (165–167).

CDI is a clinical disease that is confirmed by various laboratory methods. The diagnosis of CDI has gained more attention since the appearance of hypervirulent strains, such as ribotype 027, which have contributed to the increased incidence and severity of infection. The optimum diagnostic assay or algorithm remains a matter of debate, but methods can be stratified into two major categories—those that detect toxin A, toxin B, or both in fecal samples (enzyme immunoassays [EIAs] and cell culture cytotoxicity neutralization assays [CCCNAs]) and those that detect the organism (anaerobic culture, glutamate dehydrogenase [GDH], and nucleic acid amplification tests [NAATs]). Since nontoxicogenic strains can colonize individuals, assays that detect the organism alone should be combined with a test that can also assess toxin status.

Submission of Specimens
A single, freshly passed fecal specimen (ideally 10 to 20 ml of watery stool; minimum of 5.0 ml or 5 g) is the preferred specimen for C. difficile culture and toxin assays. To lessen the chance of obtaining positive culture results from patients merely colonized with the organism, only liquid or unformed stool specimens should be processed. Swab specimens of stool are inadequate for toxin tests because the sample volume is insufficient. However, swabs can be processed for culture or NAATs obtained for epidemiological reasons. Other appropriate specimens include bowel luminal contents and surgical or autopsy samples of the large bowel.

Specimens should be transported in tightly sealed, leak-proof plastic or glass containers. For optimal recovery, stool specimens should be cultured within 2 h of collection. Although spores survive in refrigerated stool for several days, there will probably be a large decrease in the number of viable vegetative cells of C. difficile in refrigerated specimens. Stools should be placed in an anaerobic environment (anaerobic transport vial or bag) if culture must be performed after storage. Adequate recovery of C. difficile organisms may be expected from stools stored at 4°C for up to 2 days. Specimens for toxin assay may be stored at 4°C for up to 3 days or should be frozen at −70°C if performance of the assay is delayed. Freezing at −20°C results in a dramatic loss of cytotoxin activity, so detection limits may no longer be reached.

Methods for the Detection of C. difficile in Clinical Samples

Anaerobic toxigenic culture. Cultivation of C. difficile is encouraged for subsequent molecular strain typing and epidemiologic studies and is considered one of two diagnostic gold standards. Anaerobic culture and C. difficile identification methods are described in “Isolation Procedures” below. As recovery of C. difficile from fecal samples using culture does not assess toxicity, culture is usually combined with a method to assess toxin production.

Antigen detection (GDH) for diagnosis of CDI. GDH is a metabolic enzyme expressed at high levels by all strains of C. difficile, both toxigenic and nontoxigenic strains, so a positive test must be combined with an assay that detects toxin. GDH assays exist in two forms, as a solid-phase microtiter plate format and as a lateral flow immunochromatographic membrane version of the test combined with a toxin A and B EIA (reviewed in references 165 and 166). Before the widespread availability of NAATs, many laboratories turned to GDH testing in two-step algorithms and performed toxin testing on specimens that were GDH-positive, while GDH-negative samples were deemed negative for C. difficile. Patients whose samples were positive by GDH assay but negative by a toxin test were considered colonized with nontoxicogenic isolates. Such algorithms predicated on GDH as the initial step were supported by the reportedly high negative predictive value (NPV) of GDH tests, 98.4 to 100%, compared to both toxigenic culture and CCCNAs (165, 166), an observation that has recently been confirmed (NPV of 99.5 and 99.8% compared to toxigenic culture and a cytotoxin assay, respectively) in the largest diagnostic study to date of CDI (168).

Nucleic acid amplification methods. The first nucleic acid amplification assay was approved by the U.S. Food and Drug Administration (FDA) in 2009. At the time of this writing, close to a dozen platforms are approved and are available for testing using a variety of techniques that include PCR, loop-mediated isothermal amplification, and microarray technologies (166, 169). Some platforms are designed for low-volume laboratories, and others are more amenable to high-throughput testing. These assays detect a variety of gene targets, including tcdA, tcdB, cdtA, and the Δ117 deletion in tcdC, the latter two as surrogates for ribotype 027. Although NAATs are rapidly replacing other methods in clinical microbiology laboratories, these new technologies have yet to be endorsed by professional society guidelines. Like GDH assays, NAATs have a very high NPV and analytical and clinical sensitivity (166, 169), but there are concerns regarding specificity and positive predictive values (PPVs). In the study by Dubberke et al. (170), when clinical parameters were used to assess assay performance, NAATs had the lowest specificity among diagnostic assays (170). This was in part due to inappropriate test ordering, as 36% of patients tested did not have diarrhea and 20% of tested patients had received a laxative (170). Likewise, in a very large prospective multicenter study in the United Kingdom, the authors found that tests that were positive by a NAAT but negative for toxin by CCCNA correlated with neither mortality nor prolonged length of stay (168). The authors concluded that the use of NAATs leads to overdiagnosis of CDI (168). They suggested that NAATs could be used as first-stage tests to exclude the presence of C. difficile, followed by a more specific toxin test to identify those patients most likely to have C. difficile disease (168). The major limitation to algorithms that begin with either a GDH assay or a NAAT is that a sensitive assay for detection of toxin does not exist. Some recommend a three-tiered approach, with a GDH assay followed by a toxin EIA and progression to a NAAT for confirmation of GDH-positive, toxin EIA-negative samples. Such three-step algorithms complicate and delay testing, may not be reimbursed, and may be less cost-effective than NAAT testing alone (166, 171, 172). Regardless of how a laboratory chooses to utilize a NAAT (i.e., alone or as part of a multi-step algorithm), to optimize interpretation of results, testing should be limited to patients who clearly have diarrhea.

Methods to detect C. difficile toxins. CCCNAs have long been considered diagnostic gold standards of C. difficile toxin testing in spite of the fact that there is no agreed-upon standard method. CCCNAs involve inoculating a filtrate of stool onto a monolayer of an appropriate cell line and observing for cytotoxic effect after 24 to 48 h of incubation at 37°C. A number of different cell lines, such
as human foreskin fibroblasts, Vero cells, and MRC-5 lung fibroblasts, among others, have been used. Once cytopathic effect is observed, neutralization is required to assess the specificity of cytopathic effect, and can be performed using C. sordellii or C. difficile antisera. The need for neutralization of the cytopathic effect marks a limitation of the test. Performance characteristics of CCCNAs vary considerably, likely related to the comparative method and also to technical factors that can affect accurate performance (reviewed in reference 166). However, in a large prospective study in the United Kingdom, a CCCNA performed using Vero cells showed the best correlation with clinical outcome (168) compared to assays that detected the presence of the organism. As laboratories embrace molecular techniques for viral diagnostics, many have abandoned cell culture facilities, making CCCNAs less attractive assays for C. difficile diagnosis. In addition, the length of time required to complete testing has also limited their utility (Table 2).

**Toxin immunoassays for diagnosis of CDI.** A number of commercial EIAs are available for detection of C. difficile toxins. These assays detect toxin A alone or both toxins A and B using monoclonal or polyclonal antibodies embedded in rapid immunochromatographic/lateral flow membranes or in microwell and solid-phase devices. The result of toxin testing is the declaration of the sample as being toxin positive or negative without any differentiation of TcdA and TcdB. Testing using assays that detect TcdA alone is not recommended, since some epidemic strains produce only TcdB (78). Immunoassays generally show lower sensitivities and specificities (31 to 99% and 84 to 100%, respectively) than CCCNAs (165, 166). Such variability in performance led to the common practice of submitting multiple specimens to the laboratory (“stools for *C. difficile* times three”), adding expense and reducing the PPV of such testing (173). Due to the poor sensitivity and specificity of these tests, EIAs are considered suboptimal for the diagnosis of CDI, and many laboratories have replaced them with GDH- or NAAT-based testing algorithms.

In summary, a variety of diagnostic test methods are available for the diagnosis of *C. difficile* disease (Table 2). The optimum method is still a matter of debate, but multistep algorithms predicated on the initial results for GDH followed by a sensitive toxin test and/or a NAAT test provide the best options at present. EIAs for toxin detection lack sensitivity and specificity. Positive CCCNA results seem to correlate the best with poor patient outcomes. Diagnostic accuracy will be enhanced by restricting testing to patients with appropriate clinical symptoms regardless of the method. Toxigenic culture remains useful for epidemiologic studies.

| **Suspected Neutropenic Enterocolitis Involving *C. septicum*** | The specimens of choice for suspected neutropenic enterocolitis involving *C. septicum* are (i) three blood cultures collected from three different venipuncture sites, (ii) stool (at least 25 g, or 25 ml if liquid), and (iii) luminal contents or tissue from the involved ileocecal area collected at surgery or autopsy and transported in tightly sealed, leak-proof containers. In addition, a biopsy sample of muscle (or an aspirate of fluid from the involved area, taken with a needle and syringe) should be collected if the patient is also suspected of having myonecrosis or another form of progressive infection. |
| **Suspected *C. botulinum* or *C. tetani* Infection or Intoxication | Most hospital laboratories are not properly equipped to process specimens from patients suspected of having botulism. In the United States, before collecting any specimens, medical care providers who suspect a diagnosis of botulism in a patient should immediately call their state health department’s emergency 24-h telephone number or the Centers for Disease Control and Prevention (CDC) in Atlanta, GA [(770) 488-7100, 24-h/7-day emergency service] so that appropriate action can be taken to establish the diagnosis, initiate treatment, and investigate the case. |

ISOLATION PROCEDURES

Isolation and Appearance on Plated Media
A summary of useful procedures for culture and isolation of clostridia is provided below. Clostridia usually produce good growth on commercially available CDC anaerobe blood agar and phenylethyl alcohol blood agar (PEA) after 1 to 2 days of incubation. Brucella agar with 5% sheep blood, Columbia agar, or brain heart infusion agar supplemented with yeast extract, vitamin K, and hemin may also be used as the nonselective blood agar medium. Colony characteristics vary on different media. A few species, such as C. perfringens, form colonies after overnight incubation or in as little as 6 h. When clostridia are suspected in wound or abscess specimens (e.g., gas gangrene), egg yolk agar (modified; see chapter 19) should also be inoculated.

After incubation, the blood agar and PEA cultures should be examined under a dissecting microscope, with attention being paid to the hemolysis pattern, colony structure, and evidence of swarming or motile colonies. Egg yolk agar should be examined for evidence of lecithinase (Fig. 2) or lipase production. Lecithinase activity is indicated by the development of an insoluble, opaque, whitish precipitate within the agar. An iridescent sheen or oil-on-water appearance (pearly layer) indicates lipase activity. Proteolysis, the third reaction that can be seen on egg yolk agar, is indicated by a zone of translucent clearing in the medium around the colonies. The same reactions can be visualized on the hemin-supplemented egg yolk agar formulation recommended by Jousimies-Somer et al. (184) or on Lombard-Dowell egg yolk agar (185), in addition to on the modified McClellan-Toabe egg yolk agar formulation (186).

Isolation of additional strains in the presence of swarming Proteus species or C. septicum may require short incubation times (18 to 24 h), subculture onto PEA, or use of anaerobe blood agar with 4% agar (“stiff blood agar”). When isolated colonies can be picked, they should be subcultured to chopped meat medium and incubated overnight for the inoculation of differential media. Prereduced, anaerobically sterilized (PRAS) peptone-yeast-glucose media may be inoculated for detection of metabolic products by gas-liquid chromatography (GLC) if the laboratory has that capability.

Spore Selection Techniques
Heat or ethanol treatment procedures can aid in detecting spores (184, 187). Ethanol may be more effective than heat if the specimen contains relatively heat-sensitive clostridia (e.g., C. butylicum type E and some strains of C. perfringens involved in foodborne outbreaks). Heat treatment may be more effective than alcohol if homogenization is incomplete and the specimen contains particulate matter that is not penetrated adequately by the alcohol. For any spore selection technique, an untreated control subculture should be prepared.

For alcohol treatment, an equal volume of absolute (or 95%) ethanol is added to a 1-ml sample of fecal suspension or homogenate of a wound or exudate in a sterile screw-cap tube. The specimen is gently mixed at room temperature (22 to 25°C for 1 h). An Ames aliquot mixer (Miles Laboratories, Inc., Elkhart, IN) is a convenient way to provide continuous mixing. The treated material is used to inoculate chopped meat-glucose or thioglycolate medium, anaerobe blood agar, or egg yolk agar. The culture is incubated and inspected for growth.

For heat treatment, a tube of chopped meat-glucose or thioglycolate medium (5 ml) is preheated in an 80°C water bath for 5 min, and 1 ml of sample suspension is added.
The culture is incubated for 10 min at 80°C, and the tube is removed and cooled in cold water. The treated sample suspension is subcultured into an unfatted tube of chopped meat-glucose or thioglycolate medium, anaerobe blood agar, or egg yolk agar. The cultures are incubated anaerobically and examined for growth.

**Isolation of C. difficile**

Since C. difficile can be isolated from stool in asymptomatic patients, culture alone is not sufficient to diagnose CDI and may misdiagnose AAD caused by other agents unless stool samples are also assayed for the presence of C. difficile toxins. However, the recent emergence of epidemic, hypervirulent strains has reinforced the need for cultivation of C. difficile for subsequent typing, molecular studies, and determination of antimicrobial susceptibility.

A variety of media exist for recovery of C. difficile from fecal samples or rectal swabs, but there are very few studies that compare media and culture conditions. The original cycloserine-cefoxitin-fructose agar (CCFA), as described by George et al. (188), was based on the ability of C. difficile to ferment fructose. Subsequently, additives such as horse blood, taurocholate, and lysozyme (all of which stimulate vegetation) have been shown to enhance recovery (165, 166, 189). Routine cultivation is done at 35 to 37°C, and prereduction of the medium is required for better growth. Growth depends on strict anaerobic conditions. Typically, the culturing time ranges from 2 to 7 days depending on the methods used. Chromogenic agars have also been developed for C. difficile. Studies have shown that they are as sensitive as other selective agars and more rapid, yielding identifiable colonies within 24 h of incubation (166, 190). The major drawback is the high cost of some of these products.

Some reports indicate that the best results are achieved if specimens are inoculated into an enrichment broth containing taurocholate, such as cycloserine-cefoxitin-mannitol broth with taurocholate-lysozyme-cysteine broth (CCMB-TAL; Anaerobe Systems, Morgan Hill, CA) (166, 191, 192). If an enrichment broth is not used, a spore enrichment step using either alcohol or heat shock will improve isolation on selective media (165, 192). In the recent study by Hink et al. (192) that compared a variety of specimen processing and culture methods, the most cost-effective and sensitive procedure for recovery of C. difficile from rectal swabs and stool was heat shock followed by inoculation of CCMB-TAL and subsequent plating of growth onto prerduced blood agar.

Following incubation, plates should be examined using a dissecting microscope. Colonies of C. difficile are yellowish to white, circular to irregular, and flat, with a rhizoid or erose edge and a ground-glass appearance (Fig. 3). The colonies have a distinctive odor like para-cresol (or horse manure). In addition, C. difficile colonies on CCFA fluoresce chartreuse under UV light (184).

Gram staining of C. difficile reveals rods that are Gram positive to Gram variable, thin, with parallel sides, and 0.5 μm wide by 3- to 5-μm long. Isolation may be difficult due to the presence of both vegetative and spore-forming bacteria. Presumptive identification of C. difficile can be made by demonstrating typical colonies, Gram stain morphology, and characteristic odor. Biochemical differentiation is easiest with detection of proline aminopeptidase. Definitive identification depends on demonstration of the unique pattern of short-chain fatty acid metabolic products by GLC, by biochemical characterization of isolates, by 16S rRNA gene sequencing (12, 193–195), or by matrix-assisted laser desorption ionization–time-of-flight mass spectrometry (MALDI-TOF MS) (Table 1). It is likely that the latter method will replace the other more time-consuming and expensive methods (see “Identification” below) in laboratories that have this technology available.

**IDENTIFICATION**

**Preliminary Identification**

Identification of Clostridia in specimens from sites of infection due to mixed organisms can be time-consuming and expensive. Use of selective and differential media for initial enrichment can provide rapid and relevant information to the clinician. When isolated from normally sterile sites and sites of serious infection, bacteria should always be completely identified. Some of the organisms that warrant identification include C. septicum (associated with gastrointestinal malignancy), C. ramosum, C. innocuum, and C. clostridiiforme (which are frequently resistant to antibiotics), and C. perfringens (196).

Clostridia are typically Gram-positive rods by microscopic morphology. Some clostridia appear to be Gram negative, especially C. ramosum, C. innocuum, and the C. clostridiiforme group, but the special-potency antibiotic disk pattern (see below) verifies the presence of Gram-positive organisms. Second, it may be difficult to detect spores, so an enrichment treatment, heat spore treatment, or malachite green stain may be necessary, and phase-contrast or dark-field microscopy may be helpful. Third, the colonial morphology of pure cultures may be variable, so the culture may appear to be mixed. Subcultures of single, well-isolated colonies yield the same variable morphologies. Examination of colonies by stereomicroscopy is helpful for noting colonial characteristics. Fourth, the aerotolerant clostridia may be confused with Bacillus or Lactobacillus spp. Clostridium species sporulate anaerobically only, grow much better anaerobically (larger colonies), and are almost always catalase negative. Bacillus spp. sporulate aerobically only, usually grow better aerobically, and are usually catalase positive. Aerobically grown C. tertium has colonial and cellular morphologies similar to those of Lactobacillus spp. Certain clostridia can be identified with relative ease by Gram staining, colony morphology determination, a positive indole reaction, hemolysis on blood agar, and the tests described below (Table 3).

**Special-Potency Disks**

The isolate should be subcultured on blood agar with special-potency disks containing vancomycin (5 μg), kanamycin (1 mg), or colistin (10 μg) and incubated anaerobically for 48 to 72 h at 35 to 37°C. Clostridia are colistin resistant and are usually susceptible to kanamycin and vancomycin (Table 3), except for occasional C. innocuum isolates, which may be only moderately susceptible to vancomycin (184, 197).

**Lecithinase and Lipase**

The isolate should be subcultured on egg yolk agar and incubated anaerobically for 48 to 72 h at 35 to 37°C. Lecithinase activity is demonstrated by a white, opaque, diffuse zone around the colonies that extends into the medium (Fig. 2). Lipase activity is indicated by an iridescent sheen on the surface of bacterial growth and on the agar surface around the colonies.

**Spore Test**

Media for the demonstration of spores include chopped meat agar or broth and thioglycolate medium. The culture

should be incubated anaerobically at 5 to 7°C below the optimum temperature (30°C) for the growth and sporulation of clostridia, except with C. perfringens (should be induced at 37°C). Actively growing cultures may stand at room temperature for several days to 1 week, and ethanol or heat spore treatments can be performed as described above.

### Definitive Identification of Clostridium Species

The traditional method for the phenotypic characterization and identification of clostridia is the use of PRAS media for the determination of fermentation profiles and other characteristics, combined with GLC analysis of metabolic end products (198, 199). However, only a few laboratories have PRAS media or GLC available. Table 1 lists characteristics that are useful for definitive identification of clinically relevant clostridia. The key reactions (bold in Table 1) require minimal PRAS medium and can be used in conjunction with commercial identification kits or individual preformed enzyme tests, such as Wee tabs (Key Scientific, Round Rock, TX) or Rosco diagnostic tablets (Rosco, Taastrup, Denmark). Gelatin and esculin hydrolysis, carbohydrate fermentation reactions, and metabolic end product analysis are based on results obtained with PRAS media (Anaerobe Systems).

**PRAS Biochemical Inoculation**

Actively growing broth cultures (without carbohydrate) or cell pastes suspended in broth medium (e.g., peptone-yeast or thioglycollate) may be used to inoculate PRAS media. Cultures are incubated for 48 to 72 h at 35 to 37°C, but overnight incubation is sufficient for many clostridia.

**Gelatin Hydrolysis**

A PRAS gelatin tube with an actively growing culture is refrigerated along with an uninoculated tube for at least 1 h. The tubes are removed to room temperature, inverted immediately, and observed for liquefaction every 5 min. In a positive reaction, the gelatin is hydrolyzed and thus fails to solidify, dropping to the top of the inverted tube immediately (184). In a negative reaction, the medium fails to liquefy when it reaches room temperature (>30 min). A weakly positive reaction yields liquid medium at the time that it reaches room temperature (<30 min).

**Esculin Hydrolysis**

Five drops of 1% ferric ammonium citrate are added to a tube of actively growing bacteria in a PRAS esculin tube, and the tube is observed for a color change and fluorescence under UV (366-nm) light. In a positive reaction, a black or dark-brown color develops, and there is no fluorescence under UV light. In a negative reaction, no color develops, and the tube fluoresces white-blue under UV light. Since many clostridia produce hydrogen sulfide (H₂S), which also reacts with the reagent to form a black complex, all tubes that darken after the addition of reagent should be confirmed under UV light (184). Carbohydrate Fermentation

The pH of actively growing organisms (≥2 + turbidity) should be measured in a PRAS carbohydrate tube. A positive reaction (“acid”) yields a pH ≤5.5, and a negative reaction results in a pH ≥5.9. “Weak acid” is indicated by a pH of 5.6 to 5.8. Details of GLC procedures used for the analyses of metabolic end products listed in Table 1 are outlined elsewhere (184).

Commercial kits, based on the detection of preformed enzymes with chromogenic or fluorogenic substrates, have been marketed for the rapid identification of anaerobes. These panels include RapID ANA II (Remel), API 20A and Rapid ID 32A (bioMérieux, Durham, NC), VITEK ANI card and VITEK 2 ANC card (bioMérieux), and the BBL Crystal anaerobe identification system (Becton Dickinson, Franklin Lakes, NJ). The overall performances of these panels vary, and the panels are not always satisfactory as the sole identification method for clostridia (197, 200–203). In general, Gram stain reaction, cellular morphologies, colonial characteristics, and aerotolerance of isolates (characteristics noted above and in Tables 1 and 3) should be determined in conjunction with the use of commercial microsystems. Supplementation of tests in these kits with individual tablets (e.g., Wee tabs or Rosco tablets) can be helpful. Other useful supplemental tests for clostridia include the tests outlined above, such as lipase and lecithinase production; the reduction of nitrate; gelatin and esculin hydrolysis; carbohydrate fermentation; and metabolic end product analysis using GLC.

Clostridial biochemical activity is quite variable, being saccharolytic/proteolytic and saccharolytic/nonproteolytic to asaccharolytic. The identification of asaccharolytic species is most sophisticated. Liquid chromatography-mass spectroscopy (206) and molecular biological methods such as 16S rRNA gene sequencing (22, 32) can be useful in these cases. 16S rRNA gene sequencing is becoming more popular, though interpretation of results must be done by those with special training. Other promising methods for the identification of Clostridium species are fluorescent in situ hybridization (207, 208) and MALDI-TOF MS (209).

Numerous reports have been published on the utility of MALDI-TOF MS for identification of anaerobic bacteria, including Clostridium species. This method, described in detail in chapter 4, identifies a broad range of organisms based on the analysis of ribosomal proteins ranging in size.
from 2,000 to 20,000 Da. Two commercial MALDI-TOF MS systems, the Bruker Microflex (Bruker Daltonik GmbH, Bremen, Germany) and the VITEK MS (bioMérieux) (previously Shimadzu MS; Shimadzu Corp., Kyoto, Japan), are available. The VITEK MS has FDA clearance for identification of both Gram-positive and Gram-negative bacteria as well as yeasts, while the Bruker system is FDA cleared for only Gram-negative bacterial identification. Neither system is FDA cleared for identification of anaerobic bacteria.

One of the first papers specifically evaluating the utility of MALDI-TOF MS for anaerobic bacterial identification focused on optimizing the system for characterization of clostridial strains (209). The authors carefully controlled the temperature (37°C), anaerobic atmosphere, and incubation time prior to testing. A subanalysis evaluated the effect of sporulation on the spectral patterns. In addition, the authors evaluated the impact of various types of agars to establish whether the medium had any impact on the mass spectra (209). All isolates underwent an inactivation step using 80% trifluoroacetic acid followed by addition of water and acetonitrile; the suspension was centrifuged for 2 min at 6,500 × g. One microliter of the supernatant was then transferred to the MALDI target in five separate spots. The instrument used in this study was the Bruker Microflex LT, and the spectra generated were analyzed using the Bruker Biotype II software (209). Sixty-four reference strains representing 31 different species, including various C. botulinum subtypes and strains otherwise difficult to identify such as C. chauvoei and C. septicum, were evaluated and used to construct a library for identification of 25 “field strains” representing 6 species, most of which were C. perfringens (209). Several important observations were made. The culture medium used had minimal effects on the mass spectra. However, allowing the isolates to sporulate did result in significant changes to the spectra, especially as the cultures aged, so the authors suggested that when testing isolates, fresh cultures should be used. That said, the authors noted that since spectra could also be used to differentiate among the clostridia (209). All 31 species in this study displayed characteristic mass spectrometric patterns that provided unequivocal identification to the species level and could be used to generate a dendrogram similar to what is generated after 16S rRNA gene sequencing. Strains of the same species clustered into distinguishable groups, including the C. butyricum metabolic groups (209). The authors concluded that MALDI-TOF MS can replace cumbersome and often inaccurate biochemical methods for the identification of Clostridium species (209).

After the landmark study by Grosse-Herrenthay et al. (209), most of the studies evaluating MALDI-TOF MS for identification of Clostridium species have been in papers that have evaluated large numbers of different anaerobes recovered from clinical specimens and have, in general, included fewer Clostridium species (210–214).

In the study by Nagy et al. (210), the authors evaluated the Bruker cutoff values for species-level identification of a variety of Gram-positive and Gram-negative, anaerobic bacteria. The manufacturer uses a log score between 0 and 3 log, which is calculated from comparison of the spectra of the unknown organism to those spectra in the reference database. The somewhat arbitrary cutoff that has been established for interpretation is as follows: a log score of ≥1.7 is indicative of genus-level identification, while a log score of ≥2.0 is indicative of a species-level match. In this 2-year study, 283 anaerobes, including 68 isolates of 11 species of Clostridium, were evaluated after a formic acid extraction procedure prior to target inoculation in duplicate and testing on the Microflex LT (Bruker Daltonik), using the Biotyper 3.0 software for spectra interpretation (210). Compared to conventional phenotypic methods and 16S rRNA gene sequencing, MALDI-TOF accurately identified 67 of the 68 isolates using the manufacturer’s suggested cutoff. An isolate identified as C. baratti (log score, 1.727) was identified as C. fallax by phenotypic methods and could not be resolved by 16S rRNA gene sequencing (210).

Three groups have directly compared the Shimadzu/bioMérieux VITEK system to the Bruker system (215–217) for the identification of a variety of anaerobes. Both systems performed equally well for identification of Clostridium species that were contained in the respective databases at the time of the evaluation. In one study that compared extraction methods, C. ramosum was the only species that required pretreatment with formic acid for accurate identification (215).

Important caveats to consider as one evaluates the literature are the instrument manufacturer, the method used (direct application to the target versus pretarget or on-target extraction), the software version of the database, and finally the version of the library used for spectra interpretation. Investigators have shown that on-plate formic acid preparation and direct smear without extraction yield acceptable results for many genera and species of anaerobes (211, 214, 215). Both groups noted that the major limitation of MALDI-TOF MS is the number of anaerobic species in the libraries (211, 214). As databases are frequently updated, readers are encouraged to seek out the latest information provided by the manufacturers.

**Characteristics of Commonly Encountered Clostridia**

Key characteristics that aid in the presumptive identification of the most common species are listed below. See also Tables 1 and 3.

- **C. bifera**: colonies chalk-white on egg yolk agar; irregular, scalloped edge; many free spores, often in chains; urease negative; indole and lecithinase positive. *C. sordellii* is similar but is usually urease positive.
- **C. bolteae**: colonies usually have a slightly irregular edge; greening of agar around colonies; Gram negative; tapered ends; spores rare; lactose negative and β-N-acetylglucosaminidase (β-NAG) negative.
- **C. butyricum**: very large, irregular colonies with mottled-to-mosaic internal structure; subterminal spores; ferment many carbohydrates.
- **C. cadaveris**: white-gray; entire or slightly irregular; raised to slightly convex; oval terminal spores; spot indole positive.
- **C. clostridiiforme**: same as for *C. bolteae* but lactose positive and β-NAG negative.
- **C. difficile**: colonies creamy yellow to gray-white (Fig. 3); irregular, coarse, mottled-to-mosaic internal structure; matte or dull surface; horse stable odor (paracresol); subterminal and free spores or spores infrequent; gelatin hydrolysis can be slow; mannitol and proline positive; colonies fluoresce chartreuse on selective CCFA.
- **C. glycolicum**: colonies are gray-white with an entire or scalloped edge and convex; subterminal and free spores.
- **C. hathewayi**: same as for *C. bolteae* but lactose and β-NAG positive.
C. botulinum from the proteolytic group I strains of C. sporogenes species.

C. perfringens: double zone of beta-hemolysis around colonies (Fig. 4); boxcar-shaped rods; spores rare; lecithinase positive (Fig. 2).

C. ramosum: colonies resemble Bacteroides fragilis but usually have a slightly irregular edge; Gram stain variable; palisading, slender rods; small round or oval terminal spores (Fig. 1); nonmotile; mannitol positive.

C. septicum: swarms (Fig. 5); large, filamentous bacilli (Fig. 6); subterminal spores often in "lemon" forms; DNase positive and sucrose negative.

C. sporgenex: Medusa-head colonies; possible swarming; colonies adhere firmly to agar; subterminal and many free spores; lipase positive.

C. symbiosum: rods with tapered ends, football shaped; may form chains; often has spores.

C. tertium: aerotolerant; terminal spores when anaerobically incubated.

C. tetani: may form a thin film of growth over entire agar plate, especially on moist media; drumstick spores.

Toxin tests are necessary for the identification of a few species. C. sporgenex cannot be differentiated with certainty from the proteolytic group I strains of C. botulinum unless toxin tests are used. A few strains of C. botulinum produce lecithinase as well as lipase and are difficult to distinguish from C. novyi type A except by toxin tests. As a supplement to the methods described, the various types of C. botulinum and other clostridia can be presumptively identified on the basis of differences in their CFA profiles and by typing methods such as pulsed-field gel electrophoresis (PFGE) or other molecular analyses. Finegold et al. (6) described a multiplex PCR procedure for rapid distinction of the three species of the Clostridioforme group.

Typing Systems

Typing of C. difficile fosters understanding of the epidemiology of infections and has become increasingly important with the emergence of outbreaks caused by hypervirulent strains. In the event of a pattern of an increase in the number of severe cases of disease in communities or increased transmission in hospitals, typing of strains may provide useful information on a dominant, more transmissible clone. Physicians should be aware of their local C. difficile situation and should know whether hypervirulent strains are circulating in the community, as this allows for risk assessment for patients and perhaps heightened infection control practices. It is obvious from investigations of C. difficile strains that every region may have its particular pattern of strains, with ribotypes differing between different countries in Europe but also between different regions of a single state (218).

To resolve endemic-disease situations, to monitor the spread of infection, and to assess the genetic relatedness of the associated strains, the successful cultivation of C. difficile is required. Starting with the pure culture, several approaches have been used for such analyses. Restriction endonuclease analysis (REA), PFGE, PCR ribotyping, multilocus sequence typing (MLST), and whole-genome sequencing represent the most common methods used in epidemiologic studies (166, 219). For example, the initial epidemic North American hypervirulent isolates were typed as 027 by PCR ribotyping, designated toxinoype III by typing the toxin A and B genes of the PaLoc, and designated NAP1 by PFGE and type BI by REA (66). These methods are briefly discussed here, as each has distinct advantages and disadvantages. Various tools (Simpson’s index of diversity, Rand coefficients, and Wallace coefficients) have been used to assess the congruence between results of various typing methods (166, 220). In general, the more cumbersome and time-consuming restriction digest methods are being replaced by PCR and sequencing-based methods. Restriction endonuclease DNA analysis of C. difficile using HindIII restriction digest of total genomic DNA was one of the earlier molecular methods to be adopted for strain characterization (221). Several studies over a decade describe it as a sensitive, discriminating, and reproducible method (220, 222). In the study by Tenover et al. (220) that compared REA to PCR ribotyping and PFGE, REA typing appeared to define a broader group of isolates than the other two methods, consistent with the sampling of total genomic DNA. This study also demonstrated that extrapolation of the results of one typing method to another must be done carefully and that there may be advantages to combining methods for outbreak investigations (220). Currently, few laboratories employ this method of strain typing C. difficile, likely because of the complexity involved in its performance and interpretation (221).

PFGE has been the major method used for strain characterization of C. difficile in North America (221). Smal has been the most-often-used infrequently cutting restriction enzyme for this purpose. Early technical issues have been resolved by using younger cultures and adding thiouracil to the electrophoresis buffer (223). While this method has excellent discriminatory power, it is laborious, expensive to perform, and may yield patterns that cannot be assigned to existing NAP types (220, 221).

PCR ribotyping has been used globally to define the epidemiology of C. difficile and has been more readily adopted by clinical laboratories. PCR ribotyping is done with two specific primers that amplify the spacer region in between the 16S and the 23S rRNAs. The spacer region is known for its heterogeneous nature, as opposed to the highly conserved rRNA genes themselves. C. difficile contains 10 rRNA copies, and variations in the spacer regions are seen between different strains but also between different rRNA copies of a single strain. PCR ribotyping is less complex than PFGE and REA and has shown good interlaboratory agreement (219). More than 200 ribotypes exist. The Health Protection Agency in the United Kingdom created the Clostridium difficile Ribotyping Network as part of an enhanced national surveillance program (224). Prospective C. difficile typing results provided an understanding of regional and national prevalence of C. difficile ribotypes and their associated complication rates, particularly with respect to ribotype 027 (224). It was believed that access to these data would contribute to heightened infection control and clinical interventions (224). Variations of PCR ribotyping methods are discussed by Huber et al. (221).

MLST involves partial amplification and sequencing of several housekeeping genes. Data generated with this and other sequence-based methods are unambiguous compared to fragment-based methods and thus may be more easily compared between laboratories (166, 219, 221). The costs with MLST are high compared with PCR methods.
Whole-genome sequencing is being used by several investigators to elucidate the evolutionary history of virulent clones such as ribotype 027 (227). Availability of next-generation sequencing platforms will likely allow laboratories to employ rapid whole-genome data in routine epidemiologic investigations. Next-generation sequencing has the potential to replace existing methods, as the extra resolution provided clarifies differences that may not be detected by more traditional typing methods, and costs are decreasing. One group detected a probable outbreak of community transmission of *C. difficile* using a next-generation sequencing platform (226). The availability of adequate bioinformatics is the major impediment at this time to more widespread implementation.

MLST has been successfully used as a reproducible and discriminating system for strain typing of *C. botulinum* type A using clinical and food isolates (227), *C. perfringens* isolates from necrotic enteritis outbreaks in broiler chicken populations (228), and *C. septicum* isolates recovered from poultry flocks experiencing episodes of gangrenous dermatitis (229). Leclair et al. (230) described a modified PFGE protocol to be the most useful method for typing epidemiologically related *C. botulinum* type E strains, in comparison with randomly amplified polymorphic DNA analysis and automated ribotyping using clinical and food isolates associated with four botulism outbreaks. Furthermore, analysis of the variable numbers of tandem repeats (VNTRs) within the genome, called multiple-locus VNTR analysis, has been described for *C. perfringens* (231, 232). Epidemiologically related isolates previously typed by PFGE were also examined by multiple-locus VNTR analysis, and the congruency of the two methods was found to be very high. Macdonald et al. (106) described VNTR regions in *C. botulinum* strains, providing a rapid and highly discriminatory tool to distinguish among *C. botulinum* BoNT/A1 strains for investigations of botulism outbreaks.

SEROLOGIC TESTS
Serologic procedures are not practical for secure strain identification from colonies. Furthermore, no standardized tests are available for the detection of antibodies against *Clostridium* species in clinical specimens to confirm diagnoses of clostridial infections. To evaluate the vaccination status, determination of immunoglobulin G antibodies against tetanus toxin may be useful, but in cases of an unclear immunization status, preventive vaccination should be done.

ANTIMICROBIAL SUSCEPTIBILITIES
Antimicrobial susceptibility studies with strains of a number of clostridial species are summarized in Table 4. Basic methodology for such testing of anaerobes can be found in two recent references (233, 234). Now that more laboratories are identifying anaerobes by 16S RNA gene sequencing, more accurate species identification will be available and more-reliable susceptibility data can be generated. In addition, because of the inherent difficulty in performing susceptibility studies in anaerobes, new methods using phenotypic and molecular techniques are being developed (235). Drugs lacking antimicrobial activities against various clostridia include trimethoprim-sulfamethoxazole, ampicillin, and clindamycin. No resistance of clostridia to ampicillin-sulbactam or piperacillin-tazobactam has been noted, and antimicrobial resistance is uncommon among clostridia with respect to imipenem, metronidazole, and vancomycin. Five species (all with small numbers of strains) and *C. perfringens* show little or no resistance to the antimicrobial agents under consideration (Table 4). Organisms with some resistance to three drugs include *C. ramosum*, *C. innocuum*, and *C. clostridioforme*.

Multiple studies have described resistance to various antibiotics among clostridia. Resistance to penicillin is especially common in *C. ramosum*, *C. clostridioforme*, and *C. butyricum*; these species produce β-lactamases that are induced by β-lactam antibiotics. *C. tertium* has resistance features unusual among clostridia, including resistance to β-lactam antibiotics, metronidazole, and clindamycin. When treating CDIs with metronidazole, a considerable time lag in the onset of its antibiotic activity has to be considered due to its prodrug nature (195). Resistance to clindamycin has been documented for strains of *C. perfringens* (as noted above), *C. ramosum*, *C. difficile*, *C. tertium*, *C. subterminale*, *C. butyricum*, *C. sporogenes*, and *C. innocuum* (185).

Chloramphenicol, piperacillin, metronidazole, imipenem, and combinations of β-lactams with β-lactam inhibitors (e.g., ampicillin-sulbactam) were active against most clostridia (185), and this has not changed significantly over the last 10 years (236). In a 2009 study by Finegold et al. (237), ampicillin-sulbactam and nitazoxanide had the best activities in comparison with neomycin, rifaximin, teicoplanin, and vancomycin. The clostridia are variably resistant to cephalosporins and tetracyclines, and they are usually resistant to the aminoglycosides. Many clostridia other than *C. perfringens* (particularly *C. ramosum*, *C. clostridioforme*, and *C. innocuum*) are resistant to cefoxitin, cefotaxime, cefazidime, ceftriaxone, ceferoperazone, and other broad-spectrum β-lactams (185, 197). Most strains of *C. innocuum* were only moderately susceptible to vancomycin (197, 237, 238).

Earlier quinolones, such as ciprofloxacin, levofloxacin, and lomefloxacin, have demonstrated low or intermediate activities against anaerobes. More new quinolones, like moxifloxacin, gatifloxacin, and garenoxacin, initially had good activities in vitro against most anaerobes, including clostridia (239, 240), though this is changing rapidly in Europe (234). A high frequency of moxifloxacin resistance has also been described among *C. difficile* isolates (241).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS
The isolation of a *Clostridium* species from a clinical specimen, even a blood culture, may or may not be significant clinically, and culture results should be interpreted in relation to the patient’s clinical findings. Clostridia of the patient’s own intestinal microbiota may be present on the skin and may contaminate blood samples or other specimens. Bacteremia may be transient or clinically insignificant. In addition, most clostridia currently encountered in wounds, exudates, blood, and other normally sterile body fluids are opportunistic and may not cause serious or progressive disease unless conditions are suitable in the host. As discussed earlier in this chapter, one exception to this generalization is *C. septicum*, which is rarely encountered in blood cultures except from patients who have an underlying malignancy or neutropenic sepsis. *C. septicum* sepsis is an infectious disease emergency that requires prompt and clear communication between the laboratory and the clinician in order to institute early surgical measures and treatment with antimicrobial agents to improve outcomes. *C. tertium*, *C. perfringens*, and other clostridia, to a lesser extent, may be involved in serious infections that require emergency measures. The best approach for preventing tragic consequences

that may be avoidable is good communication between microbiologists and clinicians.

The accurate and timely reporting of preliminary results (e.g., findings from direct microscopic examinations of clinical specimens), as well as early culture results (after 24 and 48 h of incubation), can be extremely valuable to the physician. For smaller laboratories without anaerobic chambers, incubation of the appropriate media in anaerobic jars provides acceptable recovery for most clinically significant anaerobes, assuming that optimal collection and transport of specimens are performed. The colony characteristics and microscopic features of some clostridia (e.g., C. perfringens, C. sordelli, and C. sporogenes) may be distinctive, so preliminary or presumptive reports may be released before aerotolerance studies are completed. Accurate, definitive identification is needed to better define the role of clostridia in disease, to aid the clinician in selecting optimal treatment, and for public health purposes (e.g., hospital-acquired C. difficile disease).

Potentially life-threatening diseases due to Clostridium species or their toxins, such as botulism, tetanus, or severe cases of CDI, should be carefully examined by the physician and the microbiologist together to ensure optimal sample collection and transport, immediate processing, and initiation of specific therapy. Furthermore, health care institutions require accurate and rapid diagnosis for early detection of possible outbreaks and to implement effective control measures.

Bacteroides, Porphyromonas, Prevotella, Fusobacterium, and Other Anaerobic Gram-Negative Rods*

EIJA KÖNÖNEN, GEORG CONRADS, AND ELISABETH NAGY

TAXONOMY AND DESCRIPTION

OF THE GROUP

Most of the obligately anaerobic, Gram-negative, non-spore-forming rods of clinical relevance belong to the phylum Bacteroidetes, the order Bacteroidales, including the families Bacteroidaceae, Porphyromonadaceae, Prevotellaceae, and Rikenellaceae, and to the phylum Fusobacteria, the order Fusobacteriales, including the families Fusobacteriaceae and Lepotrichiaceae. In addition, clinically important taxa representing anaerobic, Gram-negative, non-spore-forming rods exist in some other phyla, such as the Firmicutes, Proteobacteria, and Synergistetes. There have been a considerable number of changes in the taxonomy of the taxa that are covered in this chapter; some new genera have been named, and several novel species have been described in the past few years. The changes made since 2010 are listed in Table 1.

Within the family Bacteroidaceae, the genus Bacteroides consists of saccharolytic, bile-resistant, and nonpigmented species, mainly isolated from the gut (1). Currently, the genus is limited to species within the Bacteroides fragilis group, which includes more than 40 species, of which about 25 have been recovered from humans (2) for an update, see http://www.bacterio.net). Of these, especially B. fragilis, B. thetaiotaomicron, and B. ovatus are highly relevant in human infections. Only a few taxonomic changes have occurred within the genus since 2010 (Table 1); some isolates from feces of healthy subjects have been described as novel Bacteroides species (3, 4), while B. capillosus has been reassigned to a new genus, Pseudoflavonifractor, which represents a distinct lineage in clostridial cluster IV of the phylum Firmicutes (5), and B. ureolyticus has been reclassified as Campylobacter ureolyticus (6).

The genus Alstipes, which belongs to the family Rikenellaceae, currently includes A. finegoldii, A. indistinctus, A. asaccharolytica, A. putredinis, and A. shahii (7–9). Recently, three new species, “A. obesi,” isolated from feces of a young woman with morbid obesity (10), and “A. senegalensis” and “A. timonensis,” both isolated from feces of the same, healthy subject, were proposed (11, 12). Of those, A. senegalensis was described as having weak growth under microaerobic conditions and as being resistant to metronidazole (12), while A. obesi was described as being motile (10), thus differing from other members of the genus. In general, Alstipes species are anaerobic, nonmotile, and straight or slightly curved rods, except for A. indistinctus cells, which are coccus shaped. Most of the species are pigmented, weakly saccharolytic, and bile resistant.

The family Porphyromonadaceae includes five genera with species detected in humans: Barnesiella, Odoribacter, Parabacteroides, Porphyromonas, and Tannerella. Of these genera, Porphyromonas is clinically the most relevant. There are currently 17 validly published Porphyromonas species, many of which are of animal origin. P. asaccharolytica, P. bennonii, P. catoniae, P. endodontalis, P. gingivalis, P. somerae, and P. veronii are frequently detected in humans (13–17). Most species are saccharolytic and, except for P. catoniae, pigmented and are generally considered pathogens. Human Parabacteroides species consist of three former Bacteroides species, P. distasonis, P. goldsteinii, and P. merdae, and the novel species P. gordonii and P. johnsonii (18–20), and the genus is phylogenetically closely related to the genera Tannerella (21) and Barnesiella (22). Parabacteroides organisms are saccharolytic and resistant to 20% bile. The genus Tannerella contains only one species, T. forsythia (formerly T. forsythensis) (21), which is an important oral pathogen, and the genus Barnesiella contains one human species, B. intestinorum, isolated from feces (23). Both of these species are anaerobic, nonpigmented, nonmotile, pleomorphic rods. The recently described genus Coprothermobacter with C. fastidious, a nonmotile Gram-negative rod isolated from infant feces, is most closely related to Barnesiella (24). The new genus Odoribacter includes two human-derived species, O. sputnichus (formerly Bacteroides) and O. laneus, and one canine-derived species, O. denticanis (7, 225). O. sputnichus is saccharolytic and bile resistant, while O. laneus is asaccharolytic and susceptible to 20% bile.

The family Prevotellaceae includes saccharolytic or moderately saccharolytic short rods that produce acetic and succinic acids as their major end products of fermentation (25). This family has been confronted by a tremendous number of novel species in the past years. Most novel Prevotella species have been isolated from the oral cavity (26–30) but also from feces (31) and from other sites of the body, where they have been associated with various clinical conditions (32–37). P. heparinolytica and P. zoogloeaformans, isolated mainly from infected cat and dog bite wounds (38), are only loosely connected to other Prevotella species and, instead, cluster phylogenetically with Bacteroides species (39). A new genus phylogenetically close to Prevotella,
TABLE 1  Recently classified or reclassified genera and species (from 2010 onwards) of non-spore-forming anaerobic Gram-negative rods isolated from humans

Alloprevotella, was recently described (40); it contains the former Prevotella tannerae (reassigned to A. tannerae) and a novel species, A. rava. Another genus distantly related to Prevotella, Paraprevotella, consists of P. clara and P. xylaniphila, which were isolated from human feces (41).

In the family Fusobacteriaceae of the phylum Fusobacteria, the genera of clinical interest are Fusobacterium, Leptotrichia, and Sneathia. These organisms are nonmotile, pleomorphic rods, isolated mainly from the oral cavity and female genital tract. In a study using sequencing of the 16S-23S rRNA gene internal transcribed spacer regions of Fusobacterium species (42), three phylogenetic clusters were formed. The first cluster included F. mortiferum, F. varians, and F. ulcerans. The second cluster contained F. nucleatum subspecies, F. simiae, F. periodonticum, and F. naviforme (note that there are considerable inconsistencies in the phenotypic and genotypic characteristics between F. naviforme strains obtained by different laboratories; the strain used in the study by Conrads et al. [42] fits with the original description of the species). The third cluster included F. necrophorum subspecies and F. gonoideformans. F. tissii and F. perfoetens formed separate branches. The somewhat fuzzy phylogeny of fusobacteria and wide heterogeneity of F. nucleatum, in particular, have been explained by potential horizontal gene transfer that occurred in the close interaction of oral bacteria within dental biofilms (43).

The genus Leptotrichia consists of nonmotile, highly saccharolytic, long rods that typically produce lactic acid. Currently, there are six validly described Leptotrichia species: L. buccalis, L. goodfellowii, L. hofstadii, L. shahii, L. trevisanii, and L. wadei (44, 45). In addition, a blood isolate from a patient with disseminated breast carcinoma was characterized, and a novel species, L. hongkongensis, was proposed (46) and validated. By using a molecular method, this species was also detected in an oral specimen of a healthy subject. “L. amnionii,” originally isolated from amniotic fluid (47), is not validly published, and in fact, it phylogenetically clusters closer to Sneathia sanguinegens (formerly Leptotrichia sanguinegens) than to other Leptotrichia species (44). A strain phenotypically and phylogenetically similar to L. amnionii from a vaginal specimen was recently characterized, and a novel species, Sneathia amnii, was proposed (48).

Among the phylum Synergistetes, only a few cultivable species, namely, Fretibacterium fastidiosum (49), Jonquettella anthropi (50), and Pyramidobacter piscolens (51), have been isolated from humans so far. They are obligately anaerobic, nonmotile, Gram-negative organisms. Fluorescent in situ hybridization analysis has revealed that the oral cavity harbors a diverse population of unculturable Synergistetes spp., which are large, curved bacilli (52). Also, Synergistetes organisms are widely distributed in various human ecosystems in settings of both health and disease (53).

In the Gram-positive phylum Firmicutes, the novel class Negativicutes harbors organisms with a traditional Gram-negative cell wall structure (54), including some clinically
important genera, such as Didister, Megamonas, Selenomonas, and Centipeda. The genus Didister includes five species of human origin: D. invius (55) and D. pneumosintes (formerly Bacteroides pneumosintes) isolated from the oral cavity, D. microaerophilus and D. propionicifaciens (56) from clinical specimens, and D. succinatophilus from feces (23). These anaerobic or microaerobic, Gram-negative coccobacilli are asaccharolytic and largely unreactive in biochemical tests (56). The two human species of the genus Megamonas, M. hypermegale and M. funiformis (57), are anaerobic, Gram-negative, very large rods. In the genus Selenomonas, S. spatipigens, S. artemidis, S. diamae, S. flueggei, S. infulens, and S. noxia and also the closely related Centipeda periodonti have been isolated from the human oral cavity (58). They are anaerobic, Gram-negative, curved motile rods. Recently, two strictly anaerobic, Gram-negative, nonmotile, long-rod-shaped strains from human feces were characterized and classified as a novel species, Phascolarctobacterium succinatum, in the family Acidaminococcaceae (59). The novel Christensenella minuta from human feces is an anaerobic short rod with a Gram-negative cell wall (60). Phyllogenetically, it belongs to a novel family, Christensenellaceae, within the phylum Firmicutes.

Various families in the phylum Proteobacteria include genera and species of clinical importance in humans. The genera Sutterella and Parasutterella were recently placed in a novel family, Sutterellaceae (61). They consist of asaccharolytic, bile-resistant, Gram-negative, short rods or coccobacilli, of which S. wadsworthia, S. parvipla, P. excrementis, and the novel P. secunda (61) have been isolated from human specimens. The family Desulfovibrionaceae contains two genera of clinical interest, Bilophila and Desulfovibrio. Bilophila wadsworthia is an anaerobic, asaccharolytic, bile-resistant, Gram-negative rod and is a significant pathogen in humans (62). Of the more than 60 Desulfovibrio species and subspecies, only a few infrequently cause a variety of human infections (63). In the family Desulfovibrionaceae, the genus Desulfovibrio includes one human species, D. orale, which is associated with periodontal diseases (64). In the family Succinivibrionaceae, the genus Anaerobiospirillum includes two species, A. succiniciproducens and A. thomissii, isolated from feces of humans, cats, and dogs (65), and the novel genus Succinatimonas has one species, S. hippii, isolated from human feces (66). While the last species is nonmotile and has nonspiral cells without flagella, Anaerobiospirillum, Desulfosobrio (except D. piger), and Desulfomicrobium are motile, spiral-shaped bacteria that reduce sulfate.

Since 2002, genome projects have produced a tremendous number of complete-genome sequences for a variety of Gram-negative anaerobic species, currently including members of the genera Bacteroides, Alistipes, Porphyromonas, Parabacteroides, Tannerella, Odoribacter, Prevotella, Alloprevotella, Paraprevotella, Fusobacterium, Lepotrichia, Jinquettella, Pyramidobacter, Dialister, Megamonas, Selenomonas, Centipeda, Sutterella, Bilophila, and Desulfovibrio. Readers are directed to the NCBI home page (http://www.ncbi.nlm.nih.gov/sutils/genom_table.cgi) for detailed information. Interestingly, the genome sequence for F. nucleatum revealed that although this species has a Gram-negative cell wall, including an outer membrane, a significant proportion of its genes are related to homologues from Gram-positive species in the phylum Firmicutes, suggesting that Fusobacterium has a Gram-positive evolutionary history (67).

Current methods used for taxonomic studies are based mainly on nucleic acid analyses, in particular, sequencing of the 16S rRNA gene and the comparison of these sequences, in order to reveal the phylogenetic relatedness of taxa. This approach does not necessarily correlate with phenotypic characteristics, such as cell and colony morphologies, atmospheric growth requirements, and various biochemical test results, which are still widely used in clinical microbiology laboratories. However, appropriate atmospheric requirements should be determined for all isolates, because the true anaerobes can be differentiated from facultatively anaerobic bacteria by their inability to grow in the presence of oxygen and by their susceptibility to metronidazole (68). Table 2 presents differential characteristics of clinically relevant genera within the Gram-negative anaerobic rods.

### EPIDEMIOLOGY AND TRANSMISSION

Gram-negative anaerobic rods inhabit the mucosal surfaces of the oral cavities and gastrointestinal tracts of animals and humans. Infants acquire oral and intestinal anaerobic commensals mainly from their mother and become simultaneously colonized by multiple strains of commensal species, e.g., Prevotella melanogenica, Fusobacterium nucleatum, or Bacteroides fragilis (69–71). In fact, some of these organisms, such as Fusobacterium and Prevotella, are ubiquitous members of the mouth from the early months of life and, when teeth erupt, form an integral part of dental biofilms (69, 72). Furthermore, Prevotella has been found among the dominant genera in other habitats, such as the esophagus, stomach, and lungs (73–75), which have previously been considered to have a very limited microbial diversity. In the gut, Bacteroides organisms become part of the microbiota in early infancy (71), although as a result of cesarean section, colonization by the B. fragilis group of organisms can be delayed in infants and their levels are greatly reduced (76). Moreover, the composition of Bacteroides populations varies depending on the type of milk feeding (77). Two bacterial phyla, Firmicutes and Bacteroidetes, dominate in the gut. Changes in microbial composition affect the gut barrier function, with consequences for host physiology, energy balance (obesity risk), or mucosal immune system. In this context, Gram-negative anaerobes play a key role (2, 78). In the female genital tract, when the vaginal hydrogen peroxide-producing lactobacilli decrease in numbers, some Prevotella species increase and become an important part with other commensal vaginosis-associated microorganisms (79, 80). Notably, the microorganisms at different body sites are still poorly defined due to considerable proportions of not-yet-cultivated bacteria (53, 81–83).

Also, an important point to be mentioned is the considerable variation observed in the microbiota due to geographical and ethnic differences. This fact clearly influences the rates of recovery of disease-associated organisms in different populations (80, 84, 85).

### CLINICAL SIGNIFICANCE

Anaerobes, originating mainly from the indigenous microflora, are detected typically in polymicrobial infections associated with mucosal surfaces close to the site where they reside. Most infections are acquired when the integrity of the colonized mucosa or lumen is breached by trauma, by underlying disease, or during surgery. Biofilm-associated infections, such as periodontitis and bacterial vaginosis, occur when certain indigenous organisms with virulent properties are enriched within subgingival or vaginal biofilms, respectively, thus causing dysbiosis of the local microbiota (80, 86). Exceptions to endogenous acquisition include acquisition from clenched-fist wounds and animal and human bite
wounds. Gram-negative anaerobes, such as *B. fragilis*, are involved in a variety of infections, with considerable morbidity and mortality (2). Table 3 summarizes the infectious sites where Gram-negative anaerobic organisms have been frequently isolated from clinical specimens. Anaerobic bacteria can occasionally spread to adjacent tissues and the bloodstream, with serious consequences. Localized dental-veolar infections can result in life-threatening spread of oral anaerobes along tissue spaces of the head and neck down to the mediastinum (87). In cases in which Gram-negative anaerobes gain entrance to the bloodstream and trigger a systemic inflammatory response, the result may be sepsis or infective endocarditis, with a fatal outcome. The gastrointestinal tract and the oropharynx are the most common sources for anaerobic bacteremias, with gastrointestinal surgery and underlying malignancies being the major predisposing factors (88–90). In the oral cavity, inflamed periodontal tissues offer an open portal for a myriad of oral anaerobes (91, 92). This calls attention to the importance of prevention of oral infections, especially in patients at increased risk for infective endocarditis.

**Bacteroides and Related Genera**

Among the anaerobes in clinical specimens, members of the bile-resistant *B. fragilis* group are the most commonly encountered and are more virulent and resistant to antimicrobial agents than most other anaerobes. Although other intestinal *Bacteroides* species outnumber *B. fragilis* 10 to 100-fold, *B. fragilis* has been proved to be the most frequent *Bacteroides* species found in specimens from blood, ulcers, abscesses, bronchial secretions, bone, intra-abdominal infections, inflamed appendixes, and the head (2). In the Wadsworth Anaerobe Collection database, consisting of more than 3,000 clinical specimens, *B. thetaiotaomicron* and *B. ovatus*, as well as *B. capillosus* (currently known as *Prevotella bivia*), in descending order, were also detected in these specimens but less frequently. A large U.S. study series that included over 6,500 isolates of the *B. fragilis* group from clinical specimens, collected yearly between 1997 and 2007, confirmed this; *B. fragilis* was the most common (51%), followed by *B. thetaiotaomicron* (19%) and *B. ovatus* (10%) (93). Most isolates came from blood and intra-abdominal infections. In children, *B. fragilis* is the main anaerobic organism recovered from intra-abdominal infections (2, 94); for instance, it is isolated from nearly all tissue specimens of acute appendicitis (95). Around 10 to 20% of the *B. fragilis* strains are able to produce enterotoxin; these strains have been associated with diarrhea in children as well as in adults, and in addition, their proportion seems to be higher than that of nontoxigenic strains among blood culture isolates (96). The *B. fragilis* group organisms (here also including *Parabacteroides distasonis*) and other *Bacteroides* species are the most frequently isolated pathogens from bloodstream infections with involvement of anaerobes (2, 88–90, 97). In a population-based 9-year retrospective analysis on anaerobic bloodstream infections conducted in the province of Alberta, Canada, the *B. fragilis* group was found in 277 (31%) of the 904 cases (90). Comorbidities, especially colorectal cancer, formed a common risk factor for anaerobic bacteremia. Also, recoveries of novel *Bacteroides* species, *B. dorei*, *B. finegoldii*, and *B. nordii*, have been reported from blood (97, 98). In cases of infective endocarditis in which *Bacteroides* species are involved (*B. fragilis* of gastrointestinal origin is the most frequent finding in such infections), the endocarditis tends to be more serious than that caused by other anaerobes and sometimes has a fatal outcome (99, 100). The *B. fragilis* group has been recovered from samples from patients with pericarditis (101) and, often as a single isolate, from patients with septic arthritis as well as osteomyelitis (102). Although spondylodiscitis caused by anaerobes is not common, the involvement of *B. fragilis* needs to be taken into account in cases of potential bacteremia of intestinal origin (103). In peritoneal-dialysis patients, anaerobic peritonitis is a rare event; however, *B. fragilis* and *B. thetaiotaomicron* can then be isolated (104). By hematogeneous spread, the *B. fragilis* group and other *Bacteroides* organisms can reach the brain, causing abscesses.

eP. catoniae is nonpigmented, is resistant to vancomycin, and does not produce butyric acid. *P. bennonis* produces succinic acid but not butyric or propionic acid.
(105–107). In addition, members of this group are among the predominant isolates from burn wound infections, with potential involvement in sepsis in this context (108). Bacteroides species can be involved in part in polymicrobial necrotizing soft tissue infections (2), and the B. fragilis group is, after Gram-positive anaerobic cocci, one of the most common findings of anaerobes in infected moderate-to-severe foot wounds in diabetics (109, 110). Many novel Bacteroides species, such as B. massiliensis, B. nordii, and B. xalerae, have been detected in various clinical materials (98). In cat and dog bite infections, B. pyogenes/B. tectum can be found (38, 111, 112).

Pigmented, bile-resistant Alistipes species, A. finegoldii, A. onderdonkii, and A. shahii, have been strongly connected to appendicitis, both in children and in adults (9, 95). In addition, all three species, but especially A. onderdonkii, have been isolated from intra-abdominal fluid, and A. onderdonkii has been isolated from intra-abdominal abscesses and urine (9, 97, 113). There is one report of two cases of A. finegoldii in blood (114); by phylogenetic reanalysis, one isolate was later identified as A. onderdonkii (113).

**Porphyromonas and Related Genera**

Pathogenic potential varies between different Porphyromonas species. Of the three oral Porphyromonas species, P. endodontalis and P. gingivalis are known significant pathogens. The detection rate of P. gingivalis, one of the major periodontal pathogens, increases with age (115, 116). In addition to being detected in cases of periodontitis, it has frequently been detected in oral specimens from necrotizing ulcerative gingivitis, infected root canals, peri-implant lesions, and acute apical abscesses (85, 117–119). It has been detected, besides in the oral cavity, in clinical specimens from various body sites, e.g., intra-abdominal sites (120), the vaginas of women with bacterial vaginosis (121), amniotic fluid (122), and synovial fluid of patients with rheumatoid arthritis and psoriatic arthritis (123); together with some other periodontal organisms, it has also been found in occluded arteries of the lower extremities of patients with Buerger’s disease (124). P. endodontalis is one of the dominant organisms in infected root canals and in acute dental abscesses (85, 118, 125) but may also be involved in chronic periodontitis (126). P. uenonis, which is phenotypically similar to P. endodontalis and P. asaccharolytica, has been detected in polymicrobial infections below the waistline: appendicitis, peritonitis, pilonidal abscess, an infected incision, decubitus ulcer, and bacterial vaginosis (13, 127). P. asaccharolytica and P. somerae were among the anaerobic isolates from moderate-to-severe foot infections of diabetics (109). At the VA Wadsworth Medical Center laboratory, the 58 P. somerae isolates originated from a variety of specimens, including lower extremity skin and soft tissue or bone, in particular, inguinal or sacral area abscess, intra-abdominal abscess, transtracheal aspirate, axillary abscess, mastoiditis, blood culture, brain tissue, and infected scalp (presented in order of their frequency) (16). P. bernenis has been detected in human wound infections and abscesses, especially in patients with chronic skin and soft tissue lesions in the perirectal, buttock, and groin regions (17). Although P. catoniae inhabits the oral cavity without any disease association described to date, it has been isolated from an abdominal abscess (14). P. gingivalis and Porphyromonas species of animal origin, e.g., P. cangiivalis, P. canoris, P. cansulci, and P. macacae, have been encountered in humans with animal bite infections (112).

Parabacteroides species are common inhabitants of the human gut, and P. distasonis is one of the anaerobes of clinical importance in specimens from intra-abdominal infections and inflamed appendixes, where P. goldsteinii and P. merdae can also be found (2, 128). In addition, P. distasonis, P. merdae, P. goldsteinii, and P. gordonii have been isolated from human blood (2, 20, 97, 129, 130).

Tannerella forsythia is considered one of the major periodontal pathogens (115, 131). In addition, it is one of the predominant organisms in root canal infections (85, 125) and has been found in infected sites around dental implants (119). Moreover, T. forsythia can be detected in substantial amounts from tonsillar crypts of adults (82). In laryngecto-
mized patients with voice rehabilitation, *T. forsythia* proved to be one of the main biofilm-forming anaerobes on voice prostheses that needed replacement (132). This oral bacterium has also been recovered from vaginal samples in women with bacterial vaginosis (121) as well as from synovial specimens of patients with rheumatoid arthritis and psoriatic arthritis (123).

**Preoptovella and Related Genera**

*Prevotella* species are among the dominating microorganisms of the oral cavity, where they, despite their commensalism, can be involved in nearly all types of oral infections. Interestingly, *Prevotella melaninogenica*, which is a common anaerobic organism in saliva (69, 133), is also one of the most prevalent anaerobes, together with *F. nucleatum*, *Prevotella intermedia*, and *Prevotella buccae*, in infected human bite lesions (134). Although the cariogenic microbiota consists mainly of Gram-positive species, some proteolytic Gram-negative taxa, including *P. denticola* and *P. tannerae* (currently *Alloprevotella tannerae*), can frequently be encountered in advanced carious lesions (135). *P. intermedia* (sensu stricto) has been strongly linked to chronic and aggressive periodontitis (84, 116, 136), and *P. intermedia* and/or the phenotypically identical *P. nigrescens* has been detected in samples from pregnant patients and patients with gingivitis, necrotizing ulcerative gingivitis, periarteritis, periimplantitis, root canal infections, and dentoalveolar abscesses (85, 117–120, 137, 138). Also, *P. baronii* proved to be common in root canal infections and acute dental abscesses (85, 125). In noma (*cancri oris*), *P. intermedia* is considered a key organism (139, 140). In spreading odontogenic infections, members of the genus *Prevotella* seem to play an important role, with *P. buccae* and *P. oris* being the most prominent findings in this context (87, 141). Recently, *P. melaninogenica* and *P. histicola* were found to be significantly associated with recurrent tonsillitis in adults.

<sup>a</sup>CNS, central nervous system.

<sup>b</sup>Presented in alphabetical order; order is not related to the frequency of isolation.
(82). A new concept of the polymicrobial bacteriology of patients with cystic fibrosis has been presented, and indeed, not only aerobic Pseudomonas aeruginosa or Staphylococcus aureus but also some anaerobes, especially Prevotella, such as P. melaninogena, P. denticola, P. oris, and P. salitae, have been detected as one of the persistently dominating organisms in the sputa of these patients (142). Also, Prevotella taxa were recovered from bronchoalveolar lavage fluid of patients with ventilator-associated pneumonia (143). Furthermore, various Prevotella species are found in extraoral infections and abscesses at a wide range of body sites; for instance, P. amnii, P. bivia, P. corporis, P. disiens, P. intermedia, P. nigrescens, and P. timonensis in the female genital tract (36, 80, 121, 136, 144); P. buccalis in urine (145); P.bergensis, P. bivia, and P. melaninogena in infectious lesions of the skin and soft tissues, including foot lesions in diabetics (33, 109); P. intermedia and P. nigrescens from intra-abdominal and soft tissue abscesses (120); P. intermedia (sensu lato) and P. melaninogena from peritonsillar and retropharyngeal abscesses (144); P. timonensis from breast abscesses (34); P. intermedia in the synovial fluid of arthritis patients (123); and P. intermedia and P. nigrescens (with some other periodontal bacteria) in occluded arteries of lower extremities of Buerger’s disease patients (124). Several Prevotella species, such as P. bivia, P. buccalis, P. denticola, P. disiens, and P. nigrescens, have been found among anaerobic organisms in patients with bloodstream infections (97, 120). P. heparinolytica is a relatively common anaerobic isolate from animal bite wounds (38, 112).

**Fusobacterium and Related Genera**

Clinically, the most important *Fusobacterium* species are *F. nucleatum* and *F. necrophorum* (146–149). Over the past few years, there has been an increased interest in the role of fusobacteria in human infections, especially recurrent tonsillitis, Lemierre’s syndrome, and bacteremia (82, 150–154), but also in diseases not usually regarded as typical infections, such as acute appendicitis, inflammatory bowel disease, and colon cancer (155–157). Moreover, in children, fusobacterial infections of otogenic origin deserve attention due to potential invasive complications (158, 159). *F. nucleatum* is an oral species which has been divided into several subspecies with variable pathogenic potentials (146). It is a key organism in the maturation of pathogenic biofilms in periodontal pockets (160) and is considered an important pathogen in peri-implantitis, root canal infections, dental alveolar abscesses, and spreading odontogenic infections (85, 119, 125, 141). *F. nucleatum* was found as a dominant species in tonsillar crypts (82), which may explain its dominance in biofilms on voice prostheses that needed replacement (132). It is also an important etiologic agent in extraoral infections and abscesses at a wide range of body sites, being detected from blood, brain, chest, heart, lung, liver, appendix, joint, long bone, abdomen, gut, genitourinary tract, and fetal membranes as well as infected human bite lesions (95, 97, 99, 101, 102, 105, 134, 145, 148, 150, 153–155, 157, 161–166). Bacteremia cases with the involvement of *F. nucleatum* often have underlying comorbidities (150, 153, 154). Nosocomial *F. nucleatum* bacteremia may be seen as a significant mortality predictor (154). In a tertiary-care hospital where all episodes of documented brain abscess cases between 1991 and 2000 were reviewed, in 40% of cerebral puncture specimens, only anaerobes were found; of these, *F. nucleatum* proved to be the most frequently isolated organism, found in one of three of the patients diagnosed (105). In another study, which used molecular methods for bacterial detection in 51 brain abscess pus specimens, *F. nucleatum* was among the most frequent findings, especially in patients with preceding sinitis or dental treatment (161). The presence of *Fusobacterium* adhesin A seems to allow separation of oral fusobacteria, i.e., *F. nucleatum*, *F. periodonticum*, and *F. nucleatum*—a monomorphism from nonoral fusobacteria, including *F. gordonii* (154), *F. mortiferum*, *F. naviforme*, *F. russii*, and *F. ulcerans* (167). Because the adhesin was present in *F. nucleatum* isolated from intrauterine infections but absent among the vaginal species *F. gordonii* and *F. naviforme*, it was hypothesized that intrauterine *F. nucleatum* originates from the oral cavity rather than the vaginal tract. As a novel observation, an overabundance of *F. nucleatum* organisms was demonstrated in colorectal tumor tissue, and furthermore, this had a positive association with metastases of lymph nodes (156). Of the two *F. necrophorum* subspecies, *F. necrophorum* subsp. *fundiiforme* (biovar B) is the dominating isolate in humans, while *F. necrophorum* subsp. *necrophorum* is a common pathogen in animals (147, 149). Important virulence factors, explaining the invasiveness of *F. necrophorum*, are the leukotoxin and plasminogen binding virulence factors (168). *F. necrophorum* is best known for its connection to Lemierre’s syndrome (necrobacillosis), which can be considered an invasive *F. necrophorum* disease, often with pleuropulmonary involvement, in previously healthy adolescents and young adults (147, 149, 151, 152, 169). It is notable that invasive disease with *F. necrophorum* may be on the increase (147). In Denmark, the overall mortality of Lemierre’s syndrome, originating mainly from oropharyngeal sites, was reported to be 9% in adolescents, and that of disseminated *F. necrophorum* infections, originating from lower parts of the body, was 26% in elderly patients with predisposing diseases (169). In the latter type of cases, underlying cancers should be considered. Interestingly, *F. necrophorum* can be found in adolescents as the causative agent in approximately 10% of the cases of tonsillitis (persistent sore throat) not caused by group A streptococci (147, 149, 170). In a Danish retrospective study including 847 patients with peritonsillar abscesses in the years 2001 to 2006, *F. necrophorum* was detected in 23% of the pus aspirate or swab specimens, in most of which the organism grew as a pure culture (171). Another Danish study of 1,930 throat swabs taken from 15- to 24-year-old patients by general practitioners between 2007 and 2009, reported the detection rate of 22% for *F. necrophorum* (172). A wide variety of infections can be caused by *F. necrophorum*: in the head and neck, tonsillitis, peritonsillar abscess, deep neck space infection, mediastinitis, otogenic infection, mastoiditis, sinusitis, and odontogenic infection; as an intracranial complication, sinus thrombosis, cerebral abscess, and meningitis; and as systemic manifestations, bacteremia, septicemia, pleuropulmonary infections, bone and joint infections, soft tissue infections, intra-abdominal sepsis, endocarditis, and pericarditis (149, 150–153, 158, 159, 171, 173). Other *Fusobacterium* taxa, such as *F. nucleogenes*, *F. ulcerans*, and the *F. mortiferum-* *F. varium* group, have only occasionally been isolated from human clinical specimens (94, 109, 148, 158, 174). *F. nucleatum* and an *F. nucleatum*-like species of animal origin, *F. caninum*, and *F. russii* are of importance in cat and dog bite wounds (112, 175).

Commensal *Leptotrichia* species are increasingly implicated in anaerobic bacteremias in immunocompromised patients with lesions of the oral or gastrointestinal mucosa but are also occasionally considered etiologic agents of bac-
teremia and infective endocarditis in immunocompetent individuals (45, 88, 176–179). L. buccalis, L. goodfellowii, L. trevisanii, and L. wadei are the main Leptotrichia findings in blood specimens. According to a recent 3-year retrospective analysis of Leptotrichia organisms in a national reference laboratory in Utah, L. trevisanii comprised 75%, L. goodfellowii, L. wadei, and the newly described L. hongkongensis each comprised 9%, and L. buccalis comprised 1.5% of the 68 Leptotrichia-positive cultures (177). Interestingly, L. hongkongensis findings came especially from multiple myeloma patients. In an immunocompetent subject, L. wadei was reported as a causative organism of a severe pneumonia (180). In the female genital tract, some infectious cases, including bacterial vaginosis, intrauterine fetal demise, and septic abortion, have been reported in connection with L. amnionii (currently Sneathia amnii) (47, 80, 127, 162, 181). In fact, this organism significantly associates with all four Amsel’s criteria (pH, whiff test, vaginal discharge, clue cells) used in clinical diagnostics of bacterial vaginosis (80). Furthermore, a few bacteremia cases in connection to delivery (182) and one neonatal meningitis case (183) have been reported. However, it has also been isolated from a knee joint specimen of a male patient (184), revealing that the organism is not restricted to the female genital tract. Based on the high number of L. amnionii organisms in urine samples from renal transplant recipients, it may also be considered one of the etiologic agents of urinary tract infections (145). One case of septic arthritis with an involvement of a Sneathia organism most closely related to Sneathia sanguinogenes has been reported in an immunocompetent woman (185). Although S. sanguinogenes was originally isolated from blood (186), it has been reported mainly from various infectious conditions of the female genital tract, such as preterm labor, neonatal sepsis, postpartum bacteremia, and pyosalpinx, and in amniotic fluid associated with various clinical syndromes (127, 162, 166, 182, 186). In a recent study using metagenomic 16S rRNA gene identification for Sneathia in midvaginal samples from 736 women in an urban outpatient clinic in Virginia, the target organism was detected in 30 to 43% of the samples, depending on the selected abundance threshold (48). It was also shown that S. amnii is able to adhere to the cervical epithelium and, presumably, to invade the uterine cavity. Leptotrichia/Sneathia species can be considered clinically relevant intra-amiotrophic pathogens (162, 163), and in fact, their role in preterm labor may be currently underestimated.

Other Gram-Negative Anaerobic Rods

In the novel phylum Synergistetes, there are three cultivable species representing three genera, i.e., Freitibacterium fastidiosum, Jonquetella anthrophi, and Pyramidobacter pisolonic, which have been isolated from human clinical specimens. J. anthrophi isolates have been found in breast abscess, pelvic abscess, sebaceous cyst, wound, and peritoneal fluid specimens (50), while infectious F. fastidiosum and P. pisolonic have been found in patients with periodontitis, dental root canals, and odontogenic abscesses (49, 51, 85).

Two Dialister species, D. pneumosintes and D. invius, are inhabitants of the oral cavity, where they have been implicated as pathogens in endodontal and periodontal infections as well as acute dental abscesses (55, 85, 187–189). In addition, they have been recovered from infectious specimens from blood, brain abscesses, urine, human bite wounds, and bronchoalveolar lavage fluid from patients with ventilator-associated pneumonia and cystic fibrosis (91, 134, 142, 143, 145, 190, 191). A considerable part of D. pneumosintes isolates originate from various cutaneous/soft tissue infections (190). It may be that the patient’s poor dental hygiene is a predisposing factor in certain nonoral cases, e.g., bacteremia and brain abscess (143, 191). D. microaerophilus, which is not a strict anaerobe, and D. propionifaciens have been isolated from a variety of clinical specimens, mainly below the waistline (56, 80, 190).

Selenomonas species and Centipeda periodontii are motile organisms recovered from the oral cavity, where they are components of dental biofilms (69, 192). Selenomonas spuitigena has been found in specimens from necrotizing ulcerative gingivitis, generalized aggressive periodontitis, and acute dental abscesses (84, 85, 117). Selenomonas noxia has been reported in chronic and aggressive periodontitis lesions (84, 193), and Centipeda periodontii has been recovered from endodontic infections (194). Furthermore, there have been a few reports on the involvement of Selenomonas in nonoral infections, including cystic fibrosis and bacteremia (142, 195, 196).

Sutterella wadsworthensis, a microaerophilic organism phenotypically but not phylogenetically close to fastidious Campylobacter species, has been isolated from a variety of infections, such as appendicitis, peritonitis, and rectal or perirectal abscesses (197, 198). Recently, Sutterella was suggested to play a dominant role in gastrointestinal disturbances in children with autism after these organisms were detected in ileal mucosal biopsy specimens but not in those from control children with gastrointestinal symptoms (199).

Bilophila wadsworthia is a significant human pathogen that is being isolated from polymicrobial intra-abdominal infections, especially appendicitis, at an increasing frequency, with deteriorating disease status (62). B. wadsworthia is even more common in gangrenous appendixes of children than in those of adults (95). Moreover, B. wadsworthia has been isolated from abscesses at various body sites as well as from blood (62, 200).

Some Anaerobiospirillum and Desulfovibrio organisms reside in the gastrointestinal tracts of humans but can also be infrequently encountered in clinical specimens; typical cases are bacteremia and abdominal infections in immunocompromised patients (63, 196, 201–203). Of the two Anaerobiospirillum species, A. succiniciproducens has been connected to bacteremia and diarrheal illness, whereas A. thomasi is considered a potential cause of diarrhea but not of bacteremia (65, 201). In most cases, A. succiniciproducens bloodstream infections have an underlying condition, and patients often suffer from gastrointestinal symptoms (201). In the case of diarrhea, the possibility of zoonotic transmission exists (202). The main Desulfovibrio species isolated from human infections include D. desulfuricans, “D. faeijeldensis,” D. piger, and D. vulgaris (63, 196, 204–206). D. desulfuricans is also common in the environment, whereas D. faeijeldensis and D. piger have been detected only in humans so far. The first human findings of D. intestinalis came from vaginal specimens of four Japanese women (207). D. faeijeldensis, a taxon never validly described, has been isolated from blood, in particular, but also from various intra-abdominal sites, urine, and peridontal pockets (205). D. desulfuricans bacteremia cases have also been reported (208, 209). In addition to D. faeijeldensis, an oral Desulfovibrio species, D. orale, has been connected to periodontitis (64). On the basis of differences in pyrosequencing results of stools collected from autistic children with gastrointestinal symptoms and their sibling and nonsibling controls, Desulfovibrio was recently suggested as being linked to regressive autism (210).
COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

General guidelines for the collection, transport, and storage of specimens are discussed in chapters 11 and 18 of this Manual. Specimens suitable for the isolation of anaerobes include aseptically taken blood, tissue biopsy specimens, aspirates (e.g., cerebrospinal fluid, joint fluids, and pus), dental root canal exudates, and subgingival plaque. Appropriate tract specimens include bronchoscopic protected bronchoalveolar lavage fluid, and expectorated sputum samples may be collected from patients with cystic fibrosis (211). Also, wound and ulcer specimens should preferably be taken by tissue biopsy, wound curettage, or aspiration. For example, for diabetic foot ulcers, the lesion is cleaned and carefully debrided, and tissue samples are collected from the base or progressive edge, where bacteria actively multiply (109). Infected tissue, obtained by excision or biopsy, is always preferable to pus as a clinical specimen. However, when pus is collected, it is best aspirated into a syringe through a needle and injected into an anaerobic transport vial containing an oxidation-reduction indicator (e.g., products from Anaerobe Systems, Morgan Hill, CA, and Becton, Dickinson, Sparks, MD). It is notable that syringes used for aspiration should not be used as transporters because of the potential danger of needle stick injuries or accidental expulsion and because oxygen diffuses through plastic syringes (68). Mucosal or cutaneous swabs are not recommended. In cases where bacteremia is suspected, a 20-ml volume of blood (at least two separate samples) is recommended for cultures. Anaerobic culture is important, especially in patients with complex underlying diseases and when the source of bacteremia is unknown (89, 130). Also, blood collected from patients with abdominal or gynecological processes, peritoneal abscess, dirty wounds, decubitus ulcers, osteomyelitis, or spreading oropharyngeal disease should be examined for anaerobes.

Specimens must be transported to the laboratory under anaerobic conditions (e.g., in Anaerobe Systems PRAS anaerobic transport medium [ATM] AS-911, in Becton, Dickinson BBL Port-A-Cul transport medium or a BBL Vacutainer anaerobic specimen collector [the last is medium free in order to minimize sample dilution], or in AnaeroGRO [Hardy Diagnostics, Santa Maria, CA]) without delay for further processing. An optimal transport system is able to maintain the viability of anaerobic organisms without allowing the overgrowth of aerobic bacteria. However, if clinical specimens contain fastidious organisms, the transport to the clinical laboratory should occur within 24 h (212). Tissue samples are best transported in specific anaerobic transport vials or in loosely capped containers sealed in gas-impermeable bags in which an anaerobic atmosphere has been generated. For small tissue and biopsy specimens and for subgingival and dental root canal samples, a semisolid anaerobic transport medium (e.g., those of Anaerobe Systems, Becton, Dickinson, and Hardy Diagnostics), in which the specimen can be submerged, can be used. Further guidance for the collection of specimens from different body sites and by various methods as well as transport systems and anaerobic techniques can be found in more detail elsewhere (68).

For long-term storage, 2- to 3-day-old cultures can be transferred into vials containing sterilized 20% skim milk and kept frozen at −70°C.

DIRECT EXAMINATION

The gross appearance, fluorescence under long-wave UV light, and odor of the specimen can give the laboratory valuable clues as to the presence of anaerobes. A fetid or putrid odor due to volatile short-chain fatty acids and amines is always associated with the presence of anaerobes in the sample. Black necrotic tissue and/or red fluorescence of the sample may be indicative of the presence of pigmented Gram-negative rods (68).

The Gram stain is still the fastest, simplest, and most likely to yield significant information and should be prepared from all specimens accepted for anaerobic culture. Many Gram-negative anaerobic rods, e.g., different species within the genus Fusobacterium, have unique cell morphology (see Table 7). For instance, a Gram-stained smear with highly pleomorphic Gram-negative rods in a positive blood culture bottle from a septic patient following a sore throat may indicate invasive F. necrophorum infection (147). The morphotypes and relative quantities of the bacteria and host inflammatory cells present in the preparation should be reported. Gram staining using the Nugent criteria for interpretation of vaginal discharge is still considered the best method for diagnosis of bacterial vaginosis (213).

Molecular Detection

Molecular methods are increasingly used for direct detection of bacteria from clinical specimens or for confirmation of identity. As yet, they are used mainly in specialized oral and research microbiology laboratories, but their use also for routine diagnostics is expanding.

For the detection of fastidious organisms and potential pathogens, almost-complete or partial sequencing (the V3-V6 regions are most informative) of the 16S rRNA gene has been successfully used not only for bacterial identification in typical polymicrobial lesions, such as periodontitis, endodontic infections, and spreading odontogenic infections (52, 83, 126, 141, 188), but also in infections where the involvement of anaerobic bacteria has not traditionally been taken into account, e.g., cystic fibrosis (142). It is notable that a culture-based approach can underestimate the presence of etiologic but fastidious or uncultivable organisms in clinical specimens. For example, Prevotella species are highly prevalent in the lungs of cystic fibrosis patients (142, 211), but routine culture of sputum does not include anaerobes and potential anaerobic pathogens have not been reported. Furthermore, in women who experienced preterm labor and whose amniotic fluid tested positive by culture or PCR, seven species, including Sneathia sanguinegens and Leptotrichia amnionii (currently Sneathia amnii), were detected by PCR only (162). In addition, in a study of urinary tract specimens from renal transplant recipients (145), the 16S rRNA PCR method detected a wide range of bacteria, including Gram-negative anaerobes, such as Bacteroides vulgatus, Dialister invisus, Fusobacterium nucleatum, L. amnionii, Prevotella buccalis, and Prevotella ruminicola, in culture-negative samples. A recent study that subjected pus specimens from 51 brain abscesses to 16S rRNA gene amplification, cloning, and sequencing revealed 19 cases of polymicrobial infections with 76 different species, including 22 uncultured taxa, among them 10 Bacteroides phylogenotypes (161). Pyrosequencing studies by the same research group have demonstrated that the species diversity in such polymicrobial infections is much richer than previously assumed. With decreasing prices and new methods, e.g., bar code labeling and V6 tagging, next-generation sequencing will expand the power to investigate health- and disease-associated mixed anaerobic microbial communities or outbreak histories (214–216). Challenges associated with molecular techniques include differences in lysis efficiency depending on the bacterial cell wall composition, the presence of human...
ISOLATION PROCEDURES
Except for blood and joint fluid cultures, the use of liquid medium as the only anaerobic culture technique is not acceptable [68]. The use of solid nonselective medium together with selective medium increases the yield and saves time in terms of recognition and isolation of colonies. The selective media are chosen based on the expected microbiota at the collection site or, in the case of bite wounds, on the oral microbiota of the biter (human or animal). Freshly prepared or preduced and anaerobically sterilized medium should be used [68]. Different basal media differ in their abilities to support the growth of anaerobes; brucella base and fastidious anaerobe agar (Lab M, Bury, United Kingdom) may be the best basal media for the isolation of Gram-negative anaerobic rods. In particular, fastidious-anaerobe agar enhances the growth of fusobacteria [147]. In academic centers performing large-scale anaerobic bacteriology, it would be ideal to use two different basal media to maximize isolation efficiency.

Culture methods are found in chapters 18 and 19 of this Manual. The minimum medium setup for isolating Gram-negative anaerobic rods includes (i) a nonselective, enriched, brucella base sheep blood agar plate supplemented with vitamin K$_1$ and hemin (BA); (ii) a kanamycin-vancocinmycin laked sheep blood agar plate for the selection of Bacteroides and Prevotella species; and (iii) a Bacteroides bile-esculin (BBE) agar plate for specimens from areas below the diaphragm for the selection and presumptive identification of the B. fragilis group and Bilophila species. BBE and kanamycin-vancocinmycin laked sheep blood are also available as biplates. A phenethyl alcohol sheep blood agar plate used to prevent overgrowth by aerobic Gram-negative rods and swarming of some clostridia is indicated for putulent specimens and in the case of mixed infections. Use of a metronidazole disk (5 μg) on nonselective agar is useful for the detection of Gram-negative obligate anaerobes; however, it may mask the presence of infrequently encountered metronidazole-resistant organisms.

After inoculation, the anaerobic plates are immediately incubated at 36 to 37°C in an anaerobic environment, such as an anaerobic bag, jar, or chamber. Alternatively, setup and incubation may all be done in an anaerobic chamber. Plates should not be exposed to air during the first 48 h to avoid loss of the more oxygen-sensitive species. The availability of an anaerobic chamber enables the examination of the culture whenever necessary. An incubation period of 48 h will reveal the presence of rapidly growing strains, such as Bacteroides or clostridia, but reincubation for at least 4 to 5 days for growth [62, 63, 68]. For successful culture and susceptibility testing of anaerobes, a strictly anaerobic atmosphere needs to be maintained inside the chamber, jar, or bag. Chambers especially may fail to keep a proper gaseous condition when kept in busy use, and therefore, repeated quality controls should be performed; e.g., with a simple method of growing an aerotolerant Clostridium perfringens strain with a metronidazole (5 μg) disk, an inhibition zone of >27 mm indicates acceptable anaerobiosis [219].

Increased awareness of the importance of anaerobic organisms as a cause of systemic infections may contribute to the increase of their isolation and detection in blood samples in clinical microbiology laboratories. For instance, to reliably detect anaerobic organisms, the LYTIc 10 anaerobic/F BACTEC medium (Becton, Dickinson) has been shown to be a rapid and reliable method, improving the detection of low levels of anaerobic bacteria, such as Prevotella and Fusobacterium, in the sample [91].

IDENTIFICATION
After anaerobic incubation, the relative quantities of distinct colony types are recorded. Plates should be examined with a dissecting microscope to facilitate detection. Even after incubation for 7 days, certain species, such as Desulfovibrio and Dialister, grow as transparent colonies that are pinpoint in size and are easily overlooked in mixed cultures [56, 63, 204, 205]. The isolates should then be subcultured onto BA and at this point, a rabbit laked blood agar plate for the rapid demonstration of pigment production and an egg yolk agar plate for the demonstration of lipase, lecithinase, and proteolytic activities may also be inoculated. The primary plates are reincubated along with the purity and test plates.

Presumptive Identification
Colony morphology of an isolate in pure culture can be useful for presumptive identification. For example, F. nucleatum can appear on the plate as speckled, iridescent, or bread-crumble-like colonies, while B. wadsworthia typically has black-centered colonies on BBE [68]. Colony morphology, together with the capability of erythrocyte agglutination, is among the features that can be used to separate the two F. necrophorum subspecies by phenotypic testing [220]. The agglutination procedure, using human and chicken erythrocytes, is performed by a glass slide method in which agglutination is observed by mixing a drop of bacterial suspension and a drop of erythrocyte suspension on a microscope slide. F. necrophorum subsp. funduliforme (agglutination-negative) colonies are pulvinate, creamy, and glistening, with entire margins, whereas F. necrophorum subsp. necrophorum (agglutination-positive) colonies are convex or umbonate, waxy, and dull, with erose margins. Also, observation of hemolysis may be of diagnostic value; for instance, both F. necrophorum subspecies exhibit beta-hemolysis when grown on horse blood agar [220]. Hemolytic properties on human blood may aid in the separation of different Leptotrichia species [44]. Production of pigment is another visible characteristic valuable in presumptive identification; pigmented Gram-negative anaerobic rods are saccharolytic and asaccharolytic species of the genera Prevotella and Porphyromonas and the pigment-producing Alastipes species A. isigoldii, A. onderdonkii, A. shahii, and A. timonensis. In this context, it is pertinent that the statement “after 4 days incubation on laked rabbit blood agar, colonies appear black” in the original description of A. onderdonkii and A. shahii [9] is incorrect. Instead, the grade of pigmenting is light or moderately brown on rabbit laked blood agar and, under long-wavelength (365-nm) UV light, colonies appear black. Appearance of pigment requires fresh medium and expanded incubation [113]. As a novel observation, a diffusible brown pigment on BBE can be useful in the presumptive identification of Alastipes species [113]. The pigmented Prevotella and Porphyromonas species vary greatly in degree and rapidity of pigment pro-
duction (2 to 21 days), which ranges from buff to tan to black, depending primarily on the type of blood and the composition of the base medium used in the agar (68). Fluorescence under long-wavelength UV light can be helpful in presumptive identification; pigmented *Prevotella* and *Porphyromonas* colonies typically fluoresce red, *F. nucleatum* and *F. necrophorum* fluoresce yellow-green, and *Desulfovibrio* and *Bilophila* species, when tested with a drop of 2 N NaOH on a swab of cell paste, fluoresce red due to the presence of desulfovirdin pigment (68, 206, 220). Microscopic determination of the morphology of Gram-stained bacterial cells can aid in the presumptive identification of the organisms present. Among fusiforms, *F. nucleatum* usually exhibits long, spindle-shaped cells with tapered ends, while *F. necrophorum* and *F. mortiferum* have highly pleomorphic cells, with or without swollen areas and large round bodies (8, 147, 220). *Leptotrichia* cells, which often stain Gram positive in fresh cultures, have usually been considered long rods; however, this description fits only *L. buccalis*, *L. hofstadii*, *L. shahii*, and *L. trevisanii* (44, 179). *Dialister* species are small coccobacilli, making their separation from Gram-negative cocci difficult (56). *Desulfovibrio* *pig* typically stains in a bipolar manner (206). Wet slide preparations for microscopic examination reveal the motility of Gram-negative anaerobes; *Selenomonas* displays a characteristic tumbling motility, often moving laterally across the field, *Anaerobiospirillum* cells are spiral with corkscrew-like motility, and *Desulfovibrio* species, except for *D. piger*, appear as curved rods with rapid, progressive motility (63, 65, 221).

The *B. fragilis* group, in particular, and most *Bacteroides* species are typically bile resistant (2, 68). Pigment-producing *Alistipes* can readily be distinguished from pigmented *Porphyromonas* and *Prevotella* species by their resistance to 20% bile (9, 11). Among fusobacteria, *F. mortiferum*, *F. varium*, and some strains of *F. necrophorum* grow in the presence of bile, whereas *F. nucleatum* does not. The profile of susceptibility to special-potency antimicrobial disks (a zone size of ≥10 mm is considered susceptible) containing vancomycin (5 μg), kanamycin (1,000 μg), and colistin (10 μg) is useful in the presumptive identification of many Gram-negative anaerobic taxa (Table 2). Gram-negative anaerobic rods are typically resistant to vancomycin, with pigmented *Porphyromonas* species and *S. amnii* being the only exceptions (13, 16, 17, 48, 68). Susceptibility to both kanamycin and colistin is characteristic of *Fusobacterium* and *Leptotrichia* species and *S. wadsworthensis*. To differentiate members of the genera *Dialister* and *Veillonella*, special-potency disks can be helpful; *Dialister* species are resistant to colistin, whereas *Veillonella* species are usually susceptible, except for *V. montpellierensis* and *V. ratti* (56). Among motile Gram-negative organisms, *Anaerobiospirillum* is usually susceptible to colistin, unlike most *Desulfovibrio* and *Selenomonas* isolates.

In addition to tests used to determine the characteristics listed above, there are some simple tests that are within the scope of most clinical laboratories. For example, a bile-resistant organism with typical darkening of the center of colonies on BBE can easily be recognized as *B. wadsworthia* by its strong catalase reaction with 10 to 15% H₂O₂ (62) and by combining positive indole and lipase reactions, a *Fusobacterium*-like organism can be tentatively identified as *F. necrophorum* (147). An indole- and lipase-positive short rod that forms black-pigmented colonies and fluoresces red can be identified as *P. intermedia/P. nigrescens*, while *Prevotella pallens* resembles these indole-positive species but has a lighter pigment and is lipase negative (68). *Bilophila* and *Sutterella* typically reduce nitrate. A characteristic smell may guide the identification; a foul smell produced by butyric acid and other metabolites is typical for *Fusobacterium* species, while a strong sulfur smell is typical for the presence of *Desulfovibrio* species (63, 206).

### Biochemical Testing

In culture-based biochemical testing, the main techniques for classification of anaerobic organisms and distinction of individual species include sugar fermentation reactions, the use of prereduced, anaerobically sterilized (PRAS) carbohydrates or commercial test kits, and the determination of enzyme profiles with individual diagnostic tablets or preformed enzyme kits. In addition, the determination of major volatile fatty acid end products of glucose metabolism, as detected by gas liquid chromatography (GLC), is a useful adjunct to biochemical and physiological tests (68), but together with analysis of the long-chain fatty acids found in bacterial cell walls, it is beyond the scope of most clinical laboratories.

Commercially available test kits, such as the API 20A, *API ZYM*, and Rapid ID 32A (*bioMérieux*, Marcy-l’Etoile, France), RapID ANA II (Remel, Lenexa, KS), BBL crystal identification (Becton, Dickinson), and AN microplate (Biolog Inc., Hayward, CA) systems, are used for testing preformed enzyme and carbohydrate fermentation profiles in clinical microbiology laboratories (222). Diagnostic tablets (e.g., from Rosco, Taastrup, Denmark, and Key Scientific, Stamford, TX) are also useful for determining individual enzyme reactions of anaerobic isolates. A heavy inoculum from 2- to 3-day-old cultures should be used for testing to obtain optimal reactions. When different test systems are used, variation of test results is expected due to differences in the substrate specificities. These rapid, easy-to-use systems are best suited for fast-growing and biochemically reactive anaerobes, such as the *B. fragilis* group of organisms, but even then, it may not be possible to reliably identify the isolate to the species level. The Vitek ZANC card (*bioMérieux*) is a new automated system for rapid identification of anaerobic bacteria from clinical specimens (223, 224). According to the results of a clinical trial performed in three large tertiary-care centers (224), the Vitek ZANC card (*bioMérieux*) proved to be acceptable for routine use in laboratories; however, the system incorrectly identified a considerable number of clinically relevant species, such as *F. necrophorum*, *P. intermedia*, and *P. melaninogenica*, and did not include clinical isolates that were not in the system’s rather-limited database. However, skillful reading of Gram stain preparations considerably improves the percentage of correct identifications (223).

The most commonly encountered bile-resistant organisms in clinical specimens belong to the *B. fragilis* group of organisms. They grow as gray, circular, convex, and entire colonies on BA and, in addition, grow well on BBE, where they (except for *B. vulgatus*) blacken the agar by hydrolyzing esculin. Based on their resistance to special-potency antibiotic disks (vancomycin, kanamycin, and colistin) and a few rapid tests, such as the catalase, indole, esculin, and α-fucosidase tests, they can initially be reported as the *B. fragilis* group or as organisms most closely related to this group (68). The genus *Parabacteroides* includes the former *Bacteroides* distasonis and *Bacteroides merdae* (18), and *Bacteroides splanchnicus* has been moved to the genus *Odoribacter* (225). In addition, clinically relevant species include *B. massiliensis*, *B. nordii*, *B. salyersiae*, *P. goldsteinii*, and *P. gordonii* (20, 128, 226, 227). All *Parabacteroides* species are negative for indole and α-fucosidase, which distin-
guishes them from the B. fragilis group organisms. P. goldsteinii is phylogenetically and phenotypically very similar to P. merdae; however, P. goldsteinii is positive for α-glucosidase and β-glucosidase (Rosco), whereas P. merdae is not (128). Furthermore, its positive β-glucuronidase reaction separates it from Parabacteroides distasonis. Unlike other Parabacteroides species, P. gordonii does not hydrolyze esculin and does not ferment trehalose (20). Most of the B. fragilis group and related organisms are highly fermentative. Table 4 presents the key characteristics for distinguishing the B. fragilis group organisms, including Parabacteroides species and O. splanchnicus.

In general, most Alistipes species can be separated from Bacteroides by their pigment production; however, culture on fresh rabbit laked blood agar and prolonged incubation are then requested (9, 113). Exceptions are the type species of the genus, A. putredinis, and the newly described species A. senegalensis and A. obesi; not only are A. senegalensis and A. obesi nonpigmented, but A. putredinis is also bile sensitive and asaccharolytic (8) and A. obesi is motile (10), while A. senegalensis is able to grow microaerobically, being resistant to metronidazole (12). A. finegoldii, A. onderdonkii, and A. shahii strains grow well on solid media, where colonies appear to be beta-hemolytic, but hardly in liquid media, with or without supplements (9, 113). They are variably saccharolytic due to their poor growth in liquid media and are bile resistant and catalase negative. Two enzyme reactions may be able to separate pigmented Alistipes species; A. finegoldii is positive for α-fucosidase but negative for β-glucosidase, whereas A. onderdonkii is negative and A. shahii is positive for both enzymes (9).

Tannerella forsythia is a fastidious oral pathogen, and human strains require exogenous N-acetyl-l-muramic acid for growth in pure cultures (21, 131). Key characteristics of T. forsythia are its sensitivity to bile and positive trypsin and esculin reactions. Notably, strains from animal bite wound infections are positive for catalase and indole (228).

Porphyromonas species, except for P. catoniae, pigmen. The identification of the closely related and phenotypically similar P. asaccharolytica, P. endodontalis, and P. unonis is difficult due to their slow pigment production and inactivity in biochemical testing. Testing with prereduced, anaerobically sterilized carbohydrates is not helpful in distinguishing these species, but glyoxylic acid and glycerol in the AN microplate system (Biolog Inc.) enable their separation; P. asaccharolytica is positive for glyoxylic acid and P. unonis is positive for glycerol (13). P. asaccharolytica is also positive for α-fucosidase, while the other two species are negative. In addition, the differences in the degrees of pigmentation may be helpful, with P. unonis being the most and P. endodontalis the least pigments (13). Positive indole, N-acetyl-β-glucosaminidase, and trypsin reactions

179, 186). Interestingly, the cells of the novel *Sneathia* species *S. amnii* (formerly *L. amnii*) were described as variously sized rods of over 10 μm; however, tandem electron microscopy revealed that the long rods were actually formed of chains of bacilli with rounded ends (48). Fresh cells may stain Gram positive (45). Lactate production as the major end product of glucose fermentation is characteristic for *Leptotrichia* and *Sneathia* (Table 2). *Sneathia* species are extremely fastidious and, thus, not much is generally known about their biochemical characteristics (47, 48, 182, 186). The genome sequence analysis of *S. amnii* revealed a small genome size that might explain its fastidious nature (48). Positive reactions by Rapid ID 32A (bioMérieux) have been reported for β-glucuronidase, alkaline phosphatase, arginine arylamidase activity, and raffinose fermentation (182, 186). Table 8 presents some characteristics helpful in the biochemical identification of *Leptotrichia* and *Sneathia* organisms.

Within the phylum Synergistetes, *Fretibacterium fastidiosum* (49), *Jonquettella anthropi* (50), and *Pyramidobacter piscicolens* (51) are the human-derived species that have been cultured so far. They are extremely fastidious in nature, requiring the incubation time of 7 to 21 days, and thus are characterized with the utmost difficulty. Synergistes organisms are asaccharolytic rods, and acetic acid is their major metabolic end product of glucose fermentation. *F. fastidio-

sum forms very small, highly convex colonies on blood agar, but the colony morphology can vary (49). A coculture with Fusobacterium nucleatum subs. nucleatum is requested for optimal growth. Fretbacterium fastidiosum is motile, unlike J. anthropi and P. piscolens. J. anthropi is susceptible to bile and forms pinpoint colonies on blood agar, while the colonies of P. piscolens are somewhat bigger and highly convex to pyramidal, and its culture has a specific fishy odor (50, 51). All three species are unreactive to most biochemical tests. In the Rapid ID 32A system (bioMérieux), F. fastidiosum and J. anthropi are positive for both glycine arylamidase and leucyl glycine arylamidase, while P. piscolens is highly positive for glycine arylamidase (49-51).

Dialister species are coccobacilli that form tiny colonies on blood agar. They are asaccharolytic and grow poorly in liquid media; lack of reactivity in conventional biochemical tests hampers their identification. They are often confused with Veillonella because of their tiny cell size. There are a few enzymes in the Rapid ID 32A system (bioMérieux) that may be useful in distinguishing three Dialister species. D. pneumosintes is positive for glycine arylamidase, D. micraerophilus for alanine, phenylalanine, serine, tyrosine arylamidases, and arginine dihydrolase, and D. succinophilus for alkaline phosphatase (23, 56). However, D. invisus and D. propionicifericus are negative for all tests in this kit. The latter species produces propionate, which can be detected by GLC (56). Molecular methods, such as 16S rRNA gene sequencing, are often needed for the accurate detection of Dialister species in clinical specimens (56, 191).
**Anaerobiospirillum** species have a corkscrew shape and a jerky motility. *A. succiniciproducens* is sensitive to colistin, and it ferments glucose, maltose, lactose, and sucrose. A. *thomasi* can be differentiated from *A. succiniciproducens* by carbohydrate fermentations and by α-glucosidase and β-galactosidase activities, the former being negative and the latter positive for both reactions (65). *Desulfovibrio* species are curved rods with a rapid, progressive motility (except the nonmotile *D. piger*) and are resistant to colistin and to 20% bile (except for bile-sensitive *D. desulfuricans*) (206). A rather simple test scheme, including catalase, indole, nitrate, and urease tests, is able to separate the four *Desulfovibrio* species isolated from human clinical specimens. *D. desulfuricans* is positive for nitrate and urease, *D. faeihieldensis* is positive for catalase and nitrate, and *D. vulgaris* is positive for indole, while *D. piger* is negative for all these reactions (206). Table 9 presents an identification scheme for motile Gram-negative anaerobic genera.

**Advanced Techniques for Identification**

Whole-cell bacterial identification by matrix-assisted laser desorption–ionization time of flight mass spectrometry (MALDI-TOF MS) has proven to be a promising method for the identification of anaerobic bacteria, including Gram-negative organisms (234–238). Conserved proteins at the taxon level, such as ribosomal proteins, are used as identification targets. These characteristic peptides and small proteins (ranging in m/z mainly from 3 to 15 kDa) can be measured after laser desorption and ionization of whole cells, cell lysates, or crude bacterial extracts. Accurate identification depends on the unknown organism being present in the database. At present, two systems are available for the routine identification of aerobic and anaerobic bacteria: the MALDI Biotyper system (Bruker Daltonik GmbH, Bremen, Germany), which uses microflex or autoflex MS with the MALDI Biotyper database (research use only [RUO] and in vitro diagnostic [IVD] versions), and the Vitek MS (bioMérieux), which uses the Shimadzu Axima MS with an IVD database and SARAMIS as the RUO database. Currently, more anaerobic species are included in the Biotyper (Bruker Daltonik) system. The percentage of correct identifications of Gram-negative anaerobes at the species or genus level, compared to those of phenotypic identification or 16S rRNA gene sequencing, depends on the active development of the databases of the different systems in the field of anaerobic bacteria (234, 238, 239). Different sample preparation methods may also influence the correct identification; however, no significant differences have been observed in success of species identification among the tested strains of *Bacteroides* and *Fusobacterium* species, whether the direct smear or a full chemical extraction was used (240). *Bacteroides* strains resulted in species-level identification, whereas *Fusobacterium* strains were usually identified at the genus level, but problems encountered within the *Fusobacterium* genus may be resolved by adding well-characterized strains into the databases. Even phylogenetically closely related species within the genera *Bacteroides* and *Prevotella*, such as *B. salsusiae* and *B. nordii* (235) or *P. intermedia* and *P. nigrescens* (236, 237), are correctly identified by MALDI-TOF MS. As with some other aerobic and anaerobic species, peak shifts can be found and used for typing of divisions I and II of *B. fragilis* (240, 241). As only isolates in division II harbor the cfiA gene, which is responsible for the production of carbapenemase, typing of *B. fragilis* by MALDI-TOF MS may have a direct influence on the selection of antibiotic treatment. The main problem today with the MS-based identification of newly described Gram-negative anaerobes is that they are not frequently isolated (or are misidentified) in routine microbiology laboratories, and therefore, integrating them into the database does not, unfortunately, have any priority.

Another method which can reliably detect as-yet-unnamed taxa as well as identify known species is 16S rRNA gene sequence analysis (242). For clinical purposes, a 500-bp sequence from the 5′ end of the gene is able to identify most, but not all, members of this group to the species level.

*Nonmotile.
Even more information per amplicon length can be derived by using V6-specific primers (215). These methods are being increasingly used for identification of anaerobic bacteria, because (partial) sequencing of the gene is faster and more accurate than biochemical testing and, notably, independent of the growth characteristics (97, 243). Recently, sequencing of the 16S rRNA gene has also proven its potential for bacterial identification (244). For instance, 16S rRNA gene analysis has been successfully used for distinguishing two closely related Fusobacterium species, F. nucleatum and F. periodonticum, and for distinguishing oral isolates from isolates from intestinal biopsy specimens (245). However, sequencing as a routine method may not be feasible for many clinical laboratories. The development of algorithms to screen for those isolates that can be adequately identified by conventional methods and to refer difficult-to-identify isolates for 16S rRNA gene sequencing has been proposed (97, 242). Also, commercial 16S rRNA gene sequence-based identification kits containing reagents for DNA extraction and amplification are available. However, they require instruments, including a thermal cycler, automated gene sequencer, and software for interpretation, and the data needed to assess their value in identifying Gram-negative anaerobes are not available. Although sequencing of the 16S rRNA gene is a useful method for identification of fastidious anaerobic organisms, providing a much faster turn-around time than conventional methods, molecular analysis should complement but not replace culturing in the clinical setting. Phenotypic characteristics obtained by culture and biochemical testing assist in correlating the sequence-based data, which can sometimes be difficult to interpret, for example, due to incomplete sequences stored in the reference database. More importantly, culture is necessary for antibiotic susceptibility testing of isolates from clinical specimens.

Unculturable Anaerobic Gram-Negative Rods
In many chronic infections, if not in all, several as-yet-uncultivated phylotypes representing Gram-negative anaerobic phyla can be detected. In the human mouth, organisms with unculturable phylotypes in the genera Prevotella, Fusobacterium, Dialister, and Selenomonas, as well as members of the phylum Synergistetes, have been associated with various oral and nonoral infections (83). Microbiotas in tonsillar crypts include unculturable organisms; for instance, a Porphyromonas genomospecies (most closely related to P. catoniae) was significantly associated with children, while two Fusobacterium genomospecies were related to adults with recurrent tonsillitis (82). A metagenomic analysis of brain abscesses revealed several unculturable taxa belonging to the phyla Bacteroidetes and Firmicutes, among polymicrobial consortia in pus specimens from patients with preceding sinusitis or dental treatment (161). In the female genital tract, several organisms with Prevotella-like phylotypes have been strongly associated with bacterial vaginosis (80). Currently, chronic venous leg ulcers are considered polymicrobial infections in which unknown Bacteroidales are among the most ubiquitous organisms (246).

ANTIMICROBIAL SUSCEPTIBILITIES
Trends among Gram-negative anaerobes of increasing resistance to antimicrobial agents with antianaerobic activities still continue (93, 94, 98, 247, 248). Although susceptibility to antibiotics can vary considerably among species within the same genus, most clinical laboratories neither perform the accurate species-level identification of the isolated organism nor test the susceptibilities of anaerobic isolates (222). Without knowledge of the local susceptibility patterns, the choice of proper antimicrobial therapy can be hampered and make the treatment outcome of anaerobic infections less predictable.

According to recent surveys conducted in the United States, Canada, Argentina, Kuwait, Taiwan, and several countries in Europe, members of the B. fragilis group are among the anaerobes most resistant to various antimicrobial agents; this situation is independent of geographical location (93, 94, 98, 247, 249–253). Some variation, however, exists in resistance rates of different species between countries and areas. In a large U.S. study series, yearly changes in the B. fragilis group (here also including P. distasonis) patterns of susceptibility to ertapenem, imipenem, meropenem, ampicillin-sulbactam, piperacillin-tazobactam, ceftoxitin, clindamycin, moxifloxacin, tigecycline, chloramphenicol, and metronidazole were followed from 1997 to 2007 (93). The first time that metronidazole-resistant isolates were detected in the United States was in 2002, but the susceptibility to metronidazole has remained stable. The latest 3-year study period included >1,300 isolates for testing, and B. fragilis continued to be the most susceptible species. Different species within the tested isolates showed high rates of resistance to several antimicrobials, especially to clindamycin and moxifloxacin. In addition, some isolates that were resistant to carbapenems were detected among strains of B. fragilis, B. ovatus, B. thetaiotaomicron, and B. uniformis (93). A European susceptibility survey examining 824 B. fragilis group isolates collected from 13 countries between January 2008 and March 2009 revealed increased rates of resistance to amoxicillin-clavulanate, piperacillin-tazobactam, ceftoxitin, clindamycin, and moxifloxacin, whereas rates of resistance to imipenem, metronidazole, and tigecycline were low (98). In a Canadian study, the susceptibilities of 387 B. fragilis group isolates from nine hospital laboratories obtained between January 2010 and August 2011 were determined for 10 antimicrobial agents (247). B. fragilis was encountered in over half of the tested isolates, and B. ovatus and B. thetaiotaomicron were also common (>10%). The lowest resistance rates observed were to metronidazole, piperacillin-tazobactam, imipenem, and ertapenem, while B. ovatus and B. thetaiotaomicron, in particular, were often resistant to several antimicrobials (247). This underlines the significance of species-level identification as well as susceptibility testing for individual strains in the treatment of severe infections. In a Taiwanese hospital survey, the proportion of isolates of Bacteroides, Prevotella, and/or Fusobacterium species that were susceptible to many antimicrobials, especially cefmetazole, clindamycin, and the combination of ampicillin-sulbactam, decreased during the period from 2000 to 2007 (94). Noteworthy was the presence of strains that were intermediate or resistant to carbapenems among the tested B. fragilis, Fusobacterium, and Prevotella isolates from blood; one B. fragilis isolate was even resistant to all four carbapenems tested (94). Indeed, blood isolates seem to be less susceptible than those from intra-abdominal, obstetric, or other infections (254).

Multidrug-resistant B. fragilis as well as a few multidrug-resistant B. vulgatus and P. distasonis strains have been identified, mainly in blood and pus specimens after surgical procedures, with the strains being resistant to antianaerobic agents, such as carbapenems, ß-lactam-ß-lactamase inhibitors, clindamycin, and/or metronidazole (247, 255). Interestingly, one of these cases was successfully treated with linezolid (256). The cflA gene regulates the metallo-beta-lactamase behind carbapenem resistance; increased MICs
of imipenem and meropenem have been observed for cfa-positive B. fragilis isolates, while cfa-negative isolates were susceptible (241). Moreover, the presence of the cfa gene can be associated with nim genes, which are responsible for resistance to nitroimidazoles (257).

Despite the extensive use of metronidazole against anaerobes, acquired resistance has generally been considered rare (258). In susceptibility surveys conducted in the United States and Taiwan, metronidazole-resistant Bacteroides isolates were hardly ever found (93, 94, 259), whereas in Europe, resistance to metronidazole is more common (98, 252, 253). Prolonged exposure of nim gene-carrying Bacteroides and Prevotella strains to metronidazole can select for therapeutic resistance (260, 261). Among 188 Prevotella strains isolated from various infections in two university centers in France, all together 30 strains (most after prolonged incubation) showed reduced susceptibility to metronidazole, with MICs ranging from 8 to 32 μg/ml (260). Interestingly, none of the strains harbored known nim genes, whereas a novel nim gene was found in seven susceptible strains identified as P. baroniae. Rare strains of Prevotella species may appear highly resistant to metronidazole, resulting in poor treatment outcome (262). A considerable number of Dialister strains isolated from a variety of clinical specimens showed decreased susceptibility to metronidazole but did not harbor nim genes (190).

Newer fluoroquinolones have previously been considered to have good antianaerobic effects, but the resistance to moxifloxacin is rapidly increasing (98, 248). The situation is worsening, especially among non-fragilis Bacteroides species; for instance, B. thetaiotaomicron, B. stercoris, B. uniformis, B. vulgatus, and P. distasonis (formerly Bacteroides thetaiotaomicron) were listed with the highest rates of moxifloxacin resistance in Argentina (249). Pseudoflavonifractor capillosus (formerly Bacteroides) has been shown to be prevalent and to exhibit a high rate of resistance to moxifloxacin in Greece, with the caveat that the isolates examined in the study were not identified using sequence-based methods (263). The relatively new antimicrobial drugs tigecycline and linezolid have demonstrated good antianaerobic effects; however, Bacteroides and Parabacteroides strains with increased rates of resistance to tigecycline have been reported (248, 259). A significant number of intermediate/resistant strains have been found especially among non-fragilis Bacteroides species, such as B. caccae and B. thetaiotaomicron (259). Noteworthy is that Bacteroides strains for which MICs are elevated (>4 μg/ml) can harbor the tetX and tetX1 genes, indicating the potential development and spread of resistance to tigecycline (264). Moreover, concern over the efficacy and safety of tigecycline therapy has recently been raised (265).

Although the agar dilution method is recommended as the method of choice for susceptibility testing of anaerobic species, many studies have shown that the Etest (bioMérieux) provides reliable results with regard to the susceptibilities of anaerobic isolates from clinical specimens (260, 261). The Etest is simple to perform and readily available when needed, offering a useful method for susceptibility testing in clinical microbiology laboratories. It has been observed that some slow-growing metronidazole-resistant clones can be overlooked when the standard incubation time of 48 h is used; therefore, it has been recommended that labs reexamine the Etest plates after 72 h to look for small colonies within the metronidazole inhibition zone (260, 262). Another gradient endpoint method available for antimicrobial susceptibility testing of clinical isolates, including anaerobes, is the M.I.C. evaluator device (Thermo Fisher Scientific, Basingstoke, United Kingdom). Its performance is equivalent to that of the Etest; however, discordant results between gradient endpoint methods and reference agar dilution have been obtained when testing penicillin and metronidazole susceptibilities of the B. fragilis group (266). For isolates for which MICs of carbapenem agents are increased, carbapenemase production can be tested by Etest MBL strips (bioMérieux). Susceptibility testing methods for anaerobes are described further in chapter 75.

In general, carbapenems, some β-lactam–β-lactamase inhibitor combinations, chloramphenicol, and metronidazole are the most useful antianaerobic agents, whereas most cephalosporins, clindamycin, and most fluoroquinolones are currently considered less active for use against Gram-negative anaerobic bacteria in severe infections (2, 93, 94, 98, 247, 249, 251, 254). Table 10 summarizes the current antimicrobial activity rates of the clinically most relevant Gram-negative anaerobic taxa.

to anticipate the likely infecting species at different body sites. Training for anaerobic techniques, in general, and introduction of advanced methods for the detection and precise identification of anaerobic organisms are urgently needed in clinical microbiology laboratories, considering the current reports of considerable frequencies of anaerobic bacteremia and septicemia (89, 90) and increasing numbers of patients with fusobacterial infections, especially F. necrophorum-associated invasive diseases (147, 159), as well as increasing rates of anaerobes with resistance to various antimicrobials (94, 247, 248). In cases of inaccurate microbiology and inappropriate choices of antimicrobial agents in treating an anaerobic infection, mortality rates and other treatment failures increase significantly (267). Collecting of clinical specimens should avoid the mucosal microbiota, and proper transport medium and times should be used for keeping the anaerobes alive. Factors such as foul-smelling discharge, proximity of infection to mucosal surfaces, abscess formation, and necrotic tissue indicate the presence of anaerobes in the specimen. A definitive identification of an anaerobic isolate should be obtained for all isolates from normally sterile body sites, including blood, spinal fluid, and organs or body cavities, when the patient is gravely ill and not responding to treatment, and when prolonged treatment is necessary. It is desirable for reference laboratories to periodically provide information on local susceptibility patterns of anaerobic species within the clinically important taxa. However, not only an accurate antimicrobial therapy but also proper surgery, such as the drainage of abscesses and excision of necrotic tissue, are important in resolving anaerobic infections. It is notable that chronic infectious lesions, in particular, include consortia of bacteria organized in biofilms. This leads to reduced diffusion of antimicrobials and increased MICs.

The most important, and often difficult, task in the reporting of results of the isolation of Gram-negative anaerobes is determination of whether the organism is involved in the infectious process or is merely a bystander originating from the patient’s commensal microbiota. All isolations from normally sterile sites should be regarded as significant. A secondary challenge is that these organisms are often found in polymicrobial infections, with a number of different species present, and often as a biofilm. Obtaining pure cultures for susceptibility testing can therefore be time-consuming, and the resulting susceptibility profiles may be conflicting, making the recommendation of appropriate antimicrobial therapy difficult. Fortunately, such infections typically respond well to empirical treatment, as partial disruption of the bacterial consortium responsible is sufficient to allow the body’s defenses to deal with the infection.

Curved and spiral-shaped bacteria have a common microscopic morphology but represent diverse bacterial pathogens. These organisms are curved, helical, or spiral-shaped Gram-negative rods. Specific detection of these organisms may require a combination of tests, including microscopy, histologic staining of tissue, biochemical tests, antigen tests, serologic tests, bacteriologic culture, and molecular diagnostics.

Most bacteria in this group of organisms are isolated from patients with gastrointestinal-tract-related infections. *Campylobacter jejuni* subsp. *jejuni* is the most frequently isolated curved Gram-negative rod associated with diarrheal illness, but under proper culture conditions, other *Campylobacter*, *Helicobacter*, *Arcobacter*, and *Vibrio* species may be detected in routine stool cultures (Fig. 1). *Helicobacter cinaedi* and *Helicobacter fennellaei* are two important *Helicobacter* species isolated from fecal specimens (see chapter 57). *Helicobacter pylori* is the most common curved Gram-negative rod isolated from gastric tissue, but other *Helicobacter* species have also been reported at this site.

Other less commonly isolated curved Gram-negative rods include the anaerobes *Desulfovibrio* spp., *Sutterella wadsworthensis*, *Wolinella succinogenes*, and *Anaerobiospirillum succiniciptroducens*, which may be isolated from blood, abscess material, or other clinical samples (Table 1). Several oxidase-positive nonfermenters, including *Herbaspirillum* species (see chapter 43), may also have a curved appearance.

The spirochetes *Borrelia* spp. and *Leptospira* spp. cause systemic infections and are infrequently isolated in clinical laboratories, usually only with specialized media. These bacteria are strictly aerobic, and their optimal growth temperatures are from 28 to 30°C (*Leptospira* spp.) and 30 to 33°C (*Borrelia* spp.). *Treponema* spp. of clinical importance are diagnosed based on clinical and epidemiologic findings, as well as microscopic, serologic, and molecular test procedures.

Campylobacter and Arcobacter

COLLETTE FITZGERALD AND IRVING NACHAMKIN

TAXONOMY
Three closely related genera, Campylobacter, Arcobacter, and Sulfurospirillum, are included in the family Campylobacteraceae (1, 2). The family Campylobacteraceae includes 24 species within the genus Campylobacter, 18 species in the genus Arcobacter, and 8 species in the genus Sulfurospirillum. Two reviews on comparative genomics of Campylobacter have been published (3, 4). Since the last edition of this Manual, several new species and subspecies of Campylobacter have been published, including C. subantarcticus (5), closely related to C. lari subsp. conchae and isolated from arctic birds (grey-headed and black-browed albatrosses); C. volubris, closely related to C. lari subsp. lari and isolated from black-headed gulls (6); C. coraciensis, isolated from macaques (168); and C. fetus subsp. testudinum, isolated from blood cultures (169). One Bacteroides species, Bacteroides ureolyticus, has been reclassified as Campylobacter ureolyticus (7). New Arcobacter species include A. anaoerophilus, an obligate anaerobe isolated from estuarine sediment in Gangasagar, India (8), A. cloacae and A. suis from food and sewage (9), A. bivalviorum from mussels and clams (10), A. defluvii isolated from sewage samples in Catalonia, Spain (11), A. ellisi from mussels (12), A. marinus isolated from seawater in the East Sea, Korea (13), A. molluscum from mussels and oysters (10), A. trophiarum from pigs (14), A. venereus from mussels and clams (15), A. aquimarinus from seawater, and A. ebronensis from mussels (170). A detailed review on the taxonomy of Campylobacteraceae was previously published (16).

DESCRIPTION OF THE AGENTS
Campylobacter spp. are curved, S-shaped, or spiral rods that are 0.2 to 0.9 μm wide and 0.5 to 5 μm long. Occasional species, such as C. hominis, form straight rods. Campylobacter species are Gram-negative, non-spore-forming rods that may form spherical or cocoid bodies in old cultures or cultures exposed to air for prolonged periods. Organisms are usually motile by means of a single polar unsheathed flagellum. A. anaoerophilus is nonmotile (8). Arcobacter spp. grow microaerobically at 15, 25, and 30°C but have variable growth at 37 and 42°C. Organisms are microaerobic and do not require increased hydrogen for growth. Arcobacter spp. may grow aerobically at 30°C and anaerobically at 35 to 37°C. Most strains are nonhemolytic. A. skirrowii may be alpha-hemolytic (18). A. halophilus is an obligate halophile and grows poorly on media containing less than 2% NaCl (19).

Originally classified as free-living Campylobacter species, Sulfurospirillum spp. are slender, curved Gram-negative rods, 0.1 to 0.5 μm wide, and 1 to 3 μm long. All of the species are sulfur reducers and exhibit variable metabolic activity. S. deleyianum is the type species of the genus. These species have no known pathogenicity for humans or animals, are environmental organisms isolated from water sediments, and are not further discussed in this chapter (2).

EPIDEMIOLOGY AND TRANSMISSION
Campylobacter species are primarily zoonotic, with a variety of animals implicated as reservoirs for human infection (Table 1). In addition to food animals, such as poultry, cattle, sheep, and pigs, Campylobacter species may be present in domestic pets. Humans appear to be the only recognized reservoirs for the periodontal-disease-related species C. concisus, C. rectus, C. curvus, and C. showae. Campylobacter infections are common in both developed and developing countries. The reported incidence of culture-confirmed infections varies considerably from country to country, and as culturing practices and reporting requirements can vary, direct comparison of the reported incidences can be complex. In the United States, where reporting practices vary from state to state, the foodborne disease active surveillance program FoodNet (www.cdc.gov/foodnet) provides uniform reporting from a panel of sentinel sites, giving an accurate incidence of laboratory-confirmed infections. The incidence of culture-confirmed Campylobacter infections declined in the United States in the early 2000s (30% decline comparing 2009 to a 1996–1998 baseline) but subsequently showed a 14% increase in 2012 compared with a 2006–2008 baseline, its highest level since 2000 (20). C. jejuni subsp. jejuni (referred to as C. jejuni) continues to be the most common enteric pathogen isolated from patients reported from some states in FoodNet, with 1.3 million cases estimated in the United States annually (21, 22). Because of underdiagnosis and underreporting, the actual incidence in

*Rabbits.*

any country is substantially greater than the reported incidence. The epidemiology of campylobacteriosis in the United States does not appear to have changed over the last 20 years (23). *Campylobacter* infections are usually sporadic; the incidence starts to rise in March, with a peak in the summer, and declines in early fall (23). Infection usually follows ingestion of improperly handled or cooked food, primarily poultry products. Case-control studies in both the United States and Europe continue to find eating poultry to be a significant risk factor for developing campylobacteriosis (23). Outbreaks usually occur in the spring and fall, and in recent years, most outbreaks have been associated with food (poultry or unpasteurized dairy products) or water. Approximately one-half of the outbreaks in the United States from 1998 to 2004 were associated with dairy products or water; the remaining outbreaks were mostly foodborne and 44% were attributed to poultry (23). From 1998 to 2002, there were 64 foodborne *Campylobacter* outbreaks causing 1,628
illnesses, compared to 92 outbreaks and 1,431 illnesses during 2003 to 2007. Outbreaks in other developed countries are also associated with food, water, or dairy contamination (23). In developing countries, *Campylobacter* is often isolated from persons who may or may not have diarrheal disease. Most symptomatic infections occur in infancy and early childhood, and incidence decreases with age. Travelers to developing countries are at risk for *Campylobacter* infection, with isolation rates ranging from 0 to 39% reported in different studies. The incidence of infection follows a bimodal age distribution with the highest incidence in infants and young children, followed by a second peak in adults 20 to 40 years old (22). Secondary transmission of *Campylobacter* from ill persons to other individuals is rare, even though the infectious dose for developing illness is not particularly high, as low as 500 CFU (23).

**CLINICAL SIGNIFICANCE**

*C. jejuni* and *C. coli*

*C. jejuni* and *C. coli* have been recognized since the early 1970s as agents of gastrointestinal infection. *C. jejuni* is one of the most common causes of bacterial enteritis in the United States. *C. jejuni* and *C. coli* continue to be the most common *Campylobacter* species associated with diarrheal illness and produce clinically indistinguishable infections. Most laboratories do not routinely distinguish between these organisms. In patients with gastroenteritis caused by *C. jejuni*/*C. coli*, patients' symptoms range from none to severe, including fever, abdominal cramping, and diarrhea (with or without blood/fecal white cells) that lasts several days to more than 1 week (10). The usual incubation period is about 3 days, with a general range of 1 to 7 days. Symptomatic infections are usually self-limited, but relapses may occur in 5 to 10% of untreated patients (10). Hospitalizations are common for *Campylobacter* infections with 15% of laboratory-confirmed infections reported to FoodNet requiring hospitalization in 2012 (20). *Campylobacter* infection may mimic acute appendicitis and result in unnecessary surgery. Extraintestinal infections have been reported following *Campylobacter* enteritis and include bacteremia, hepatitis, cholecystitis, pancreatitis, abortion and neonatal sepsis, nephritis, prostatitis, urinary tract infection, peritonitis, myocarditis, and focal infections including meningitis, septic arthritis, and abscess formation (24, 25). Bacteremia has been reported to occur at a rate of 1.5 per 1,000 intestinal infections, with the highest rate in the elderly (26). Persistent diarrheal illness and bacteremia may occur in immunocompromised hosts, such as patients with human immunodeficiency virus infection, and may be difficult to treat (24). Deaths attributable to *C. jejuni* infection are uncommon (20, 24). The health burden of campylobacteriosis appears to be substantial and may be underestimated (27).

*C. jejuni* is the most often recognized infection preceding the development of Guillain-Barre syndrome (GBS), an acute paralytic disease of the peripheral nervous system (28). Certain heat-stable (HS) serotypes appear to be overrepresented in some GBS cases, such as HS:19 and HS:41, but other more common serotypes are frequently reported (28). The pathogenesis of *Campylobacter*-induced GBS involves host immune responses to ganglioside-like epitopes present in the core region of the lipooligosaccharide (29), which in the susceptible host mediates damage to the peripheral nerves, where ganglioside targets are highly enriched (30).

Reactive arthritis sometimes follows *Campylobacter* infection, with the onset of pain and joint swelling averaging 2 weeks, with an average range lasting from a few weeks to nearly a year. Reiter’s syndrome may also occur in some patients (24). The literature is mixed on the role of HLA B27 as a risk factor for reactive arthritis (24).

The pathogenesis of *Campylobacter* enteric infection is not well understood. The infective dose of *Campylobacter* is not well defined, but as few as 500 organisms may be capable of causing illness (24). The use of proton pump inhibitors increases susceptibility to campylobacter infection (31). The signs and symptoms of infection suggest an invasive mechanism of disease. A variety of determinants may be important in the virulence of *C. jejuni* infection, including adherence to the intestinal mucosa, bacterial effects on the cell, and host inflammatory responses (32).

**Campylobacter Species Other than *C. jejuni* and *C. coli***

*Campylobacter* species other than *C. jejuni* and *C. coli* are increasingly isolated from human infections by improved culture methods that are more optimal for the non-*C. jejuni* and non-*C. coli* species.

*C. fetus* subsp. *fetus* is primarily associated with bacteremia and extraintestinal infections during pregnancy or in the compromised host (33). Although gastroenteritis does occur with this species, the incidence is probably underestimated because the organism may not grow well at 42°C and is usually susceptible to cephalothin (cefalotin), an antimicrobial agent used in some common selective media for stool culture (34). *C. fetus* subsp. *fetus* produces a surface protein microcapsule composed of a high-molecular-weight surface layer protein that is essential for virulence (33). *C. fetus* subsp. *venerealis* causes bovine venereal campylobacteriosis and is a cause of bovine infertility but is rarely the cause of human infection (33).

*C. upsaliensis* is a thermotolerant species that causes diarrhea and bacteremia in humans and is also associated with canine and feline gastroenteritis (35). Over a 10-year period, *C. upsaliensis* was the most common non-*C. jejuni*/non-*C. coli* species isolated from stool samples submitted to the laboratory for culture (36). *C. upsaliensis* is susceptible to many antimicrobial agents present in *C. jejuni* selective media and thus is usually not isolated on routine primary isolation media; it can be recovered using the filtration technique described below.

*C. lari* is a nalidixic acid-resistant, thermophilic species first isolated from gulls of the genus *Larus* and from other avian species, dogs, cats, and chickens. *C. lari* has been infrequently reported from humans with bacteremia and gastrointestinal and urinary tract infections (35). Recent phylogenetic studies have described two subspecies, *C. lari* subsp. *conchets* and *C. lari* subsp. *lari* (37).

Other *Campylobacter* species have been isolated from clinical specimens of patients with a variety of diseases, but their pathogenic role has not been determined (35). *C. jejuni* subsp. *doyleri* is a nitrate-negative subspecies of *C. jejuni* rarely recovered from patients with upper gastrointestinal tract infections and gastroenteritis (35). *C. concisus* has been isolated from both fecal and blood specimens. There are reports on the association of this species with gastrointestinal disease, but additional case-control studies are needed to establish the pathogenicity of this organism (38, 39). *C. avium* is a hippurate hydrolyase-positive species that was isolated from broiler chickens and turkeys but has not been reported from human samples (40, 41). *C. canadensis* (41) has been isolated from whooping cranes at the Calgary Zoo and *C. pelorida* (37) from human feces, dialysis fluid, and shellfish. *C. canicola* was isolated from the cecum of
rabbits but not reported from humans (42). C. hyointestinalis has been occasionally associated with proctitis and diarrhea in human infection. There is some suggestion that C. curvus may be an etiologic agent in diarrheal illness (43), but it was rarely isolated from stool samples in another large study (44). C. curvus is also isolated from patients with periodontal infections and in patients with a liver abscess and pneumonia (45). C. gracilis has been isolated from patients with appendicitis/peritonitis, bacteremia, soft tissue abscesses, and pulmonary infections (46). C. hominis has been isolated from fecal samples of healthy individuals and may be a commensal of the oral cavity (47). C. laniensis was isolated from two asymptomatic abattoir workers, but its clinical significance is unknown (48). C. sputorum has been associated with lung, axillary, scrotal, and groin abscesses (49). C. sputorum bv. paraureolyticus, formerly referred to as catalase-negative urease-positive campylobacter, has been isolated from patients with diarrhea, but the significance of this finding is unknown (50). C. mucosalis was reported to have been isolated from two children with enteritis, but subsequent testing showed that the isolates were actually C. concisus (51). C. helveticus (32) has been recovered from domestic cats and dogs and has not been reported from human sources. C. rectus is primarily isolated from patients with active periodontal infections but has also been isolated from a patient with pulmonary infection (35, 53) and breast abscess (45). C. showae has been isolated from the human gingival crevice (54) and from a blood culture in a patient with cholangitis (55).

Arcobacter

Arcobacter spp. are aerotolerant, Campylobacter-like organisms frequently isolated from bovine and porcine products of abortion and feces of animals with enteritis (56). Two of the 18 Arcobacter species have been associated with human infection. A. butzleri has been isolated from patients with bacteremia, endocarditis, peritonitis, and diarrhea and was recently identified as the causative agent, using molecular methods, of an outbreak of foodborne illness in Wisconsin (34, 35, 57). A. cryaerophilus has been previously characterized into two DNA-related groups, 1A and 1B (58). A. cryaerophilus group 1B has been isolated from patients with bacteremia and diarrhea (34, 35) and also from healthy individuals (59), suggesting a commensal role for this species. Group 1A has been isolated from animal sources (58). Arcobacter butzleri was reported to be the fourth most common Campylobacter-like organism isolated from patients with diarrhea by Vandenberg et al. (34) and was also one of the most common non-C. jejuni/non-C. coli species isolated over a 10-year period from over 73,000 stool samples (36). Thus, A. butzleri may be underrecognized if appropriate culture conditions are not used. In a survey of 2,853 Campylobacter-like isolates submitted for characterization from laboratories in France, A. butzleri was identified in 1%, primarily from fecal samples of patients with a diarrheal illness (60). A. skirrowii was reported to be isolated from a human stool culture in a patient with chronic diarrhea, but the role of this species in human disease is unknown (61). Arcobacter cibarius has been isolated only from poultry carcasses; the medical significance of this species is unknown (62). Arcobacterthereus has been isolated from liver and kidney of spontaneous porcine abortions and from the cloacae of ducks but has not been reported from human samples (63). Arcobacter mytili was isolated from shellfish from northeastern Spain and has not been reported from human samples (64). None of the 10 new species described since 2010 have yet been associated with human disease, including A. nitrofugilis and A. halophilus.

Collection, Transport, and Storage of Specimens

Fecal Samples

Fecal specimens are preferred for isolating Campylobacter species from patients with gastrointestinal infections; however, rectal swabs are acceptable for culture. For hospitalized patients, the “3-day” rule (rejection of specimens collected >72 h after admission) should be used as a criterion for acceptability of routine culture requests (65, 66). For routine purposes, a single stool sample has high sensitivity for common enteric pathogens, but two samples may be desirable, depending upon clinical circumstances, such as a >2-h delay in transport of the first sample that could affect recovery (56). A transport medium should be used when a delay of more than 2 h is anticipated and for transporting rectal swabs. Several types of transport media are useful for Campylobacter, including alkaline peptone water with thioglycolate and cystine, modified Stuart medium, and Cary-Blair medium (56). Transport media such as commercial Stuart medium and buffered glycerol saline do not appear to perform well. Modified Cary-Blair medium containing reduced agar (1.6 g/liter) appears to be the most suitable single transport medium for Campylobacter as well as other enteric pathogens. Specimens received in Cary-Blair medium should be stored at 4°C if processing is not performed immediately. Use of Cary-Blair medium supplemented with laked sheep blood may be useful for prolonged storage of stool samples and recovery of C. jejuni (67).

Blood

Campylobacter species, primarily C. fetus, C. jejuni, and C. upsaliensis, have been isolated from blood; however, in only a few studies have optimal conditions for isolating Campylobacter from blood culture systems been evaluated. The Bactec (aerobic bottles) and Septi-Chek systems (both from BD, Sparks, MD) appear to support the growth of the common Campylobacter species (56). The BacT/Alert system (bioMérieux, Inc.) also supports the growth of Campylobacter fetus (68). Other systems such as anaerobic broth or lysis centrifugation may not be as sensitive (56).

Microscopy

Clinical microbiologists do not normally consider performing Gram stain analysis of stool samples for diagnosis of bacterial gastroenteritis; however, this is a rapid and sensitive method for presumptive diagnosis of Campylobacter enteritis. Campylobacter spp. are not easily visualized with the safranin counterstain commonly used in the Gram stain procedure and are somewhat thinner than other enteric Gram-negative bacteria; carbol-fuchsin or 0.1% aqueous basic fuchsin should be used as the counterstain for smears of stools or pure cultures (56). Because of their characteristic morphology, Campylobacter spp. may be detected by direct Gram stain examination of stools obtained from patients with acute enteritis, with sensitivity ranging from 66 to 94% and specificity above 95%. Phase-contrast and dark-field microscopy have also been used to directly detect motile campylobacters in fresh stool samples; however, the sensitivity of these approaches has not been studied widely.
and in our opinion, these methods require significant microscopic expertise (56).

Fecal white cells may be present during Campylobacter infection and have been reported in 25 to 80% of culture-proven cases (69). There is no known correlation between the number of cells present and infection. While the likelihood of infection with Campylobacter or other enteroinvasive pathogens may be higher in the qualitative presence of fecal leukocytes, the absence of fecal leukocytes does not rule out the diagnosis. Thus, routine examination of stool samples for fecal leukocytes is not recommended as a test for predicting bacterial infection or for selective culturing for Campylobacter or other stool pathogens (65, 69).

**Antigen Detection**

Several commercially available antigen detection systems for Campylobacter in stool samples are cleared by the FDA in the United States: the ProSpecT Campylobacter assay (Alexon-Trend, Inc., distributed through Remel), the Premier Campylobacter assay (Meridian Biosciences), and the ImmunoCard Stat! Campy assay (Meridian Biosciences). When compared with culture, the ProSpecT immunoassay has been shown to vary in sensitivity from 80 to 96% and has a specificity of >97% (70–72). This enzyme immunoassay (EIA) was found to cross-react with C. upsaliensis (70). The STAT! Campy antigen assay (Meridian Biosciences) was also found to detect C. upsaliensis (73). Antigen may be detected in stored stool samples at 4°C for several days (74). The Premier Campylobacter assay is a microtiter plate-based EIA, while the ImmunoCard STAT! Campy assay is a one-step lateral flow immunoassay; both are reported to be specific for the detection of Campylobacter jejuni and C. coli but cannot differentiate them. Variable data on their performance characteristics have been reported to date (75–77, 94). Initially shown to have good performance characteristics during an initial verification study, the performance of the Premier Campy EIA following implementation of the test did not reflect initial verification data, with lower sensitivity and poor positive predictive values (78). Other EIAs available outside the United States have variable performance (79). Given that a Campylobacter infection is a low-incidence disease, the specificity values described to date for the Campylobacter antigen detection assays mentioned above suggest that these tests can lead to poor positive predictive values and thus, we do not recommend that these tests be used as the sole method for diagnosis of campylobacter infection.

**Nucleic Acid Detection Techniques**

Nucleic acid amplification tests (NAAT) have been used directly to detect Campylobacter in stool samples (80, 81). Molecular approaches to detecting Campylobacter directly in fecal samples may improve the time to detection, identification to the species level, and identification of the less common Campylobacter species often missed by conventional culture. Four NAAT assays are FDA cleared for use in the United States. The xTag Gastrointestinal Pathogen Panel (Luminex Corp.), Prodesse ProGastro SSCS (Hologic Gen-Probe), BioFire FilmArray Gastrointestinal Panel (BioFire Diagnostics, Salt Lake City, UT), and Verigene (Nanosphere Inc., Northbrook, IL) are multiplex assays for the detection of numerous gastrointestinal pathogens, including Campylobacter spp. While the assays look promising, there is insufficient published information on the U.S. products to assess their performance characteristics or to suggest that they replace culture-based techniques (82–85,171–173).

**ISOLATION PROCEDURES**

Campylobacter species require a microaerobic atmosphere containing approximately 5% O₂, 10% CO₂, and 85% N₂ for optimal recovery. Several manufacturers produce microaerobic gas generator packs that are suitable for routine use. A tri-gas incubator or evacuation and replacement of an anaerobic jar with the approximate gas mixture may also be used for routine cultures (56). The Anoxomat (Mart Microbiology, distributed through Advanced Instruments, Inc.) is a convenient automated system for the evacuation and gas replacement of jars used for generating different atmospheric conditions, including microaerobic conditions (86). The concentration of oxygen generated in candle jars is suboptimal for the isolation of Campylobacter and should not be used for routine laboratory isolation procedures (56).

Some species of Campylobacter, such as C. sputorum, C. concisus, C. mucosidis, C. curvus, C. rectus, and C. hyointestinalis, require increased hydrogen for primary isolation and growth. These species will usually not be recovered under the conventional microaerobic conditions, since the amount of hydrogen generated in properly used commercial gas packs is <2% and we recommend that commercial suppliers develop a gas pack with appropriate concentrations of H₂ for isolation of the hydrogen-requiring Campylobacter species. The use of anaerobic gas packs without catalyst to generate high H₂ concentrations creates a laboratory safety hazard and should not be used for this purpose. A gas mixture of 10% CO₂, 6% H₂, and the balance N₂ used in an evacuation-replacement jar is sufficient for isolating hydrogen-requiring species. A study by Vandenberg and colleagues reemphasized the requirement of increased hydrogen for isolating certain Campylobacter spp. (34).

Media containing selective agents should be used for primary plating of primary stool samples (nonenriched) for reliable isolation of C. jejuni/C. coli. A number of selective media using blood-containing and blood-free formulations are available from commercial sources. These include two blood-free media, charcoal cefoperazone deoxycholate agar (CCDA) and charcoal-based selective medium (CSM), and two blood-containing media, Campy-CVA (cefooperazone, vancomycin, amphotericin) medium and Skirrow medium (56). Although CVA medium is commonly used in the United States for isolating Campylobacter from clinical stool specimens, there are limited data available to assess the ability of CVA to recover Campylobacter species from stool specimens, when compared to other Campylobacter-selective media; additional evaluation studies are warranted. Charcoal-based media containing cefoperazone, amphotericin, and teicoplanin (CAT media) are selective media for the primary isolation of C. upsaliensis (87). Two studies, however, did not isolate C. upsaliensis from any stool samples by use of this medium (44, 71). C. upsaliensis may occasionally be recovered on some other selective media. C. upsaliensis isolates can also be recovered by using the filtration method, and some strains may grow better in a hydrogen-enriched atmosphere (49, 88).

To achieve the highest yield of Campylobacter from stool samples, a combination of media that includes either CCDA or CSM appears to be the optimal method (89) and may increase the recovery of Campylobacter by as much as 10 to 15% over the use of a single medium. As a single medium, CCDA was found to be the most sensitive for detecting C. jejuni/C. coli when compared with Skirrow medium, CAT agar, and filtration (44). Recent evaluations of campylobacter-selective media are limited, but based on previous studies, blood-free formulations (e.g., CCDA, CSM) appear
to have better performance than blood-containing media, including CampyBAP, Skirrow, and Butler formulations (44, 90–93). More recently, a multicenter U.S. study found that there was no difference in detection of C. jejuni/C. coli comparing blood-free media (CCDA and CSM) and blood-containing media (Campy-CVA), although the blood-free media were more selective, making isolation easier (94). If only a single medium is used, we suggest using Campy-CVA, CCDA, or CSM. If Campylobacter infection is suspected at the time blood specimens are drawn, broth media should be subcultured after 24 to 48 h to a nonselective blood agar medium and plates incubated under microaerobic conditions at 37°C, preferably with increased hydrogen. This allows for the isolation of thermophilic and nonthermophilic species. While commonly used blood culture systems should support the growth of Campylobacter and give appropriate signals if positive, it may be prudent to perform a blind subculture. Similarly, blood drawn in Isolator (Wampole Laboratories, Cranbury, NJ) tubes for bacterial culture should include a nonselective blood agar plate incubated under microaerobic conditions at 37°C if Campylobacter infection is suspected. If a curved, Gram-negative rod is observed upon Gram stain examination of a positive blood culture bottle, an aliquot should be cultured on a nonselective blood agar plate and incubated under microaerobic conditions at 37°C. An alternative staining method such as acridine orange may also be useful for detecting campylobacters in blood culture bottles if the Gram stain is negative.

Optimal conditions for recovery of Arcobacter from clinical specimens have not been determined. Arcobacter spp. were first isolated on semisolid media designed to isolate Leptospira spp. (56). Arcobacter species are aerotolerant and have been recovered on certain selective media, such as Campy-CVA (95), incubated under microaerobic conditions at 37°C and on nonselective media used in the filtration method (34). Selective media for isolation of Arcobacter spp. from human stool samples were evaluated by Houf and Stephan (39). Both selective plates and enrichment broth containing selective supplements with 5-fluorouracil, amphotericin B, ceferazone, novobiocin, and trimethoprim showed good recovery of Arcobacter sp. (39).

**Enrichment Cultures**

Enrichment broths formulated to enhance the recovery of Campylobacter from stool include Preston enrichment, Campy-thio, and Campylobacter enrichment broth (56). The clinical advantage and cost-effectiveness of using enrichment cultures as part of the routine stool culture setup have not been studied adequately; therefore, enrichment cultures are not recommended for routine use.

**Filtration**

Filtration techniques designed to isolate C. jejuni and C. coli as well as other Campylobacter species (34, 44, 56) and Arcobacter spp. (34, 36, 58) that are susceptible to antibiotics present in most selective media should be used to complement direct culture to selective plating media. As only stool samples containing ~10^5 CFU/ml of Campylobacter will be detected with filtration, it should not be used as a replacement for direct culture, because the filtration method is not as sensitive as primary culture with selective media (88).

The method is based on the principle that campylobacters can pass through membrane filters (0.45-µm to 0.65-µm pore size) with relative ease (because organisms are thin and highly motile) while other elements of the stool microbiota are retained during the short processing time. Cellulose acetate membrane filters with a 0.65-µm pore size are recommended for routine use and available from a number of suppliers (56). Filtration is performed by placing a sterile 0.65-µm-pore-size cellulose acetate filter onto the surface of an agar medium such as antibiotic-free CCDA, CSM, or blood-containing medium. After diluting approximately 1 g of stool in 10 ml of sterile saline, 10 to 15 drops of fecal suspension are placed on the filter, and the plate is incubated at 37°C for 45 to 60 min (96). The filter is then removed, and the plate is incubated at 37°C under microaerobic conditions, preferably with an atmosphere containing increased hydrogen (for the hydrogen-requiring species).

Species within the genera Campylobacter and Arcobacter have different optimal temperatures for growth. The choice of incubation temperature for routine stool cultures is critical in determining the spectrum of species that will be isolated. By convention, most laboratories use 42°C as the primary incubation temperature for Campylobacter. This temperature allows growth of C. jejuni and C. coli on selective media while inhibiting other fecal microflora. C. upsaliensis grows well at 42°C but usually is not recovered on selective media. C. fetus exhibits variable growth at this temperature and may not be recovered. Arcobacter species will generally not be recovered at 42°C.

In contrast, most Campylobacter and Arcobacter species grow well at 37°C. Selective media, such as Skirrow medium, were devised for use at 42°C and have poor selective properties at 37°C, whereas CCDA and CSM show good selective properties at 37°C (89). Plates should be incubated a minimum of 72 h before being reported as negative. It has been reported that incubation of CCDA medium for 5 to 6 days increased the yield of C. jejuni and C. coli compared with 2 days of incubation (44).

Because of the expense of including several types of media and the filtration method in the initial workup for Campylobacter, a practical approach is to use a single medium for isolation of thermophilic Campylobacter spp. in the workup of acute bacterial gastroenteritis, such as Campy-CVA, CCDA, or CSM incubated at 42°C. If the primary culture workup is unrewarding, and for patients with persistent diarrhea, cultures for non-C. jejuni/non-C. coli species may be appropriate. Additional stool samples should be plated on multiple selective media (e.g., CCDA or CVA), processed by the filtration method as well, and incubated at 37°C under microaerobic conditions with increased hydrogen.

**IDENTIFICATION**

The identification of Campylobacter species is made difficult because of their complex and rapidly evolving taxonomy, fastidious growth requirements, and biochemical inertness (Table 2). These problems have resulted in a proliferation of phenotypic and genotypic methods for identifying members of this group (56).

**Campylobacter spp. and Arcobacter spp.**

Depending on the growth medium used, Campylobacter colonies may have different appearances. In general, Campylobacter spp. produce gray, flat, irregular, and spreading colonies. Spreading along the streak line is commonly seen, particularly on freshly prepared media. As the moisture content decreases, colonies may form round, convex, and glistening colonies with little spreading observed. Thus, proper storage of media to ensure moisture content is important for optimal isolation and recognition of Campylobacter spp. Hemolysis on blood agar is not observed. Arcobacter...

⁴Adapted from references 5, 37, 42, 56, and 64. +, positive reaction; −, negative reaction; V, variable reaction; ND, not determined; TSI, triple sugar ion.

³C. lari subsp. concheus can be differentiated from C. lari subsp. lari by lack of growth on media containing 0.05% safranin (37).

⁴Anaerobic growth only.

⁵Strains of C. sputorum and C. hyointestinalis subsp. lawsonii normally produce large amounts of H₂S in TSI agar (47).
colonies are morphologically similar to those of Campylobacter (2, 18).

The Gram stain appearance of Arcobacter may differ from that of typical Campylobacter. A. butleri is only slightly curved, while A. cryoacophilus tends to be much more helical in appearance than Campylobacter. Commercial systems for identification of Campylobacter species were not found to be more accurate than conventional tests (97). Unfortunately, Campylobacter species are difficult to differentiate from Arcobacter species based on phenotypic tests. However, an aerotolerant species (i.e., exhibiting growth under aerobic conditions) that grows on MacConkey agar under anaerobic conditions could be presumptively identified as Arcobacter. The failure to grow on MacConkey, however, does not rule out Arcobacter species.

C. jejuni and C. coli

For initial analysis, a Gram stain examination of the colony should be performed along with an oxidase test. Oxidase-positive colonies exhibiting a characteristic Gram stain appearance (e.g., Gram-negative, curved to S-shaped rods) isolated from selective media incubated at 42°C under anaerobic conditions can be reliably reported as Campylobacter spp. The most common species, C. jejuni, is relatively easy to identify phenotypically; hydrolysis of sodium hippurate is the major test for distinguishing C. jejuni (and also C. jejuni subsp. doylei) from other Campylobacter species. Strains isolated on selective media that grow at 42°C, are oxidase positive, show characteristic microscopic morphology, and are positive for hippurate hydrolysis should be reported as C. jejuni, and for routine clinical purposes, no other tests need to be performed. Methods for this test are described elsewhere (98). Occasional strains of C. jejuni are hippurate hydrolysis negative, making them more difficult to identify. Gas-liquid chromatography for detecting benzoic acid (liberated from hydrolysis of sodium hippurate) or detection of hipO by molecular methods can be used for definitive determination.

With the exception of hippuricase activity, which C. coli is lacking, C. coli and C. jejuni are similar biochemically (Table 2). Therefore, molecular methods are needed to accurately identify C. coli and differentiate it from hippurate-negative C. jejuni; most have proved both accurate and sensitive (99) (Table 3). If molecular testing is not available, strains isolated on selective media that grow at 42°C, are oxidase positive, show characteristic microscopic morphology, and are hippurate negative and indoxyl acetate positive should be reported as hippurate-negative C. jejuni/C. coli.

Additionally, C. coli and Helicobacter pullorum have similar phenotypic profiles and support the use of molecular identification methods for these species (100). Susceptibility (inhibition) or resistance of Campylobacter spp. to nalidixic acid and cephalothin was historically used as an aid for species identification. However, with the increasing prevalence of fluoroquinolone resistance in these species, the use of these disk identification assays can no longer be relied upon. For species other than C. jejuni, phenotypic characterization alone will not allow definitive species-level identification; the use of additional molecular identification methods is recommended. If performing phenotypic testing, it is important to use a standardized suspension and inoculum in order to obtain consistent and reproducible results. For growth temperature and oxygen tolerance studies, a suspension of the organism in heart infusion broth or tryptic soy broth with turbidity at a McFarland standard of 1 should be used. A fiber-tipped swab dipped in the broth suspension should be used to make a single streak across the plate (Mueller-Hinton agar with 5% sheep blood is a suitable medium), and the plates should be incubated at the desired temperature and/or atmospheric conditions (101, 102).

Several commercial systems have been developed as an aid to identifying Campylobacter spp. to the genus level. Two immunologic reagents are currently available in the United States for culture identification: Campy-JCL (Scimedx Corp., Denville, NJ) and Dryspot Campylobacter test kit (Thermo Scientific-Remel). The Dryspot Campylobacter latex test is reported by the manufacturer to identify but not differentiate C. jejuni, C. coli, C. lari, and C. upsaliensis and to yield variable results for C. fetus subsp. fetus (Oxoid USA; www.oxoid.com).

Because many species of Campylobacter and Arcobacter are difficult to identify by phenotypic testing alone, tests for detection of species-specific sequences via PCR have been developed. The 16S and 23S rRNA genes are widely used for genus- and species-specific tests; PCR assays based on these targets have been described for different Campylobacter (98) and Arcobacter (103, 104) species. Broad-range molecular identification schemes involving restriction fragment analysis of PCR-amplified regions of the 16S or 23S rRNA genes have also been described for identification of Campylobacter and Arcobacter species (105–107).

Many other gene targets have been used in species-specific PCR assays, including gyrA (108, 109), gapA (110), ceuE gene (111), asp (112), lpxA (113), and a GTPase gene (109). Subspecies identification by PCR within C. fetus (114, 115) and C. jejuni (116) has also been described. While the use of such PCR tests combines the advantages

**Abbreviations:** cc, C. coli; cj, C. jejuni.
of being quick and easy to perform with low cost and high-throughput capability, amenable to automation, it is important to validate PCR tests to fully determine their specificity and sensitivity before use. Comparison of 16S rRNA gene sequences is also a useful tool for differentiation of Campylobacter spp. from closely related taxa, such as Arcobacter and Helicobacter. However, it is important to note that species-level identification based on 16S is much more difficult, particularly for the common species of Campylobacter. At or above 97% identity, some groups of closely related species such as C. jejuni, C. coli, and C. lari; C. upsaliensis and C. helveticus; and C. fetus, C. hyointestinalis, and C. lari cannot be confidently distinguished from each other based on 16S rRNA gene sequences (117). Conversely, intraspecies 16S rRNA gene diversity is seen in other species, such as C. hyointestinalis (118).

Matrix-assisted laser desorption ionization—time of flight (MALDI-TOF) analysis may also be used to identify both common and uncommon Campylobacter species. In a study of nearly 1,000 isolates, MALDI-TOF (MALDI Biotyper, Bruker Daltonics) had 99.4% accuracy for identifying C. jejuni (n = 785), and 100% accuracy for C. coli (n = 149). C. fetus subsp. fetus (n = 40) and C. lari (n = 8) as well as A. butzleri (n = 14) (119). Other studies also confirm the value of MALDI-TOF identification of Campylobacter species (120, 121). Conditions for growth may need to be optimized for successful MALDI analysis (122).

**TYPING SYSTEMS**

Typing systems for Campylobacter epidemiologic studies vary in complexity and ability to discriminate between strains. Common phenotypic methods that have been applied include biotyping, phage typing, and serotyping (123, 124). The heat-labile serotyping scheme, originally described by Lilj, can detect over 100 serotypes of C. jejuni, C. coli, and C. lari (124). Uncharacterized bacterial surface antigens and, in some serotypes, flagellar antigens are the serodeterminants for this serotyping system (125). The HS Penner serotyping scheme detects 60 types of C. jejuni (n = 785), and 100% accuracy for C. coli (n = 149). C. fetus subsp. fetus (n = 40) and C. lari (n = 8) as well as A. butzleri (n = 14) (119). Other studies also confirm the value of MALDI-TOF identification of Campylobacter species (120, 121). Conditions for growth may need to be optimized for successful MALDI analysis (122).

**SEROLOGIC TESTS**

Serum immunoglobulin G (IgG), IgM, and IgA levels rise in response to infection, but serum and fecal IgA levels appear during the first few weeks of infection and then fall rapidly (141, 142). Serum antibody assays vary in both sensitivity and specificity for detecting Campylobacter infection, and test performance appears to be population dependent. Campylobacter antibody assays have been used to study patients with GBS and reactive arthritis (143). Patients with Campylobacter infection may give false-positive Legionella antibody test results (144). Serologic testing appears to be useful for epidemiologic investigations and is not recommended for routine diagnosis (145).

**ANTIMICROBIAL SUSCEPTIBILITIES**

C. jejuni and C. coli have variable susceptibilities to a variety of antimicrobial agents, including macrolides, fluoroquinolones, aminoglycosides, phenicols, and tetracycline. Azithromycin and erythromycin are drugs of choice for treating C. jejuni gastrointestinal infections, and for susceptible organisms, ciprofloxacin or norfloxacin may also be used. Early therapy of susceptible Campylobacter infection with erythromycin or ciprofloxacin is effective in eliminating the organism from stool and may also reduce the duration of symptoms associated with infection (24).

C. jejuni is generally susceptible to erythromycin, with resistance rates of less than 10% (24, 146, 147). Nationally, 1.7% of C. jejuni and 2.7% of C. coli isolates reported by NARMS (National Antimicrobial Resistance Monitoring System for Enteric Bacteria) in 2011 were macrolide resistant (www.cdc.gov/NARMS). Macrolide resistance is generally mediated by mutations in the 23S rRNA gene (148).
Rates of erythromycin resistance in C. coli are generally higher than in C. jejuni and vary considerably, with up to 25 to 50% of strains showing resistance in some studies (24, 147). Although ciprofloxacin has been effective in treating Campylobacter infections, emergence of ciprofloxacin resistance during therapy has been reported (149). Several in vitro studies show significant rates of resistance to fluoroquinolones (146, 150, 151). Resistance to fluoroquinolones has ranged from <5% in Australia to approximately 80% reported in Thailand (24, 152). In 2011, 24% of Campylobacter strains reported through NARMS at CDC were fluoroquinolone resistant with higher rates of resistance (36%) in C. coli (http://www.cdc.gov/NARMS/). Individuals with fluoroquinolone-resistant C. jejuni have been shown to have a longer duration of diarrhea, and thus, routine testing of isolates may be indicated (24, 153). C. jejuni and C. coli are resistant to β-lactam antibiotics, general penicillins, and narrow-spectrum cephalosporins, but imipenem has good anti campylobacter activity.

Parenteral therapy is used to treat systemic C. fetus infections; drugs used include ampicillin, aminoglycosides, imipenem, and metronidazole, depending upon the type of infection. C. lari is resistant to nalidixic acid but may be susceptible to fluoroquinolones, and resistance to macrolides is generally low (152). C. upsaliensis is generally susceptible to a variety of antimicrobial agents and shows low rates of resistance to macrolides and fluoroquinolones (152). Arcobacter butzleri and A. cryaerophilus have variable resistance to macrolides and fluoroquinolones (152).

Agar dilution is the method recognized by the Clinical and Laboratory Standards Institute (CLSI) for testing Campylobacter spp.; quality control ranges for several antimicrobial agents have been published (154, 155). A broth microdilution method with published quality control ranges for several antimicrobial agents and a disk diffusion screening method are also approved by CLSI (156, 157). The European committee on antimicrobial susceptibility testing (EUCAST) recently developed a standardized disk diffusion method for ciprofloxacin, erythromycin, and tetracycline with defined breakpoints. Studies testing Campylobacter with the Etest have been published (158).

A review of susceptibility testing methods recommended by CLSI and EUCAST was recently published. Methodologies currently vary between different countries and breakpoint committees, and there is a need for harmonization of both methods and interpretive criteria (159).

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

Campylobacter species, including the common thermophilic species C. jejuni and C. coli, should be sought in all diarrheic stools submitted to the laboratory for routine culture. Except for epidemiological purposes, cultures of formed stools should not be performed. Isolation of Campylobacter from a patient with acute diarrhea is usually significant, since the carrier rate in developed countries is quite low; however, in developing countries, isolation might be more difficult to interpret, especially in the presence of other enteric pathogens. In acute infection, there are usually a high number of organisms in the stool, but the quantity of organisms is not related to the severity of infection or indicative of a carrier state. Gram stain analysis of fecal samples to look for organisms with typical Campylobacter morphology is a highly sensitive and specific test that is underused; it should be performed for rapid preliminary diagnosis of Campylobacter infection. Other species, such as C. fetus subsp. fetus and C. upsaliensis, may be important causes of diarrhea and are not isolated on routine selective media. Special methods, including alternative incubation techniques, are required as described in this chapter and should be performed by special request. Oxidase-positive, curved, Gram-negative rods that are hippurate hydrolysis positive should be reported as C. jejuni without further workup. The importance of identifying other species depends on the clinical circumstance, but identification tests should always be performed with isolates from blood or other sterile sites, since this could influence antimicrobial therapy decisions. Because fluoroquinolone resistance is present in a significant proportion of C. jejuni isolates, fluoroquinolone susceptibility testing is suggested for patients who are receiving or being considered for therapy of gastroenteritis. Susceptibility testing should be performed with all isolates from sterile clinical sites.

TAXONOMY
The genus Helicobacter is classified in the family Helicobacteriaceae of the class Epsilonproteobacteria, formerly known as the epsilon subclass of the Proteobacteria, with Helicobacter pylori as the type species (1). The other genus in the family is Wolinella, with the type species Wolinella succinogenes, and both genera are phenotypically similar to the genus Campylobacter. Helicobacter is a genus of expanding diversity. Since the genus name was formally proposed in 1989 (2) with two species (H. pylori and Helicobacter mustelae) and revised in 1991 to include Helicobacter cinaedi and Helicobacter fennelliae (3), it has grown to comprise more than 30 species (including a species with “Candidatus” status) (Table 57). Species of Helicobacter have genomic G+C base contents ranging from 30 (H. acinonychis) to 48 (H. canis) mol%, which is similar to the G+C content range of Campylobacter species. In addition, there are a number of unique Helicobacter 16S rRNA gene sequences listed in GenBank that represent sound taxa that have not yet met the criteria for official recognition but could be the basis of future new species.

Interest in gastric spiral bacteria, observed for more than 100 years in animals and humans but rarely cultured, was triggered in 1982 by the discovery of Campylobacter pyloridis (later renamed Helicobacter pylori) which was cultured from stomach biopsy specimens from human patients with gastritis (4). Phylogenetic analyses based on 16S rRNA gene sequences indicate distinct groups of species within the genus; these fall broadly into groups of gastric (stomach) and enterohepatic (intestine, liver, or biliary tract) origins and include a subgroup of enterohepatic species lacking the characteristic sheathed flagella but possessing an N-linked glycosylation system similar to campylobacter (5) (Fig. 1). Phylogenetic analyses reliant on 16S rRNA gene sequences alone have sensitivity limitations in investigations of closely related helicobacters, which have a high degree of natural transformation and genetic plasticity. Additional phylogenetically informative genes, such as those encoding 23S rRNA and heat shock protein 60, have been used to construct phylogenies of taxa closely related by 16S rRNA gene sequences and to resolve any discordance (6, 7).

The classification of many non-H. pylori gastric helicobacters has proven particularly problematic because they are difficult to culture and closely related by 16S rRNA gene sequence analysis (Fig. 1). Large gastric spiral bacteria originally referred to as “Gastrospirillum hominis” were subsequently designated “Helicobacter heilmannii” (8) and have since been fully characterized as Helicobacter heilmannii (9). Further developments have provided clarification that Helicobacter suis, recently cultured and formally recognized and named (6), includes samples identified and closely related cultured species (Helicobacter bizzozeronii, Helicobacter salmonis, and Helicobacter felis) typically found in dogs and cats (10). For convenience, H. heilmannii and allied species of gastric origin are collectively referred to in this chapter as “H. heilmannii”-like organisms (HHLO), as the accuracy of identifications is uncertain in earlier clinical reports (11). In addition, the classification is not fully resolved for organisms with spindle-shaped cells surrounded by periplasmic fibrils and bipolar tufts of sheathed flagella originally referred to as “Flexispira rappini” (8). Phylogenetic analysis identified 10 different taxa, of which several grouped with named species of Helicobacter (12). Flexispira taxa 2, 3, and 8 are now considered to constitute a single species, Helicobacter bilis (13), while taxa 1, 4, and 5 are assigned to Helicobacter trogontum (14). Further insights into the taxonomy of the genus are now possible with the availability of complete genome sequences of a number of Helicobacter species besides H. pylori. Comparative genomics should enable deeper levels of taxonomic analysis as further Helicobacter genomes become available.

DESCRIPTION OF THE AGENTS
Members of the genus Helicobacter typically are curved, helical or spiral, or fusiform rod-shaped bacteria with or without periplasmic fibers. The cells have sizes ranging from 0.3 to 0.60 μm in width and 1 to 10 μm in length. Cells may become spheroid or form coccoid bodies if they are cultured for a prolonged period or if growth conditions are not optimal. Such forms typically cannot be subcultured. Helicobacter species are all Gram negative, cytochrome oxidase producing, and non-spore-forming. Cells are motile and possess either single or multiple flagella. There is considerable diversity among species in flagellum morphology. Flagella are typically sheathed; for example, H. pylori has multiple (four to eight per cell) monopolar sheathed flagella with terminal knobs (Table 2). In contrast, Helicobacter pullorum, H. canadensis, and five other species with unsheathed flagella form a distinct phylogenetic group within

*This chapter is an updated version of the one that appeared in the 10th edition of this Manual; as such, it contains elements contributed by James G. Fox, Francis Megraud, and Robert Owen.

the genus (Fig. 1) (note, *H. equorum* clusters with this group by 16S rRNA gene phylogeny but has sheathed flagella and lacks the glycosylation system). Gastric helicobacters found in animals, with the exception of *Helicobacter baculiformis* (a rod-shaped bacterium), have distinctive, tightly spiraled morphologies and can exhibit tufts of up to 20 multiple flagella per cell. The optimum temperature for growth is 37°C. Helicobacters are organotrophs, possess a respiratory type of metabolism, and are microaerobic. The optimal atmosphere for growth varies, as some species, such as *Helicobacter ganmani*, a rodent enteric organism, grow best in an anaerobic cabinet, although strict anaerobiosis is lethal. Successful cultivation of helicobacters typically requires a humid atmosphere maintained at 37°C with reduced levels of oxygen (5 to 10%) and increased levels of carbon dioxide (5 to 12%). The addition of hydrogen (3 to 5%) to the microaerobic atmosphere usually improves growth. Helicobacter species grow poorly, if at all, in routine aerobic atmospheres. Key biochemical characteristics, such as urease hydrolysis, nitrate reduction, indoxyl acetate hydrolysis, and alkaline phosphatase activity, vary among species of *Helicobacter* and so are utilized in species identification (Table 2). However, there is no single common feature which reliably distinguishes all species of *Helicobacter* from those of *Campylobacter*. All helicobacters lack the carbohydrate utilization pathways typically exploited in conventional laboratory biochemical tests. Genomic analysis of *H. pylori* shows that it does not appear capable of using complex carbohydrates as energy sources, and comparisons with the *Campylobacter jejuni* genome indicate significant differences in energy metabolism and chemotaxis systems (15).

**EPIDEMIOLOGY AND TRANSMISSION**

*Helicobacter* species are isolated from the gastrointestinal and hepatobiliary tracts of a variety of mammalian hosts that include humans, dogs, cats, cattle, sheep, swine, rodents, nonhuman primates, cheetahs, ferrets, rabbits, dolphins, whales, and horses, as well as chickens and wild birds (Table 1).
H. pylori

H. pylori, with its characteristic strong urealytic ability, is the gastric helicobacter of humans and is found almost exclusively in the human stomach, which provides the reservoir of infection. Exceptions are isolates from primates previously named Helicobacter nemestrinae, which is now considered a synonym of H. pylori (16). There is no evidence of animal-to-human transmission. The organism colonizes the cardia, corpus, and antrum of the stomach and may also be found in areas of gastric metaplasia of the proximal duodenum. Studies primarily using serology have been used to study the prevalence of H. pylori infection. These studies show a widespread distribution, with estimates that close to half the human global population is colonized, with clinical disease being the exception rather than the rule (17). In the developed world, the prevalence of H. pylori seems to be declining; for example, in the United States, an ongoing survey showed that there had been a significant decline over 2 decades, with an overall decline to 30.7%. The decline is most marked in non-Hispanic whites, but that prevalence was still high amongst Hispanics and African-Americans (18). Likewise, in Europe, the prevalence is higher in eastern countries than in western countries; there is evidence that prevalence rates are declining in developed

societies with improvements in sanitation and living standards (19, 20). The prevalence of *H. pylori* infection differs markedly between developing and developed countries (20). In developing countries, infection occurs early in life; most children are infected by the age of 10, and prevalence remains high (up to 90%) for all adult age groups. In contrast, in developed countries, a progressive increase in prevalence is observed, from a low percentage of infection in those born after 1980 (<30 years old) to 40 to 50% infection rates in the older age groups. This is not the consequence of a progressive acquisition of the infection but rather the result of a cohort effect (20, 21). Reported incidences of culture confirm that infections vary considerably from country to country depending on local treatment guidelines and cultivating practices.

The modes and routes of transmission of *H. pylori* from person to person remain to be definitely proven. There is epidemiological evidence for both oral-oral and fecal-oral transmission, with the latter being more likely in developing countries, where sanitation and contaminated water supplies may pose a greater risk (20). The role of contaminated public water supplies has never been convincingly proven because of the rarity of culture-positive water samples (22). There is no evidence that viable cells of *H. pylori* can survive the disinfection levels in properly maintained main supplies, although survival may be possible as a viable nonculturable form (23). Biofilms within water distribution systems have been suggested as possible sites of passive accumulation (24). The rationale for oral-oral transmission relies on the presence of *H. pylori* in regurgitated gastric juice, thus allowing *H. pylori* to temporarily colonize the oral cavity. Another possibility is via vomitus, in which *H. pylori* can remain viable for hours (25). Person-to-person transmission appears to be most frequent in intrafamilial settings during childhood, particularly between mothers and siblings, as well as among siblings and between other household contacts (26). Family groups provide the best opportunity to study person-to-person transmission, but interpretation of evidence is complex. Patterns of frequent horizontal spread deduced from DNA sequence types were found both within families and between unrelated individuals in rural South Africa, which may be a situation representative of high-prevalence areas in large parts of the developing world (27). In urban families, in contrast, clonal transmission of *H. pylori* was more frequent between first-degree relatives.

**HHLO**

Human infections with HHLO are generally considered uncommon, with prevalence rates detected by histological observation ranging from <0.3% in developed countries to about 6% in other regions (27). A higher rate of 2% was indicated for some United Kingdom patients by a direct biopsy PCR assay designed to detect multiple HHLO species (28). Now that individual HHLO taxa are better defined, retrospective reassessment using species-specific assays of past cases attributed to *H. heilmannii* provides evidence of infection with one or more species of zoonotic origin, notably *H. salomonis*, *H. felis*, *H. suis*, and "Candidatus Helicobacter bovis" (10). These findings indicate cats, dogs, and swine as possible sources of infection, but modes of transmission are unknown.

**Enterohepatic Helicobacters**

Enterohepatic helicobacters inhabit the intestinal and hepato-biliary tracts of various mammal and bird hosts, and several species, such as *H. bilis*, *H. canadensis*, *H. canis*, *H. cinaedi*, *H. fennelliae*, *H. pullorum*, and "*H. winghamensis*," infect humans with clinical symptoms (Table 1). Little is known about prevalence and routes of transmission of these species, but the implications are that they are transmitted to humans from animals. *H. pullorum* is a recognized zoonotic risk, as it has been identified in carcasses of broiler chickens and laying hens (29) and on uncooked retail chicken (30).

**CLINICAL SIGNIFICANCE**

**H. pylori**

Marshall and Warren (31) first proposed the association of *H. pylori* with peptic ulcer disease, and since then it has become established as the most clinically important species of *Helicobacter*. It is recognized as the main cause of peptic ulcer disease and a major risk factor for gastric cancer (32). *H. pylori* infection is also an independent risk factor for the development of atrophic gastritis, gastric ulcer disease, gastric adenocarcinomas, and gastric mucosa-associated lymphoid tissue (MALT) lymphomas (21). Individuals infected with *H. pylori* may develop acute gastritis (abdominal pain, nausea, and vomiting) within 2 weeks following infection. The species establishes a chronic infection in the majority of infected people, represented by chronic gastritis. Prominent mucosal inflammation is often evident in the antrum (antrum-predominant gastritis), predisposing patients to hyperacidity and duodenal ulcer disease. Many patients infected with *H. pylori* have recurrent abdominal symptoms (nonulcer dyspepsia) without ulcer disease, and there appears to be a clinical benefit in eradicating *H. pylori* in these patients (33). Duodenitis often occurs with *H. pylori* infection, and duodenal ulcers develop in as many as 16% of infected individuals (34). Gastric MALT lymphoma, a rare stomach cancer, is caused by *H. pylori* infection and is the only cancer which can possibly be cured by antibiotics (35). Eradication of *H. pylori* is also recommended in cases of unexplained iron deficiency anemia and chronic idiopathic thrombocytopenic purpura (36). The clinical significance of *H. pylori* infection remains speculative in a number of other chronic conditions, notably ischemic heart disease, inflammatory bowel disease, and liver and biliary tract diseases (37).

**HHLO**

HHLO infection has been associated with mild-to-moderate gastritis, peptic ulcer disease, and gastric MALT lymphomas in adults, although it has not unequivocally been established as a causative agent (10, 38). The etiology of HHLO infections is unclear because they are uncommon, and organisms are unculturable in a routine clinical laboratory (10).

**Enterohepatic Helicobacters**

Isolated cases of infections in adults and children with enterohepatic helicobacters have been reported over the past 25 years, but their clinical significance is often not clearly established. Isolates are mainly from blood and, to a lesser extent, from fecal samples (39, 40). The bacteremia-associated helicobacters, although rare, are the most clinically significant, as they occur more frequently in patients with underlying conditions. It is presumed that these helicobacters are able to invade the bloodstream via colonization of the human lower gastrointestinal tract, possibly from mucosal cells damaged by combined chemo- and radiotherapy. *H. cinaedi* infections may present in various clinical manifestations (proctocolitis, gastroenteritis, neonatal meningitis, localized pain and rash, and bacteremia), particularly in individuals with underlying immunosuppressive conditions.
It has also been associated with coronary artery disease (39, 41). H. fennellae has been implicated as a cause of human proctocolitis, gastroenteritis, and bacteremia, particularly in immunocompromised individuals (40, 41). H. pullorum has been associated with several cases of human gastroenteritis (42).

Other species of Helicobacter isolated occasionally from infected humans but of unclear clinical significance include H. canadensis (43) and “H. winghamensis” (44) from cases of gastroenteritis. H. canis has been associated with inflammatory bowel disease and H. hepaticus with hepatobiliary disease (39). Recently, a possible link between H. suis and Parkinson’s disease has been proposed (45). In this study, H. suis DNA was detected by a real-time PCR assay in archived DNA from gastric biopsy specimens with a higher frequency from patients with Parkinson’s disease than from a control group.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Gastric Biopsy Specimens

Gastric biopsy specimens for the direct diagnosis of H. pylori are routinely obtained from the antrum and corpus by esophagogastroduodenoscopy. While sterile normal saline may be sufficient for short-term (up to approximately 2 h) transport of gastric biopsy specimens, a transport medium should be used if available to maintain the viability of the organisms for culture. H. pylori is sensitive to desiccation and to ambient atmosphere and temperature. A semisolid transport medium (e.g., Portagerm pylori [bioMerieux Inc., Durham, NC]) or an in-house transport medium that comprises brain heart infusion broth (3.5%), yeast extract (2.5%), sterile horse serum (3%), and Helicobacter pylori selective supplement (Dent’s, 10-μg/ml vancomycin, 5-μg/ml trimethoprim, 5-μg/ml cefsulodin, and 5-μg/ml amphotericin B [Oxoid Ltd., Basingstoke, United Kingdom]) may be used. Alternatively media include Stuart’s transport medium or brucella broth with 20% glycerol. If culture of H. pylori is not possible within 24 h, it is recommended that biopsy specimens be stored overnight at 4°C in a transport medium and then transported at ambient temperature. For longer-term storage, biopsy specimens should be frozen at −70°C in a 10% glycerol-containing medium.

Fecal Specimens

H. pylori and other gastric helicobacters cannot ordinarily be isolated from human fecal specimens, so samples are not recommended for routine culture. Fecal samples are used for H. pylori stool antigen tests (SAT) and either should be tested immediately or should be stored immediately at −20°C. Repeated thawing and freezing of samples should be avoided. As enterohelobacters can cause enteric disease, fecal specimens may be required for culture. However, campylobacters are more likely to be tested for in the first instance, and relevant protocols for their collection, transport, and storage also can be used for enterohelobacteria species of Helicobacter (as for Campylobacter, see chapter 56).

Blood Specimens

Blood specimens are required for serological diagnosis of an H. pylori infection and may be collected, transported, and stored by standard protocols. Also, as the enterohelobacter helicobacters may translocate across the intestinal barrier and cause invasive infections, peripheral venous blood from suspected cases may be required for microbiological testing. Blood may be collected in commercially available aerobic and anaerobic blood culture bottles and transported and stored according to the protocols used for campylobacters, which are more likely be tested for in the first instance (for Campylobacter, see chapter 56).

Other Clinical Specimens

Laboratory tests requiring the collection of other types of specimen have been developed to assist in the diagnosis of H. pylori infection and may be undertaken under some circumstances.

Gastric juice, obtained from the patient either by aspiration after the introduction of a nasogastric tube or by the so-called string test (basically, the patient swallows a string which is then regurgitated), has been used as a possible source of H. pylori for culture and PCR. Gastric juice does not offer a satisfactory alternative to a biopsy specimen as a routine specimen because of problems caused in culture by overgrowth of nasopharyngeal microbiota unless preventive steps such as acid pretreatment are taken (46). Specimens, if used, should be transported at 4°C and processed without delay.

Urine

Fresh urine samples required for antigen testing tests should be collected and transported by standard protocols. Urine samples cannot be frozen because any resultant protein precipitation may interfere with the tests.

Saliva

Saliva samples required for serological tests can be collected easily by having the patient spit into a tube. An alternative that may be preferable is use of a special swab device rubbed over the gums that is designed to obtain gingival transudate enriched in immunoglobulin G (IgG) (47). Specimens should then be transported by routine protocols.

DIRECT EXAMINATION

Microscopic Examination of Gastric Biopsy Specimens

Histopathological examination of gastric biopsy specimen sections preserved in a fixative (10% formaldehyde) and embedded in paraffin is widely used for diagnosis of H. pylori infection. Standard hematoxylin and eosin tissue staining is not sufficient to detect H. pylori, whereas the Warthin-Starry stain allows excellent visualization of bacteria if performed by trained histology personnel. Although the specificity is usually adequate, the presence of bacteria with atypical morphologies may result in misinterpretations. Under optimal conditions, histological diagnosis has a sensitivity and specificity of 95% (20, 48). Immunohistological staining with specific H. pylori antibodies can improve specificity. Histological methods and interpretation of histological findings are outside the scope of this chapter, but from the microbiology laboratory perspective, microscopic examinations of a smear prepared directly from a biopsy specimen or from imprint cytology provide rapid bacteriological test results for observation of cells of H. pylori. Staining can be performed using Gram stain, rapid Giemsa stain, or the fluorescent acridine orange stain. The less-common gastric HHLO can also be Giemsa stained and, when observed microscopically, can be distinguished from H. pylori by their distinct tightly spiral morphology (49).
Microscopic Examination of Feces and Other Pathological Specimens

Direct Gram stain analysis of fecal smears and other clinical samples is not routinely performed for the detection of *H. pylori* or other helicobacters. Direct identification of helicobacters in positive blood cultures may require special stains, particularly if tests are performed by personnel unaccustomed to looking for such organisms. Thin, gull-shaped bacteria such as *H. cinaedi* can be difficult to observe by Gram staining and require acridine orange staining, dark-field microscopy, or Giemsa staining. A modified Gram stain with carbol (0.5%) or basic fuchsin (0.1%) as the counterstain is also recommended for detection (50).

Urease Testing of Gastric Biopsy Specimens for *H. pylori*

*H. pylori* produces large amounts of extracellular urease, which can rapidly be detected following introduction of gastric biopsy tissue into a urea-containing medium as a rapid urease test (RUT) (20). Urease catalyzes the hydrolysis of urea into ammonia and carbonate. The net effect of ammonia production is to increase local pH. Detection of urease activity forms the basis of several simple, inexpensive, and easy-to-perform tests that are usually performed in an endoscopy unit by clinicians. Biopsy specimens are placed either in an agar gel or on a paper strip containing a pH indicator. If organisms are present in sufficient numbers, a color change will occur as a result of urea breakdown and ammonia production. Commercial RUTs that include agar gel-based tests (e.g., CLOtest [Kimberly-Clark, Neenah, WI]) and paper-based strip tests (e.g., PyloriTek [BARD, Murray Hill, NJ] and *H. pylori* Quick test [Biohit, Helsinki, Finland]) have been critically evaluated, and specificities are usually excellent (20). Detection sensitivity also is high but is dependent on the *H. pylori* density in mucosal biopsy specimens and the number of biopsy specimens sampled. RUTs have their optimal sensitivity after 24 h of incubation, whereas strip tests are optimal within an hour, making them truly rapid tests. Urease broth media commonly available in microbiology laboratories, such as modified Christensen medium and urea-indole medium, can be used but are not optimized to have sensitivities equivalent to those of commercially available kits.

Urea Breath Test

Another important clinically performed test, based on the ability of *H. pylori* to produce urease and develop specifically for detection of an active infection, is the urea breath test (UBT). The UBT has the advantage of being noninvasive, as urea, labeled with a nonradioactive natural isotope (¹³C), is ingested by the patient. The labeled CO₂ is absorbed by the blood and exhaled in expired air. The testing methodology and factors influencing the result, standardization, and application in different clinical settings have been comprehensively reviewed (20). The use of the UBT has high diagnostic accuracy (>95%) (36) and, where available, is consistently recommended for the diagnosis of *H. pylori* infections in adults in both pre- and posttreatment settings. A recent prospective multicenter study indicated that the ¹³C UBT was also simple and accurate for diagnosis of *H. pylori* infections in children (51).

*H. pylori* Fecal Antigen Detection

SAT using an enzyme-linked immunosorbent assay (ELISA) provide another valuable aid in the diagnosis of an active *H. pylori* infection. The test is easy to perform and has the advantage of being noninvasive. Since becoming commercially available, kits consisting of a polyclonal antibody fixed on microwells (e.g., Premier Platinum HpSA [Meridian Bioscience, Inc., Cincinnati, OH]) have been extensively evaluated on samples from adults and children and have proven to be an excellent diagnostic tool. A systematic review of published data up to 2004 confirmed the value of such kits for primary pretreatment as well as for follow-up posttreatment diagnosis (52). The test was further developed by using specific monoclonal antibodies, and reviews and meta-analysis based on evaluations of kits (e.g., IDEIA HpStAR [Oxoid Ltd., United Kingdom] and Premier Platinum HpSA PLUS [Meridian Bioscience, Inc., Cincinnati, OH]) indicated improved sensitivity compared to those of polyclonal tests. For example, high sensitivity (94%) and specificity (100%) were reported for tests on pretreatment adult stools in England (53), and the performance of tests was reported to be excellent for young children in Finland (54). If the UBT is not available, the laboratory-based stool antigen test is recommended for confirmation of eradication between 2 and 4 weeks after treatment (20). The presence of some false positives has been noted in the use of stool antigen tests for posttreatment diagnosis, possibly attributable to the presence of antigen in stools from degraded coccoid forms (54). Some stool samples that were transiently positive by ELISA also have been reported for children and were thought to have transient infections with *H. pylori* or other *Helicobacter* species (55). Monoclonal antibodies are used also in immunoenzymatic rapid point-of-care tests for diagnosis of *H. pylori* infection (e.g., the ImmunoCard STAT! HpSA [Meridian Bioscience, Inc., Cincinnati, OH]) and RAPID HpStAR (Oxoid Ltd., Basingstoke, United Kingdom), and their performance in the clinical/near-patient setting has been critically evaluated and in general they are not thought to be as accurate or reliable as the ELISA-based tests (36, 53).

Nucleic Acid Detection

Detection of *H. pylori* in Gastric Biopsy Specimens

Nucleic acid assays based on PCR amplification and on fluorescence in situ hybridization with species-specific probes provide useful approaches for the detection of *H. pylori* in gastric biopsy specimens, as they are significantly faster than culture. The commonest targets for amplification are 16S rRNA, ureA, glmM, and rRNA genes (56), and in addition, 23S rRNA genes have been targeted for both detection and antibiotic susceptibility testing (21, 93). There is currently no gold standard method for use in the clinical laboratory setting for PCR of gastric biopsy specimens, and so it is advised that PCR-based assays should not be the sole basis of determining the *H. pylori* status of a patient (56). Nevertheless, PCR assays can provide added value in investigating culture-negative gastric biopsy specimens, particularly those from cases for which other clinical tests indicate an *H. pylori* infection. A systematic study of primers for *H. pylori* detection found that the four best-performing assays each attained a detection limit of <100 CFU/ml from gastric tissue (56). However, no assay had 100% specificity or sensitivity, and all produced false positives. Two of the best all-around assays based on the HP64-r/HP64-pr primers for the ureA gene and HP1/HF2 primers for the 16S rRNA genes had sensitivities and specificities of >90% with gastric biopsy specimens.

Detection of *H. pylori* in Feces

The PCR assays developed for biopsy specimen testing, in particular those using primers targeting the 16S rRNA and
ureA genes, have been applied to stools to detect *H. pylori* with various success rates, and their value for routine laboratory use is questionable. Feces is a complex material containing a number of PCR inhibitors (57), and complex DNA purification methods are needed to either eliminate or reduce the levels of such compounds. The performance of the assays is restricted by the low numbers of *H. pylori* cells in feces and by degradation of DNA during transit through the intestinal tract. Another test uses a biprobe 23S rRNA with various success rates, and their value for routine laboratory use is questionable. Feces is a complex material containing various *Helicobacter* species with symptomatic children (59), has been applied to detection (for further details, see “Antimicrobial Susceptibility” below). However, it should be noted this assay was applied to extremely fresh fecal samples.

Detection of HHLO in Gastric Biopsy Specimens

Specialist assays have been developed for direct PCR detection of species of HHLO in gastric biopsy specimens (60), and simultaneous testing for both *H. pylori* and HHLO can be performed using a multiplex PCR assay (28). Fluorescence in situ hybridization tests with species-specific probes can also be applied to detect HHLO in human gastric biopsy specimens (61).

Detection of Other Helicobacters in Clinical Samples

With the exception of an unvalidated 16S rRNA gene PCR assay for detection of *H. pullorum* in human fecal extracts (62), there are no assays suitable for fecal detection of enterohepatic *Helicobacter* species of clinical relevance. Genus-level PCR-based assays targeting mainly 16S rRNA genes have been developed and used for direct detection of other helicobacters in a variety of clinical samples that include dental plaque and saliva (63), intestinal tissue biopsy specimens (64), and liver biopsy specimens and associated tissues (bile and gallbladder) (65). These assays are generally undertaken for specific epidemiological and disease association investigations and so are unlikely to be used in the routine laboratory. Results of such PCR-based assays performed in the absence of other evidence therefore should be interpreted with caution (56).

**ISOLATION PROCEDURES**

**Isolation of H. pylori**

*H. pylori* is readily isolated by culture from gastric biopsy specimens. Tissue should be streaked over the culture medium with a minimum of delay or first homogenized to facilitate a higher yield of bacteria. Agar-based media such as brain heart infusion agar, brucella agar, Wilkins Chalgren agar, and Trypticase soy agar can be used for primary culture. In our experience, Columbia agar base supplemented with 10% defibrinated horse blood gives excellent results. A selective medium (e.g., *Helicobacter pylori* selective medium [Oxoid Ltd., Basingstoke, United Kingdom]) containing Dent’s antibiotic supplement (see “Collection, Transport, and Storage of Specimens” above) also gives adequate isolation results. Plates should be incubated at 35 to 37°C in a humid microaerobic atmosphere (4% O₂, 5% CO₂, 5% H₂, and 86% N₂) achieved using either a gas jar and gas-generating system or an incubator (e.g., the MACS VA500 microaerophilic workstation [Microbiology International, Frederick, MD]). The exact gas mixes used vary between laboratories, but the presence of 5% H₂ in the atmosphere enhances growth. Culture plates should be observed daily for the appearance of small, smooth, circular colonies, which should appear after 48 h of incubation. Plates must be incubated for a minimum of 10 days before a negative result is given. Colonies should be subcultured on nonselective medium for further investigation. Isolates may be stored at −80°C in cryovials (e.g., the Microbank bacterial preservation system [PRO-LAB Diagnostics, Austin, TX]).

**Isolation of Other Helicobacter Species**

There are no recommended culture methods available currently for use in routine clinical laboratories for isolation of HHLO from human gastric biopsy specimens. The first and only reported successful isolation of “*H. heilmannii*” from a human, achieved after 7 days with a nonselective medium (7% lysed horse blood) in a 5% O₂ and 10% CO₂ atmosphere, was subsequently identified as *Helicobacter bizzozeroi* (66). A novel isolation method using high acidity and modified gaseous conditions has now been developed for isolation of *H. suis* from pig gastric tissue (6) and has recently been applied to human tissue.

Enterohepatic helicobacters such as *H. bilis*, *H. canadensis*, *H. canis*, *H. cinaedi*, *H. fennelliae*, *H. pullorum*, and “*H. winghamensis*” are isolated typically during investigation for campylobacters in feces from humans with gastroenteritis. These organisms grow at 37°C but not uniformly at 42°C, the temperature most often used for isolation of *C. jejuni*. Fresh stool specimens should be examined using a selective medium or the nonselective membrane filter method (67) with incubation for a minimum of 7 days at 37°C in a microaerobic atmosphere (68). Strains of some species may require 5 to 10% H₂ for optimum growth, and recovery may be hindered if they are susceptible to antibiotics present in the selective isolation medium.

Some enterohepatic helicobacters, such as *H. cinaedi*, *H. canis*, and *H. fennelliae*, are isolated occasionally from the blood of patients with suspected bacteraemia using commercial blood culture systems (e.g., the BacTec system [BD, Sparks, MD]). Isolates are usually detected in aerobic blood culture bottles only and may be problematic to recover, as they are difficult to see microscopically and will probably grow poorly on subculture if plates are not incubated for an extended period (minimum of 6 days) in a microaerobic atmosphere. The isolation of *Helicobacter* species from other sterile body fluids is rare, but a notable example is the isolation of *H. cinaedi* from joint fluid using a nonselective blood medium (69).

**IDENTIFICATION**

Identification of *Helicobacter* species is based on a limited range of morphological, physiological, and biochemical characteristics (Table 2). *Helicobacter* species have various colony phenotypes on blood agar, ranging from the discrete, gray, and translucent colonies of *H. pylori* to swarming phenotypes of some gastric helicobacters (e.g., *H. felis*). Most isolates are motile and should be routinely tested for oxidase, catalase, and urease activities according to recommended procedures (70). The advent of whole-cell matrix-assisted laser desorption ionization–time-of-flight spectrometry (MALDI-TOF) promises to make the identification of *Helicobacter* species a great deal easier but will ultimately depend on the quality of the databases used by the laboratories (71).

**H. pylori and Other Gastric Helicobacters**

In stained gastric biopsy samples, *H. pylori* cells usually have a curved or helical morphology. However, on subculture,
this “classical” morphology is often lost, and in Gram-stained preparations, cells may appear curved, U shaped, or even as straight rods. HHLO cells are larger in size and have a more pronounced helical morphology in histological examinations of gastric biopsy specimens (49). Helicobacter cells may appear faint on conventional Gram staining and require prolonged counterstaining with carbol fuschin (0.5%) for enhanced visualization. Urease-negative organisms may be present occasionally in gastric biopsy specimens, as H. cinaedi, although not cultured, has been identified by DNA analysis (72). It is important, therefore, to perform other key biochemical tests, such as indoxyl acetate hydrolysis and catalase, to identify isolates of any unexpected species. Ultimately, MALDI-TOF identification will probably be the simplest approach. However, at the time of writing, it is unclear how extensive the Bruker databases for Helicobacter species are. However, from personal experience, the most common species are present (71, 73). The MALDI-TOF technique was used to great effect in a recent study of H. cinaedi strains (74) where the facility of the technique to subtype strains was explored.

**Enterohepatic Helicobacters**

Enterohepatic helicobacters may appear as a swimming thin film (e.g., H. cinaedi and H. fennelliae) or as discrete single colonies (e.g., H. canadensis and H. pullorum). By light microscopy, they morphologically resemble other Gram-negative spiral or curved bacteria. The enterohepatic species possess several distinguishing characteristics (Table 2), and biochemical and tolerance tests should be carried out according to the recommended procedures (43). Species lacking urease activity isolated from humans, such as H. canadensis, H. canis, H. cinaedi, H. fennelliae, and H. pullorum, superficially resemble enteric campylobacters, and definitive identification may not be possible from phenotype alone. Useful distinguishing tests are growth at 42°C, as both H. cinaedi and H. fennelliae are negative, and indoxyl acetate hydrolysis, for which C. jejuni and Campylobacter coli are positive and H. pullorum is negative. A PCR assay is described for identification of H. pullorum (42), but the assay does not distinguish H. pullorum from H. canadensis, which characteristically hydrolyzes indoxyl acetate and is resistant to nalidixic acid (43). H. canis is unlike most other helicobacters in being both catalase negative and urease negative, features that may cause confusion with “H. winghamensis” and H. bilis. Growth at 42°C and the nitrate reduction and indoxyl acetate hydrolysis may be useful to distinguish H. canis from other catalase-negative campylobacters. It is important to be aware that fecal specimens occasionally can be cocolonized with multiple Helicobacter and Campylobacter species, so making a complete diagnostic evaluation is challenging. Helicobacter genus-specific PCR assays may be useful and sequencing of 16S rRNA genes may be required for a definitive identification. However, 16S rRNA gene phylogeny is not suitable for distinguishing clades of closely related species such as the HHLO (10).

**TYPING SYSTEMS**

**Typing of H. pylori**

Typing isolates of H. pylori has no role in direct patient management (36). Even so, typing data may be useful in monitoring the effects of therapy and to establish whether a persistent infection is due to eradication failure or reinfection, in investigating associations between strain type and disease severity, in epidemiological investigations of routes and modes of transmission, and in investigating the ancestry of strains worldwide that might be relevant in vaccine development. There is no generally agreed-upon system for typing isolates of H. pylori; although many different methods have been applied and evaluated, genotypic methods are the most widely used means of characterizing individual isolates of H. pylori. A key feature of H. pylori is its high genetic diversity, with almost every isolate having a unique genotype arising from within-genome diversification and reassortment by natural homologous recombination (27). This diversification is thought to aid H. pylori in persistence during chronic infection and in adapting to new gastric environments.

The highly polymorphic vacuolating cytotoxin (vacA) gene provides the basis of a widely adopted PCR-based genotyping scheme with recommended primers (75). The vacA allelic type is determined by the presence or absence of short, conserved nucleotide inserts within the signal and middle regions (76). Common vacA allelic types identified worldwide are s1/m1 (vacuolating), s1/m2 (selectively vacuolating), and s2/m2 (nonvacuolating). The signal region alleles can be further divided into s1a, s1b, and s1c subfamilies, and likewise, the middle region is subdivided into m2a and m2b subfamilies (77). Genotyping can be performed by using either individual PCR assays or multiplex PCR assays (78, 79). Molecular fingerprinting methods applied to H. pylori include electrophoretic protein profiling, ribotyping, restriction fragment length polymorphism analysis, pulsed-field gel electrophoresis, amplified fragment length polymorphism analysis, and plasmid profiling (77). Multilocus sequence typing is probably the most widely used molecular subtyping system for H. pylori; it has been used to investigate intrafamilial transmission (73) and to study global patterns of H. pylori epidemiology (79). The PubMLST database currently holds somewhere in the region of 2,000 H. pylori profiles. It is perhaps a little outside the scope of this chapter, but with the advent of so-called next-generation sequencing, it is possible to sequence whole genomes relatively quickly and inexpensively. The advent of the Bacterial Isolate Genome Sequence Database (BIGSdb) (80) will ultimately allow complex analysis of whole genomes in a scalable fashion.

**Typing of Other Helicobacters**

The need to type species of Helicobacter other than H. pylori is unlikely, and the genotyping schemes described are of questionable value for routine use.

**SEROLOGIC TESTS**

**Detection of H. pylori Antibody in Blood**

H. pylori infection induces a specific systemic immune response to multiple antigens, with only 2% of patients failing to seroconvert (81). The immune response typically shows a transient rise in specific IgM antibodies followed by a rise in IgG and IgA antibodies that persists during infection. Serology is widely used in primary screening for H. pylori infection, as it is a simple, noninvasive test. A number of in-house and commercial kits have been developed over the past 20 years for antibody detection, with the essential laboratory technique being the standard ELISA. The performance and diagnostic utility of laboratory ELISA kits (e.g., Cobas Core enzyme immunoassay [Roche, Mannheim, Germany]) and rapid near-patient immunochromatographic tests (e.g., FlexSure HP [Beckman Coulter Inc., Brea, CA]) have been critically evaluated in several reviews and meta-analyses (20). Serology (ELISA)
kits that measure IgG antibodies are recommended based on overall performance as an accurate means of diagnosing infection (20, 36). The relevance of IgA in testing is more controversial (82). Some investigators have observed IgA to be equal to IgG in performance, but a recent evaluation concluded that IgA alone yielded poorer overall sensitivity and specificity, although it performed better in samples from children than those from adults (82). IgM has been found to have little diagnostic value, with an unacceptably low sensitivity (82). The Maastricht IV Consensus Report recommended serological test kits with high accuracy (>90%) in validated settings (36).

Serology is not recommended for post eradication follow-up when tests detecting an active infection are preferable (81). Antibody titers decrease very slowly after eradication, so a single serum sample does not differentiate past and ongoing infections. Some 30% of patients have elevated IgG antibodies even after 5 years of successful eradication therapy (83). False positives, therefore, could result in some patients being inappropriately treated for presumed H. pylori infection, particularly in low-prevalence populations. Serology is useful in epidemiological studies of H. pylori infections, but such analyses likewise need to take into account that some asymptomatic individuals without an active infection may test positive.

Detection of H. pylori Antibodies in Urine and Saliva

Specific H. pylori IgG antibodies are present in urine at low concentrations. A review of 18 published studies over the period 1998 to 2004, using kits that included commercial ELISAs and rapid immunoenzymatic tests, listed sensitivities and specificities ranging from 82 to 100% and from 68 to 100%, respectively (81). While the accuracy is not affected by the pH or the presence of bacteria, it may be influenced by a large amount of total IgG. Detection of H. pylori antibody in urine is attractive because it is non invasive and it could be useful for epidemiological studies.Salivary antibodies are secreted during the immune response to H. pylori infections. Several commercial kits and in-house ELISAs have been developed to detect H. pylori-specific IgG in saliva, and a review of 15 published studies between 1994 and 2002 listed sensitivities and specificities ranging from 64 to 94% and from 58 to 95%, respectively (81).

Detection of Other Helicobacter Antibodies in Clinical Samples

Serology has no application in the routine diagnosis of human infections with gastric HHLO and enterohepatic helicobacters, as there are no validated IgG or IgA assays currently available. Sustained immunoglobulin responses to multiple antigens of H. cinaedi and H. fennelliae have been documented.

ANTIMICROBIAL SUSCEPTIBILITY

H. pylori Antibiotic Therapy and Relevance of Resistance

The first-choice standard triple therapy to eradicate H. pylori comprises a proton pump inhibitor, clarithromycin, and either amoxicillin or metronidazole (36). Therapy should ideally be based on pretreatment antibiotic susceptibility testing, although this is not always practical. The main cause of failure to eradicate H. pylori with the standard antimicrobial regimen is clarithromycin resistance (81). In 2004, clarithromycin resistance rates were 13% in the United States (84), while in Europe there are distinct regional variations with resistance rates of 8, 19, and 22% in Northern, Central, and Southern Europe respectively (53).

The clinical impact of resistance is marked, with an eradication rate for the standard therapy that decreased by 70% (from 88 to 18%) (81). The key risk factor for clarithromycin resistance is previous consumption of macrolides, and prevalence of resistance after failure of treatment is extremely high. Monitoring local clarithromycin prevalence rates is important, as the recommended threshold at which clarithromycin should not be used or susceptibility testing should be performed is 15 to 20% (53). Resistance to metronidazole, a key component of the triple-therapy regimen, is also widespread and is estimated to decrease treatment success rates by 26% (85). Resistance rates are 25% in the United States (84), with rates in Europe ranging from 29 to 44% (54). In some other countries, resistance rates may be as high as 60 to 90%. In vitro resistance to metronidazole may not accurately reflect in vivo resistance (85), and for that reason, routine susceptibility testing is not recommended in Maastricht IV guidelines (36). Nevertheless, laboratory testing is important for surveillance of resistance, as a threshold of resistance in the population of 40% provides a guide in deciding on the choice of treatment (36).

Resistance of H. pylori to other antibiotics used in therapy, such as amoxicillin and tetracycline (an antibiotic used in second-choice treatment), is rarely found (<1%) in the United States and Europe (48, 84), although higher rates to both antibiotics have been reported in some Asian populations (86). Two other classes of antibiotics have emerged as third choices (rescue therapy) in the treatment of H. pylori infection: a fluoroquinolone, levofloxacin, and a rifamycin, rifabutin. Increasing consumption of fluoroquinolones may lead to higher prevalence of resistance in H. pylori, as rates of resistance to levofloxacin are currently about 9% in the United States (87) and between 8 and 19% in Europe (48). Resistance to rifabutin is virtually absent in H. pylori (48, 88), although its use in eradication therapy has been limited. The efficacy of furazolidone has also been evaluated (89), but no data are available on resistance rates.

Phenotypic Susceptibility Testing of H. pylori Cultures

Gastric biopsy isolates of H. pylori should be tested against the antibiotics commonly used in eradication therapy, in particular, clarithromycin, as resistance in vitro is clinically relevant. Phenotypic methods of susceptibility testing, such as broth microdilution, disk diffusion, the Etest, and agar dilution, can be applied to H. pylori. The Clinical and Laboratory Standards Institute (CLSI) and a workgroup of the European Helicobacter Study Group have made a similar recommendation of an agar dilution method and breakpoint for testing susceptibility to clarithromycin (48). In this method, Mueller-Hinton agar base with 5% aged sheep blood is incubated for 72 h at 35°C, with an MIC breakpoint for resistance of 1 μg/ml. The Etest (bioMérieux Inc., Durham, NC) may also be used to determine MIC (90), and its results correlate well with agar dilution results. The disk diffusion method is cost-effective for routine testing, and an inhibitory zone of less than 17 mm around a clarithromycin disk indicates a resistant strain (91).

Metronidazole in vitro susceptibility testing is intrinsically less reliable in terms of inter- and intralaboratory reproducibility and is more difficult to standardize, as results appear to be highly dependent on atmospheric conditions (81). Elevated MICs (>8 μg/ml) have been correlated with...
treatment failures, and 8 \mu g/ml is the threshold commonly used to define metronidazole resistance (81). The Etest is also used to determine metronidazole MICs for resistant isolates, but comparisons with broth dilution results may not correlate fully (81). The agar diffusion method with disks can be used for testing susceptibility to other antibiotics less commonly used in eradication, such as tetracycline, ciprofloxacin, and rifabutin. For instance, isolates were recorded as resistant if the growth inhibition zone for tetracycline was <30 mm (10-\mu g disk) and if any inhibition zone was observed for ciprofloxacin (1-\mu g disk) and rifampin (5-\mu g disk) (90). The present tentative agar dilution MIC interpretive criteria for resistance to those antibiotics are >1 \mu g/ml for tetracycline, >0.5 \mu g/ml for levofloxacin, and >1 \mu g/ml for rifabutin (81, 90). For resistant isolates, the MICs can be determined using the Etest.

**Genotypic Susceptibility Testing of H. pylori Cultures and in Biopsy Specimens**

Resistance to clarithromycin in H. pylori is attributed to point mutations at sites (A2142G and A2143G) in the peptidyl transferase region of domain V of the 23S rRNA gene which inhibit macrolide binding (92). Several methods involving gene amplification, rapid sequencing by pyrosequencing, or fluorescent in situ hybridization have been developed for the rapid detection of mutations associated with clarithromycin resistance (81). PCR-restriction fragment length polymorphism analysis was initially used on isolates to detect relevant mutations, but real-time PCR now provides a simpler and more rapid approach. Adaptations allow detection with excellent sensitivity of both H. pylori and its resistance to clarithromycin directly from gastric biopsy specimens (28). Real-time PCR assays also are available to ascertain resistance to tetracycline by rapid detection of 16S rRNA gene point mutations (93) and to ciprofloxacin/levofloxacin by rapid detection of point mutations in the quinolone resistance-determining region of the gyrA gene (94). Likewise, a real-time PCR test has been developed to ascertain resistance to rifabutin by rapid detection of point mutations in the rpoB gene (95). In contrast, development of a DNA-based assay to detect H. pylori resistance to metronidazole has proven more problematic, as the mechanisms of in vitro resistance have yet to be fully elucidated. Multiple null mutations in the NADPH nitroreductase gene (rdxA) and in the NAD(P)H flavin oxoreductase gene (fdxA) may contribute to the induction of resistance, but neither provides consistent markers for in vitro resistance testing (96, 97).

**Genotypic Susceptibility Testing of H. pylori in Feces**

A biprobe 23S rRNA gene real-time PCR assay has been developed for direct clarithromycin susceptibility testing of H. pylori in stool specimens (58), and an evaluation of a modified version, the Helicobacter pylori ClariRes assay (Ingenuetix, Vienna, Austria), reported that it was at least as sensitive and more specific than the stool antigen test. However, another evaluation of the assay on stool specimens from symptomatic children reported a sensitivity of only 63% (59).

**Susceptibility Testing of Gastric HHLO**

Optimal treatment remains to be established for HHLO, although there is evidence that eradication by antimicrobial therapy, such as that used in conventional H. pylori eradication, results in the resolution of gastritis and peptic ulcer disease (49) as well as H. heilmannii-associated, primary, low-grade MALT lymphoma (38). Although susceptibilities in vitro were described for multiple isolates (from one patient) of an HHLO subsequently identified as H. bizzozeronii (66), usually there are no cultures of HHLO available for testing. Consequently, there is no information for HHLO on their frequency of resistance to clarithromycin and other antibiotics. To ascertain possible treatment options for HHLO, triple therapy was shown to significantly reduce burden in experimentally infected mouse stomachs (98). However, no PCR assays, such as those used to determine H. pylori clarithromycin and tetracycline resistance in gastric biopsy tissue, have been developed for direct testing of resistance in HHLO.

**Susceptibility Testing of Enterohepatic Helicobacters**

No recommended guidelines are available for treatment of a diagnosed infection with the enterohpatic helicobacters H. cinaedi, H. canis, H. felinellae, and H. pullorum. Various antibiotic agents alone or in combination have been successfully used in treating such infections, but there is insufficient information to determine resistance rates for individual species. For the more commonly reported H. cinaedi, effective therapy for infection may require prolonged courses for at least 2 to 3 weeks of multiple antibiotics, such as erythromycin, ciprofloxacin, gentamicin, levofloxacin, tetracycline, and beta-lactams (40).

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

The principal noninvasive tests for diagnosis of an H. pylori infection before treatment are the UBT, ELISA SAT, and high-accuracy ELISA-based IgG serology (20). According to the clinical setting, endoscopic investigation may be indicated, and then rapid urease testing, histology, and culture of gastric biopsy specimens can be used. To assess H. pylori status for posttreatment follow-up, the UBT and SAT are the recommended noninvasive tests, but not IgG serology, as serum antibody concentrations fall slowly after eradication. In addition to test performance, other factors, such as cost-effectiveness and patient attitudes, need to be considered in test selection (99, 100). To perform antimicrobial susceptibility testing, bacteriological culture of H. pylori from gastric biopsy specimens is recommended, especially in cases of repeated treatment failure. Successful culture may be reported if the organism is microaerobic, has a Gram-negative morphology, and is oxidase, catalase, and urease positive. If culture is not positive after 10 days of incubation, it can be reported as negative, but if clinical tests indicate an H. pylori infection, it may be informative to perform a species-specific PCR assay directly on the gastric biopsy specimen. Because of the potential unreliability of PCR assays, resulting in false positives, such tests should not be used as the sole basis for diagnosis. Testing for clarithromycin susceptibility should be performed using either the CLSI reference method or a substantially equivalent method. Direct PCR testing of cultures or biopsy specimens provides a rapid alternative to phenotypic testing to detect the presence of discrete mutations conferring macrolide resistance. Eradication therapies are also likely to include other agents, such as amoxicillin, metronidazole, and tetracycline, and in problem cases, possibly rifabutin, levofloxacin, and furazolidone, depending on local clinical practice. Interpretive criteria for these antimicrobials,
where available, may be “tentative” but should be used in the absence of recommended guidelines.

Gastric infection with non-\textit{H. pylori} Helicobacter species is less common and should be diagnosed from bacterial morphology in gastric biopsy specimens. In the microbiology laboratory, they may be detected by an HHLO-specific PCR assay. Because of the lack of rapid diagnostic methods for the enterohelipatic species, these must be cultured for a definitive identification. Enteric species such as \textit{H. canadensis} and \textit{H. pullorum} may occasionally be isolated by techniques employed for the isolation of \textit{Campylobacter} species, particularly if nonselective media and incubation at 37°C are employed. As \textit{Campylobacter} isolates are typically only cursorily identified routinely, enteric \textit{Helicobacter} species are likely to be missed. Although they may have a limited role in human gastroenteritis, their significance remains unclear. Other species such as \textit{H. cynaedi}, \textit{H. canis}, and \textit{H. fennellae}, may be rarely encountered from blood culture and other sites of infection. They are unlikely to grow well aerobically but may be apparent after prolonged incubation in an atmosphere containing additional \text{CO}_2 or on plates incubated “anaerobically” (conditions of strict anaerobiosis will not support growth). As these enterohelipatic helicobacters are typically urease negative and can be confused with campylobacters, accurate identification is often difficult, and a reference laboratory should be consulted unless MALDI-TOF is available locally. The clinical significance of isolates may be unclear and should be assessed on a case-by-case basis. Determination of antibiotic susceptibilities should be performed if needed to guide antibiotic therapy decisions.

TAXONOMY

Serologic Classification
The genus *Leptospira* is comprised of spiral-shaped bacteria with hooked ends (1). This genus, along with the genera *Leptonema* and *Turneriella*, makes up the family *Leptospiraceae*, within the order *Spirochaetales* and the class *Spirochaetes* of the phylum *Spirochaetes* (2). The genus was formerly divided into two species: *Leptospira interrogans*, comprising all pathogenic strains, and *L. biflexa*, containing the saprophytic strains isolated from the environment (1). *L. biflexa*, sensu lato, makes up the family *Leptospiroaceae*, within the order *Leptospirales*, and the class *Spirochaetes* (2). The genus was formerly divided into two species: *Leptospira interrogans*, comprising all pathogenic strains, and *L. biflexa*, containing the saprophytic strains isolated from the environment (1). *L. biflexa* and *L. interrogans* were differentiated by a number of biochemical tests (1).

Leptospires are divided into serovars defined by agglutination after cross-absorption with homologous antigens (1, 3, 4). Serovars are considered distinct if more than 10% of the homologous titer remains in at least one of the two antisera on repeated testing (5). Over 60 serovars of *L. biflexa sensu lato* and more than 200 serovars of *L. interrogans sensu lato* are recognized. Serovars that are antigenically related have traditionally been grouped into serogroups (4). Serogroups have no taxonomic standing, but the concept has proved useful for epidemiological understanding, particularly for interpreting serological results from the microscopic agglutination test (MAT). The serogroups of *L. interrogans sensu lato* and some common serovars are shown in Table 1.

Genotypic Classification
The phenotypic classification of leptospires was replaced by a genotypic one, in which 21 genomospecies include all serovars of *Leptospira* (6–15). Table 2 lists all species of *Leptospira*. DNA hybridization studies have also confirmed the taxonomic status of the monospecific genera *Leptonema* (9) and *Turneriella* (16). The genetically defined species of *Leptospira* do not correspond to the previous two species (*L. interrogans sensu lato* and *L. biflexa sensu lato*), and both pathogenic and nonpathogenic serovars occur within some species (17). Neither the serogroup nor the serovar reliably predicts the true species of *Leptospira*. Moreover, genetic heterogeneity resulting from horizontal transfer of genes coding for cell surface antigens occurs within serovars (9, 18), resulting in strains of some serovars being classified as multiple species (Table 3). In addition, the phenotypic characteristics formerly used to differentiate *L. interrogans sensu lato* from *L. biflexa sensu lato* do not differentiate the genetically defined species (6, 9). Both *L. interrogans* and *L. biflexa* are retained as specific names in the genomic classification, and in this chapter, specific names refer to the genetically defined species, including *L. interrogans sensu stricto* and *L. biflexa sensu stricto*.

Classification of leptospires requires the identification of both the species and serovar of each isolate. Identification of *Leptospira* species is readily accomplished by sequencing of rrs (19), rpoB (20), or gyrB (21). Phylogenetic analysis of rrs sequences demonstrates three clades of leptospires, representing pathogens, saprophytes, and a group of species of uncertain pathogenicity (Fig. 1). Two hundred strains were recently sequenced through the *Leptospira* Genomics and Human Health Project (http://gsc.jcvi.org/projects/gsc/leptospira/). The analysis of these sequences will further inform the taxonomy of the *Leptospiroaceae*. In future, it may be possible to identify serovars by sequence-based analysis.

DESCRIPTION OF THE FAMILY
Leptospires are tightly coiled spirochaetes that are usually 0.1 μm by 6 to 20 μm. The helical conformation is right-handed, with an amplitude of approximately 0.1 to 0.15 μm and a wavelength of approximately 0.5 μm (22). The cells have pointed ends, either or both of which are usually bent into a distinctive hook (Fig. 2). Two axial filaments (periplasmic flagella) with polar insertions are located in the periplasmic space. Leptospires exhibit two distinct forms of movement: translational (rapid back-and-forth movements) and rotational (spinning rapidly about the long axis of the cell) movements (23). Morphologically, all leptospires are indistinguishable.

Leptospires are obligate aerobes with an optimum growth temperature of 28 to 30°C. The optimum pH for growth is 7.2 to 7.6. They produce both catalase and oxidase. They grow in simple media enriched with vitamins (vitamins B$_2$ and B$_12$ are growth factors), long-chain fatty acids, and ammonium salts (1).

EPIDEMIOLOGY AND TRANSMISSION
Leptospires are ubiquitous, either free-living in water or associated with renal infection of animals (24). Leptospirosis is presumed to be the most widespread zoonosis in the world (25). The source of infection in humans is usually either direct or indirect contact with the urine of an infected animal. The incidence is very much higher in countries...
with a warm climate than in temperate regions, due mainly to longer survival of leptospires in the environment under warm, humid conditions. Leptospirosis is seasonal. Peak incidence occurs in summer or fall in temperate regions, where temperature is the limiting factor in survival of leptospires, and during rainy seasons in warm-climate regions, where rapid desiccation would otherwise prevent survival.

Animals, including humans, can be categorized as maintenance hosts or accidental (incidental) hosts. A maintenance host is defined as a species in which infection is endemic, usually transferred from animal to animal by direct contact. Infection is usually acquired at an early age, and the prevalence of chronic excretion in the urine increases with the age of the animal. Other animals (such as humans) may become infected by indirect contact with the maintenance host. Animals may be maintenance hosts of some serovars but incidental hosts of others, with infection in which may cause severe or fatal disease. The most important maintenance hosts are small mammals, which may transfer infection to domestic farm animals, dogs, and humans. Different rodent species may be reservoirs of distinct serovars, but rats are generally maintenance hosts for serovars of the serogroup Icterohaemorrhagiae, and mice for serogroup Bal-

*Based on data reported by Brenner et al. (9) and by Fereus et al. (18).
with infected animals accounts for most infections in farmers, veterinarians, abattoir workers, rodent control workers, and workers in other occupations which require contact with animals, while indirect contact is important for sewer workers, miners, soldiers, septic tank cleaners, fish farmers, rice field workers, and sugar cane cutters. Livestock farming is a major occupational risk factor throughout the world. The highest risk is associated with dairy farming and is associated with serovar Hardjo and, in particular, with milking of dairy cattle. There is a significant risk associated with recreational exposures occurring in water sports (28). The increasing popularity of adventure sports and ecotourism has led to an increase in leptospirosis in travelers (29, 30).

**CLINICAL SIGNIFICANCE**

The usual portal of entry is through abrasions or cuts in the skin or via the conjunctiva. The great majority of infections are either subclinical or of very mild severity, and patients will probably not seek or be brought to medical attention. The clinical presentation of leptospirosis is biphasic, with a septicemic phase lasting about a week, followed by the immune phase, characterized by antibody production and excretion of leptospires in the urine. Most of the complications of leptospirosis are associated with localization of leptospires within the tissues during the immune phase and thus occur during the second week of the illness.

The overwhelming majority of patients with recognized cases will present with a febrile illness of sudden onset, the symptoms of which include chills, headache, myalgia, abdominal pain, and conjunctival suffusion. Aseptic meningitis may be found in ≤25% of all leptospirosis cases. Between
5 and 10% of all patients with leptospirosis have the icteric form of the disease (Weil's disease), in which the clinical course is often very rapidly progressive. In addition to jaundice, patients with icteric leptospirosis may develop acute renal failure, pulmonary hemorrhage, and cardiac arrhythmias. Patients with severe cases often present late in the course of the disease, and this contributes to the high mortality rate, which ranges from 5 to 15%.

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

Leptospires can be isolated from blood, cerebrospinal fluid (CSF), and peritoneal dialysate fluids during the first 10 days of illness. Specimens should be collected before antibiotic therapy is initiated and while the patient is febrile. Under optimal conditions, one or two drops of venous blood are inoculated directly into culture medium at the bedside. Survival of leptospires in commercial blood culture media for several days has been reported (31). There are no transport media available, but blood can be collected and shipped at ambient temperature in tubes containing heparin, oxalate, or citrate (22). Citrate- or EDTA-containing tubes are optimal for PCR detection, whereas tubes containing heparin, sodium polyethanol sulfonate, or saponin are inhibitory to PCR reactions (32, 33).

Urine can be cultured after the first week of illness. Specimens should be collected aseptically into sterile containers without preservatives and must be processed within a short time of collection; best results are obtained when the delay is less than 1 hour. If culture is not possible, urine specimens intended for PCR testing may be stabilized at ambient temperature by use of one of several commercial products for this purpose, allowing for transport over long distances (33).

**DIRECT EXAMINATION**

**Microscopy**

Leptospires may be visualized in clinical material by dark-field microscopy (magnifications of ×100 and ×400) or by immunofluorescence or light microscopy after appropriate staining. Dark-field microscopic examination of body fluids, such as blood, urine, CSF, or dialysate fluid, is insensitive and lacks specificity (34). Approximately 10⁴ leptospires/ml are necessary for one cell per field to be visible by dark-field microscopy (35). Direct dark-field microscopy of blood is also subject to misinterpretation of fibrin or protein threads, which may demonstrate Brownian motion (22, 35). Leptospires in tissues were first visualized by silver staining (36), and the Warthin-Starry stain is widely used for histologic examination. More recently, immunohistochemical methods have been applied (37, 38). Immunohistochemical staining can be performed at the Centers for Disease Control and Prevention, Atlanta, GA (contact the Infectious Diseases Pathology Branch prior to shipping specimens; e-mail pathology@cdc.gov).

**Antigen Detection**

Antigen detection is generally regarded as insensitive. There are no commercial antigen detection assays.

**Nucleic Acid Detection**

Several primer pairs for detection of leptospiral nucleic acids by conventional PCR have been described (17), and real-time PCR assays have been developed, targeting either rrs or pathogen-specific sequences (33, 39–43). Leptospiral DNA has been amplified from serum, urine, aqueous humor, CSF, and tissues obtained at autopsy (44, 45).

Clinical evaluations have shown that PCR detection of leptosomal DNA is comparable to or more sensitive than diagnosis by culture (41, 44, 46, 47), while detection of cases by serologic diagnosis by testing acute- and convalescent-phase sera with the MAT remains more sensitive (46, 47). The principal advantage of PCR is the ability to confirm the diagnosis during the acute illness, while treatment is likely to be most effective (47, 48).

Real-time PCR assays have been applied to quantify the burden of infecting organisms in human cases and animal models (47, 49–51). A limitation of PCR-based diagnosis of leptospirosis is the inability of most PCR assays to identify the infecting serovar. While this is not significant for individual patient management, the identity of the serovar has both epidemiological and public health value.

**ISOLATION PROCEDURES**

Leptospiremia occurs during the first stage of the disease, beginning before the onset of symptoms, and has usually finished by the end of the first week of the acute illness (52). Therefore, blood cultures should be taken as soon as possible after the patient's presentation. One or two drops of blood (approximately 50 μl) are inoculated into 10 ml semisolid oleic acid-albumin medium (53, 54), such as Ehrlich-McCullough-Johnson-Harris medium or Fletcher's medium (Difco EMJH or Difco Fletcher's medium; BD Diagnostic Systems, Sparks, MD), containing 0.1% agar and 200 μg/ml 5-fluorouracil, at the patient's bedside. Blood is allowed to drop onto the surface of the medium; mixing is not necessary. Care should be taken to avoid overinoculation of the medium, as blood contains inhibitors of leptospiral growth. For the highest recovery rate, multiple cultures should be performed, but this is rarely possible. Survival of leptospires in commercial blood culture media for up to a week has been reported (31, 53). Thus, if leptospirosis is not initially suspected, blood cultures may be used as a source for PCR testing if other samples are no longer available.

Other samples that can be cultured during the first week of illness include CSF and peritoneal dialysate. Urine cultures can yield growth from the beginning of the second week of symptomatic illness. Survival of leptospires in voided human urine is limited, so urine should be processed immediately, by neutralization of pH with sodium bicarbonate followed by centrifugation. After centrifugation in 15-ml tubes for 30 min at 1,500 × g, the sediment is resuspended in 1 ml of phosphate-buffered saline, and one or two drops are inoculated into semisolid EMJH medium containing 5-fluorouracil as described above.

Cultures in EMJH medium are incubated in sealed bottles at 28 to 30°C and examined weekly by dark-field microscopy for up to 13 weeks before being discarded. Growth often develops in a discrete band several millimeters below the surface of the medium, known as Dinger's ring. Cultures that show growth of other bacteria may be passed through a 0.2-μm or 0.45-μm filter before subculture into fresh medium.

**IDENTIFICATION**

Isolated leptospires are identified either by serological methods or, more recently, by molecular techniques. Traditional methods relied on cross-agglutinin absorption (3). The number of laboratories that can perform these identification
methods is very small. The use of panels of monoclonal antibodies allows laboratories which can perform the MAT to identify isolates of frequently encountered serovars with relative rapidity (56). Monoclonal antibodies are available from the WHO/OIE Leptospirosis Reference Laboratory at the Royal Tropical Institute, Amsterdam, the Netherlands.

The current taxonomy of Leptospira necessitates the identification of isolates to both the species and serovar levels. Species identification is most practically determined by sequence analysis (57), using the rrs (16S rRNA) (19), gyrB (21), rpoB (20), or secY (58) gene. Identification of leptospires by matrix-assisted laser desorption ionization–time of flight mass spectrometry has been reported (59).

**TYPING SYSTEMS**

Because of the difficulties associated with serological identification of leptospiral isolates, there has been great interest in molecular methods for identification and subtyping (48, 57). Methods employed have included digestion of chromosomal DNA by restriction endonucleases, restriction fragment length polymorphism analysis, ribotyping, and a number of PCR-based approaches (57). The most widely applicable of these for identification of serovars is pulsed-field gel electrophoresis, largely because this technique is widely used for infection control studies and for public health typing of enteric pathogens (60, 61). This approach has been standardized by the PulseNet model, in which standardized profiles can be exchanged electronically (61–63).

The availability of full-genome sequences of several *Leptospira* strains has led to the development of sequence-based methods, such as amplified fragment length polymorphism and variable-number tandem-repeat analyses. Several studies have applied multilocus sequence typing (MLST) to understand the epidemiology of leptospirosis (64–66). The application of these powerful tools will lead to a greater understanding of leptospiral epidemiology at the population level (24, 57).

**SEROLOGIC TESTS**

Most cases of leptospirosis are diagnosed by serology. Antibodies are detectable in the blood approximately 5 to 7 days after the onset of symptoms. The definitive serologic investigation of leptospirosis remains the MAT, in which patient sera are incubated with live or killed antigen suspensions of leptospires of different serovars. After incubation, the serum-antigen mixtures are examined microscopically for agglutination, and the titers are determined. The MAT is a complex test to control, perform, and interpret (67), and its use is limited to regional or national reference laboratories. Protocols for performing the MAT have been described in detail (22, 68). An international proficiency testing scheme under the auspices of the International Leptospirosis Society has stimulated improvement in the performance of the MAT by participating laboratories (69).

The range of antigens used should include those of serovars representative of all serogroups (22, 67). The wide range of antigens is used in order to detect infections with uncommon or previously undetected serovars. The test is read by dark-field microscopy. The endpoint is the highest dilution of serum in which 50% agglutination occurs and is determined by the presence of approximately 50% free, unagglutinated leptospires by comparison with the control suspension (22). Considerable effort is required to reduce the subjectivity of observer variation, even within laboratories.

Interpretation of the MAT is complicated by the high degree of cross-reaction that occurs between different serogroups, especially in acute-phase samples. Paradoxical reactions, in which the highest titers are detected for a serogroup unrelated to the infecting one, are also common (17). The broad cross-reactivity in the acute phase, followed by relative serogroup specificity in convalescent-phase samples, results from the detection in the MAT of both IgM and IgG antibodies and the presence of several common antigens among leptospires (70).

Paired sera are required to confirm a serologic diagnosis with certainty. A 4-fold or greater rise in titer between paired sera confirms the diagnosis, regardless of the interval between samples. The interval between the first and second samples depends very much on the delay between onset of symptoms and presentation of the patient. If symptoms typical of leptospirosis are present, an interval of 3 to 5 days may be adequate to detect rising titers. However, if the patient presents earlier in the course of the disease, or if the date of onset is not known precisely, then an interval of 10 to 14 days between samples is more appropriate. Less often, seroconversion does not occur with such rapidity, and a longer interval between samples (or repeated sampling) is necessary. MAT serology is insensitive, particularly with early-acute-phase specimens (71, 72). Moreover, patients with fulminant leptospirosis may die before seroconversion occurs (72, 73).

A presumptive diagnosis can be made by detection of a single elevated titer in association with an acute febrile illness. The magnitude of such a titer is dependent upon the background level of exposure in the population, and hence the seroprevalence.

Titers following acute infection may be extremely high (≥25,600) and may take months or even years to fall to low levels (74, 75). Thus, in a high-incidence population, a low cutoff titer for presumptive diagnosis is inappropriate and will generate many false-positive diagnoses. In areas where the disease is endemic, a single titer of ≥800 in symptomatic patients is generally indicative of leptospirosis, but titers as high as ≥1,600 have been recommended (68). Rarely, seroconversion may be delayed for many weeks after recovery, and longer serological follow-up will be necessary to confirm the diagnosis.

Formalized antigens have been used in the MAT in order to overcome some of the difficulties associated with the use of live antigens. Titers obtained with these antigens are somewhat lower, and more cross-reactions are detected (22). These antigens are not available commercially but may be obtained from WHO Collaborating Centers.

The MAT is the most appropriate test to employ in epidemiological serosurveys, since it can be applied to sera from any animal species, and because the range of antigens utilized can be expanded or decreased as required. It is usual to use a titer of ≥100 as evidence of past exposure (67). Contrary to a widely held belief, the MAT is a serogroup-specific assay. However, conclusions about infecting serovars cannot be drawn without isolates; at best, the MAT data can give a general impression of which serogroups are present within a population (76, 77).

Because of the complexity of the MAT, rapid screening tests for leptospiral antibodies in acute infection have been developed. Traditional methods based upon agglutination have largely been superseded by IgM detection assays. IgM antibodies become detectable during the first week of illness, allowing the diagnosis to be confirmed and treatment to be
initiated while it is likely to be most effective. IgM detection has repeatedly been shown to be more sensitive than MAT when the first specimen is taken early in the acute phase of the illness (72, 78). IgM-based dipstick assays have been shown to be as sensitive as microtiter plate IgM-based enzyme-linked immunosorbent assays (79–81). Other rapid assays include a latex agglutination assay (82) and a lateral flow assay (83).

ANTIBIOTIC SUSCEPTIBILITIES

Leptospires are susceptible to many antimicrobial agents, including β-lactams, macrolides, tetracyclines, fluoroquinolones, and streptomycin. Problems in the determination of susceptibility include the long incubation time required (84), the use of media containing serum (85, 86), and the difficulty in quantifying growth accurately. These constraints limited the development of rapid, standardized methods for susceptibility testing. However, broth microdilution methods were described recently (87), which facilitated the testing of larger numbers of isolates against a wide range of antimicrobial agents (88). Such studies will lead to the identification of potential new agents for inclusion in clinical trials.

Penicillin and doxycycline are both effective for treatment of leptospirosis and remain the drugs of choice (89); clinical studies have shown that third-generation cephalosporins may be equally effective (90, 91). Prophylaxis with once-weekly oral doxycycline can give short-term protection in high-risk environments and is effective at preventing disease but not seroconversion (89).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

A diagnosis of leptospirosis can be made by isolation of the organism or by amplification of leptospiral DNA from blood, urine, or other specimens, by demonstration of leptospires in tissues by immunohistochemical staining, or by detection of a 4-fold or greater rise in titers between acute- and convalescent-phase serum samples tested by the same methodology at the same time. In populations and/or regions where leptospirosis is not endemic, MAT titers of ≥200 in a single specimen obtained after the onset of symptoms are suggestive but not diagnostic of acute or recent leptospirosis. A titer of ≥800 in the presence of compatible symptoms is strong evidence of recent or current leptospirosis. Delayed seroconversions are common. Assays that detect IgM antibodies give presumptive evidence of recent exposure to leptospirosis but require confirmation by another method, such as the MAT, since IgM titers are persistent (75). Negative test results in the presence of compatible symptoms do not rule out the diagnosis of leptospirosis, and further samples should be examined. The isolation of leptospires, the demonstration of leptospiral DNA by molecular methods, or the detection of leptospires in tissues by immunohistochemistry confirms the diagnosis and differentiates between current infection and past exposure, which may not be differentiated clearly by serology.

Despite recent advances in molecular detection and characterization of leptospires and in the development of rapid serologic tests, there are still relatively few laboratories throughout the world with the appropriate capabilities for Leptospira diagnostics. In the United States, leptospirosis was reinstated as a nationally notifiable disease in January 2013. Instructions for specimen submission and case reporting are available at the CDC website (http://www.cdc.gov/leptospirosis). Additional information regarding leptospirosis is available at the Leptospira Library website (http://www.kit.nl/biomedical-research/leptospirosis-reference-centre/leptospira-library/), and a current list of international diagnostic centers of expertise (92) is available on the International Leptospirosis Society website (http://www.med.monash.edu.au/microbiology/staff/adler/ils.html).

The bacterial genus *Borrelia* is divided into the relapsing fever (RF) and Lyme borreliosis groups based on genetic relatedness among dozens of member spirochete species (Table 1). All species are vectored by blood-feeding arthropods, are environmentally restricted to animal systems, and (with few exceptions) cause zoonotic infections, with humans being rare and dead-end hosts. Human infection is most commonly self-limited, may be asymptomatic, or may cause disease ranging from acute and relapsing fevers to staged illness that may involve the skin and the musculoskeletal, neurological, and cardiovascular systems.

RF *borrelia* species are vectored by lice (lobe-borne RF [LBRF]) or ticks (tick-borne RF [TBRF]). LBRF has been known to humans for thousands of years and has been the cause of massive epidemics as recently as the early 1900s (1). LBRF is one of the few examples of human-specific *borrelia* disease; it is caused by *Borrelia recurrentis* and is vectored by the human body louse, *Pediculus humanus humanus*. Although improved personal hygiene and use of antibiotics and dichlorodiphenyltrichloroethane (DDT) in the 20th century resulted in global case and morbidity declines, LBRF continues to severely impact impoverished and displaced populations in parts of East Africa (2). In contrast to LBRF, TBRF was first described in the medical literature in the late 1800s, and human disease, which presents in small clusters or as isolated cases, is now known to occur in focal areas throughout most of the world (3–5). In parts of Northwest Africa, however, it is one of the most common bacterial infections, and in Tanzania, it is a leading cause of prenatal and child mortality (2, 6). Over a dozen *Borrelia* species (Table 1) are the agents of TBRF, and with the possible exception of *Borrelia duttonii*, cause zoonotic disease. Most TBRF species are vectored by soft-bodied ticks of the *Ornithodoros* (Table 1; Fig. 1).

*Lyme borrelia* is known as *erythema chronicum migrans*, which encom- passes the families *Spirochaetaceae* and *Leptospiraceae*. Within the *Spirochaetaceae*, two genera, *Borrelia* and *Trepone- ma*, cause human disease. *Borreliae* are agents of LBRF and both tick-borne Lyme borreliosis and relapsing fever. The type species of the genus *Borrelia* is *Borrelia anserina*, which causes borreliosis in birds. Based on rrs (16S rRNA gene) sequence analyses, spirochetes form a distinct entity (division D) within the eubacterial kingdom. They are neither Gram positive nor Gram negative. In the case of the spirochetes, morphological criteria and DNA data produce concordant phylogenies, a rare trait in other bacterial groups.

*Modified from reference 132 with permission.*
pathogenic spirochetes, the treponemes and the leptospires (13). They are highly motile organisms, with corkscrew and oscillating motility enabling movement through highly viscous mediums, such as connective tissue. In contrast to the exoflagella of other bacteria, the flagella of spirochetes are endoflagella. The endoflagella (7 to 20 per terminus) are localized beneath the outer membrane and insert subterminally at one end or the other of the protoplasmic cylinder. The protoplasmic cylinder consists of a peptidoglycan layer and an inner membrane which encloses the internal components of the cell (13). If cultivable, borreliae grow slowly under microaerophilic (14) or anaerobic (15) conditions. They require N-acetylglucosamine and long-chain saturated and unsaturated fatty acids and produce lactic acid through glucose fermentation (16).

Species Diversity
The causative agent of Lyme borreliosis, *Borrelia burgdorferi*, was first described by Burgdorfer et al. in the early 1980s (10). Studies published since 1992 have divided *B. burgdorferi* sensu lato into 3 prevalent, human-pathogenic species—*B. burgdorferi* sensu stricto, *Borrelia afzelii*, and *Borrelia garinii* (17)—and 12 other species, some of which have been linked to human cases (Table 1) (18). With few exceptions, *B. burgdorferi* sensu stricto is the only well-documented human-pathogenic Lyme borreliosis species found in North America; in contrast, all three species have been isolated from humans in Europe. From central to eastern Asia, *B. garinii* and *B. afzelii* are the agents of almost all human cases of Lyme borreliosis.

There is a high prevalence of *B. afzelii* among human skin isolates from Europe, whereas isolates from cerebrospinal fluid (CSF) in Europe are most often *B. garinii* (Table 2) (19, 20). All three genospecies cause Lyme arthritis in Europe (Table 2) (21–23).

A few studies have reported the detection of other *Borrelia* species (*B. valaisiana*, *B. spielmanii*, "*B. bissetii*", *B. bunyavensis*, and *B. lusitaniae*) in patient samples in Europe (24–28). Similarly, *B. lonestari* and *B. miyamotoi*, two species carried by hard ticks but genetically more closely related to the relapsing fever spirochetes vectored by soft ticks, have been reported in a small number of cases in Russia, the Netherlands, and the United States (29–31).

In North America, the TBRF-causing *Borrelia* species *B. turicatae*, *B. parkeri*, and *B. hermsii* have been isolated from *Ornithodoros turicatae*, *Ornithodoros parkeri*, and *Ornithodoros hermsii* ticks, respectively, although they may be a single species because their DNA-DNA similarity is greater than 70%. The species status of other cultivable borreliae, such

as B. anserina, B. crocidurae, B. recurrentis, and B. coniaceae, has been supported by greater DNA-DNA dissimilarity findings (32).

Genomes

The genomes of the borreliae are unusual among prokaryotes in that they have a small linear chromosome of approximately 1,000 kb and both linear and circular plasmids. Also unlike most bacteria, borreliae have a low G+C content (approximately 30 mol%). The complete nucleotide sequence of the chromosome and 21 plasmids (9 circular and 12 linear) has been published for the type strain, B. burgdorferi B31 (33). A total of 59% of the chromosomal open reading frames (ORFs) have homologs in other bacterial species; in contrast, homologs have been identified for only one-third of the plasmid ORFs. The genome encodes a basic set of proteins for DNA replication, transcription, and energy metabolism but, interestingly, lacks most cellular biosynthetic pathways. Of some surprise is the tremendous number (>150) of genes that encode putative lipoproteins, suggesting an essential role for these molecules in the life cycle of the spirochete. Genomic analysis of another Lyme disease spirochete, B. garnini (strain PB1), revealed that most of the chromosome is conserved (>90% identity at the DNA and amino acid levels) in the two species. Furthermore, two colinear plasmids (lp54 and cp26) seem to belong to the basic genome inventory of the Borrelia species that cause Lyme disease. However, the authors did not find counterparts of the B. burgdorferi plasmids lp54 and lp38 or their respective gene repertoires in the B. garnini genome (34).

The large linear plasmid lp54 encodes two major outer surface proteins, OspA and OspB, which are tandemly arranged by one operon (35). OspC, another major outer surface protein, is encoded on a circular plasmid (cp26), and sequence analysis of ospC from different strains suggests that gene exchange might play a role in diversity and immune evasion of Lyme disease borreliae (36).

Whole-genome microarray analysis revealed that a total of 215 ORFs, 136 of which are plasmid borne, were differentially expressed at 23 and 35°C. These findings highlight the potential importance of plasmid-borne genes in the adaptation of B. burgdorferi sensu lato to mammal hosts and tick vectors (37). The linear plasmids of B. hermsii and B. turicatae contain genes encoding outer membrane lipoproteins, called variable major proteins (Vmps). These genes are silent except when they are translocated to an expression site immediately adjacent to one of the linear plasmid telomeres. Antigenic variation of Vmp-like proteins due to recombination of tcs (Vmp-like small) gene sequence cassettes has also been described for B. burgdorferi. These tcs genes have highly varied regions, as well as highly conserved sequences which encode immunogenic epitopes important for serodiagnosis (38, 39).

Epidemiology and Transmission

The ecological components that maintain Borrelia species in nature are quite diverse and are spread throughout the world (Table 1).

Relapsing Fever Borreliae

Rodents serve as reservoirs of most relapsing fever borreliae, which are transmitted by soft-bodied ticks of the genus Ornithodoros (Table 1; Fig. 1). One exception, B. recurrentis, the agent of LBRF, is found only in humans and transmitted only by the human-specific body louse, Pediculus humanus humanus. Although LBRF had a global distribution only 100 years ago, recent reported outbreaks have been limited to parts of East Africa. LBRF is not communicable between its human hosts, but rapid transfer of the infected louse between persons by direct contact and shared clothing and bedding enables efficient disease dissemination among crowded populations, particularly when personal hygiene is compromised.

Over a dozen Borrelia species (Table 1) are the agents of TBRF. Endemic cycles of TBRF between rodents and Ornithodoros ticks are recognized globally (Table 1). Human infections occur in western Canada and the United States (reportable in 11 western states), portions of Mexico, Central and South America, the Mediterranean, Central Asia, and much of Africa. Ornithodoros ticks are rapid (10 to 30 min) and typically nocturnal feeders; human victims most often do not recall tick bites. In parts of northwest Africa, TBRF is one of the most common bacterial infections, and in Tanzania, it is a leading cause of prenatal and child mortality (2, 6).

Lyme Disease Borreliae

The Lyme disease borreliae of B. burgdorferi sensu lato are transmitted by hard-bodied ticks (genus Ixodes) (Fig. 1). Globally, Lyme borreliosis is limited to temperate regions of the Northern Hemisphere (Table 1). The prevalence of vector-competent ticks and their infection-permissive vertebrate hosts largely defines human risk and case numbers. For example, in the United States during the 15-year period from 1992 to 2006, 93% of the total cases (n = 248,074) reported to the CDC by health departments were from 10 of the 50 states (Connecticut, Delaware, Massachusetts, Maryland, Minnesota, New Jersey, New York, Pennsylvania, Rhode Island, and Wisconsin), and these case incidences were mirrored by B. burgdorferi sensu stricto infection rates among I. scapularis ticks and reservoir vertebrates (40–42).

Ixodes species feed on three different hosts, depending on the developmental stage of the tick. The larvae and nymphs feed primarily on small rodents, whereas adult ticks feed on a variety of mammals (deer, raccoons, domestic and wild carnivores, larger domestic animals, and birds). The feeding period of Ixodes ticks is rather long (several days to over a week) and contributes to their geographic dispersal along the course of the movement of the host. Birds, particularly migratory seabirds, can transport the ticks (Ixodes uriae) over very long distances and thus distribute borreliae (especially B. garnini) worldwide (22).

There appears to be an association between B. afzelii and small rodents and B. garinii and birds, likely due to different serum sensitivities of the borreliae (43) mediated by complement regulator-acquiring surface proteins (44). In unfed ticks, B. burgdorferi sensu lato lives in the midgut. During the blood meal, transcriptional changes are induced in the spirochetes and precede their migration to the salivary glands (45). Migration of spirochetes from the midgut of the feeding I. scapularis tick to the skin of the animal host takes >36 h (46). For Ixodes ricinus, however, spirochete migration has been observed with ticks feeding for as few as 17 h (47).

Clinical Significance

Relapsing Fever

Relapsing fever is an infectious disease with an acute onset of clinical signs and symptoms, including high fever, shaking chills, severe headache, nausea, myalgias, and severe malaise. Initial physical findings often are conjunctival effusion,
petechiae, and diffuse abdominal tenderness. Fever attacks of 3 to 7 days are interspersed with afebrile periods of days to weeks. Detailed descriptions and reviews have been published elsewhere for louse-borne (48) and tick-borne relapsing fever (49, 50).

TBRF is, in general, less severe than LBFR. An exception to this rule is *Borrelia duttonii* TBRF in East Africa. TBRF studies in Tanzania and the Democratic Republic of the Congo have documented severe morbidity among pregnant women, the young, and the elderly; pregnancy loss rates of 47% have been reported in some areas of endemicity (2). In TBRF, up to 13 febrile attacks have been documented, and a rash is more often reported than in LBFR (28% versus 8% of cases). Splenomegaly, hepatomegaly, and jaundice are observed in 41%, 17%, and 7% of TBRF cases, respectively, whereas these signs are reported in 77%, 66%, and 36% of LBFR cases. In TBRF, 16% of the patients have respiratory symptoms and 9% have central nervous system involvement; in patients with LBFR, these figures are 34% and 30%, respectively (51). Complications leading to death (the mortality rate for LBFR patients is up to 40%) are acute heart and hepatic failure and cerebral hemorrhage. Disease severity increases with compromising conditions common to many areas of endemicity.

The initial treatment of relapsing fever cases with appropriate antibiotics may elicit the Jarisch-Herxheimer reaction (JHR) (50). This reaction, associated with the rapid clearance of spirochetes from circulation and an overwhelming release of cytokines, typically occurs within 1 to 4 h of antibiotic treatment. Signs include hypotension, tachycardia, chills, rigors, diaphoresis, and sudden elevation of body temperature. Death caused by JHR associated with LBFR has been reported. While generally not as severe, JHR associated with TBRF in the United States is reported in approximately 50% of cases. Therefore, patients with either LBFR or TBRF should be monitored closely upon initial treatment.

Acute respiratory distress syndrome (ARDS) may occur more frequently in patients with TBRF than previously recognized. In 2004 and 2005, three cases of posttreatment ARDS in severe-TBRF patients were reported from California, Washington, and Nevada. A retrospective investigation of 111 TBRF cases reported from these states during the preceding 10 years revealed two additional ARDS cases, both occurring after 2001. Continued surveillance is needed to determine whether the risk of ARDS in cases of TBRF is increasing. If so, possible correlates might include changed medical practices, use of newer antimicrobials, or the emergence of more-virulent TBRF strains (52).

**Lyme Borreliosis**

Lyme borreliosis can be defined by early localized, early disseminated, and late-stage manifestations similar to the three stages of syphilis (53). The natural courses of untreated *B. burgdorferi* infections vary considerably, and clinical manifestations can occur alone or in various combinations (53, 54). In the majority of cases, the infection is self-limiting, but in some cases, *B. burgdorferi* will disseminate to other skin sites, the nervous system, joints, heart, or (occasionally) other organs.

EM at the site of the infectious tick bite is the most common manifestation of early (stage I) Lyme borreliosis and occurs in 60 to 90% of patients. The center of the expanding annular lesion often fades to produce a bull’s-eye appearance. However, the extents, color intensities, and durations of EM vary considerably. In Europe, the skin lesion often develops more slowly and persists longer, hence, the initial description of *chronicum migrans* (3). One or more general symptoms, such as fatigue, arthralgia, myalgia, and headache accompany a majority of primary EM cases (55, 56).

In some patients, hematogenous dissemination of spirochetes to other organs and tissues occurs within days to weeks of infection (stage II). Patients often feel quite ill and can present with fatigue, headache, fever, malaise, arthralgia, and myalgia. Multiple (secondary) erythema are common in the United States but uncommon in Europe. Neurologic structures, including the meninges, brain, spinal cord, peripheral nerves, and nerve roots, are also potential sites of early-dissemination infection. In the United States, 15 to 20% of untreated patients develop neurologic signs, most commonly facial nerve palsy (unilateral or bilateral), meningitis, and radiculoneuropathy. CSF findings in cases of Lyme meningitis almost always include a mononuclear pleocytosis (10 to 1,000 cells/μl) and elevated protein concentration. Meningitis, or even facial palsy without meningismus, is more common among children than adults. Severe encephalitis is occasionally observed in stage II. Bannwarth’s syndrome is the most common neurologic manifestation of early, disseminated Lyme borreliosis in Europe. The syndrome is characterized initially by intense, migratory focal radicular pain, particularly at night, and by cranial nerve palsy. Paresis of the extremitities and the trunk are less frequent. Borrelial lymphocytoma, a reddish to livid swelling of the skin that typically occurs in locations such as the earlobe, nipple, or scrotum, is manifested among some patients in Europe (53, 54). Symptomatic infection of the heart is rare in recognized Lyme disease cases and most often presents as anterograde conduction blocks, which can fluctuate between first-, second-, and third-degree blocks; these typically occur in conjunction with other manifestations of disease, such as EM, arthritis, or neurological disease. Symptoms, including light headedness, palpitations, shortness of breath, chest pain, and syncope, may occur within days to months of disease onset. Cardiac involvement typically resolves promptly with appropriate antibiotic treatment but can occasionally cause life-threatening cardiac conduction abnormalities. Three cases of sudden cardiac death between 2012 and 2013 in the United States were attributed to previously undiagnosed Lyme carditis (57).

Lyme arthritis and acrodermatitis chronica atrophicans (ACA), occurring months to years after the initial infection, are the most common manifestations of late (stage III) disease. Lyme arthritis can be monoarticular or oligoarticular, typically affecting the knee, and usually takes an intermittent course. Patients with ACA initially develop an infiltrative stage, followed by alterations characteristic of the atrophic stage: creased skin with livid discolorations and plastic protrusion of vessels. ACA is observed almost exclusively in Europe, a finding highly correlated with *B. afzelii* infections. Neuroborreliosis is a very rare manifestation of late (stage III) disease. Paraparesis and tetraparesis are the most common symptoms. Examination of the CSF reveals a marked elevation of protein concentration, with a low to moderate increase of cells in the CSF. The detection of intrathecally produced specific antibodies is currently regarded as the best marker of neuroborreliosis (53, 54, 58).

Early manifestations of Lyme borreliosis are observed most frequently in the spring, summer, and autumn, coinciding with tick activity. Late manifestations do not show a seasonal pattern.

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

**General Remarks for Collection and Transport**

For culture and nucleic acid detection of *borrelia*, collection and preparation of specimens under sterile conditions are...

...of utmost importance. Body fluids should be transported without any additives, and biopsy specimens should be placed in a small quantity of sterile saline or suitable culture medium (see “Isolation Procedures,” below). Samples should reach the laboratory as quickly as possible (within 2 to 4 h). Before specimens are collected and transported, the laboratory should be contacted so that details of methodology can be agreed upon. If postal transport is unavoidable, overnight delivery is recommended. Specimens for laboratory confirmation of Lyme borreliosis are presented in Table 3.

**Blood and Serum**

For relapsing fever, blood is the specimen of choice. During febrile attacks, borreliae may be easily detected by dark-field or bright-field microscopy of a wet-mount blood sample or a stained blood smear, respectively (see “Direct Examination” and “Microscopy,” below) (Fig. 3). During early febrile periods, the spirochetemia may reach $10^6$ to $10^8$ cells per ml (16). Blood from acutely ill patients is also the best source for culture confirmation (32). However, the spirochetemia diminishes with each successive relapse, and visualization or culture isolation of borreliae is most often unsuccessful during afebrile periods. In contrast to what occurs in relapsing fever patients, spirochetemia in Lyme borreliosis patients is below the level of microscopic detection, with estimates of 0.1 spirochete/ml of whole blood. The rate of culture recovery from EM patients’ blood has generally been 5% or less (59). However, in a series of experiments, it was demonstrated that *B. burgdorferi* culture recovery from untreated adult patients with EM was better from plasma than from serum or from an identical volume of whole blood. Approximately 50% of large-volume plasma cultures from EM patients have yielded *B. burgdorferi* (60). Serum is suitable for indirect (antibody) evidence of *Borrelia* exposure. Specific antibody detection tests are the most widely utilized tests for laboratory confirmation of Lyme borreliosis (see “Sero logical Tests,” below). Serodiagnosis of relapsing fever is performed in only a few specialized laboratories.

**Cerebrospinal Fluid**

Patients with suspected Lyme neuroborreliosis (LNB) may have evidence of immunoglobulin synthesis against *B. burgdorferi* antigens in their CSF, elevated numbers of CSF inflammatory cells (usually lymphocytes, monocytes, or plasma cells), and elevated protein. CSF along with serum drawn at the same time should be obtained for laboratory demonstration of *Borrelia*-specific, intrathecal (CSF/serum antibody index [AI]) antibody production (see “Sero logical Tests,” below). For culture or PCR detection, rates are only...

*Sensitivity can be up to 50% in patients with a disease duration of less than 2 weeks, compared with only 13% in patients for whom the illness duration was greater than 2 weeks.

The sensitivity of direct pathogen detection is higher from synovial biopsy specimens.

about 20% (61). Positive PCR results in CSF also seem to correlate inversely with duration of neurologic disease. Among neuroborreliosis patients, 7 of 14 (50%) with a disease duration of less than 2 weeks had a positive PCR result, compared with only 2 of 16 (13%) patients in whom the illness duration was greater than 2 weeks (P = 0.045) (61).

**Synovial Fluid or Synovial Biopsy Specimens**

Investigation of synovial fluid or a synovial biopsy specimen by PCR can be useful in special circumstances where Lyme arthritis is suspected or the efficacy of antibiotic treatment is questioned (see "Nucleic Acid Detection Techniques," below) (59, 62). Culture is usually negative, with few exceptions. Due to the high protein permeability of the synovium, synovial fluid and serum display roughly equivalent antibody titers. Thus, it is sufficient to monitor antibody in serum.

**Skin Biopsy Specimens**

Skin biopsy samples are the best sources for isolation of *B. burgdorferi*; spirochetes can be isolated in most untreated cases of EM and acrodermatitis (Table 4). In cases of EM, culture success is highest (up to 56%) with biopsy samples taken close to (4 mm inside) the expanding border of the lesion (63), although this is a technique primarily for research, not for routine diagnosis. There are indications that the number of spirochetes in the skin is rather low or unevenly distributed, since an increase in sensitivity is observed if more than one biopsy sample is investigated (64). Without treatment, *B. burgdorferi sensu lato* can persist for long periods in the skin, as shown by isolation from a 10-year-old acrodermatitis lesion (65). Biopsy samples (taken after thorough disinfection of the skin) should be sent in a small amount of sterile saline or Barbour-Stoenner-Kelly (BSK) medium (with or without rifampicin) as soon as possible to a microbiology laboratory capable of culturing *B. burgdorferi*.

**Other Materials**

Ticks are often tested for borreliae as part of epidemiological studies to assess risk to human populations in a given geographic area. Although specialized laboratories offer diagnostic services for individual ticks, detection of spirochetes within ticks by PCR or other methods has not been shown to provide clinically useful information.

**DIRECT EXAMINATION**

**Microscopy**

Direct microscopic visualization of borreliae in clinical samples is applicable only to cases of relapsing fever. During acute phases, spirochetemia often reaches 10^6 to 10^8 borreliae/ml, and motile spirochetes can be visualized by dark-field microscopy from wet preparations made from a drop of blood. This simple confirmatory test is often overlooked because of the increasingly common use of automated differential blood counting. Spirochetes can be visualized by stained (e.g., Giemsa stain) thin or thick films (Fig. 3).

Detection of low-level spirochetemias may be assisted by a microhematocrit concentration technique. The hematocrit capillary is filled 75% with anticoagulated (e.g., EDTA- or citrate-treated) blood and centrifuged for 2 min. The buffy coat is then examined directly under the microscope at magnifications of ×400 to ×1,000 (66). Failure to observe spirochetes does not rule out disease, and culture isolation (see "Isolation Procedures," below) can be considered.

**Antigen Detection**

Enzyme-linked immunosorbent assay (ELISA) and immunoblotting have been used for the detection of borrelial antigen in body fluids, including CSF and urine (67, 68). However, a commercial assay for antigen in urine was shown to lack reproducibility, and its use is not recommended (69).

**Nucleic Acid Detection Techniques**

Nucleic acid amplification techniques (NAAT) may serve as an adjunct to clinical diagnosis but should be restricted to experienced and specialized laboratories (70, 71). A variety of chromosomal and plasmid targets for NAAT have been developed (for reviews, see references 59 and 72 to 74). For PCR, an analytical sensitivity of approximately 10 to 20 borreia per test sample has been demonstrated. For Lyme borreliosis, test sensitivities for both NAAT and culture are greater with tissue specimens than with body fluids, except for synovial fluid, with which NAAT is superior. Sensitivities of 96% (62) and 86% (75) were reported for NAAT from synovial fluid from American patients with Lyme arthritis. European authors found NAAT sensitivities ranging between 50 and 70% (21–23, 76). Patients with Lyme borreliosis are nearly always seropositive, so PCR of synovial samples is not used as a primary diagnostic technique. A positive PCR result after antibiotic therapy is of uncertain significance, since the presence of *B. burgdorferi* DNA does not necessarily mean that spirochetes are viable (75, 77–79).

From skin biopsy and CSF specimens, NAAT demonstrated diagnostic sensitivities of approximately 60% and 20%, respectively (19, 61, 80). A prospective study of PCR and culture detection of *B. burgdorferi* in EM biopsy samples from Slovenian patients showed comparable sensitivities (36% were culture positive with modified Kelly Preac-Mursic [MKP] medium, 24% were culture positive with BSK II medium, and 25% were PCR positive) (81). PCR targeting ospA, a plasmid-borne gene, is more sensitive than flagellin PCR, which uses a chromosomal target (84, 82). Borreliae can shed blebs containing plasmids, leading to greater abundance of plasmid than chromosomal genes.

PCR amplification of *B. burgdorferi* sequences from urine has been described (74, 83) but is not recommended. Although *Borrelia*-specific DNA was demonstrated in over 70% of skin biopsy samples from patients with florid EM, parallel testing of urine samples was uniformly negative (80).

**ISOLATION PROCEDURES**

Many Lyme and relapsing fever borreliae are successfully cultured in artificial media. However, for diagnostic purposes, culturing is a slow, time-consuming method charac-
terized by low sensitivity, especially from body fluids of patients with Lyme borreliosis (Table 4). For these reasons, culture attempts are most often limited to research applications and performed by reference laboratories (e.g., the National Reference Center for Borreliae in Germany and the CDC in the United States).

Several media (modified Kelly media, e.g., BSK II, BSK-H, or MKP) (14, 15, 84) are capable of supporting the growth of borreliae. It is important to verify the quality of each lot of medium by growing a reference strain from a small inoculum (<10 cells). Optimum growth (the generation time of B. burgdorferi is about 7 to 20 h) in these media is obtained at 30 to 37°C under microaerophilic conditions. Positive cultures from skin and biopsy or fluid specimens (blood and CSF) may be obtained in as few as 4 days, but most isolates require several weeks of incubation, and negative cultures should be monitored by dark-field microscopy (Fig. 3) for at least 6 weeks.

IDENTIFICATION

Molecular Techniques

Most species of the genus Borrelia were initially delineated using DNA-DNA reassociation analysis (16, 32) or diversity at the rrs locus. B. burgdorferi has an arrangement of its rrns genes (a single rrs and tandemly repeated rrs and rrs genes) which distinguishes it from the relapsing fever borreliae (which have single copies of each) (85). Sequencing of 55-23S intergenic spacers and a number of genes, pulsed-field gel electrophoresis of large restriction fragments, PCR, and restriction fragment length polymorphism analysis of multiple targets have all been utilized for species differentiation (18, 19, 86-90). More recently, multilocus sequence analysis has been recommended as a simpler approach to taxonomic species assignment (28, 91). However, in most cases, diagnosis and effective management of individual patients are independent of species determinations beyond the Lyme disease and relapsing fever groupings.

Immunological Techniques

Serotyping methods to identify Borrelia species and strains within a species have been described (92, 93). However, as with molecular techniques, diagnosis and effective management of individual patients have yet to utilize characterizations beyond the Lyme disease and relapsing fever groupings.

SEROLOGICAL TESTS

Borrelia Antigens and the Human Humoral Immune Response

Borrelia burgdorferi possesses at least 30 immunogenic proteins, which include the outer surface proteins A to F (OspA to -F), a number of tissue binding proteins, and components of the flagellar apparatus. Proper detection and interpretation of the humoral response against B. burgdorferi must consider several variables. All Lyme borreliosis genospecies (or strains within a genospecies) do not produce qualitatively or quantitatively identical sets of antigens. In serological assays that utilize whole-cell culture extracts as the source of reactive antigens, these variables may result in different sizes of a given antigen (e.g., OspC of 21 to 25 kDa) and quantitative antigen differences or even their absence. This is particularly problematic in Europe and Asia, where multiple genospecies are present. Thus, it is imperative, even in North America, that diagnostic laboratories and manufacturers of serologic assays verify that all diagnostic antigens are present in relevant amounts. In the case of Western immunoblotting, diagnostic antigens must also be discernable from each other. For many diagnostic proteins, sequence heterogeneity, even between strains in a given genospecies, may result in amino acid variations and reduced detection of an antibody response in a patient with a heterologous infection. As an example: with 21 major OspC types recognized among North American and European isolates (94), patient reactivity in an assay with one selected OspC type may not be sufficiently cross-reactive to enable its detection (95, 96). In addition to having genospecies- and strain-dependent protein profiles as well as antigenic heterogeneity, many antigens are variably expressed in response to environmental cues, both in culture and during infection. OspC and VlsE serve as examples; while both of these potent immunogens are expressed during early infection, they are variably produced in culture, often in very small amounts. Thus, their presence in diagnostic assays must be verified. Similarly, while OspA expression is turned off in early infection (97) and is therefore an insensitive marker of this stage of disease, it is an abundant protein of most cultures. During progression to later stage II and III disease, particularly in North America, expression of OspA is often triggered and patient antibody to this antigen is strongly correlated with arthritic involvement (98).

Among immunogenic B. burgdorferi proteins, some proteins have both heterogeneous and conserved antigen epitopes. Despite the overall antigenic heterogeneity of OspC, portions of both the C and N termini harbor highly conserved and immunodominant epitopes (pepC10 and OspC1, respectively), which have been used successfully in peptide-based serodiagnostic enzyme immunoassays (EIAs) (99-101). Finally, at least one protein of great and recent diagnostic interest is capable of switching antigen epitopes during infection. The variable major protein-like-sequence expressed VlsE protein of B. burgdorferi is a surface lipoprotein that is expressed early in infection. It contains both variable and invariable regions, and extensive antigenic switching within the variable regions likely contributes to immune evasion (39, 102, 103). Nonetheless, and of some surprise, studies in the late 1990s found that Lyme borreliosis patients developed strong antibody responses to VlsE, particularly to the sixth invariant region of the protein. Reports indicate that this region was highly conserved among the three major Lyme borreliosis genospecies. These findings served as the basis of EIAs in which synthetic peptides representing the sixth invariant (or conserved) region, C6, were developed. Accumulating published studies over the last 10 years have shown that VlsE- and C6-based assays have high sensitivities in most stages of Lyme borreliosis and suggest that they may serve as future, single-tier assays for serodiagnosis (38, 59, 100, 104-108).

The earliest IgM responses to all B. burgdorferi infections are directed against OspC (21 to 25 kDa), the flagellar antigens p 41 (FlaB) and p37 (FlaA), and p35 (BBK32, fibronectin binding protein) and are typically detectable within the first few weeks. Detectable IgM against BmpA (39 kDa) is in part strain dependent and most often appears after the response to OspC and FlaB and FlaA (98, 109-111). Although the level of IgM antibody to most spirochetal antigens peaks within the first weeks, it often persists at detectable levels for many months.

The IgG response increases and broadens slowly over the first weeks of disease. Among the reactive antigens to which there is an early IgG response are OspC, p35 (BBK32), p37 (FlaA), VlsE, and p41 (FlaB) (38, 109,
During early-dissemination (stage II) disease, IgG levels increase and reactivity against Osp17 (DbpA [decorin binding protein A]), p39 (BmpA), and p58 often appears (115). The late-stage immune response (stage III) is characterized by IgG antibodies to a wide variety of antigens (110, 115). Approximately 80% of the sera from European patients with late disease (arthritis and ACA) react with p14, Osp17 (DbpA), p21 (not OspC), p30 (not OspA), p39, p43, p58, and p83/100 (homolog of p93) of B. afzelii strain PKo (115). Similarly, among North American patients with chronic neurologic abnormalities or arthritis, close to 100% react with 5 or more of the diagnostic antigens p18, p23 (OspC), p25, p30, p39 (BmpA), p41 (FlaB), p45, p58, p66, and p93 (59, 107, 110).

Notable differences in late-stage disease antibody responses between European and North American patients include those to OspC and OspA. While IgG antibodies against OspC are detected in only 20% of late-stage European patients (115), the frequency of IgG reactivity to OspC in American patients with late disease is 48% (110). Similarly, while only 5 to 7% of late-stage European patients are reactive to OspA (115, 116), over 40% of American patients with late disease are reactive to this antigen (110, 112).

Two-Step Approach in Serodiagnosis

For serodiagnosis of Lyme borreliosis, a two-step approach is recommended by the Association of State and Territorial Public Health Laboratory Directors (ASTPHLD) and the CDC (117, 118). All serum specimens submitted for Lyme disease testing should be evaluated in a two-step process in which the first step is a sensitive serological test, such as an EIA or immunofluorescence assay (IFA). Specimens found to be negative should not be tested further. All specimens found to be positive or equivocal by a sensitive first-tier test should be further tested by a standardized immuno blot procedure (117). This procedure is also recommended in the MiQ Lyme borreliosis standard published by the German expert group on the diagnosis of Lyme borreliosis of the German Society for Hygiene and Microbiology (DGHM) (Fig. 4) (71). The concept of a two-step approach, which aims at increasing the predictive value of a positive result with each step, requires that the tests be performed in succession (71, 119). Omitting the first step, a quantitative assay, and proceeding directly with qualitative immunoblotting reduces the specificity of the procedure (120).

IFA

For the IFA, borreliae fixed on glass slides are used as the antigen. IFA for serodiagnosis of relapsing fever, however, is challenging since expression of the major membrane proteins is variable. The specificity of IFA serodiagnosis for Lyme disease may be improved by adsorption of sera with Treponema phagedenis sonicate (IFA with antibodies to T. phagedenis).
EIA

Different modifications of the EIA have been used for the diagnosis of Lyme borreliosis. In the indirect EIA, antigen is used to coat the plates, followed by incubation with patient serum, enzyme-labeled anti-IgM or anti-IgG, and the EIA substrate. Capture IgM EIA (u-capture EIA) has been specially designed to avoid false-positive reactivity due to rheumatoid factor (121). Rheumatoid factor false-positive reactivity can also be overcome by pretreatment of the sera with anti-IgG (116). EIA has the advantage of objective measurement, quantification, and high throughput. Many different antigen preparations have been used, including whole-cell sonicates (122), isolated flagella (123), detergent extracts (116), recombinant protein antigens (116, 124, 125), and synthetic peptides (38). Use of crude antigen preparations, such as whole-cell sonicates, often results in unacceptable specificity. Improved tests which utilize enriched, specific, or recombinant protein antigens are now widely used. Tests using an octyl-β-D-glucopyranoside detergent extract and Reiter treponeme absorbent, isolated flagella, recombinant VlsE, or the C6 peptide of VlsE are commercially available (Dade-Behring, Marburg, Germany; Dakopatts, Copenhagen, Denmark; Diasarin, Turin, Italy; and Immunecon, Boston, MA). Since VlsE is not present in relevant amounts in cultivated borreliae, recombinant VlsE has been added to whole-cell extracts to increase sensitivity in some products (Dade-Behring).

Immunoblotting

Western immunoblotting is regarded as a supplementary (United States) or confirmatory (Europe) assay. This implies that it should be employed only when a screening assay is reactive (positive or indeterminate, sometimes called equivocal). Western immunoblotting enables assessment of the humoral immune response to protein antigens as separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE). Antigen preparations for Western immunoblotting include whole-cell lysates or recombinant protein antigens which are resolved (largely by molecular weight) by SDS-PAGE and then transferred to blot membranes. Patient antibody against dozens of borrelian antigens can be discerned by an experienced diagnostic laboratorian. However, the procedure is considered technically complex. An alternative test format is the line immunoblot, in which recombinant or native borrelia antigens that have been resolved or purified by means other than SDS-PAGE are directly striped on membranes for immunoprobing. This approach enables discrete spacing or placement of individual antigens in quantified deliveries on the membrane and avoids the overlap of comigrating antigens that often complicate reading in Western immunoblots. By either method, Western immunoblotting or line immunoblotting, it is imperative that antigen identifying and cutoff (minimal band intensity) controls are employed in each diagnostic run. These calibration controls may include antibody preparations provided with commercial kits, monoclonal antibodies (MAbs), or characterized patient samples from commercial or other (e.g., CDC) sources.

Numerous immunoblot tests which use antigens of various strains or genospecies of B. burgdorferi sensu lato are commercially available. The ASTPHLD and the CDC, as well as the DGHM, have published recommendations for interpretation of Borrelia immunoblots (71, 117). In the United States, immunoblot interpretation rules which refer to detection of antibody against whole-cell antigens of specific B. burgdorferi sensu stricto strains have been recommended (110, 111). An IgM immunoblot is interpreted as positive if at least two bands of the following proteins are reactive: p23 (OspC), p39 (BmpA), and p41 (FlaB). An IgG blot is interpreted as positive if five or more bands of the following proteins are reactive: p18, p23 (OspC), p28, p30, p39 (BmpA), p41 (FlaB), p45, p58, p66, and p93. If immunoblotting is used within the first 4 weeks of disease onset (early, stage I, or stage II), both IgM and IgG immunoblotting should be performed. Due to specificity concerns of the IgM immunoblotting criteria potentially yielding false-positive findings in persons with a low pretest likelihood of infection, initial recommendations limited application of IgM Western blotting to the first 4 weeks of infection. Despite these recommendations, errant IgM Western blotting use due to disease duration of >30 days, lack of an antigen reactive first-serum test, and misinterpretation of the blot itself continue (122). Beyond this time point, a more specific IgG-reactive Western blot test is expected. Recent studies, however, indicate that some patients do not develop a robust IgG response during the first 4 weeks of infection (107).

Interpretation of the antibody response among European patients is complicated by the risk of infection with different Borrelia species. In addition, immunoblot studies have shown that the immune response to European infections, compared with North American infections, is restricted to a narrow spectrum of Borrelia proteins (126). Interpretive rules defined in a species- and strain-specific manner have been determined (36, 115) and independently corroborated (43). B. afzelii strain PKo is preferred to Fbi (B. garinia) and PK2 (B. burgdorferi sensu stricto) strains because of a two-band criterion for the IgG test; i.e., at least two bands must be positive for p14, p17 (DbpA), p21, OspC, p30, p39 (BmpA), p43, p58, and/or p83/100 (Fig. 5) (71). According to the general Deutsches Institut für Normung (DIN) recommendations for immunoblotting (DIN recommendation 58967, part 40), at least a two-band criterion should be required for the positive interpretation of an IgG immunoblot. In IgM immunoblots, a detectable immune response is restricted to only a few bands. Therefore, the IgM blot is regarded as positive if there is a strong reactivity to OspC (71). Specific DIN recommendations for Borrelia immunoblotting (DIN 58969, part 44) which include new antigens (i.e., VlsE) and line immunoblotting as a new technique have been published.

Recombinant immunoblotting with Osp17 (DbpA), OspC, p39 (BmpA), truncated p41 (FlaB), p58, and p83/100 has demonstrated sensitivity comparable to that of whole-cell immunoblotting except for patients with isolated EM (127). Recombinant immunoblotting was substantially improved by the addition of several homologs of VlsE and DbpA, which increased the sensitivity of antibody detection in early disease (105, 106). Recombinant blots containing DbpA, OspC, p39 (BmpA), truncated p41 (FlaB), VlsE, and

p83/100 are commercially available (Mikrogen, Munich, Germany). By the line blot technique, sensitivity among early neuroborreliosis patients was significantly increased compared to that of conventional sonicate immunoblotting (92% versus 69%, respectively) (105). Listings of FDA 510(k)-approved seroassays for commercial distribution can be found at http://www.accessdata.fda.gov/scripts/cdrh/cfdocs/cfpmn/pmm.cfm by entering “LSR” as the product code.

Detection of Intrathecally Produced (CSF) Antibodies

Approximately 15% of untreated Lyme borreliosis patients will develop neurologic manifestations. Lyme neuroborreliosis (LNB) has been divided into early-dissemination and late stages. Both the central nervous system (CNS) and the peripheral nervous system (PNS), as well as blood vessels and meningeal coverings, may be involved in either stage. Laboratory testing should be used only to confirm the diagnosis and presence of B. burgdorferi-specific antibody in CSF or serum and may be indicative of past or present infection. The pattern of nervous system involvement is largely stage dependent and may affect the correlation between clinical spectrum and serologic test utility. Thus, careful evaluation of a thorough clinical history and presentation are critical to the selection of appropriate diagnostic tests and proper interpretation of their findings (38, 128–130).

In patients in whom the CNS is involved, there should be evidence of CNS inflammation. Rarely, this may be localized to the brain or spinal cord, but in most cases, inflammation involves the CSF and is evidenced by pleocytosis, elevated protein concentrations, and, in cases of protracted infection, antitborrelia-specific-immunoglobulin synthesis. In contrast, for PNS-limited disease, the CSF findings may be normal, as they are in most patients who have toxic metabolic encephalopathy (58).

Although <10% of LNB cases are culture confirmed, subtle differences in clinical presentations between European and North American LNB cases are linked to causative genospecies. North American cases are limited to B. burgdorferi sensu stricto, while most European culture-positive LNB cases are B. afzelii, and a much smaller percentage are B. garinii and B. burgdorferi sensu stricto.

The triad of symptoms of early-dissemination LNB, also known as meningoradiculoneuropathy, includes aseptic meningitis, cranial neuropathy, and radiculoneuritis; these may occur singularly or in combination. The single-most-common presentation of early-dissemination LNB in North America is meningitis. Examination of the CSF shows mononuclear pleocytosis and elevated protein. CSF-specific anti-B. burgdorferi (IgA or IgG) immunoglobulin is demonstrated in 80 to 90% of patients. Standard two-tier serology of these patients is also most often positive. Cranial neuropathy occurs both in North America and Europe in about 10% of early-dissemination LNB cases. Most frequently, this involves the facial nerve and is manifested by unilateral or bilateral facial palsy. Only about 50% of these cases will demonstrate CSF pleocytosis. European early-dissemination LNB often presents as Bannwarth’s syndrome and is highly associated with B. garinii infection. This radiculoneuropathy also occurs in up to 5% of untreated North American Lyme borreliosis patients. Most patients with Lyme radiculoneuritis are reactive in two-tier serologic testing, and CSF findings include pleocytosis and B. burgdorferi-specific antibody (58, 128–131).

Late neurological manifestations usually develop months to years after initial infection.

Encephalopathy is more common in North America, while encephalomyelitis is more frequent in Europe. For cases of late encephalopathy, serum immunoreactivity is nearly universal, while CSF pleocytosis, elevated protein, and B. burgdorferi-specific antibody are found in only 5%, 20 to 45%, and ~50% of cases, respectively. Most cases of chronic encephalomyelitis are reported from Europe, although North American cases have been described. In these cases, CSF pleocytosis and marked B. burgdorferi-specific antibody are almost universal.

Although there are no well-accepted criteria for seroconfirmation of neuroborreliosis in the United States, detection of an intrathecal Borrelia-specific immune response is a valuable tool and widely utilized in Europe (132). Methods taking into account potential dysfunction of the blood-CSF barrier, a common finding in neuroborreliosis, are required for accurate assessment of intrathecal antibody production. Long-used procedures for detection of specific intrathecal antibody production in the diagnosis of neurosyphilis have been modified for the diagnosis of neuroborreliosis (133–135). The most frequently used method is the determination of the CSF/serum antibody index (specific antibody index [Al]). CSF and serum must be obtained at the same time. By calculating the AI, CSF and serum are compared with regard to the portion of pathogen-specific IgG antibodies in the total IgG content. An AI of ≥2.0 is considered significantly elevated (71, 136). Lower indices (e.g., ≥1.3) are also considered significant by some investigators. False-positive AI results are likely with neurosyphilis patients when tested...
with whole-cell or flagellar sonicates by EIA. Here, EIAs with \( T. \) phagedenis adsorption (Dade-Behring) or recombinant antigens not cross-reacting with \( Treponema pallidum \) can be helpful for differential diagnosis. Other suitable methods for determination of intrathecal antibody production are the \( \mu \)- or \( \gamma \)-capture EIA (Dakopatts) (133) and the IgG-matched immunoblot (135). The latter allows comparison of the antibody spectra (against various \( Borrelia \) proteins) in serum and in CSF and thus permits conclusions as to the specificity of the intrathecal antibody response.

**Past and Future Vaccination and Its Impact on Serology**

The recombinant OspA vaccine (LYMExix) was withdrawn from the U.S. market in 2002. This vaccine utilized a novel approach to preventing human disease by killing \( B. \) burgdorferi in the larval tick while it fed on vaccines. Low sales and concerns regarding a putative arthritogenic T-cell epitope of OspA which mimicked human leukocyte function-associated antigen-1 (hLF-A1) led to its withdrawal. Nonetheless, continued efforts to make use of the immunogenic properties of OspA and its mode of action have led to development of a genetically engineered chimera in which the hLF-A1-1 epitope has been removed and the variable portions of several predominant serotypes of the antigen are retained (137). While promising, this vaccine has yet to go through phase III trials. Alternate vaccine candidates and strategies remain largely at the research level (138).

**Controversial Methods**

A variety of diagnostic approaches have been developed as alternatives or adjuncts to the more widely practiced methods described above. These include antigen detection, T-cell proliferation assays, antigen-specific memory/effector T cell responses, and novel culturing methods (139–146). While some of these have been disputed in the scientific literature (147–151), it is often difficult to assess the validity of other tests that have not been validated independently and/or have not been reviewed by the FDA. No test should be utilized for clinical diagnosis and case management without Clinical Laboratory Improvement Amendments (CLIA) certification. In addition, novel assays should be tested in multiple laboratory settings with blind and well-documented (clinically and epidemiologically) patient samples from positive Lyme disease controls, healthy controls, and patients with other diseases (and without a history of Lyme disease), including those that may overlap clinically with Lyme disease. Novel test results should have a positive correlation with clinical, epidemiological, and other well-established test findings of Lyme disease patients. Ideally, tests should be reviewed and cleared by the FDA, which has considerable experience with all facets of Lyme disease diagnostics and is able to address comparative test performances; without FDA clearance, it is often difficult to assess the sensitivity, specificity, and clinical utility of novel assays (41).

**ANTIMICROBIAL SUSCEPTIBILITIES**

The antimicrobial susceptibility of \( Borrelia \) species has been studied intensively in vitro (16, 152). Standard methods for the determination of the minimal bactericidal concentration have not been established. However, there is general agreement on the in vitro susceptibility of borreliae to antimicrobials, as follows. \( B. \) burgdorferi sensu lato is susceptible to macrolides, tetracyclines, semisynthetic penicillins, and the late second- and third-generation (expanded- and broad-spectrum) cephalosporins; moderately susceptible to penicillin G and chloramphenicol; and resistant to trimethoprim, sulfamethoxazole, rifampin, the aminoglycosides, and the quinolones (16). No significant differences between the Lyme disease borreliae and relapsing fever borreliae (\( B. \) hermsii and \( B. \) turicatae) were found with regard to penicillin G, amoxicillin, ceftriaxone, erythromycin, azithromycin, doxycycline, or tetracycline (16). There is no indication for routine antimicrobial susceptibility testing in cases of either Lyme disease or relapsing fever.

**Recommendations for Antibiotic Therapy**

All clinical manifestations of \( B. \) burgdorferi infection should be treated with antibiotics. The antibiotic, dosage, duration, and route of application depend on the clinical picture and the stage of the disease (153–156). In cases of solitary EM, oral treatment with doxycycline, amoxicillin, or cefuroxime axetil is recommended. In acrodermatitis, the same antibiotics and daily doses as for EM are recommended. In arthritis, oral treatment with doxycycline may be tried first, but in cases of poor therapeutic response, patients should be treated intravenously with ceftriaxone or penicillin G. Intravenous cephalosporins or penicillin G is also recommended for stage III neuroborreliosis.

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

**General Aspects**

Clinical criteria (case history and clinical findings) are decisive factors in the diagnosis and ordering of microbiological laboratory testing. The predictive value of laboratory tests is directly related to the pretest probability. It should be kept in mind that the lower the probability based on the clinical diagnosis, the lower the predictive value of a positive test result. For example, a negative serological result has a high negative predictive value for Lyme arthritis, since nearly all cases are seropositive. Whether or not a positive test corresponds with the patient’s presentation is a question that can be answered only by the clinician, e.g., by means of clinical case definitions applied to the various manifestations of Lyme borreliosis. Therefore, the laboratory report should not contain any therapy recommendations.

**Serological Report**

The serological report should contain the following.

1. Recording of individual test results. Results of the first assay, generally an EIA, are reported as positive, indeterminate, or negative. The immunoblot results are reported as positive or negative. In the case of a positive result, the reactive diagnostic bands may be reported (60). Caution against overinterpretation of minimally reactive blots must be emphasized (e.g., IgG reactivity against p41 is expected in approximately 50% of healthy adults in the United States and Europe and is excluded from the European scoring criteria).
2. Assessment of the final result of the two-step approach with regard to its immunodiagnostic significance (e.g., whether specific antibodies have been detected or not).
3. Assessment of serological findings as to the stage of the immune response, as far as test results allow pertinent statements to this effect (see below).
4. Recommendations for further reasonable diagnostic methods (PCR or culture) or for serological follow-up, if indicated.

Patterns of Serological Results in Various Stages of Lyme Borreliosis

Antibody tests performed in the early stage of Lyme borreliosis, particularly in cases lacking evidence of spirochetal dissemination, may show a negative or an indeterminate result (Table 5), often due to insufficient time for the full evolution of the immune response. In many cases, seroconversion still occurs after the initiation of treatment. Serological testing of patients with EM alone is not recommended because of the low predictive value of a negative result and the highly characteristic appearance of most rashes. In the presence of a suggestive clinical presentation and inadequate response to therapy, serologic testing is warranted up to 6 weeks after onset of disease. During the first 4 weeks of a positive clinical correlation, detection of IgM is consistent with an active infection. A robust IgG response is expected thereafter. Usually only a few bands (IgM and/or IgG) are detected by immunoblotting during the first few weeks of early disease. In late disease, a positive test for IgG antibodies is mandatory for seroconfirmation, and the IgM test is not useful for establishing the diagnosis; the absence of IgG rules out the diagnosis of late Lyme disease, even in the presence of IgM. False-positive IgM results due to a polyclonal B-cell activation immune response in the context of herpesvirus infections or autoimmune diseases and rheumatoid disorders also need to be considered. In many cases, the origin of such IgM responses remains unclear. Both IgM and IgG may persist for many months, and their presence may be compatible with past, asymptomatic, spontaneously resolved, or treated and clinically cured infections. Such patterns are often found among members of high-risk groups with frequent tick exposure (for example, forest workers) who do not show any clinical manifestations.

In cases of CNS neuroborreliosis, detection of pathogen-specific, intrathecal antibodies provides critical laboratory evidence of past or present infection. The presence of antiboreli antibodies (IgM, IgG, and IgA) in the absence of CSF pleocytosis suggests previous infection, and since specific antibody and positive AI may be detectable years after treatment and cure, repeat testing is not appropriate for monitoring therapy success.

Influence of Antimicrobial Therapy on Serodiagnosis

Clinicians are often tempted to order repeated posttreatment serologies in an effort to correlate cure and decreasing antibody titers. However, IgG antibodies against B. burgdorferi (especially as measured in whole-cell antigen assays) persist for a long time even after successful therapy. Significant titer changes can be expected only several months after the end of therapy; in cases of late manifestations, even years may elapse. Since there is practically no indication for follow-up serological tests, therapeutic success should be based on clinical criteria. A fourfold decline in titer of antibody to VlsE peptide C6 was shown to be an indicator of successful therapy for early Lyme disease (157), but this was not demonstrated for late disease (158) or posttreatment Lyme disease syndrome (159).

Sources of Error in Serodiagnosis

False results, both negative and positive, can occur from the test itself or the nature of the immune response. Seronegative results within the first days of stage I illness onset, before a mounting of the humoral immune response, are the norm. In Europe, differences between the test antigen and the species causing infection can also contribute to seronegative findings. Deficiencies in diagnostic antigen expression among cultivated borreliae will compromise the sensitivities of tests; important diagnostic antigens, such as OspC, DbpA, and VlsE, are often not expressed in cultivated borreliae. The high background reactivity of many first-generation whole-cell-based assays often results in lower specificity and therefore frequent false-positive results. Cross-reactivity with treponemes can be largely avoided by use of Reiter treponeme adsorbent, although syphilis serology should be performed in cases where treponeme exposure cannot be ruled out. Second- and third-generation assays with improved sensitivity and specificity are preferable to the first-generation tests. Nonetheless, critical assessment of pretest risk factors, clinical history, and presentation will provide the best guidance for laboratory test use and minimize false test outcomes of current and future diagnostic tests.

REFERENCES

Complement resistance of Borrelia burgdorferi correlates with the expression of BcCRASP-1, a novel linear plasmid-encoded surface protein that interacts with human factor H and FHL-1 and is unrelated to Erp proteins. J Biol Chem 279:2431–2439.

Treponema and Brachyspira,
Human Host-Associated Spirochetes

ARLENE C. SEÑA, ALLAN PILLAY, DAVID L. COX, AND JUSTIN D. RADOLF

60

TAXONOMY

The recognition of spirochetes as human host-associated organisms is believed to date from nearly 400 years ago, when Van Leeuwenhoek described spiral, nimble “animalcules” in human oral plaque (1). Determination of taxonomic relationships among spirochetes has been complicated by their fastidious nature and the refractoriness of many to cultivation. Numerous phenotypic traits have been examined in attempts to establish taxonomic hierarchies (2). Paster et al. (3) demonstrated using 16S rRNA sequences that spirochetes can be grouped into a single phylum containing five clusters: Treponema, Spirochaeta, Borrelia, Serpula (now Brachyspira), and Leptospira. The relatedness among the members of individual clusters varied considerably. Inter-species similarities among borreliae were >97%, suggesting recent evolutionary divergence. In contrast, the ~10% sequence differences among treponemes pointed toward divergence over a greater evolutionary time frame, a conclusion consistent with the diversity of vertebrate and invertebrate hosts known to harbor treponemes as symbionts (4).

Many investigators formerly believed that cultivable treponemes were closely related, non-pathogenic forms of Treponema pallidum (5). Miao and Fieldsteel (6, 7) dispelled this idea using DNA-DNA hybridization to demonstrate that T. pallidum Nichols DNA shared <5% homology with DNAs of cultivable treponemes but was indistinguishable from that of a Treponema pertenue (yaws) strain. Their work led to the reclassification of the agents of venereal syphilis, endemic syphilis, yaws, and pinta as morphologically identical and, despite advances in molecular differentiation based on genomic sequences (18), are distinguishable primarily by differences in geographic distribution, epidemiology, clinical manifestations, and host range in experimental animals (Table 1) (19–22). The extraordinarily high degree of similarity (99.8%) between the T. pallidum subsp. pallidum and T. pallidum subsp. pertenue genomes (18) implies that these profound differences arise from polymorphisms at a handful of genetic loci. Only T. pallidum subsp. pallidum is transmitted routinely by sexual contact and vertically from a pregnant woman to her fetus (19, 21, 22). It also is the only subspecies that regularly breaches the blood-brain barrier (19, 22). The type strain of T. pallidum subsp. pallidum (Nichols) was isolated in 1912 from the cerebrospinal fluid (CSF) of an individual with secondary syphilis (23) and has been propagated since by intratesticular inoculation of rabbits (24). No strain or subspecies of T. pallidum can be cultivated continuously in vitro, although limited replication has been achieved by cocultivation with mammalian cells (25). Rabbits have long been the animals of choice for studying syphilitic infection, and rabbit inoculation (rabbit infectivity testing, or RIT) is the only means by which strains can be isolated from clinical specimens (26). A murine model for venereal syphilis has been recently developed (27).

T. pallidum is ~0.2 μm in diameter, has tapering ends, and ranges in length from 6 to 20 μm (Fig. 1). Cells typically consist of 6 to 14 flat waves with a wavelength of 1.5 μm and amplitude of ~0.3 μm (Fig. 1). Because of their small diameter, pathogenic treponemes cannot be visualized by bright-field microscopy, nor do they take up Gram stain. Consequently, T. pallidum is best visualized by phase-contrast or dark-field (DF) microscopy, the latter being an important diagnostic tool. T. pallidum grows slowly (doubling time of 30 to 33 h in rabbits) (28) and poorly tolerates desiccation, elevated temperatures, and high oxygen.

<thead>
<tr>
<th>Characteristics and major clinical features of the treponematoses</th>
</tr>
</thead>
</table>

### Venerel syphilis (*Treponema pallidum* subsp. *pallidum*)
- **Global distribution**: Transmitted predominantly sexually, also congenitally and, rarely, by transfusion or organ transplantation
- **Stages/manifestations**
  - **Primary (local)**: 10–90 days postinoculation (avg, 21 days)
    - Single or multiple ulcers (chancres) on skin or mucous membranes
    - Regional lymphadenopathy
  - **Secondary (disseminated)**: 6 wk–6 mo postinfection (also seen with early latent relapses)
    - Diffuse lesions, most typically skin, but also visceral
    - Other mucocutaneous lesions: condyloma lata, alopecia
    - Generalized lymphadenopathy
  - **Latent (early latency, ≤1 yr duration; late latency, >1 yr duration)**
    - Reactive serologic tests for syphilis without manifestations
    - Relapses common during early latency and are infectious
    - Late latency is noninfectious, chronic, “asymptomatic” (may just be clinically inapparent)
  - **Tertiary**
    - Gummatous (skin, bones, or viscera)
    - Cardiovascular (classically involving proximal thoracic aorta)
    - Neurosyphilis (classically paresis, tabes dorsalis)
- **Congenital**
  - Early (perinatal): ranges from asymptomatic to disseminated to fulminant
  - Late: interstitial keratitis, bone and tooth deformities, deafness, neurosyphilis

### Yaws (*Treponema pallidum* subsp. *pertenue*)
- **Tropical areas** (Africa, Asia, Latin America, Western Pacific)
- **Infection usually occurs in childhood**
  - Typically does not involve CNS or cause congenital infection
  - **Stages/manifestations**
    - Early: 10–90 days postinoculation (avg, 21 days)
      - Primary lesion (mother yaw): papular, nontender, often pruritic, crusted, or ulcerated
    - Secondary disseminated lesions (frambesia)
      - Hyperkeratotic plaques, dactylitis
      - Malaise, fever, lymphadenopathy
    - Latent: positive serologic tests but without other signs of infection
    - Late: 10% of untreated individuals
      - Destructive lesions of bone and cartilage
      - Osteitis, periostitis

### Endemic syphilis (*Treponema pallidum* subsp. *endemicum*)
- **Saharan Africa, Middle East**
- **Infection of children or adults, rarely congenital infection**
  - **Stages/manifestations**
    - Early
      - Primary: mucosal or cutaneous lesions, often undetected
    - Secondary: disseminated oropharyngeal, cutaneous lesions
    - Generalized lymphadenopathy
    - Periostitis
    - Latent: positive serologic tests, no other signs of infection
    - Late: destructive skin, bone, and cartilage lesions

### Pinta (*Treponema carateum*)
- **Semi-arid warm areas of Central and South America**
- **Restricted to skin**
  - **Stages/manifestations**
    - Early
      - Primary lesion: hyperkeratotic, pigmented papule or plaque
    - Disseminated skin lesions
    - Regional lymphadenopathy
    - Late: pigmentary changes in skin (hyper- and hypopigmentation)
tensions (29). Once considered to be an anaerobe, it was reclassified as a microaerophile based on the finding that it replicates best in vitro in ambient oxygen concentrations of 3 to 5% (29). T. pallidum relies entirely on glycolysis for energy production and is unable to synthesize fatty acids, nucleotides, enzyme cofactors, and most amino acids (29, 30). The molecular architecture and cell envelope composition differ markedly from those of Gram-negative bacteria (31). In addition to lacking lipopolysaccharide (30), the outer membrane contains an extraordinarily low density of integral membrane proteins (31, 32). Many of the bacterium’s dominant immunogens are lipid-modified, periplasmic integral membrane proteins (31, 32). Many of the bacteria’s dominant immunogens are lipid-modified, periplasmic proteins involved in transport of nutrients across the cytoplasmic membrane (31, 32).

Host-Associated Spirochetes

Spirochetal phylotypes identified in the human mouth belong exclusively to the genus Treponema (11). Oral treponemes are anaerobic, spiral-shaped organisms ranging from 0.15 to 0.30 μm in diameter and from 5 to 16 μm in length (33). They can be differentiated based on genotypic characteristics and biochemical parameters, such as growth requirements, carbohydrate fermentation, and enzymatic activities (8, 34). Ten species of Treponema (T. denticola, T. pectinovorum, T. socranskii, T. vincentii, T. lecithinolyticum, T. maltophilum, T. medium, T. parvum, T. putidum, and T. amylolyticum) have been cultivated from the oral cavity; the large majority of treponemal phylotypes remain uncultivated (10). T. denticola, the prototype, binds to host cells and extracellular matrix components and also coaggregates with other bacteria (Porphyromonas gingivalis and Fusobacterium nucleatum) in periodontal pockets (35). The ability of treponemes to flourish in periodontal pockets also can be attributed to their ability to evade complement-mediated killing in inflamed gingival tissues prone to bleeding (36, 37). Although far less invasive than T. pallidum, T. denticola displays a limited degree of hematogenous dissemination in a SCID mouse model (38).

Brachyspira spp. are oxygen-tolerant anaerobes differentiated by phenotypic growth characteristics, degree of betahemolysis, and biochemical parameters such as the ability to produce indole and hydrolyze hippurate (39). B. aalborgi was first isolated from rectal biopsy specimens from patients with intestinal spirochetosis in 1982 and has not been detected in or isolated from animals other than nonhuman primates (40, 41). The type strain is comma shaped or helical, 2 to 6 μm long and <0.2 μm in width, with tapered ends and four flagella at each end (42). Isolation requires weeks of incubation under anaerobic conditions (43). There are no experimental animal models to study disease caused by B. aalborgi (14). B. pilosicoli colonizes the large intestine of a number of animal species and is thought to have greater pathogenic potential for humans than B. aalborgi (14, 44). Compared to B. aalborgi, isolates of B. pilosicoli are longer (4 to 12 μm), are more coiled, and have more-pointed ends (45). On blood agar plates, B. pilosicoli isolates display two morphologically distinct, weakly beta-hemolytic colony types (46). Intestinal spirochetes can be found in all regions of the colon but increase in number from cecum to rectum (47). They reside in the brush border surrounded by microvilli with their proximal tips embedded in invaginations of the host cell membrane (Fig. 2). Because of high density and orientation perpendicular to the mucosal surface, they form a characteristic basophilic fringe often described as a “false brush border” in histological samples stained with hematoxylin and eosin (H&E) (Fig. 2, top) (47). A third Brachyspira species, currently named “B. hominis” because it has been detected only in humans, has been identified exclusively by molecular means in colon biopsy specimens (17).

**EPIDEMIOLOGY AND TRANSMISSION**

**Venera Syphilis**

In 2008, the World Health Organization (WHO) estimated that there were 36 million prevalent cases of syphilis and 11 million incident cases in adults between the ages of 15 and 49 (48). The majority occur in underdeveloped countries, particularly in sub-Saharan Africa and Asia. Eastern Europe and Russia reported dramatic increases in the incidence of syphilis with the fall of Communism (49). There have been alarming increases in syphilis rates in China during the past 2 decades that have been attributed to the enormous societal and economic changes in that country (50). In 2008, ~1.36 million pregnant women worldwide were estimated to have active syphilis, causing substantial perinatal mortality and morbidity that could have been averted by early testing and treatment (51).

In the United States, the incidence of syphilis fell precipitously in the late 1940s following the introduction of penicillin, reaching a nadir in the 1950s (52). Syphilis rates
then began to rise, with peaks (all well below pre-penicillin era levels) occurring approximately every 10 years. After steady declines following the “sex for drugs” cocaine-related outbreak of the late 1980s and early 1990s (53), the United States experienced a steady increase in rates of primary and secondary (P&S) syphilis from 2001 to 2009 due to a resurgence of risky sexual behaviors among men who have sex with men (MSM) (54, 55). Although rates have started to decline, syphilis continues to be a major health problem among MSM, with an increase in the male-to-female ratio of P&S syphilis from ∼2:1 in 2000 to ∼8:1 in 2011 (56). In the United States, there has been a decrease in congenital syphilis to 8.5 cases per 100,000 live births in 2011, likely associated with the decline in rates of P&S syphilis among women in the past 5 years (57).

A statistical association between HIV infection and syphilis became evident at the outset of the AIDS epidemic (58) and has been attributed to both behavioral and biological components (59). Similar high-risk behaviors promote transmission of both HIV and T. pallidum. Genital ulcers can facilitate HIV acquisition and transmission by breaching protective mucosal barriers, recruiting HIV-susceptible CD4/CCR5-positive immune cells, and increasing HIV shedding in the genital tract (60). A recent review of studies conducted among adults living with HIV/AIDS worldwide reported a median prevalence of 9.5% for syphilis (61). The highest prevalence of coinfection was noted among individuals with newly diagnosed HIV infection.

The primary mode of syphilis transmission is through sexual contact, with exudative lesions of P&S disease being the most infectious (Table 1 and Fig. 3). Estimates of the risk of sexual transmission vary greatly from 10 to 80%; the 30% transmission rate reported by Schroeter et al. (62) is the generally accepted estimate (63). Vertical transmission of syphilis due to transfer across the placenta has been recognized for centuries (21). Neonates also can become infected from exposure to lesional exudate or infected maternal blood within the birth canal (21). Since the 1940s, transmission of syphilis through blood transfusion in the United States has been negligible due to routine testing of donor blood and refrigeration of blood products (64). However, transfusion-associated syphilis remains a concern in underdeveloped countries with inadequate screening programs (65). There have been rare instances of syphilis transmission via solid organ transplantation (66).

Endemic Treponematoses
According to WHO estimates, prior to the advent of penicillin, ~200 million persons were exposed to the endemic treponematoses during their lifetimes. In the early 1950s, the WHO and the United Nations Children’s Fund launched an extremely successful campaign that decreased the global prevalence of endemic treponematoses by >95% over an approximately 10-year period (20). Unfortunately, the failure of local health services has led to the resurgence of these diseases in many areas where they were formerly endemic (20). Yaws, the most common of the endemic treponematoses, occurs mainly in poor communities in tropical regions of Africa, Asia, Latin America, and the Western Pacific (67). Pinta is now confined to native populations in remote Central and South America (Table 1) (20). In contrast to yaws and pinta, endemic syphilis (or bejel) is a disease of hot, dry countries; major foci of endemic syphilis still exist in the Sahelian region of Africa (Table 1) (20).

The agents of yaws and pinta are transmitted primarily by direct person-to-person nonsexual contact with exudative lesions during childhood or early adolescence (Table 1). Transmission of endemic syphilis also occurs via nonsexual contact with infectious lesions on the skin and mucous membranes or via shared drinking and eating utensils (20).

Oral Treponemes: Gingivitis, Periodontal Disease, and Atherosclerosis
The epidemiologic importance of T. denticola and other oral treponemes arises to a great extent from their occurrence as members of the polymicrobial consortium that causes gingivitis and periodontitis (9). Gingivitis is ubiquitous globally in children and adults and is associated with poor oral hygiene; comprehensive oral hygiene programs are effective in preventing or reducing gingival inflammation (68). Chronic periodontitis is most common in adults and
seniors and is more common with cigarette smoking, obesity, diabetes, and alcohol consumption (69). The National Survey of Employed Adults and Seniors and the Third National Health and Nutrition Examination Survey found periodontal disease in 24% of employed adults and >60% of seniors (70, 71). Accumulating evidence supports an epidemiologic link between periodontal disease and atherosclerotic vascular disease, although a causal relationship has not been definitively established (72, 73).

**Intestinal Spirochetosis**

The frequency of spirochetal colonization of the intestinal tract declined dramatically in developed countries during the 20th century but remains high in the developing world (47). *B. aalborgi*, lacking animal reservoirs, is probably transmitted via the fecal-oral route (44). Infection with *B. pilosicoli* likely occurs by ingestion of water contaminated by feces of birds, animals, or infected humans (44). In developed countries, the prevalence of HIS is greatest among MSM with or without HIV infection, with oral-anal contact being the presumed mode of transmission (46, 74).

**CLINICAL SIGNIFICANCE**

**Venereal Syphilis**

Figure 3 illustrates the natural history of untreated syphilis, emphasizing the relationship between the infectious and noninfectious stages of the disease and reactivity in serologic tests (see below). Table 2 presents modified case definitions used by the Centers for Disease Control and Prevention (CDC) for syphilis staging and surveillance. Although the clinical consequences of spirochetal infection may be delayed for months to years, venereal syphilis typically commences with the appearance of one or more mucocutaneous lesions days to weeks following inoculation (63). Primary syphilis occurs when spirochetes replicating at the site of inoculation induce a local inflammatory response, giving rise to one or more chancres, the defining lesion(s) of primary syphilis. The clinical consequences of spirochete dissemination, collectively referred to as secondary syphilis, become manifest 4 to 10 weeks after the chancre. Because chancres tend to be painless and often are not visible in females, women tend to present with secondary disease; for the same reasons, a similar trend has been noted in MSM (75, 76). Although mucocutaneous lesions are by far the most common presentation, secondary syphilis can affect any organ (63). Mucocutaneous lesions of secondary syphilis usually resolve in 3 to 12 weeks, leading to the asymptomatic stage referred to as latency. The Oslo Study of Untreated Syphilis showed that 25% of patients experience secondary relapses, mostly within the first year but as late as 5 years after initial infection (77). All forms of tertiary syphilis have decreased markedly in incidence in the post-antibiotic era. Gummas are large, necrotizing, granulomatous lesions that may involve skin, bone, viscera, or the central nervous system (CNS) (78, 79). Cardiovascular syphilis, due to persistent infection of the blood vessels in the wall of the aorta (vasa vasorum), typically presents as aortic valvular insufficiency, coronary stenosis, and/or aortic aneurysm (80). Neurosyphilitic syndromes have been grouped into five major categories with substantial overlap in presentations: asymptomatic, meningeval, meningovascular, parenchymatous, and gummatous (81).

A multicenter, prospective, randomized trial of syphilis therapy found that HIV infection had only a minimal effect on the clinical manifestations of early syphilis (82, 83). However, there have been reports of HIV-infected patients presenting with symptomatic early neurosyphilis occurring within the first 12 months of infection, which is otherwise rare in HIV-negative persons (84). Recent studies also have suggested a higher occurrence of ocular syphilis and syphilitic hepatitis among HIV-infected patients (85, 86).

Most infants with congenital syphilis are asymptomatic at birth (21). Early congenital syphilis is analogous to secondary syphilis and can involve almost any fetal organ, most frequently the liver, kidneys, bone, pancreas, spleen, lungs, heart, and brain (21, 87). Two years of age is used to demarcate early from late congenital syphilis, which corresponds to tertiary syphilis in the adult. The best-known stigmata of late congenital syphilis are Hutchinson's teeth, interstitial...

**Congenital syphilis (neonatal)**

**Confirmed (requires 1 and 2 or 3)**

1. Clinically compatible case (e.g., hepatosplenomegaly, rash, condyloma lata, jaundice, or anemia)
2. Demonstration of *T. pallidum* by microscopic examination of specimens from lesions, amniotic fluid (antenatal), placenta, umbilical cord, nasal discharge, or autopsy material
3. Detection of *T. pallidum* DNA in lesions, tissue, blood, and/or CSF by PCR

**Probable (requires 1 or 2 and 3)**

1. Infant born to a mother who had untreated or inadequately treated syphilis at delivery, regardless of findings in the infant
2. An infant or child with a reactive treponemal test result
3. One of the following additional criteria
   a. Clinical signs or symptoms of congenital syphilis on physical examination
   b. Evidence of congenital syphilis on radiographs of long bones
   c. Abnormal CSF cell count or protein without other cause
   d. Reactive VDRL in CSF
   e. Reactive fluorescent treponemal antibody absorbed—19S-IgM antibody test or IgM ELISA

**Syphilitic stillbirth**

1. A fetal death that occurs after a 20-wk gestation
2. Fetus weighs >500 g and the mother had untreated or inadequately treated syphilis at delivery

*These criteria were modified from the Sexually Transmitted Diseases Surveillance Case Definitions for Nationally Notifiable Infectious Diseases (http://www.cdc.gov/std/stats/casedefinitions-2014.pdf).*

---

**Intestinal Spirochetosis**

In 1967, Harland and Lee (88) coined the term “intestinal spirochetosis” to describe a noninflammatory condition of the large bowel in which spirochetes attached end-on to the colonic epithelium in a dense, palisade-like arrangement, forming a basophilic “false brush border” (Fig. 2). Although they identified spirochetes in 9 of 100 consecutive biopsy specimens examined, they were unable to relate these findings to symptomatology. The confusion and controversy over the clinical significance of HIS have not abated over the years despite extensive phylogenetic and biochemical characterization of intestinal spirochetes and advances in methodologies for their isolation and/or detection (14, 89, 90). Although generally noninvasive and minimally inflammatory, *Brachyspira* spp. have been observed causing crypt abscesses, ulceration, and necrosis (91). Spirochetemia with multiple-organ failure has also been reported (14, 92).

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

**T. pallidum: Syphilis**

Because *T. pallidum* cannot be cultivated on artificial medium, the diagnosis of syphilis has to rely on the direct detection of treponemes in clinical specimens and/or reactivity in serologic tests. The method used for direct detection of *T. pallidum* depends on the stage of disease, the clinical presentation, and the type of specimen obtained (Table 3). *T. pallidum* can be detected in lesion exudate by DF...
microscopy, direct fluorescent-antibody test for *T. pallidum* (DFA-TP), or PCR. Tissue biopsies are rarely performed on genital ulcers but are used for diagnosing nongenital manifestations of secondary and tertiary disease. PCR can be performed on either fixed or unfixed tissue, although unfixed tissue is preferable. PCR assay of CSF is not recommended under routine circumstances because treponemes are present in a substantial percentage of spinal fluids from early syphilis patients who lack neurologic complaints or findings (93). Other specimens, such as lymph node aspirates and amniotic fluids, although rarely obtained, can be examined by DF microscopy, DFA-TP, and PCR, while placenta or cord tissue can be examined by silver staining, immunohistochemistry (IHC), direct fluorescent-antibody tissue test for *T. pallidum* (DFAT-TP), and PCR.

The order of sample collection from genital ulcers or moist lesions depends on the tests to be performed. Samples should be collected first for DF microscopy (see below), followed by DFA-TP and PCR. Ideally, the specimen for both DF microscopy and DFA-TP should be free of red blood cells, other microorganisms, and tissue debris. A specimen for DFA-TP is collected in the same manner but left to air dry for 15 min. To collect serous exudate for PCR, a sterile Dacron- or cotton-tipped swab should be rolled firmly along the base of the ulcer or lesion. The swab then should be suspended in a cryotube containing 1 to 2 ml of nucleic acid transport medium such as AssayAssure (Sierra Molecular Corporation, Sonora, CA) or universal transport medium (Copan Diagnostics, Murrieta, CA). Tissue or fine-needle aspirates (e.g., lymph nodes) for silver staining, IHC, or DFA-TP should be fixed as soon as possible in 10% buffered formalin at room temperature and sent to the laboratory for paraffin embedding, sectioning, and staining. To test products of conception for congenital syphilis, a 3- to 4-cm section of umbilical cord distal from the placenta should be obtained as soon as possible after delivery and processed as above.

A detailed procedure for collecting a specimen for DF examination has been described by Wheeler et al. (94). A step-by-step instructional video can be obtained without charge from Allan Pillay, Laboratory Reference and Research Branch, Division of STD Prevention, CDC [(404) 639-3446; apillay@cdc.gov]. Briefly, the site is gently cleansed and abraded with sterile gauze moistened with physiological saline until serous fluid appears; the specimen is then collected onto a clean glass slide and a coverslip is applied. Specimens obtained for DF microscopy should be examined within 20 min since diagnosis relies on identification of motile treponemes. Slides containing air-dried lesion exudates and touch preparations for DFA-TP staining can be stored in a slide container at 4 to 29°C for up to 2 weeks; otherwise, specimens should be fixed with acetone and stored at −20°C until testing. Serum, plasma, and CSF should be stored at 4°C if testing will be delayed by more than 4 h and at −20°C or lower if testing will be done more than 5 days from collection. Samples of unfixed tissue, ulcer exudate, mucosal or skin lesions, CSF, and amniotic fluid should be stored at −70°C if PCR testing cannot be performed immediately. Formalin-fixed samples should be stored at room temperature prior to embedding and sectioning or DNA extraction.

If specimens must be sent to a different laboratory for analyses, previously frozen plasma or serum must be shipped on dry ice. Transportation of whole blood for serologic testing can be done at ambient temperature if testing is done on-site; otherwise, samples should be stored at 4°C and transported overnight with cool packs. CSF for serology can be transported at ambient temperature overnight or on cold packs if also being examined by PCR. Samples collected in AssayAssure or universal transport medium for PCR can be shipped overnight at room temperature or with cool packs. Formalin-fixed tissue samples can be shipped at ambient temperature.

Serum is the specimen of choice for conventional non-treponemal and treponemal tests, but plasma can also be used with some of the enzyme immunoassays (EIAs) and newer treponemal assays. Plasma can be used for the rapid plasma reagin (RPR) and toluidine red unheated serum test (TRUST) assays but not for the VDRL test because heat inactivation of plasma enhances fibrin formation, leading to false-positive results. Plasma should be tested within 24 h to avoid false-positive test results. Fingerstick whole blood, serum, or plasma can be used for rapid point-of-care (POC) syphilis tests. Whole blood for PCR testing should be col-

*a*Applicable to all except oral and anal lesions.

*b*There is no commercial kit for this test, but FITC-conjugated polyclonal or monoclonal antibody can be purchased commercially.

*c*, not applicable.

* CDC recommends against routine lumbar puncture, but it needs to be done for neurologic symptoms.

*d*Nasal discharge or autopsy material can also be examined for *T. pallidum*.
lected in tubes containing EDTA as an anticoagulant. When screening for congenital syphilis, the mother’s serum should be used rather than cord blood. For IgM-specific tests, infant’s serum is required since cord blood specimens can be contaminated by maternal blood.

**T. denticola and Other Oral Treponemes**

Specimen collection for detection, isolation, or identification of *T. denticola* and other commensal treponemes is not normally performed in the routine clinical management of gingivitis or periodontitis. Detailed methods for propagating these organisms for research purposes have been published (95).

**Brachyspira: Intestinal Spirochetosis**

Fecal samples should be collected in sterile containers and transported at ambient temperature to the laboratory or overnight on ice if culture or DF microscopy will be performed off-site. Rectal swabs (96) can be collected and transported in Stuart medium (Becton Dickinson, Sparks, MD). Fecal samples and swabs should be processed for culture within 24 h of collection (97, 98). Fresh colonic or rectal biopsy samples should be used for culture, while samples for histological examination should be processed as described for *T. pallidum*. Biopsy specimens placed in physiological saline have been used successfully to culture *B. aalborgi* (97). Fecal samples or rectal biopsy samples should be used for culture, while samples for histological examination should be processed as described for *T. pallidum*. Biopsy specimens obtained from the colon or rectum can serve as material for culture, PCR, or histological examination by light microscopy or transmission electron microscopy (TEM) (100–102). Cultured spirochetes from solid- or broth-based media can be observed by phase-contrast or DF microscopy (99).

**DIRECT EXAMINATION**

**T. pallidum**

DF Microscopy

Samples from exudative primary, secondary, and early congenital syphilis lesions should be examined by DF microscopy whenever possible. Other specimens (e.g., lymph node aspirates and amniotic fluid) can contain enough spirochetes for successful DF examination (Table 3). DF should not be performed on oral lesions, since *T. pallidum* cannot be distinguished easily from commensal oral spirochetes.

DFA-TP

Touch preparations of lesion exudates (103) or tissue impressions (104) can serve as samples for DFA-TP, which utilizes either a fluorescein isothiocyanate (FITC)- conjugated polyclonal or monoclonal antibody for staining. There is no Food and Drug Administration (FDA)-approved DFA-TP test in the United States, although labeled polyclonal antibodies can be obtained commercially (Meridian Life Sciences, Memphis, TN; ViroStat, Portland, ME). Results with polyclonal antibodies should be interpreted with caution, since these reagents are not specific for pathogenic spirochetes.

Silver Staining, DFA-TP, and IHC

Silver staining (either Warthin-Starry or the Steiner modification of the Dieterle method) has long been used to visualize treponemes in paraffin-embedded samples. DFAT-TP is a modification of the DFA-TP test that enables immunofluorescent labeling of treponemes in tissue samples (105). For DFAT-TP, tissue sections are deparaffinized and pretreated to enhance epitope accessibility (106). Recently, impressive IHC results have been obtained using commercially available (Biocare Medical, Concord, CA; ViroStat) polyclonal anti-*T. pallidum* antibodies and avidin-biotin immunoperoxidase staining in paraffin-embedded skin biopsy specimens from secondary syphilis patients (107, 108).

PCR

Although PCR is not used routinely for syphilis testing and a commercial test is not available, numerous studies have been published since 1991 using PCR for *T. pallidum* detection based on several gene targets (109, 110). Of these, the polA (tp0105) (111) and tpn47 (tp0574) (112) are most commonly used. PCR is most useful for genital ulcers and other exudative lesions, which typically contain large numbers of treponemes and can be sampled noninvasively.

Genomic DNA for PCR is usually extracted from 200 μl of nucleic acid transport medium containing a genital ulcer swab sample using a commercial kit (e.g., QIAamp DNA mini kit; Qiagen Inc., Valencia, CA). Laboratories with real-time PCR capability can use the TaqMan-based multiplex PCR assay developed in the Laboratory Reference and Research Branch, Division of STD Prevention at the CDC. This assay simultaneously detects *T. pallidum*, *H. ducreyi*, and herpes simplex viruses 1 and 2 (HSV-1 and -2), the major causative agents of genital ulcer disease (GUD). Gene targets, primers, and probes for the assay are shown in Table 4. Laboratories that lack real-time PCR capability can use the conventional multiplex PCR assay for simultaneous detection of *T. pallidum*, *H. ducreyi*, and HPV described by Mackay et al. (113). If testing for *H. ducreyi* will not be performed, PCR products from the multiplex reaction can be analyzed by agarose gel electrophoresis. Otherwise, an enzyme-linked hybridization assay (113) must be used because the amplicons for *H. ducreyi* and HPV cannot be distinguished by size on agarose gels. When the primary diagnostic objective is to determine whether a specimen contains just *T. pallidum*, a TaqMan-based real-time PCR targeting the polA gene can be used (106). The primers consist of TP-1 (5′-CAGGATCCGGCATATGTCC-3′) and TP-2 (5′-AACGTTGAGCCGTCATCATTCC-3′) and a probe, TP-3 (5′-CTGTCTAGCACCAGCTTCC-GACGTCCTT-3′), which is labeled with 6-carboxyfluorescein (FAM) at the 5′ end and black hole quencher 1 (BHQ1) at the 3′ end. Laboratories unable to perform real-time PCR can use a conventional assay targeting the polA gene of *T. pallidum* with primers F1 (5′-TGGCGGTTGGCGATGGTGTTGTC-3′) and R1 (5′-CACAGTGTCTGAAAACC GCCGTAGCAG-3′) using PCR conditions described by Liu et al. (114).

**Brachyspira**

Fresh stool specimens or rectal swabs can be examined by DF microscopy for the presence of spirochetes (100). Colonic and rectal biopsy specimens can be examined by using periodic acid-Schiff, H&E, or silver staining: spirochetes appear as a “fuzzy coat” on the brush border of the epithelium (Fig. 2, top) (97, 115). Using TEM, the organisms appear to attach end-on to the host cell membrane (Fig. 2, bottom).

(102, 116). IHC also has been performed with polyclonal antibodies to T. pallidum, Mycobacterium bovis, and an uncharacterized intestinal spirochete (102, 115). Detection of B. pilosicoli and B. aalborgi DNA can be achieved with the PCR assays described in Table 5 (101, 117) or, alternatively, with a real-time PCR that can simultaneously detect both species plus “B. hominis” (17).

**ISOLATION PROCEDURES**

**T. pallidum**

RIT is the only means available for isolating T. pallidum from clinical specimens. Because of its extraordinary sensitivity (1 to 2 organisms), RIT has long been considered the gold standard for detection of treponemes (26). The method has been described in detail by Lukehart and Marra (24). Because of a number of factors (e.g., cost, the requirement for a specialized animal facility, the need for trained personnel, and the time required for a rabbit to test positive), RIT is not practical for routine diagnostic purposes.

**Brachyspira**

Fecal samples, rectal swabs, or colon or rectum biopsy specimens can be cultured using brain heart infusion agar (102, 118) or Trypticase soy agar medium (102) with 10% bovine blood, 400 μg/ml of spectinomycin, and 5 μg/ml of polymyxin incubated anaerobically at 37°C. Specimens should be streaked onto agar plates within 1 h of collection. Colonies of B. aalborgi appear light gray and weakly beta-hemolytic with a diameter of 1.2 mm on brain heart infusion agar medium after 21 days of incubation (99). Colonies of B. aalborgi and B. aalborgi appear as a thin film or as discrete, pinpoint colonies on Trypticase soy agar medium after 5 to 14 days (102). B. aalborgi cultures usually require a longer incubation period. B. aalborgi has been successfully subcultured on brain heart infusion agar (99) and propagated in Trypticase soy broth containing 10% fetal calf serum (97). B. pilosicoli is less fastidious than B. aalborgi and can be subcultured on media used for its isolation.

**IDENTIFICATION**

**Brachyspira**

B. pilosicoli and B. aalborgi strains can be characterized using API-ZYM (bioMérieux, Inc., Durham, NC) and using biochemical tests such as indole production and hippurate hydrolysis (92, 97, 102). A strong hippurate reaction and weak α-galactosidase activity are often used to identify B. pilosicoli.

while B. aalborgi is negative for α-galactosidase activity and gives a weak hippurate reaction (102).

**TYPING SYSTEMS**

*T. pallidum*

Identification of stable polymorphisms within the *T. pallidum* genome made possible the development of a practical molecular typing system for *T. pallidum* (119). Typing is based on PCR amplification and restriction fragment length polymorphism (RFLP) analysis of three members of the *tpr* gene family (tprE [tp0313], tprG [tp0317], and tprJ [tp0621]) (Fig. 4, top) and amplification of a variable number of 60-bp tandem repeats within *arp* (tp0433) (Fig. 4, bottom). To type *T. pallidum* strains, an ~1.8-kb region of tprE, tprG, and tprJ is simultaneously amplified using a nested PCR and primer pairs B1 (5′-ACTGGCTCTGCCACACTTGA-3′) and A2 (5′-CTACCAGGAGGGTACGC-3′) and IP6 (5′-CAGGTTTTGCCGTTAAGC-3′) and IP7 (5′-AATCAAGGGAGAATACGGTC-3′), followed by restriction digestion with MseI and RFLP analysis (120). The 60-bp repeat region of *arp* is amplified with PCR primers 1A (5′-CAAGTCAGGACGGACTGTCCCTTGC-3′) and 2A (5′-GGTATCACCTGGGGATGCGCACG-3′); an improved method has been recently developed (121).

Strain typing is performed primarily on specimens from genital ulcers and mucosal lesions, but other specimens have also been typed (122, 123). The major strain types identified are 14a, 14d, and 14f (120, 123). Only a few specimens from epidemiologically linked cases have been typed (124). To provide better discrimination among some of the more common subtypes, an enhanced typing method was recently described that utilizes the *arp/tpr* method (CDC typing system) described above, along with sequence analysis of an 84-bp variable region of the tp0548 gene (125).

**Brachyspira**

*B. pilosicoli* strains can be characterized by pulsed-field gel electrophoresis (PFGE) and multilocus enzyme electrophoresis, but the PFGE method appears to be more discriminatory. Studies using PFGE show that *B. pilosicoli* strains belong to a genetically diverse group (44, 126). There are no reports on typing of *B. aalborgi* strains.

**SEROLOGIC TESTS**

**General Principles**

Syphilis elicits two different types of antibody responses, traditionally designated “nontreponemal” and “treponemal” (Fig. 3) (33). Nontreponemal tests, which detect antibodies directed against lipoidal antigens, were the first to be developed and are still used for screening and evaluation of serologic response following therapy (Table 6). Nontreponemal tests have two inherent problems: (i) they lack sensitivity in primary and late syphilis (Fig. 3); and (ii) they lack specificity because reactive antibodies can be elicited in diseases and conditions unrelated to syphilis, giving rise to biological false positives (BFPs) (127). Conventional treponemal tests, beginning with fluorescent treponemal antibody absorption (FTA-ABS), were developed using *T. pallidum* or *T. pallidum* lysates to address the lack of specificity of the nontreponemal tests (Table 7) (33). The need for high throughput and decreased costs have prompted development of automated EIAs, immunoblots, and chemiluminescence assays, most of which now use recombinant *T. pallidum* antigens (Tables 8 to 13). The challenge of
syphilis diagnosis in developing countries necessitated the development of POC tests that can provide immediate results. The majority of the rapid syphilis tests detect only treponemal antibodies, but a few dual POC tests can also provide qualitative nontreponemal test results.

Nontreponemal Tests

Table 6 presents the predominant features of the FDA-approved nontreponemal tests. These tests use a precisely defined combination of cardiolipin, lecithin, and cholesterol that flocculates upon reaction with IgM and IgG antibodies. Detailed protocols for performing the RPR, VDRL, unheated serum reagin (USR), and TRUST assays can be found in A Manual of Tests for Syphilis, published by the American Public Health Association (http://www.apha.org) (128); an online version can be accessed at http://www.cdc.gov/std/syphilis/manual-1998/.

The VDRL test is a quantitative flocculation reaction performed on special glass slides (128). The results are read microscopically at ×100; the highest titer causing flocculation is the endpoint. The USR microflocculation test uses a modified VDRL antigen containing choline chloride, which eliminates the need for heating of the serum sample (USR), and the TRUST is a macroflocculation assay, very similar to the RPR, in which the charcoal is replaced with toluidine red (128). The sensitivity of the TRUST is similar to that of the RPR (Table 6), while its specificity is slightly higher (33).

The VDRL test can also be performed on CSF to identify cases of neurosyphilis. The VDRL-CSF test is performed identically to the serum VDRL except that the VDRL antigen is diluted 1:1 with 10% saline. RPR testing of CSF is available but has a lower sensitivity of 58%, compared to 67% for the VDRL-CSF, for the diagnosis of symptomatic neurosyphilis (130).

Treponemal Tests

The salient features of the FDA-approved treponemal antibody-based assays, as well as several others that are commercially available worldwide, are summarized in Tables 7 to 13. Detailed protocols for the FTA-ABS, the microhemagglutination assay for antibodies to T. pallidum (MHA-TP), the T. pallidum particle agglutination assay (TP-PA), and some of the initial treponemal EIAs can be found in A Manual of Tests for Syphilis (128).

syphilis diagnosis in developing countries necessitated the development of POC tests that can provide immediate results. The majority of the rapid syphilis tests detect only treponemal antibodies, but a few dual POC tests can also provide qualitative nontreponemal test results.

Nontreponemal Tests

Table 6 presents the predominant features of the FDA-approved nontreponemal tests. These tests use a precisely defined combination of cardiolipin, lecithin, and cholesterol that flocculates upon reaction with IgM and IgG antibodies. Detailed protocols for performing the RPR, VDRL, unheated serum reagin (USR), and TRUST assays can be found in A Manual of Tests for Syphilis, published by the American Public Health Association (http://www.apha.org) (128); an online version can be accessed at http://www.cdc.gov/std/syphilis/manual-1998/.

The VDRL test is a quantitative flocculation reaction performed on special glass slides (128). The results are read microscopically at ×100; the highest titer causing flocculation is the endpoint. The USR microflocculation test uses a modified VDRL antigen containing choline chloride, which eliminates the need for heating of the serum sample (USR), and is read microscopically like the VDRL. The USR test is rarely used, since the RPR test is essentially equivalent but does not require a microscope for determination of results. The RPR card test, performed on serum or plasma, contains finely divided charcoal particles as a visualizing agent (128). In the RPR card test, serial dilutions of serum or plasma (heated or unheated) are prepared on a plastic-coated card after which the RPR antigen is added. The presence of antibodies causes flocculation, while suspensions without antibodies remain uniformly gray. The TRUST is a macroflocculation assay, very similar to the RPR, in which the charcoal is replaced with toluidine red (128). The sensitivity of the TRUST is similar to that of the RPR (Table 6), while its specificity is slightly higher (33).

The VDRL test can also be performed on CSF to identify cases of neurosyphilis. The VDRL-CSF test is performed identically to the serum VDRL except that the VDRL antigen is diluted 1:1 with 10% saline. RPR testing of CSF is available but has a lower sensitivity of 58%, compared to 67% for the VDRL-CSF, for the diagnosis of symptomatic neurosyphilis (130).

Treponemal Tests

The salient features of the FDA-approved treponemal antibody-based assays, as well as several others that are commercially available worldwide, are summarized in Tables 7 to 13. FTA-ABS Test
In the FTA-ABS test (Table 7), a serum sample, adsorbed with an extract of T. phagedenis Reiter (Sorbent) to remove naturally occurring cross-reactive antibodies, is reacted with treponemes fixed to glass slides; FITC-conjugated anti-human immunoglobulin is used to visualize antibody-labeled organisms. Because of the nature of the conjugate used, the FTA-ABS test cannot distinguish between IgG or IgM antibodies. The serum is subjectively scored based on the fluorescence intensity. Standardized controls, which produce negative, weak, and strong fluorescence readings, must be included in each assay. The test can be performed with unheated CSF for diagnosis of neurosyphilis (see below). Because of the subjectivity involved in reading samples and the need for expensive microscopy equipment, the FTA-ABS is used much less frequently than in the past and is no longer recommended by the CDC (131).

MHA-TP, TPHA, and TP-PA Tests
The MHA-TP test (Table 7) is a passive hemagglutination assay using formalinized, tanned sheep erythrocytes sensitized with T. pallidum antigen; the T. pallidum hemagglutination assay (TPHA) uses fowl erythrocytes. Both the MHA-TP and the TPHA have been supplanted by the TP-PA. The TP-PA test (Fujirebio Inc., Tokyo, Japan) is a modification of the MHA-TP test that uses gelatin particles sensitized with T. pallidum antigens to reduce the number of nonspecific interactions (132). With all three tests, agglutination indicates the presence of IgG and/or IgM antitreponemal antibodies.

EIAs
Since the 1980s, >20 EIAs have been developed for syphilis diagnosis, the majority of which use recombinant T. pallidum antigens and detect IgM or IgG (Table 8) or both (Table

*AlkP, alkaline phosphatase; C, CSF; NS, not specified; P, plasma; r, recombinant; S, serum.

The 15-, 17-, 44.5-, and 47-kDa lipoprotein antigens are the most frequently utilized because they induce strong, persistent antibody responses (133) and are thought to be expressed only by pathogenic treponemes (134). Although EIAs using recombinant antigens might be expected to perform better than assays using T. pallidum lysates (135), this has not been borne out (136–138). EIAs utilize several different formats, including (i) antibody class capture, (ii) sandwich capture, and (iii) competitive assay. Most of the EIAs that specifically detect treponemal IgM (Table 8) are based on antibody class capture using goat or rabbit anti-human antibodies and purified T. pallidum antigens labeled covalently to peroxidase (conjugates) to complex with the patient’s antitreponemal antibodies. Examples are the Captia Syphilis-M (Trinity Biotech, Bray, Ireland) and the Trep-Chek IgM (Phoenix Bio-Tech Corporation, Mississauga, Ontario, Canada). Two-step sandwich EIAs use either immobilized whole or recombinant T. pallidum antigens to coat microplate wells. Serum or plasma patient specimens are incubated in the wells, and antitreponemal antibodies are captured to the antigens on the wells. After washing unbound components, the conjugate consisting of antigens labeled with horseradish peroxidase (HRP) is then added and captured by the antitreponemal antibodies bound to the microplate. Unbound conjugate is then washed away, and bound conjugate is detected by a reaction with a substrate. Examples include the Captia Syphilis-G (Trinity Biotech) and the ICE Syphilis (Murex Biotech Ltd., Dartford, United Kingdom). One-step sandwich EIAs have similar formats but specimen and conjugate are added at the same time; examples include the Enzywell Syphilis Screen (Diesse Diagnostica, Siena, Italy) and Syphilis EIA II (Newmarket Laboratories Ltd., Newmarket, United Kingdom). One disadvantage of EIAs using antigen-antibody conjugates can be high background signals that give rise to false-positive results. An increasing signal indicates a more reactive serum and is proportional to the antitreponemal antibodies in the patient’s serum.

The competitive format EIAs, such as the Pathoyme Syphilis (Omega Diagnostics, Alva, United Kingdom) and the Enzygost Syphilis (Dade Behring, Marburg, Germany), use immobilized antigen to capture specific IgG and IgM antibodies from patient serum, which then block binding of an antibody conjugate of identical specificity. With this format, optical density is inversely related to the amount of antibody bound.

Rapid POC Tests

Most of the POC tests for syphilis are immunochromatographic strip assays that detect treponemal antibodies using whole blood from fingerstick specimens, serum, or plasma (Table 10). All of the rapid syphilis tests use recombinant T. pallidum antigens to detect IgM and IgG antibodies. These POC tests can provide results within 20 min, but a positive result needs follow-up nontreponemal antibody testing for further evaluation. A recent meta-analysis of treponemal POC tests used for screening in antenatal and sexually transmitted disease clinic populations reported sensitivities and specificities comparable to those of conventional treponemal tests (139).
Two dual POC tests have the ability to detect both nontreponemal and treponemal antibodies (Table 11), features that are highly advantageous in resource-poor settings (140). The ChemBio Dual Path Platform Screen and Confirm (ChemBio Diagnostic Systems, Inc., Medford, NY) is a lateral-flow dual POC test that requires only 5 μl of serum, plasma, or whole blood and can be read visually or with a digital card reader for quantitative results (141). The Span Signal Spirolipin (Span Diagnostics Ltd., Surat, India) is a flowthrough dual POC test in which control, nontreponemal, and 17-kDa antigens are located, respectively, at the 12, 4, and 8 o’clock positions on the test pad.

**Immunoblotting Assays**

Immunoblotting techniques confer specificity because they identify the specific treponemal proteins recognized by serum antibodies; they also can separately detect IgG or IgM antibodies when the appropriate anti-immunoglobulin serum antibodies; they also can separately detect IgG or IgM antibodies when the appropriate anti-immunoglobulin conjugates are used (Table 12). The Western blot (WB) techniques use T. pallidum antigens that are fractionated with polyacrylamide gel electrophoresis, transferred to nitrocellulose membranes, and reacted with patient serum. The MarDx test (Trinity Biotech), which uses whole T. pallidum lysate, is used to define serum reactivity when screening and confirmatory treponemal tests are discrepant (142). The INNO-LIA (Innogenetics NV, Ghent, Belgium) and ViraBlot (ViraMed Biotech, Planegg, Germany) tests are pseudo-WBs that employ several recombinant antigens (15, 17, 44.5, and 47 kDa) applied onto a nitrocellulose membrane. In addition to some of the same recombinant antigens as the INNO-LIA, the ViraBlot strip (IgG or IgM) has five strips with increasing quantities of VDRL antigen, which allows for semiquantitative nontreponemal results.

**CLIAs**

Automated chemiluminescence immunoassays (CLIAs) can be performed using random access analyzers with a turn-around time of <1 h (Table 13). Recombinant T. pallidum antigens are used to coat paramagnetic beads and the conjugate consisting of antigens linked to alkaline phosphatase or isoluminol derivative. After an incubation period with the patient specimen and removal of unbound antibodies-conjugate with a wash cycle, a chemiluminescent substrate is added, which generates a signal relative to the proportion of bound conjugate. Examples of CLIAs include the Architect Syphilis TP (Abbott Laboratories, Abbott Park, IL) and the Liaison Treponema Screen assay (DiaSorin S.p.A., Vercelli, Italy).

**Multiplex Flow Immunoassays and Other New Technologies**

Multiplex flow immunoassays (Table 13) are based on LumineX fluorescent bead technology. Performed in 96-well microtiter plates, this format enables high throughput. The LumineX assay differs from ELAs in two ways: (i) the capture antibody is attached to a suspension of polystyrene beads instead of the wells; and (ii) the polystyrene beads are dyed with fluorophores of differing intensities that confer on each bead a unique fingerprint, enabling multiplex antibody detection. After the sandwich immunoassay, the bead suspension is analyzed using a dual-laser flow cytometry detection system. Currently, two multiplex flow immunooassays are available: the BioPlex 2200 Syphilis (Bio-Rad Laboratories, Hercules, CA) and the AthelNA Multi-Lyte (Zeus Scientific, Branchburg, NJ).

**ANTIMICROBIAL SUSCEPTIBILITIES**

### T. pallidum

Routine antimicrobial susceptibility testing of T. pallidum is not possible due to the lack of an in vitro cultivation system. T. pallidum strains are highly susceptible to penicillin G, which has been used successfully for the treatment of syphilis over the past 65 years (93). Ceftriaxone is highly active against T. pallidum in vitro and is effective in the treatment of early syphilis when a sufficient number of doses is given (93). Because efficacy data for ceftriaxone are limited, its use as an alternative therapy for syphilis is recommended only when better-established regimens are contraindicated (93). Tetracyclines have long been the second-line class of drug recommended for treatment of syphilis in patients allergic to penicillin and have well-established track records; doxycycline, which has a much longer half-life and better CNS penetration, is preferable to tetracycline (93). In vitro studies indicate that quinolone compounds have low antimicrobial activity against T. pallidum (29).

Erythromycin treatment failure were recognized years ago, and one case was reported to be due to an infection with an erythromycin-resistant T. pallidum strain (143). Enthusiasm for azithromycin, administered orally in a single 2-g dose, has been tempered by the discovery of geographically widespread macrolide-resistant strains of T. pallidum associated with an A2058G or A2059G mutation in both copies of the bacterium’s 23S rRNA genes (144–146). The 23S rRNA gene segment conferring macrolide resistance is detectable by nested PCR and RFLP analysis. A TaqMan-based real-time triplex PCR assay has been recently reported for the rapid detection of both point mutations (144).

### Brachyspira

The in vitro antimicrobial susceptibilities of B. pilosicoli isolates from a number of geographic locations have been tested using an agar dilution method (147). Isolates were found to be susceptible to amoxicillin-clavulanic acid, ceftriaxone, chloramphenicol, meropenem, tetracycline, and metronidazole. Metronidazole remains the drug of choice for treating B. pilosicoli infections; resistance has not been reported (148).

**EVALUATION, INTERPRETATION AND REPORTING OF RESULTS**

### Direct Detection of T. pallidum

DF Microscopy and DFA-TP

Identification of a single motile T. pallidum by DF microscopy is sufficient for diagnosis. The predictive value of DF microscopy is difficult to discern (149), with one study claiming a 97% positivity rate in patients with clinically diagnosed primary syphilis (80% for patients positive on their first clinic visit) (94). The development of PCR provided a much needed standard for assessing the sensitivity and specificity of DF microscopy. In two independent studies in which conventional multiplex PCR was used to evaluate the etiology of genital ulcers (112, 150), the sensitivity and specificity of DF ranged from 39 to 81% and 82 to 100%, respectively. DF microscopy has fallen into disfavor because it requires a specialized microscope and highly trained laboratory personnel. However, the continued need for DF microscopy proficiency is underscored by studies demonstrating that substantial percentages of DF microscopy-positive primary syphilis patients lack detectable antibodies (Fig. 3).
(33, 151). Although DFA-TP is at least as sensitive as DF microscopy and more specific (33), it has never gained wide acceptance and is unlikely to see increased usage in the PCR era.

Visualization of *T. pallidum* in Tissues

Silver impregnation is the traditional method for *T. pallidum* detection in formalin-fixed tissues (152) and should be performed when routine histopathologic findings suggest syphilis. When performed by a credible laboratory and accompanied by reactive serologic tests, visualization of spirochetes by silver staining can be considered definitive evidence for syphilis (Table 2). Of note, rare cases of seronegative secondary syphilis in HIV-infected patients are described in which silver staining was instrumental in establishing a diagnosis (153, 154). Nevertheless, silver staining has some drawbacks: it is prone to staining artifacts, its sensitivity is limited and not well determined, and it is not *T. pallidum* specific. The Steiner modification of the Dieterle stain is said to be more sensitive than the Warthin-Starry stain (155). IHC using commercially available polyclonal antibodies largely circumvents the limitations of silver staining, although it must be borne in mind that these immunological reagents can react with spirochetes other than *T. pallidum* (e.g., *Borrelia burgdorferi*).

PCR Detection of *T. pallidum*

PCR enhances detection of *T. pallidum* in genital ulcer exudates. An additional advantage of PCR for diagnosis of GUD is that multiplex analysis for other causes of GUD, most importantly HSV-1 and HSV-2 (see above), is possible. CSF has also been examined extensively by PCR. In a multicenter study, PCR in conjunction with RIT confirmed the long-held view that neuroinvasion by *T. pallidum* occurs with high frequency in early syphilis patients without neurologic symptoms (82). Unfortunately, very little is known about the utility of CSF PCR for diagnosing symptomatic neurosyphilis. A study from South Africa found that 56% of 50 patients with suspected neurosyphilis had positive CSF PCRs (122), but these findings need corroboration. Cumulative evidence suggests that PCR is also useful for detection of treponemes in fresh and processed tissues. Comparative analysis of paraffin-embedded secondary syphilis skin biopsy specimens revealed that PCR is equivalent to IHC staining and is easier to perform (155). Studies using conventional and real-time PCR indicate that analysis of blood has diagnostic utility, although results have varied (111, 123, 156). Nevertheless, PCR assays of blood should be used cautiously in suspected cases of acquired syphilis given the lack of consensus on the specific clinical scenarios in which it complements conventional diagnostic methods.

**Serologic Tests**

Serologic tests play an important role in syphilis diagnosis by supplementing direct detection methods for diagnosing early syphilitic lesions, diagnosing latent infection, and confirming suspected tertiary disease (Table 2 and Fig. 3). On the other hand, many problems in syphilis management stem from the fact that the nontreponemal antibody titers used to assist in staging of infection and monitoring response to therapy are poor surrogate markers for syphilitic infection. As noted earlier, nontreponemal and treponemal assays measure two distinctly different kinds of antibody reactivities with different kinetics during untreated and treated infection (Fig. 3). None of the currently available serologic tests can distinguish venereal syphilis from the endemic treponematoses (Table 1).

**Nontreponemal Tests**

Nontreponemal antibody tests are reported as the highest dilution giving a fully reactive result. Titers for the same serum can differ by 2- to 4-fold when tested using microscopic versus macroscopic nontreponemal tests, underscoring the importance of using the same method for serial serologic tests, preferably in the same laboratory. Sera with extremely high nontreponemal test titers can give weak, atypical, or even negative “rough” reactions at low dilutions when antibody excess prevents agglutination. This prozone phenomenon occurs in 1 to 2% of patients with secondary syphilis (157). Most laboratories circumvent this problem by routinely determining the titers of all samples to at least 16 dilutions.

Traditional algorithms utilize nontreponemal tests as the primary screening tests for suspected syphilis. Nontreponemal tests must be interpreted according to the suspected stage of syphilis as well as the population being tested. Reactive results require confirmation using a treponemal test, since the proportion of false-positive tests increases with decreasing prevalence of syphilis. Approximately 30% of those with early primary syphilis have nonreactive nontreponemal test results on the initial visit (Fig. 3 and Table 6), underscoring the importance of direct detection methods for genital ulcers and the use of treponemal antibody-based tests, which have increased sensitivity. In secondary syphilis, nearly all patients have nontreponemal test titers of ≥1:4. Approximately one-third of patients with tertiary disease have nonreactive nontreponemal tests.

Conditions other than treponemal infection can elicit antipoidal antibodies that cause BFP reactions, defined as reactivity in a nontreponemal test with a negative treponemal test result. Review articles cite a number of conditions and diseases that cause BFPs (158); however, many of these lack strong scientific evidence. Acute BFP reactions, which last >6 months, are associated with transient diseases or conditions such as malaria (159), brucellosis (160), mononucleosis (161, 162), viral hepatitis (163), lymphogranuloma venereum (164), viral pneumonias (165), tuberculosis (162), and chancroid (164). More recently, smallpox vaccination was shown to cause an increased frequency of BFP reactions (166). Causes of chronic BFP reactions, which last >6 months, include autoimmune diseases, particularly systemic lupus erythematosus (167), HIV infection (163, 168), intravenous drug use (163), and leprosy (169). Patients with hepatitis C infection are noted to be 5 times more likely to have BFPs than hepatitis C-negative controls (170).

Treatment response in syphilis patients is defined by resolution of disease manifestations, at least a 4-fold decline in nontreponemal titers (or a change in 2 dilutions, e.g., from 1:16 to 1:4) using the same assay, or seroreversion to a nonreactive test (93). For serologic monitoring after therapy, repeat nontreponemal titers are recommended at 6 and 12 months for early syphilis and at 6, 12, and 24 months for late syphilis. More frequent serologic monitoring can be conducted for HIV-infected persons and pregnant women after syphilis treatment. A 4-fold increase in nontreponemal titers is suggestive of either reinfection or treatment failure and requires further clinical evaluation for HIV coinfection and CNS involvement from *T. pallidum*.

Early investigators reported that nontreponemal tests serorevert or become nonreactive in the majority of treated patients with primary and secondary syphilis (171). How-
ever, a large historical cohort review found that the seroreversion rate ranges from 26 to 74% for patients at 12 to 36 months after treatment for early syphilis, which varies in part based on whether the patient has an initial or repeat episode of infection (172). A more recent analysis of the serologic response to syphilis treatment demonstrated that up to 21% of patients with early syphilis can remain serofast at 6 months after treatment (173). The serofast status is defined as a <4-fold decline in nontreponemal titers from initial titers or persistent low-level nontreponemal titers over time despite adequate treatment. The serofast state is more likely to occur in patients with low baseline titers (i.e., <1:32) or later stages of syphilis infection compared to primary syphilis (173). The clinical relevance of the serofast state is uncertain and requires further investigation to determine its optimal management.

Treponemal Tests

Conventional treponemal tests (i.e., FTA-ABS and TP-PA) and the majority of newer, commercially available treponemal assays measure both IgG and IgM without distinguishing the class responsible for reactivity. This property accounts for the primary strength of treponemal tests, which is their high level of sensitivity for syphilitic infection of all stages, but also their cardinal weakness, the inability to distinguish active from inactive disease. The greatest value of the treponemal tests is in distinguishing between true- and false-positive nontreponemal test results.

In contrast to nontreponemal tests, treponemal tests are performed at a fixed titer or serum dilution and titers are not normally determined. FTA-ABS reactivity is graded on a scale of 1 to 4+; 1+ reactivity, which is highly observer dependent, is considered equivocal evidence for syphilis, while 2+ reactivity also has a significant probability of being false positive due to naturally occurring cross-reacting antibodies (174). Another type of false positivity, beaded fluorescence due to anti-DNA antibodies, is observed in sera from patients with systemic lupus erythematosus and other autoimmune diseases (175). Authorities no longer consider the FTA-ABS to be the gold standard treponemal test (131). In head-to-head comparisons, the TP-PA has been shown to be as sensitive and specific for all stages of syphilis as any treponemal test currently on the market, including EIAs using recombinant antigens (176–179).

Three head-to-head comparisons of treponemal assays, including EIAs, provide some guidance on their use (137, 178, 179). All of the commercially available EIAs have high specificities (at or near 100% in tested panels) and, not surprisingly, nearly 100% sensitivities in diagnosing secondary syphilis. Schmidt et al. (137) evaluated nine EIAs using highly selected sera from patients with primary syphilis, all with nonreactive MHA-TP tests. Higher sensitivity correlated with (i) the volume and dilution of serum used, (ii) assay format (i.e., capture and competitive tests showed higher sensitivities than sandwich-based assays), and (iii) detection of IgM as well as IgG antibodies. The greater sensitivity for primary syphilis of assays that include IgM detection is presumed to be due to the earlier appearance of IgM versus IgG antitreponemal antibodies. IgM-specific EIAs have sensitivities ranging from 88 to 90% in primary syphilis, 76 to 100% in secondary syphilis, and 19 to 69% in early latent syphilis (180). IgM-specific assays can assist in distinguishing between early and late infections but are not currently recommended by the CDC for diagnosis of acquired syphilis (93).

The availability of high-throughput EIAs resulted in a dramatic shift in the way that serologic screening for syphilis is performed in many patient care settings. In recent years, numerous laboratories switched from the traditional (i.e., nontreponemal test followed by treponemal test confirmation) to a reverse algorithm in which screening is performed with a treponemal test, such as an EIA or CLIA, followed by reflex nontreponemal test when the former is reactive (131). Patients with a positive treponemal assay but negative nontreponemal test could have (i) very early syphilis, (ii) long-standing latent syphilis, (iii) past treated syphilis, or (iv) a false-positive treponemal test. Therefore, a careful clinical history is important to distinguish at-risk individuals in whom a reactive treponemal test is likely to be a true positive from individuals with previously treated syphilis. For persons who do not have a prior history of syphilis treatment, a second treponemal test, preferably the TP-PA, should be performed (131). A reactive second test confirms that the person has or had syphilis while leaving unresolved the issue of disease activity. If the second treponemal test is nonreactive, the clinician could decide that no further evaluation or treatment is indicated or that treatment is indicated for individuals at high risk. The reverse screening algorithm for syphilis testing could lead to increased patient follow-ups, overtreatment, and potentially higher costs (181). Therefore, several issues should be considered prior to its implementation, including disease prevalence, pretest probability of the patient having syphilis, and the laboratory’s need for automation.

Rapid POC Tests

Head-to-head comparison of nine rapid syphilis tests at geographically diverse sites has shown good performance relative to TPHA or TP-PA reference standards (182). However, the stability of the test results was affected if the reading was delayed past the recommended period, which resulted in previously negative tests becoming false positives. Since the majority of the rapid syphilis tests are treponemal assays, nontreponemal testing is recommended following a positive result if feasible. The exceptions are the dual POC tests, which can detect both nontreponemal and treponemal antibodies from the same patient specimen.

Tests for Neurosyphilis

CSF abnormalities are common in early syphilis patients without neurologic symptoms, and a high proportion of such individuals have treponemes in their CNS yet do not require enhanced therapy (82). For these reasons, routine lumbar puncture is not recommended in early syphilis (93). Some groups argue that this recommendation should not apply to HIV-infected patients with serum RPR titers of ≥1:32 or CD4+ counts of <350 cells/μl (183), although there are no data demonstrating long-term benefits of enhanced therapy in this patient population. The diagnosis of neurosyphilis is based on a combination of clinical and laboratory test criteria (Table 2). CSF examination should include the VDRL-CSF slide test and total protein and leukocyte counts. The VDRL-CSF test is considered to have high specificity but low sensitivity for neurosyphilis (184). A nonreactive VDRL-CSF test result, therefore, does not rule out neurosyphilis. The FTA-ABS CSF test has high sensitivity but low specificity for neurosyphilis because reactivity may be due to the passive transfer of IgG antitreponemal antibodies across the blood-brain barrier rather than intrathecal production of antibodies (185). A negative FTA-ABS CSF test, however, is strong evidence against neurosyphilis (185).
Syphilis Tests in HIV Infection

There is a clear consensus that serologic tests for syphilis perform well for persons coinfected with HIV and can be relied on for accurate diagnosis in such individuals (93). However, some caveats to this statement exist. First, HIV-infected individuals can have a higher incidence of false-positive nontreponemal tests (163, 168). Second, nontreponemal test titers in HIV-infected individuals tend to be higher than those in patients without HIV infection (82), and there is an increased risk of serologic failures among HIV-infected persons with early or late latent syphilis (186). Third, there are a small number of documented cases in which HIV-infected patients with secondary syphilis had nonreactive syphilis serologies (153, 154).

Tests for Congenital Syphilis

The CDC has issued revised criteria for congenital syphilis surveillance (21) (Table 2). A confirmed diagnosis requires demonstration ofT. pallidum in neonatal tissues, lesion exudates, and/or secretions or in the products of conception (i.e., placenta or umbilical cord) using DF microscopy, fluorescent antibody, or other specific stains. Congenital syphilis is diagnosed presumptively in a symptomatic or asymptomatic infant whose mother had untreated or inadequately treated syphilis at delivery or in an infant with a reactive treponemal test and any one of the following: (i) clinical evidence of congenital syphilis (i.e., on physical exam or radiographs); (ii) a reactive VDLR-CSF test; (iii) elevated CSF cell count or protein (without other cause); or (iv) a reactive 19S-IgM FTA-ABS or IgM enzyme-linked immunosorbent assay (ELISA). However, none of the commercially available IgM tests for congenital syphilis is currently recommended by CDC.

This work was supported in part by grant RO1 AI26756 from the National Institute of Allergy and Infectious Diseases/NIH to J.D.R.

The bacteria discussed in chapters 61 to 67 differ from bacteria described in other parts of this Manual by several characteristics, including lack of efficient characterization with the Gram stain method and, except for *Mycoplasma* and *Ureaplasma* species and to a limited degree for *Coxiella burnetii* and *Tropheryma whippelii*, the requirement for intracellular growth. Thus, the most frequently used tests in clinical microbiology laboratories, the Gram stain and culture on artificial media, are unable to detect these organisms if present in clinical samples. Diagnosis of infections caused by these bacteria has traditionally been accomplished by Romanowsky staining (Giemsa and Wright stains) of clinical samples, by detection of antibody responses to infection using a variety of serologic tests, or by histopathologic analysis of biopsy samples. Molecular diagnostic tools and better culture methods have significantly improved the ability to detect these agents and to diagnose the diseases that they cause. For some of these infections, molecular tools are standard practice. The following tables summarize the epidemiology of these infections (Table 1) and the diagnostic tests most often used for the detection of the causative bacteria (Table 2).

<td><strong>Anaplasma phagocytophilum</strong></td>
<td><strong>Microscopy:</strong> Giemsa or Wright stain of peripheral blood oruffy coat smears is positive in ~60% of infected persons. Antigen tests: None commercially available; IHC offered at CDC. Molecular tests: EDTA-anticoagulated blood collected during the pretreatment acute phase of illness is used for PCR amplification. Species- and genus-specific tests are described. Current test of choice for diagnosis during active infection. Culture: EDTA-anticoagulated peripheral blood is inoculated onto HL-60, THP1, or other myelocytic cell lines. Positive cultures may be obtained between 3 and 30 days from many samples if inoculated within 24 h and if obtained before antimicrobial therapy. Lack of timely results mitigates against frequent use. Serologic tests: IFA is the most frequently used test. In a patient with typical clinical features of HGA, a ≥4-fold rise in IgG titer confirms infection, and a single peak IgG titer of ≥80 provides supportive evidence. IgG test sensitivity is between 90 and 100%; specificity is ~95%. IgM testing is not recommended. Cross-reactivity with <em>Ehrlichia chaffeensis</em> occurs.</td>
</tr>
</tbody>
</table>

| **Chlamydia pneumoniae** | **Microscopy:** Organisms may be detected by Giemsa stain or DFA test directed against LPS, but both tests are insensitive. Antigen tests: Available EIAs directed against LPS detect all *Chlamydiaceae* but are licensed only for *C. trachomatis*. Molecular tests: FDA-cleared assays are not currently available. Culture: Recovered best if inoculated onto HL cells or Hep-2 cells. Serologic tests: MIF test is the test of choice. Diagnosis confirmed by ≥4-fold rise in titer or single samples with IgM titer of ≥16 and/or IgG titer of ≥512. |

| **Chlamydia psittaci** | **Microscopy:** Organisms may be detected by Giemsa stain or DFA test directed against LPS, but both tests are insensitive. Antigen tests: Available EIAs directed against LPS detect all *Chlamydiaceae* but are licensed only for *C. trachomatis*. Molecular tests: None commercially available. Culture: Recovered in many different cell cultures including McCoy and HeLa cells. Serologic tests: MIF test is most sensitive and specific (test of choice). |

| **Chlamydia trachomatis** | **Microscopy:** Organisms can be detected by DFA test or Giemsa stain. DFA is more sensitive, but neither test should be used alone. Antigen tests: Commercial EIAs for *C. trachomatis* are considered substandard; they are not recommended for use and are not suitable for screening urine or vaginal swabs. Point-of-care tests are only 62–72% sensitive compared to culture and 33–50% sensitive compared to molecular tests. Molecular tests: Commercial nucleic acid amplification tests (PCR, transcription-mediated amplification, strand displacement amplification) are available and are tests of choice for confirmation of *C. trachomatis* infections. Culture: Recovered in many different cell cultures including McCoy and HeLa 229 cells. Test sensitivity is lower than that of molecular tests and dependent on the quality of the submitted specimen. Serologic tests: MIF test is most sensitive and specific (test of choice) for neonatal pneumonia and lymphogranuloma venereum but is not recommended for other *C. trachomatis* infections. Fourfold or greater rise in titers are significant, but rising titers may not be observed with chronic, repeated, or systemic infections. A single IgM titer of ≥32 supports a diagnosis of neonatal pneumonia. |

| **Coxiella burnetii** | **Microscopy:** DFA or IHC may be performed, but these tests are not widely available. Antigen tests: None commercially available. Molecular tests: PCR available through reference laboratories; more sensitive than serology during first few weeks; whole blood or leukocyte fractions are preferred, and serum is less useful. Cardiac valve tissue more sensitive than blood for chronic Q fever endocarditis. Culture: Requires biosafety level 3 facility and practices; U.S. category B select agent. Animal (mouse) inoculation is most sensitive. May be cultivated in a variety of cell lines, especially HEL, Vero, RK13, THP1, or A549 cells. Axenic culture has recently been developed but is not yet proven for primary isolation. Serologic tests: Most frequently used diagnostic test. Acute Q fever is confirmed by a ≥4-fold rise in IgG titer to phase II antigens. Chronic Q fever is confirmed in a single serum with a ≥1:024 IgG titer to phase I antigen. A decreasing antibody titer suggests successful therapy. The IFA test that detects both phase I and II IgG is recommended. IgM phase II antigen enzyme-linked immunosorbent assay is commercially available but is for acute Q fever diagnosis only. |

<table>
<thead>
<tr>
<th>Organism</th>
<th>Diagnostic testa</th>
</tr>
</thead>
</table>
| **Ehrlichia chaffeensis** | **Microscopy:** Giemsa or Wright stain of peripheral blood oruffy coat smears is positive in up to 29% of infected persons.  
**Antigen tests:** None commercially available; IHC offered at CDC.  
**Molecular tests:** EDTA-anticoagulated blood collected during the pretreatment acute phase of illness is used for PCR amplification. Species- and genus-specific tests are described. Current test of choice for diagnosis during active infection. Sensitivity ranges from 56–100%.  
**Culture:** EDTA-anticoagulated peripheral blood or cerebrospinal fluid is inoculated onto DH82, THP1, HEL-22, Vero, HL-60 or other cell lines. Positive cultures may be obtained between 5 and >30 days from most samples if inoculated within 12 h and if obtained before antimicrobial therapy. Lack of timely results mitigates against frequent use.  
**Serologic tests:** IFA is the most frequently used test. In a patient with typical clinical features of HME, a ≥4-fold rise in IgG titer confirms infection, and a single peak IgG titer of ≥64 provides supportive evidence. IgG test sensitivity is believed to be high; specificity is ~95%. IgM testing is not recommended. |
| **Ehrlichia ewingii**     | **Microscopy:** Giemsa or Wright stain of peripheral blood oruffy coat smears occasionally reveals bacterial clusters (morulae) in neutrophils of infected persons.  
**Antigen tests:** None available.  
**Molecular tests:** EDTA-anticoagulated blood collected during the pretreatment acute phase of illness is used for PCR amplification. Species- and genus-specific tests are available in some reference and public health laboratories. Current test of choice for diagnosis during active infection. Sensitivity is not currently known but is suspected to be high.  
**Culture:** No method of in vitro culture has been developed.  
**Serologic tests:** No specific antibody test is available. Antibody tests are based largely on cross-reactivity with *E. chaffeensis* and alone are not diagnostic. |
| **Ehrlichia muris-like agent** | **Microscopy:** Giemsa and Wright stains of peripheral blood oruffy coat smears should be examined but have not yet revealed bacterial clusters in human leukocytes.  
**Antigen tests:** None available.  
**Molecular tests:** EDTA-anticoagulated blood collected during the pretreatment acute phase of illness is used for PCR amplification. A species-specific test is available in some reference and public health laboratories. Current test of choice for diagnosis during active infection. Sensitivity is not currently known but is suspected to be high.  
**Culture:** Isolation has rarely been attempted but was successful in ISE6 tick cell and RF/6A endothelial cell cultures.  
**Serologic tests:** Currently only available at some public health laboratories; cross-reactivity with *E. chaffeensis* occurs. |
| **Mycoplasma genitalium** | **Microscopy:** May be detected in genital fluids by use of DNA fluorochrome stains (Hoechst 33258 or acridine orange), but these are not specific.  
**Antigen tests:** Not recommended for diagnostic purposes.  
**Molecular tests:** PCR amplification may be the only practical means for detection of the pathogen. Commercial kits are not currently available in the United States but are in Europe.  
**Culture:** Growth conditions are not well established but can require long periods. Widely considered insensitive for diagnosis confirmation.  
**Serologic tests:** MIF and Western immunoblot methods have been described, although none are commercially available. |
| **Mycoplasma hominis**    | **Microscopy:** May be detected in body fluids by use of DNA fluorochrome stains (Hoechst 33258 or acridine orange), but these are not specific.  
**Antigen tests:** None commercially available.  
**Molecular tests:** PCR tests have been developed but because of rapid growth are less useful than culture. Commercial assays are available that simultaneously detect *M. hominis*, *M. genitalium*, *Ureaplasma* spp., *Trichomonas vaginalis*, *Chlamydia trachomatis*, and *Neisseria gonorrhoeae*.  
**Culture:** Organisms are isolated from a variety of clinical samples. Dacron or polyester swabs are preferred; wood-shafted cotton swabs should be avoided. Mycoplasmas are extremely labile, and appropriate transport medium should be used. Can be recovered on SP4 broth and agar supplemented with arginine (best overall), on Shepard’s 10B broth, or on A8 agar. Growth occurs within 2–4 days.  
**Serologic tests:** Not commercially available in the United States and not recommended for routine use. |

<th>Diagnostic test</th>
</tr>
</thead>
</table>
| **Mycoplasma pneumoniae**      | Microscopy: May be detected in body fluids by use of DNA fluorochrome stains (Hoechst 33258 or acridine orange), but these are not specific.  
Antigen tests: Not recommended for diagnostic purposes.  
Molecular tests: Real-time PCR amplification is the test of choice and is highly sensitive, but clinical studies have yielded variable results when compared with culture and serology. Commercial kits are available in both the United States and Europe.  
Culture: Organisms are isolated from a variety of clinical samples. Dacron or polyester swabs are preferred; wood-shafted cotton swabs should be avoided. Mycoplasmas are extremely labile, and appropriate transport medium should be used. Can be recovered on SP4 glucose broth or agar. Growth occurs after 21 days or longer. Subculture may improve yield. Widely considered insensitive for diagnosis confirmation.  
Serologic tests: EIAs are more sensitive and specific than complement fixation and IFA; detection of seroconversion by demonstration of a 4-fold increase in antibody titer is preferred, but detection of IgM antibodies in single sera may be useful. The cold agglutinin test is not recommended for diagnosis of M. pneumoniae infection. |
| **Orientia tsutsugamushi**     | Microscopy: DFA or IHC on skin or other tissues may be performed, but tests are not widely available.  
Antigen tests: None available.  
Molecular tests: PCR amplification performed on EDTA-anticoagulated blood,uffy coat leukocytes, plasma, or tissue samples obtained during acute phase of illness; available only through research laboratories.  
Culture: Isolation is performed by intraperitoneal inoculation of mice. Performed only in reference and research laboratories.  
Serologic tests: When IFA test is used on patients in a region of endemicity, a titer of ≥400 is 96% specific and 48% sensitive; lower cutoffs are used for travelers and for populations in which the infection is not endemic. Indirect immunoperoxidase uses light microscopy and is also sensitive and specific with diagnostic cutoffs of 128 for IgG and 32 for IgM. Dot EIA kits have lower sensitivity and specificity than IFA. Weil-Felix (Proteus) OX-K febrile agglutinins test is insensitive, nonspecific, and not recommended. |
| **Rickettsia africae**         | Microscopy: DFA or IHC on skin biopsy specimen of rash or eschar is sensitive and specific for spotted fever group rickettsiae. Antibodies are not commercially available.  
Antigen tests: Not available.  
Molecular tests: PCR amplification performed on EDTA-anticoagulated blood,uffy coat leukocytes, plasma, skin biopsy specimens, or tissue samples obtained during acute phase of illness; available only through reference laboratories.  
Culture: Heparin-anticoagulated plasma or Buffy coat cells or triturated skin biopsy specimens obtained before antirickettsial therapy are inoculated into shell vials seeded with cell lines such as Vero, L-929, HEL, or MRC-5. Infected cells are detected by immunofluorescence or PCR after 48–72 h; sensitivity is up to 99%.  
Serologic tests: IFA is sensitive using R. africae, R. conorii, R. parkeri, or other spotted fever group rickettsial antigens (e.g., R. rickettsii) but is low during the acute phase of illness. A 4-fold increase in titer is generally considered most specific, but single titers of ≥128 for IgG and ≥32 for IgM are considered diagnostically significant. A Dot EIA that is modestly less sensitive and specific is available for R. conorii. |
| **Rickettsia conorii**          | Microscopy: DFA or IHC on skin biopsy specimen of rash or eschar is sensitive and specific for spotted fever group rickettsiae. Antibodies are not commercially available.  
Antigen tests: Not available.  
Molecular tests: PCR amplification performed on EDTA-anticoagulated blood, Buffy coat leukocytes, plasma, skin biopsy specimens, or tissue samples obtained during acute phase of illness; available only through reference laboratories.  
Culture: Heparin-anticoagulated plasma or Buffy coat cells or triturated skin biopsy specimens obtained before antirickettsial therapy are inoculated into shell vials seeded with cell lines such as Vero, L-929, HEL, or MRC-5. Infected cells are detected by immunofluorescence or PCR after 48–72 h; sensitivity is up to 99%.  
Serologic tests: IFA is sensitive using R. conorii or other spotted fever group rickettsial antigens (e.g., R. rickettsii) but is low during the acute phase of illness. A 4-fold increase in titer is generally considered most specific, but single titers of ≥128 for IgG and ≥32 for IgM are considered diagnostically significant. R. akari-specific testing can be obtained in reference or public health laboratories. |
| **Rickettsia akari**            | Microscopy: Not available.  
Antigen tests: Not available.  
Molecular tests: PCR amplification performed on skin biopsy specimen of eschars obtained during acute phase of illness; available only through reference laboratories.  
Culture: Heparin-anticoagulated blood plasma or Buffy coat cells are inoculated into shell vials seeded with cell lines such as Vero, L-929, HEL, or MRC-5. Infected cells are detected by Giemsa, Gimenez, or fluorescent-antibody staining after 48–72 h. Sensitivity is not known.  
Serologic tests: IFA is sensitive using either R. akari or other spotted fever group rickettsial antigens (e.g., R. rickettsii) but is low during the acute phase of illness. A 4-fold increase in titer is generally considered most specific, but single titers of ≥128 for IgG and ≥32 for IgM are considered diagnostically significant. R. akari-specific testing can be obtained in reference or public health laboratories. |
| **Rickettsia felis**            | Microscopy: Not available.  
Antigen tests: Not available.  
Molecular tests: PCR amplification performed on EDTA-anticoagulated blood, Buffy coat leukocytes, plasma, or tissue samples obtained during acute phase of illness; available only through reference laboratories.  
Culture: Not available except through research laboratories. |

| Rickettsia prowazekii | **Microscopy:** Not available.  
**Antigen tests:** Not available.  
**Molecular tests:** PCR amplification performed on EDTA-anticoagulated blood, buffy coat leukocytes, plasma, or tissue samples obtained during acute phase of illness; available only through reference laboratories.  
**Culture:** Heparin-anticoagulated blood plasma or buffy coat cells are inoculated into shell vials seeded with cell lines such as Vero, L-929, HEL, or MRC-5. Infected cells are detected by Giemsa, Gimenez, or fluorescent-antibody staining after 48–72 h. Sensitivity is not known.  
**Serologic tests:** IFA is sensitive using either *R. prowazekii* or *R. typhi* as antigen. A 4-fold increase in titer is generally considered most specific, but single titers of ≥128 for IgG and ≥32 for IgM are considered diagnostically significant. |
| Rickettsia rickettsii | **Microscopy:** DFA or IHC on skin biopsy specimen of rash is 70% sensitive and 100% specific. Antibodies are not commercially available.  
**Antigen tests:** Not available.  
**Molecular tests:** PCR amplification performed on EDTA-anticoagulated blood, buffy coat leukocytes, plasma, or tissue samples obtained during acute phase of illness; available only through reference laboratories.  
**Culture:** Heparin-anticoagulated blood plasma or buffy coat cells are inoculated into shell vials seeded with cell lines such as Vero, L-929, HEL, or MRC-5. Infected cells are detected by Giemsa, Gimenez, or fluorescent-antibody staining after 48–72 h. Sensitivity is not known.  
**Serologic tests:** IFA is sensitive using *R. rickettsii* or other spotted fever group rickettsial antigens but is low during the acute phase of illness. A 4-fold increase in titer is generally considered most specific, but single titers of ≥128 for IgG and ≥32 for IgM are considered diagnostically significant. |
| Tropheryma whipplei | **Microscopy:** Tissue biopsy with periodic acid-Schiff stain, IHC, or fluorescence in situ hybridization; electron microscopy.  
**Antigen tests:** None available.  
**Molecular tests:** PCR tests are currently the preferred method for specific diagnosis; performed on fresh, frozen, or paraffin-embedded small intestinal biopsy specimens, cardiac valve tissues, lymph nodes, liver, synovium, central nervous system samples. Available through reference laboratories.  
**Culture:** Isolation requires long-term (>30 days) culture methods and is currently available in only a few research and reference/public health laboratories around the world.  
**Serologic tests:** Not currently useful. |
| Ureaplasma urealyticum | **Microscopy:** May be detected in body fluids using DNA fluorochrome stains (Hoechst 33258 or acridine orange), but these are not specific.  
**Antigen tests:** None commercially available.  
**Culture:** Organisms are isolated from a variety of clinical samples. Dacron or polyester swabs are preferred; wood-shafted cotton swabs should be avoided. Ureaplasmas are extremely labile, and appropriate transport medium should be used. Can be recovered on Shepard’s 10B urea broth and A8 agar. Growth occurs within 2–4 days. Subculture increases diagnostic yield.  
**Serologic tests:** Not recommended for routine use. |

Mycoplasma and Ureaplasma
KEN B. WAITES AND DAVID TAYLOR-ROBINSON

TAXONOMY
Bacteria commonly referred to as mycoplasmas ("fungus-form") are included within the Class Mollicutes ("soft skin"), which is comprised of 4 orders, 5 families, 8 genera, and about 200 known species, as shown in Table 1. New species, mainly in animals, are still being identified. Table 2 lists 16 species isolated from humans on multiple occasions, excluding species of animal origin detected occasionally in humans, usually in immunosuppressed hosts, but which are generally considered transient colonizers. Mycoplasma amnionforme is the most recent species to have been recognized, having been recovered from the respiratory tract of several patients with antibody deficiency and chronic bronchitis or bronchiectasis (1). Mollicutes are eu-bacteria that have evolved from clostridium-like Gram-positive cells by gene deletion. The availability of species-specific PCR technology is ameliorating difficulties of both culture and identification for fastidious mollicutes. Therefore, additional non-cultivable, and thus presently unknown, species are likely to be discovered, although this has not happened so far in the human field.

DESCRIPTION OF MOLLICUTES
The term “mycoplasma” is often used in a trivial way to refer to any members of the class Mollicutes, irrespective of whether they actually belong to the genus Mycoplasma. It is more accurate to refer to the class with the trivial term “mollicute(s)” and to organisms within the individual genera as “mycoplasmas,” “ureaplasmas,” “acholeplasmas,” etc. Mollicutes are smaller than conventional bacteria, in cellular dimensions as well as genome size, making them the smallest free-living organisms known. Mycoplasmas associated with humans range from coccoid cells of about 0.2 to 0.3 μm in diameter, as in Ureaplasma spp. and Mycoplasma hominis (2), to tapered rods 1 to 2 μm in length and 0.1 to 0.2 μm in width in the case of Mycoplasma pneumoniae (3). Mollicutes are contained by a trilayered cell membrane and do not possess a cell wall. The permanent lack of a cell wall barrier makes the mollicutes unique among prokaryotes and differentiates them from bacterial L forms, for which the lack of the cell wall is but a temporary reflection of environmental conditions. Lack of a cell wall also renders the mollicutes insensitive to the activity of beta-lactam antimicrobials, prevents them from staining by Gram stain, and is largely responsible for their pleomorphic form. The extremely small genome (<600 kb in the case of M. genitalium) and limited biosynthetic capabilities explain the parasitic or saprophytic existence of these organisms, their sensitivity to environmental conditions, and their fastidious growth requirements, which can complicate cultural detection. Mollicutes require enriched growth medium supplemented with nucleic acid precursors. Except for acholoplasmas, asteroleplasmas, and mesoplasmas, mollicutes require sterols in growth media, supplied by the addition of serum. Growth rates in culture medium vary among individual species, with generation times of approximately 1 hour for Ureaplasma spp., 6 hours for M. pneumoniae, and 16 hours for M. genitalium (4).

Typical mycoplasmal colonies vary from 15 to 300 μm in diameter. Colonies of some species, such as M. hominis, often exhibit a "fried-egg" appearance owing to the contrast between deeper growth in the center of the colony with more shallow growth at the periphery (Fig. 1), while others, such as M. pneumoniae, produce spherical colonies (Fig. 2). Whereas colonies of mycoplasmal species may be observed with the naked eye, those produced by ureaplasmas are typically 15 to 60 μm in diameter and require low-power microscopic magnification for visualization (Fig. 3).

Mycoplasmas and ureaplasmas of human origin can be classified according to whether they utilize glucose, arginine, or urea (Table 2). Except for utilization of urea for generation of metabolic energy, which is unique for ureaplasmas, these biochemical features are not sufficient for species distinction. Anaeroplasmas and asteroleplasmas, which occur in ruminants, are strictly anaerobic and oxygen sensitive, while most other mollicutes are facultative anaerobes.

Attachment of M. pneumoniae to host cells in the respiratory tract of humans is a prerequisite for colonization and infection. Cytoadherence, mediated by the P1 adhesin and other accessory proteins, described in detail in other publications (5, 6), is followed by induction of chronic inflammation and cytotoxicity mediated by hydrogen peroxide, which also acts as a hemolysin. M. pneumoniae stimulates B and T lymphocytes and induces the formation of autoantibodies, which react with a variety of host tissues and the I antigen on erythrocytes, which is responsible for production of cold agglutinins (6). An ADP-ribosylating toxin with significant sequence homology to the pertussis toxin S1 subunit, now known as the community-acquired respiratory distress syndrome (CARDS) toxin that causes vacuolation and ciliostasis in cultured host cells, has been described in M. pneumoniae (7). A murine model has shown that CARDS toxin
concentrations in bronchoalveolar lavage fluid are directly linked to the ability of specific M. pneumoniae strains to colonize, replicate, persist, and elicit lung histopathology. This variation among strains may predict the range in severity of pulmonary disease observed among patients (8). The CARDS toxin is also being studied as a gene target for PCR assays and as an antigen for use in serologic assays. M. genitalium also possesses a terminal structure, the MgPa adhesin, which facilitates its attachment to epithelial cells (Vaa), which is believed to be a major adhesin of M. hominis and could also assist in evasion of host immune

*The total number includes subspecies. The genus Mycoplasma also includes several Candidatus species of cell wall-less uncultivated parasitic bacteria. Some were previously classified in the genera Haemobartonella and Eperythrozoon. Their guanine + cytosine content and sterol requirements are unknown.

*U. urealyticum and U. parvum, formerly considered biovars of U. urealyticum, are now classified as two separate species and are the only ureaplasmas of human origin.

*Phytoplasmas are Candidatus species of mollicutes of plants and insects genetically related to the Acholeplasmatales.

*Symbols: +, positive for trait; −, negative for trait; ?, unknown.

*All isolates reported to date have been from the lower respiratory tract, but no other sites have been sampled.

*The organism has been found in the oropharynx, but it seems unlikely that this is a common or primary location.

*These species metabolize urea.
responses through antigenic variation. Ureaplasmas also attach to a variety of cell types, mediated by adhesin proteins expressed on the surface of the bacterial cell. The MB antigen contains serotype-specific and cross-reactive epitopes and is a prominent antigen recognized during human ureaplasmal infections (11). Ureaplasmas are known to produce IgA protease, which may be associated with disease production, and they release ammonia through urealytic activity (11).

**EPIDEMIOLOGY AND TRANSMISSION**

Mollicutes are common in practically all mammalian species, as well as many other vertebrates in which they have been sought. Although most mollicutes have species-specific host-organism associations, some mycoplasmas and acholeplasmas of animal origin occur in a wide variety of different animal hosts. Mollicutes in the genera *Spiroplasma*, *Mesorhizobium*, *Enthomoplasma*, and *Acholeplasma* can be isolated from insects and plants.

In humans, mycoplasmas and ureaplasmas are mucosally associated, residing predominantly in the respiratory or urogenital tracts, rarely penetrating the submucosa, except in cases of immunosuppression or instrumentation, when they can invade the bloodstream and disseminate to many different organs and tissues throughout the body. Many mollicutes exist as commensals in the oropharynx or urogenital tract (Table 2) and have been associated with invasive disease only in very rare circumstances. *M. fermentans* has been detected by culture and PCR assays in various body sites, including the urogenital tract, throat, lower respiratory tract, and other body locations, including joints, but its primary site of colonization and true disease potential are incompletely understood (11). Oral commensal mycoplasmas can occasionally spread to the lower respiratory tract and show up in cultures, but they should not cause diagnostic confusion with *M. pneumoniae* if appropriate means of organism identification are employed. The frequent occurrence of pathogenic species such as *M. hominis* and ureaplasmas in the lower urogenital tract in healthy men and women has complicated complete understanding of their disease-producing capabilities. Various investigations have found that *M. genitalium* is much less common in the lower urogenital tract of healthy females than *M. hominis* and *Ureaplasma* spp., with a prevalence of 6% or less (12, 13). Other species, as shown in Table 2, can also occur in the lower urogenital tract but are not known to be associated with disease. PCR assays have demonstrated the frequent occurrence of *M. genitalium* in the urogenital tract in men with urethritis and in lower and upper genital tract sites in women and that of *M. penetrans* in urine of homosexual males with HIV (14, 15). Although mycoplasmas are generally considered to be extracellular organisms, intracellular localization is now appreciated for *M. fermentans*, *M. penetrans*, *M. genitalium*, and *M. pneumoniae* (16). Intracellular localization may be responsible for protecting the organisms from antibodies...
and antibiotics, as well as contributing to disease chronicity and difficulty in cultivation in some cases. Variation in surface antigens of *M. hominis* and *Ureaplasma* spp. can be related to the persistence of these organisms at invasive sites. In humans, mycoplasmas and ureaplasmas can be transmitted by direct contact between hosts, i.e., venereally through genital-genital or oral-genital contact, vertically from mother to offspring either at birth or in utero, by respiratory aerosols or fomites in the case of *M. pneumoniae*, or even by nosocomial acquisition through transplanted tissues (11).

**CLINICAL SIGNIFICANCE**

**Respiratory Infections**

*M. pneumoniae* was first identified and described in the early 1960s. Prior to this time, it was believed to be a virus. It causes approximately 20% of all community-acquired pneumonias in the general population and up to 50% of pneumonias in certain confined groups (6). Although *M. pneumoniae* has long been associated with pneumonias in school-aged children, adolescents, and young adults, in recent years this organism has also been shown to occur endemicly and occasionally epidemically in older persons, as well as children under five years of age (6). The most typical clinical syndrome is tracheobronchitis, often accompanied by upper respiratory tract manifestations, such as acute pharyngitis. Pneumonia develops in about one-third of persons who are infected. The incubation period is generally 2 to 3 weeks, and spread throughout households is common. The organism can persist in the respiratory tract for several months after initial infection, and sometimes for years in hypogammaglobulinemic patients, possibly because it attaches strongly to and invades epithelial cells. Disease tends not to be seasonal, subclinical infections are common, and the disease is ordinarily mild. However, severe infections requiring hospitalization and even death are known to occur (6,17).

Extrapulmonary complications of *M. pneumoniae* infections can include meningoencephalitis, ascending paralysis, transverse myelitis, Bell’s palsy, pericarditis, hemorrhagic anemia, arthritis, and mucocutaneous lesions (6,18). An autoimmune response is thought to play a role in some extrapulmonary complications. However, *M. pneumoniae* has been isolated directly from cerebrospinal, pericardial, and synovial fluids, as well as other extrapulmonary sites, and additional evidence of direct invasion by this organism has been documented by the use of the PCR assay (18). Clinical manifestations are not sufficiently unique to allow differentiation from infections caused by other common bacteria, particularly *Chlamydia pneumoniae*. Data from animal models as well as clinical studies have suggested a potential role for *M. pneumoniae* as an etiologic or exacerbating factor in bronchial asthma, and additional clinical studies are linking this organism to stable as well as exacerbating disease (5,19,20).

*M. fermentans* has been recovered from the throats of children with pneumonia, some of whom had no other etiologic agent identified, but the frequency of its occurrence in healthy children is not known. It has been detected in adults with an acute influenza-like illness (21) and in bronchoalveolar lavage fluids, peripheral blood lymphocytes, and bone marrow from patients with AIDS and respiratory disease (22,23). It is apparent that respiratory infection with *M. fermentans* is not necessarily linked with immunodeficiency, but it can also behave as an opportunistic respiratory pathogen. *M. fermentans* has not been detected by culture or PCR in patients with urethritis or cervicitis but has been detected by PCR in amniotic fluid and in association with histologic chorioamnionitis, suggesting that *M. fermentans* can be transferred transplacentally (24).

Very little is known about *M. amphoriforme* beyond what has been described in the initial reports of its detection in the lower respiratory tract by culture and/or PCR in a series of patients with antibody deficiency and chronic bronchitis or bronchiectasis (1). Its biochemical reactivity, colonial appearance, growth characteristics, and gliding motility are similar to these features in *M. pneumoniae*, but it is genetically distinct. Repeated isolations over time and clinical improvement after antimicrobial therapy, which resulted in the elimination of the mycoplasma, suggest a possible pathogenic role, but more work must be done to determine the extent of disease that may be due to this organism (25). Thus far, there have not been any isolations of *M. amphoriforme* outside Europe and northern Africa.

**Genitourinary Infections**

Following puberty, *Ureaplasma* spp. and *M. hominis* can be isolated from the lower genital tract in many healthy sexually active adults, but there is evidence that these organisms play etiologic roles in some genital tract diseases. Results of human and animal inoculation studies and observations of immunocompromised persons are supportive of ureaplasmas being a cause of nonchlamydial, nongonococcal urethritis (NGU) in men (26). Since the identification of two distinct biovars of *Ureaplasma urealyticum*, now considered separate species, biovar 2 (*U. urealyticum*) has been implicated in NGU, whereas biovar 1 (*U. parvum*) has not been implicated in this manner in most studies (27-29). There have been attempts to link various disease conditions with individual *Ureaplasma* serovars. However, recent evidence suggests that individual serovars rarely occur alone and horizontally gene transfer among the various serovars occurs to a significant extent, making the individual distinct serovar concept no longer tenable (27). Evidence that *M. hominis* causes NGU is lacking, but *M. genitalium* has been detected by PCR technology significantly more often in urethral specimens from men with acute NGU than from those without urethritis and is now considered to be one of the causes of the disease (14). *M. genitalium*-positive men have been found to have symptomatic urethritis significantly more often than those infected with *Chlamydia trachomatis* (30). Antibody responses have been detected in some men with acute disease, and this mycoplasma has also produced urethritis in nonhuman primates (14). *M. genitalium* also may be a rare cause of conjunctivitis associated with urethritis (31). *M. fermentans*, *M. penetrans*, and *M. pirum* were not detected in the urethras of men with urethritis by PCR assays, suggesting that these organisms are unlikely to have a pathogenic role in this condition (32). In women, there is no evidence that *M. hominis* is a cause of the urethral syndrome, but ureaplasmas may be involved (33).

*M. hominis* and *Ureaplasma* spp. have not been detected by culture of prostatic biopsy samples from patients with chronic abacterial prostatitis (34), and *M. genitalium* has been found rarely by using a PCR assay (35). In contrast, ureaplasmas have been recovered from an epididymal aspirate from a patient suffering from nonchlamydial, nongonococcal acute epididymo-orchitis accompanied by a specific antibody response (36) and could be an infrequent cause of the disease. *Ureaplasma* spp. produce urease, induce crystallization of struvite and calcium phosphates in urine in...
vitre and calculi in animal models, and have been found in urinary calculi of patients with infection-type stones more frequently than those with metabolic-type stones, suggesting a possible causal association (37). M. hominis has been isolated from the upper urinary tract only in patients with symptoms of acute pyelonephritis, often with an antibody response, and causes about 5% of cases (38). Obstruction or instrumentation of the urinary tract are predisposing factors. Ureaplasmas have not been associated in the same way.

Mollicutes do not cause vaginitis but are among various microorganisms that proliferate in patients with bacterial vaginosis (BV). Some studies suggest that M. hominis contributes to BV (39), but evidence is lacking for an association of ureaplasmas with BV (11, 26). The independent association of M. genitalium with BV is controversial, as in some studies an association has been shown (40) while in others a relationship has not been demonstrated (39, 41). BV can lead to pelvic inflammatory disease (PID), and M. hominis has been isolated from the endometrium and fallopian tubes of about 10% of women with salpingitis diagnosed by laparoscopy, accompanied by a specific antibody response (42). The significance of this mycoplasma is difficult to assess in an individual case when several microorganisms are present. Nevertheless, serological evidence suggests that M. hominis could be an independent factor in tubal factor infertility (43). Ureaplasma spp. have been isolated directly from affected fallopian tubes, but not alone. This fact, together with the negative results of serologic tests and of inoculating nonhuman primates as well as fallopian tube organ cultures, does not support a causal relationship for ureaplasmas in PID (26). M. genitalium, however, can play a role in PID as indicated by its significant association with cervicitis (41, 44, 45) and endometritis (46). In addition, there is serologic evidence that this mycoplasma causes some cases of tubal infertility (47). That ureaplasmas might cause infertility still remains speculative.

Ureaplasmas have been isolated from internal organs of spontaneously aborted fetuses and from stillborn and premature infants more often than from fetuses in induced abortions or normal full-term infants (11). The results from some serologic and therapeutic studies have also supported a role for these organisms in fetal morbidity (11). BV is a possible confounding factor that must be considered in the association between ureaplasmas in the chorioamnion and low birth weight. Ureaplasmas at this site are directly associated with inflammation and may invade the amniotic sac early in pregnancy in the presence of intact fetal membranes, causing persistent infection and an adverse pregnancy outcome (48).

The notion that M. hominis causes fever in some women after abortion, or after normal delivery, is based on the isolation of this organism from the blood of about 10% of such women, but not from afebrile women who have had abortions or from healthy pregnant women (26). In addition, antibody responses have been detected in about one-half of febrile aborting women but in few of those who remain afebrile (26). Similar observations have been made for the isolation of Ureaplasma spp., which could be responsible for a few cases of postpartum endometritis (49). The ability of U. parvum and M. hominis to upregulate amniotic fluid leukocytes, proinflammatory cytokines, prostaglandins, metalloproteinases, and uterine activity to induce chorioamnionitis, a systemic fetal inflammatory response, and contribute to preterm labor and fetal lung injury is supported by experimental studies in rhesus monkeys (50). However, it is difficult to determine whether they have a role independent of all other bacteria occurring in BV, a condition strongly associated with preterm labor and birth. In addition, there are conflicting opinions about the importance of U. parvum in premature delivery, a situation that needs to be resolved. There is no evidence that M. genitalium is a cause of preterm labor or abortion (51, 52).

**Neonatal Infections**

Colonization of infants by genital mycoplasmas can occur by ascension from the lower genital tract of the mother at the time of delivery or in utero earlier in gestation and can be transient and without sequelae. The rate of vertical transmission is 18 to 55% among infants born to colonized mothers (11). Ureaplasma spp. and M. hominis can be isolated from neonates born to mothers with intact membranes and delivered by cesarean section (11). Congenital pneumonia, bacteremia, progression to chronic lung disease of prematurity with the development of inflammatory cytokines in tracheal aspirates, and even death have occurred in very low birth weight infants due to ureaplasmal infection of the lower respiratory tract (11). A meta-analysis of the literature documented since the 1980s supports the association of ureaplasmal infection with development of chronic lung disease, but so far there has been no evidence of a reduction in the incidence of chronic lung disease or death when preterm infants were treated with erythromycin (53). Additional studies using azithromycin are under way in an attempt to answer this important question. Both M. hominis and Ureaplasma spp. have been isolated from maternal and umbilical cord blood, as well as the blood of neonates. Both M. hominis and Ureaplasma spp. can also invade the cerebrospinal fluid of neonates (11). Either mild, subclinical meningitis without sequelae or neurological damage with permanent handicaps can ensue. Colonization of healthy full-term infants declines after 3 months of age, and fewer than 10% of older children and sexually inexperienced adults are colonized with genital mycoplasmas (11). Vertical transmission of M. genitalium from mother to neonate has been reported, but its significance in neonates is unknown (11).

Routine screening of neonates for genital mycoplasmas is not clinically justified based on the available evidence that many healthy neonates can be colonized without consequence. However, if there is clinical, radiological, or laboratory evidence of pneumonia, meningitis, or overall instability, particularly in preterm neonates in whom there are no obvious alternative etiologies, infection with M. hominis or Ureaplasma spp. should be considered.

**Systemic Infections and Immunocompromised Hosts**

Extrapolmonary and extragenital mycoplasmal infections probably occur more often than currently recognized. M. hominis is alone among pathogenic mycoplasmas of human origin that are occasionally detected in routine bacteriologic cultures, so that there have been many instances of accidental discovery when mycoplasmas were not specifically sought. The number of published case reports implicating Mycoplasma and Ureaplasma spp. in a variety of systemic infections involving persons with and without impaired host defenses has increased in recent years as a result of the more widespread utilization of universal PCR primers and DNA sequencing when infection is suspected and no conventional microbes are detected by culture. Mollicutes can cause invasive disease of the joints as a result of dissemination from the genital or respiratory tracts in immunocompromised persons, especially individuals with hypogammaglobulinemia, and
should always be considered early when attempting to diagnose septic arthritis in the setting of congenital antibody deficiency. *M. hominis* bacteremia has been demonstrated after renal transplantation, trauma, and genitourinary manipulations, and *M. hominis* has also been found in brain abscesses, osteomyelitis lesions, and wound infections (54, 55). Numerous mycoplasmal species, including *M. fermentans*, *U. urealyticum*, and *M. salivarium*, have been detected mainly by a PCR assay in synovial fluid of persons with rheumatoid arthritis and other arthritides, although the precise contribution of these organisms to these disease conditions is still uncertain (56–58). The significance of *M. fermentans* and other mycoplasmas as possible agents of Gulf War Syndrome received a great deal of attention several years ago, but there is no credible evidence supporting such an association or causal role (59). However, in cross-sectional and longitudinal studies, an association between *M. genitalium* and HIV infection has been found. *M. genitalium* can be found more frequently at both urethral and rectal sites of HIV-positive homosexual men than those who are HIV negative (60), and *M. genitalium*-induced cervicitis (61) occurs more often in HIV-positive than in HIV-negative women. Women who have a high burden of *M. genitalium* were more likely to shed HIV-1 than were *M. genitalium*-negative women, an observation in keeping with the ability of mycoplasmas to stimulate HIV replication (62) and possibly enhance viral transmission. The significant positive association between *M. genitalium* and HIV infection is also strongly supported by the results of a meta-analysis (63).

### COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

#### Specimen Type and Collection

Body fluids appropriate for mycoplasmal culture or detection by noncultural methods include blood, synovial fluid, amniotic fluid, cerebrospinal fluid, urine, prostatic secretions, semen, wound aspirates, sputum, pleural fluid, bronchoalveolar lavage fluid, or other tracheobronchial secretions, depending on the clinical condition and organisms of interest. Swabs from the nasopharynx, throat, cervix/vagina, wounds, and urethra are also acceptable. Tissue from biopsy or autopsy, including placenta, endometrium, bone chips, and urinary calculi can also be used. When swabs are used, care must be taken to sample the desired site vigorously to obtain as many cells as possible since mycoplasmas are mainly cell associated. Urine specimens sometimes prove more sensitive than urethral swabs for detection of fastidious mycoplasmas such as *M. genitalium* by PCR (64). If determination of the localization of mycoplasmas in the genitourinary tract is desired, urine specimens can be obtained at various stages during urination or after prostatic massage. Care should be taken to avoid collection of specimens that are contaminated by lubricants or antisepsics commonly used in gynecologic practice. Dacron or polyester swabs with aluminum or plastic shafts are preferred. Wooden shaft cotton swabs should be avoided because of potential inhibitory effects. Swabs should always be removed from specimens before transportation to the laboratory.

Successful isolation of mycoplasmas from blood can be achieved by inoculating blood, free of anticoagulant, into a liquid mycoplasmal growth medium at the bedside in a 1:5 to 1:10 ratio, using as much blood as possible (at least 10 ml is desirable for adults). Mycoplasmas are inhibited by sodium polyanethol sulfonate, the anticoagulant used in most commercial blood culture media, but the inhibitory effect can be overcome by addition of gelatin (1%, wt/vol) (65). Use of commercial blood culture media with or without automated blood culture instruments is not recommended for detection of mycoplasmas. None of the newer continuously monitored, nonradiometric, automated blood culture systems flag bottles containing *M. hominis*, even when additional metabolic substrate and gelatin are added. However, the organisms can survive in these media for several days (66).

#### Transport and Storage

Mycoplasmas are extremely sensitive to adverse environmental conditions, particularly dryness and heat. Specimens should be inoculated at the bedside whenever possible, using appropriate transport and/or culture media. Liquid growth media such as commercially prepared SP4 or 10B broths (Thermo Fisher, Waltham, MA, or Hardy Diagnostics, Santa Maria, CA) can also serve as transport media; 2 SP (10% [vol/vol] heat-inactivated fetal calf serum with 0.2 M sucrose in 0.02 M phosphate buffer, pH 7.2) and Trypticase soy broth with 0.5% (vol/vol) bovine albumin (Thermo Fisher) are also acceptable transport media. Specialized liquid transport media such as A3B (Thermo Fisher) have been designed by deletion of some of the growth supplements present in other growth media so that an increase in pH caused by the urealytic activity of ureaplasmalas can be delayed, resulting in less toxicity to the organisms during transport. Laboratories can choose to stock a single universal transport medium for mycoplasmas, ureaplasmalas, chlamydial, and viruses. Most universal transport media contain inhibitors to prevent bacterial or fungal overgrowth from specimens obtained from nonsterile sites that have their own indigenous microbial flora. M4, M5, and M6 (Thermo Fisher), UTM (Copan Diagnostics, Murrieta, CA), and BD UVT medium (Becton Dickinson, Franklin Lakes, NJ) are examples of universal transport systems suitable for transport of specimens from which mycoplasmas and/or ureaplasmalas will be sought by culture.

Liquid specimens do not require special transport media if cultures can be inoculated within 1 h, provided the specimens are protected from evaporation. Tissues can be placed in a sterile container that can be tightly closed and delivered to the laboratory immediately. Otherwise, tissue specimens should be placed in transport media if delay in culture inoculation is anticipated. Specimens should be refrigerated if immediate transportation to the laboratory is not possible. If specimens must be shipped, and/or if the storage time is likely to exceed 24 h prior to processing, the specimen in transport medium should be frozen at –80°C to prevent loss of viability and to minimize bacterial overgrowth. Mollicutes can be stored for long periods in appropriate growth or transport media at –80°C or in liquid nitrogen. Frozen specimens can be shipped with dry ice to a reference laboratory if necessary. Storage at –20°C is deleterious to detection, even by nonculture methods. When frozen specimens are to be examined, they should be thawed rapidly in a water bath at 37°C.

#### DIRECT EXAMINATION

### Microscopy

Mycoplasmas, like chlamydial and rickettsial, cannot be clearly visualized by routine light microscopy. Lack of a cell wall precludes visualization of mycoplasmas by Gram staining, but this procedure can prove useful to exclude...
containing contaminating bacteria. *M. hominis* occasionally appears as pinpoint colonies on bacteriologic media, such as Columbia agar, and the lack of a Gram stain reaction by these colonies gives a clue as to their possible mycoplasmal identity, warranting further specific evaluation and subculture to mycoplasmal media. A DNA fluorochrome or acridine orange stain can be useful to assist in organism visualization when applied to body fluids, but it is not specific for mycoplasmas.

**Antigen Detection**

Although culture is appropriate for species that can be isolated easily and rapidly from clinical specimens, such as *M. hominis* and *Ureaplasma* spp., it is not ideal for detection of fastidious and/or extremely slow-growing organisms such as *M. genitalium* and, to a considerable degree, *M. pneumoniae*. Therefore, alternate non-culture-based methods of detection should be employed even if culture is attempted for these organisms. Rapid methods for antigenic detection of *M. pneumoniae* were developed in the 1980s, but these techniques were hampered by low sensitivity and cross-reactivity with other commensal mycoplasmas. This approach for rapid diagnosis has now been abandoned in favor of PCR-based assays.

**Nucleic Acid Detection**

PCR systems have been developed for all of the clinically important mycoplasma species that infect humans, largely because of the advantages that they have over culture and serology, such as the ability to complete the procedure in one day utilizing a single specimen containing organisms that do not have to be viable, as well as the ability to detect nucleic acid in preserved tissues. PCR assays also detect the organisms earlier in the course of illness than serology, since development of measurable antibodies requires up to several days or more. Real-time PCR assays are now the preferred PCR method for detection of mycoplasmas and ureaplasmas. The advantages include a more rapid turnaround time, less handling of PCR product, and improved diagnostic sensitivity over the traditional PCR techniques. Analytical sensitivity is generally high, with some assays capable of detecting a single organism when purified DNA is used. Details of various nucleic acid amplification tests and their applications for detection of mycoplasmas and ureaplasmas have been discussed in depth in a recent review (67).

Gene targets for PCR assays for detection of *M. pneumoniae* in clinical specimens have included 16S rRNA, *P1*, *tuf*, *parE*, *dnak*, *pdaA*, ATPase operon, CARDs toxin gene (*mpn372*), and the noncoding repetitive element *repMpa* (5, 68–72). Both conventional and real-time nucleic acid sequence-based amplification (NASBA) have also been used to detect *M. pneumoniae* RNA (73). NASBA can provide rapid results with sensitivity as good as that of PCR, with a detection threshold as low as 5 to 50 CFU (73, 74). There have been very few side-by-side comparisons to determine whether one assay format or gene target is better than another. Many of the comparisons of PCR using culture or serology as a reference method yielded disparate results. Commercial PCR assays have been available in Europe for several years, and additional products are still in development. Limited evaluations showed that they work in a manner comparable to that of noncommercial assays (75–77).

One multiplex assay, the Biofire Diagnostics (Salt Lake City, UT) FilmArray RP, detects nucleic acids in nasopharyngeal swabs for 20 respiratory tract pathogens, including *M. pneumoniae*. This assay has received FDA clearance for use in the United States and is also available in Europe. Meridian Bioscience (Cincinnati, OH) has also introduced the illumigene mycoplasma assay into the United States. This loop-mediated isothermal amplification assay enables detection of *M. pneumoniae* in up to 10 clinical specimens that can be tested simultaneously within 1 h after extracted DNA is set up in the incubator/reader provided by the manufacturer. This instrumentation can easily be incorporated into clinical microbiology laboratories that do not have extensive molecular diagnostic facilities, and it has been reported to produce acceptable results in comparison to culture (78).

Quantitative, rapid, real-time PCR assays for *M. genitalium* have utilized targets such as the MgpA operon, 16S rRNA, the 115-kDa protein-coding gene, and gap, encoding glyceraldehyde-3-phosphate dehydrogenase (79–85). Use of the latter target overcomes some of the limitations that have been identified for 16S rRNA and MgpA (67). Strong associations between serology and PCR for *M. genitalium* have been described, but the analytic sensitivity of a single PCR assay for *M. genitalium* was questioned by Baseman et al., who reported that 61% of culture-positive women tested negative by PCR, despite apparently good quality control parameters for their assay (86). In view of the difficulty of culturing *M. genitalium*, culture positivity could have been due to cross-contamination. Assuming that this was not the case, the observation highlights the point that reduced sensitivity of a single PCR assay could be related to the quality of the specimen or the presence of inhibitors. Gen-Probe (San Diego, CA) developed a real-time PCR assay that performs well in comparison to other methods, but it is currently available in the United States only for research purposes (80, 87, 88). Multiplex PCR-based systems for detection of *M. genitalium* along with *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and other urogenital mycoplasmas and ureaplasmas are sold as kits in several European countries by multiple companies using various formats and instrument platforms. PCR assays for *M. hominis* have utilized mainly 16S rRNA as a gene target (89, 90). Since some heterogeneity has been reported in the 16S rRNA gene of *M. hominis* (91), assays that target other genes including *gap*, *f3Y*, and *yidC* have been developed (92–94).

PCR assays can be used to detect as well as identify individual *Ureaplasma* species. Gel-based conventional PCR assays targeted sequences of 16S rRNA and 16S rRNA-23S rRNA intergenic spacer regions, the urease gene, and *mha* (95–103), while real-time PCR assays have targeted mainly the urease genes and their subunits or *mha* (84, 104–108). The UAB Diagnostic Mycoplasma Laboratory performs a real-time PCR assay for detection and differentiation of *Ureaplasma* spp. based on UU063, which encodes a conserved hypothetical protein that is identical in all 4 *U. parvum* serovars, and a 15,072-bp open reading frame (ORF), UUR10_0680, that is conserved (>99.97%) in all 10 *U. urealyticum* serovars (105). This assay detected more positive clinical specimens than a conventional PCR assay based on a urease gene target in intralaboratory method evaluations. Some molecular assays that include detection of *Ureaplasma* spp. are commercially available in various European countries, but not in the United States. Seegene, Inc. (Rockville, MD, USA), markets their products STD6 and STD6b ACE Detection, which simultaneously detect *Trichomonas vaginalis*, *M. hominis*, *M. genitalium*, *C. trachomatis*, *N. gonorr-
Comparison of the PCR technique with culture and/or serology, in the case of M. pneumoniae, has yielded varied results that are not always in agreement. Positive PCR results for M. pneumoniae in culture-negative persons without evidence of respiratory disease suggests inadequate assay specificity, persistence of the organism after infection, or its existence in asymptomatic carriers. Positive PCR results in serologically negative persons could be due to an inadequate immune response or to the collection of specimens before specific antibody synthesis could occur. Negative PCR results in culture-proven or serologically proven infections raise the possibility of inhibitors or other technical problems with the assay. Use of a second PCR assay with a different gene target can help one to interpret results and resolve such discrepancies. This is particularly important in the setting of a positive PCR assay when culture and/or serology is negative. If mycoplasmacidal antibiotics have been administered, PCR results can be negative, even though serology is positive. There is some evidence suggesting that PCR inhibition occurs more commonly with nasopharyngeal specimens than throat swabs being assayed for M. pneumoniae (109). Commercial reagents available for purification of nucleic acid can be helpful in overcoming PCR inhibition.

PCR technology is less valuable for routine diagnostic purposes in the case of the more rapidly growing and relatively easily cultivable organisms, such as M. hominis and Ureaplasma spp., but this method can be valuable in clinical studies of ureaplasma infections and can detect a smaller number of organisms. Even though PCR-based techniques permit identification and differentiation of U. urealyticum versus U. parvum, this is not normally necessary for routine clinical diagnostic purposes.

PCR is a very good tool for identification of an unknown mycoplasma previously obtained by culture. Presently, PCR detection for mycoplasmas is still too complex to be carried out routinely in most hospital-based microbiology laboratories in the United States, although it is becoming the diagnostic method of choice for M. pneumoniae in reference laboratories that develop their own assays. Molecular detection of mycoplasmas could be used much more frequently once commercially sold rapid methods become more widely available.

**ISOLATION PROCEDURES**

**Biosafety Considerations**

M. pneumoniae, M. hominis, and ureaplasma are considered biosafety level 2 (BSL2) pathogens. Work with these microorganisms and other mycoplasmas of human origin can be undertaken on the laboratory bench and/or in a class 2 biosafety cabinet.

**Growth Media and Inoculation**

Growth of mycoplasmas pathogenic for humans requires the presence of serum, growth factors such as yeast extract, and a metabolic substrate. No single formulation is ideal for all pertinent species due to different properties, optimum pH and substrate requirements. SP4 broth and agar (pH 7.5) are the best media overall and can be used for both M. pneumoniae and M. hominis, provided arginine is added for the latter. Shepard’s 10B broth (pH 6.0) can be used for M. hominis and Ureaplasma spp. with A8 as the corresponding solid medium. Penicillin G or another broad-spectrum beta-lactam should be added to minimize bacterial overgrowth. Addition of a pH indicator, such as phenol red, is important for detection because mycoplasmas usually do not produce turbidity in broth culture owing to their small cell size. The compositions of these media are provided elsewhere (110).

For self-prepared media, quality control is crucial for each of the main components. These controls must consist of the quantitative growth of mycoplasma strain(s) in 2 media that differ only in the component to be tested. New lots or batches of broth are considered satisfactory if the numbers of organisms that grow are within one 10-fold dilution of the reference batch. Agar plates should ideally support growth of at least 90% of the colonies that are supported by the reference media. The sterility of commercially purchased medium components, such as horse serum, must be confirmed prior to their use. If a reference laboratory is to be used for mycoplasma testing, inquiry should be made of whether the medium used is self-prepared or purchased from a manufacturer, and there should also be verification of the type of quality control procedures performed. Quality control test organisms should include type strains and low-passage clinical isolates of the species of interest. When testing ureaplasmals, it is recommended to include at least one serovar representative from each of the two species. Testing inhibitory properties of media against growth of various other organisms likely present in specimens from nonsterile sites may also be worthwhile to prevent loss of mycoplasmas due to overgrowth of contaminating organisms.

Specimens should always be mixed well before inoculating media. Fluids should be centrifuged (600 × g for 15 min), and the pellet should be inoculated. Urine can be filtered through a 0.45-μm filter if bacterial contamination is suspected. Furthermore, it is wise to mince, not grind, tissues in broth prior to diluting. Serial dilution of specimens in broth to at least 10⁻¹ with subculture of each dilution onto agar is an extremely important step in the cultivation process, since it helps overcome possible interference by antibiotics, antibodies, and other inhibitors, including other bacteria that can be present in clinical specimens. Omission of this critical dilution step can be one reason why some laboratories have difficulty in recovering the organisms. Dilution also helps to overcome the problem of rapid decline in culture viability, which is particularly common with ureaplasmals, and it also provides information about the number of organisms present.

**Incubation Conditions and Subcultures**

Broths should be incubated at 37°C under atmospheric conditions. Agar plates yield the best growth if they are incubated in an atmosphere of room air supplemented with 5 to 10% CO₂, or in an anaerobic environment of 95% N₂ plus 5% CO₂. A candle jar or anaerobe jar with GasPak catalyst is adequate if dedicated incubators are not available. The relatively rapid growth rates of M. hominis and Ureaplasma spp. make identification of most positive cultures possible within 2 to 4 days, whereas M. pneumoniae usually requires 21 days or more. Several mycoplasmal species can produce similar biochemical reactions, and identification can be accomplished only by specific tests on organisms once isolated. All broths that have changed color should be subcultured into a fresh tube of the corresponding broth (0.1 ml into 0.9 ml) and onto agar (0.02 ml). Subcultures must be performed soon after the color change occurs, particularly if the organism belongs to Ureaplasma spp., because the culture can lose viability within a few hours. Subculture also increases the diagnostic yield, since some strains may
not grow sufficiently from the original specimen inoculated initially onto solid media. Blind subculture performed periodically during incubation may improve the yield of M. pneumoniae and other mycoplasmas, since a color change may not always be evident, even if growth occurs. Cultures should be incubated for at least 7 days before being designated negative for genital mycoplasmas and 6 weeks for M. pneumoniae. The growth rate of M. fermentans is similar to that of M. pneumoniae. However, for M. genitalium, and mycoplasmas of human origin other than M. pneumoniae, M. hominis, or Ureaplasma spp., cultivation conditions are not well established. Due to the advent of PCR assays for use in research and reference laboratories, the need to refine culture techniques for these slow-growing and fastidious organisms is less critical, and cultivation methods for them are not discussed here.

Development of Colonies
Broth cultures for Ureaplasma spp. should be examined for color change resulting from hydrolysis of urea twice daily for up to 7 days because of the steep death phase of this organism in culture. This is less critical for Mycoplasma spp., for which a once-daily inspection of broth cultures is sufficient. Agar plates should be examined, using a stereomicroscope at a magnification of ×20 to ×60, daily for Ureaplasma spp., at 1- to 3-day intervals for M. hominis, and every 3 to 5 days for M. pneumoniae and other slower-growing species. Ureaplasma colonies (Fig. 3) can be identified on A8 agar by urease production in the presence of the CaCl₂ indicator contained in the medium. The larger M. hominis colonies are urease negative and often have the typical fried-egg appearance (Fig. 1). Other species, such as M. pneumoniae and M. genitalium, produce much smaller spherical colonies, which may or may not demonstrate the fried-egg appearance (Fig. 2). Methylene blue stain applied directly to the agar plate to turn the colonies blue is sometimes useful if there is uncertainty about whether or not mycoplasmal colonies are present. M. hominis is the only pathogenic mycoplasma of humans cultivable on bacterial media such as chocolate agar or blood agar. However, the pinpoint translucent colonies are easily overlooked, and routine bacterial cultures may be discarded soon after the time needed for M. hominis colonies to develop, which may require 4 days or more in some cases. Occurrence of suspicious colonies warrants subculture to appropriate mycoplasma media.

Commercial Media and Culture Kits
In response to the growing desires of many independent or hospital-based clinical laboratories to offer mycoplasmal culturing on-site, numerous companies have developed transport and growth media. A variety of kits for detection, quantitation, identification, and antimicrobial susceptibility testing of Ureaplasma spp. and M. hominis from urogenital specimens are available in Europe. Two products, Mycoscreen Plus and Mycofast US, are now distributed in the United States by Wescor, Inc. (Logan, UT). These kits consist of strips with wells containing specific dried or lyophilized substrates and inhibitors. Specimens are placed in a suspension transport medium that is used to inoculate wells. The detection, identification, and quantitation of organisms are based on the color change of specific wells containing substrates and inhibitors.

Some kits and other commercial products and media sold in various countries have been evaluated by independent investigators (111, 112). Commercial products and kits can be of particular value if the need to detect mycoplasmas arises infrequently in laboratories that do not specialize in mycoplasma detection, but users should be aware of the potential limitations of existing products. If commercially prepared media are to be utilized, it is advisable that laboratories perform internal quality control tests.

IDENTIFICATION
Even though the numerous large-colony mycoplasmal species that can be isolated from humans cannot be identified based on colonial morphology or a particular biochemical profile, the body site of origin and rate of growth, in conjunction with biochemical features, give some clues. Biochemical properties such as glucose, arginine, or urea utilization are determined based on color change in the absence of turbidity in the appropriate broth. Utilization of glucose by a mycoplasma in SP4 broth produces an acidic shift (red to yellow), whereas utilization of arginine produces a red to deeper-red color change in this broth in the presence of the phenol red pH indicator. Urea or arginine utilization in 10B broth causes an alkaline shift from orange to deep red. Thus, a slow-growing glycolytic organism from the respiratory tract that produces spherical colonies on SP4 agar after approximately 5 to 20 days of incubation and exhibits hemolytic activity and hemadsorption with guinea pig erythrocytes is most likely to be M. pneumoniae. Oral commensal Mycoplasma spp. that can be present alone or simultaneously with M. pneumoniae usually result in an alkaline shift (pink to deep red) in SP4 media and produce fried-egg-type colonies on agar. An alkaline color change that occurs after overnight incubation without turbidity in 10B broth containing urea is almost certainly due to Ureaplasma spp., whereas a urogenital specimen that produces an alkaline reaction within 24 to 72 hours in broth supplemented with arginine is likely to contain M. hominis. Examination of colonial morphology is sufficient to identify Ureaplasma spp., and it is important to keep in mind that these organisms often coexist with M. hominis in urogenital specimens.

In order to identify a large-colony mycoplasma to the species level, a number of different techniques are available, although they are more appropriately performed by a reference laboratory than by a hospital microbiology laboratory because of their complexity and the lack of commercial availability of the reagents required. PCR is the best overall choice for mycoplasma species identification since it is much simpler to perform than other methods and it does not require immunological reagents that are not readily available. The PCR assay is also less subjective to interpret than some of the older methods such as epi-immunofluorescence. An emerging alternative for bacterial species identification, matrix-assisted laser desorption ionization–time of flight mass spectrometry (MALDI-TOF MS), has now been applied by Pereyre and colleagues to the identification and subtyping of human mycoplasmas (113). Following broth culture and protein extraction, MALDI-TOF MS was applied for the identification of 119 human clinical isolates that were previously identified by antigenic or molecular methods. MALDI-TOF MS was shown to accurately identify most of the organisms and to cluster M. pneumoniae isolates by their adhesin P1 type.

TYPOGRAPHY
Several methods for typing mollicutes have been described and used as a means to study epidemiology in the case of M. pneumoniae and differential pathogenicity for the 14 serotypes of Ureaplasma spp. Results of early studies have
been varied and inconsistent due to the inefficient and imprecise methods available, occurrence of multiple cross-reactions, and the fact that many persons can harbor more than one serotype in their urogenital tract in the presence or absence of disease. Development of monoclonal antibodies enabled identification of multiple-band antigens responsible for Ureaplasma serotype specificity on the cell surface. PCR-based assays have enabled more-accurate characterization of the two genomic clusters of Ureaplasma spp., which led to their designation as two separate species. Pulsed-field gel electrophoresis (PFGE) has been applied to Ureaplasma spp. to determine the size of the genome, and this technique can distinguish among most of the 14 Ureaplasma serotypes and detect differences within serotypes (114–116).

Restriction fragment length polymorphism, multiplex variable-number tandem-repeat analysis (MLVR), Western blotting, two-dimensional gel electrophoresis, and PCR assays have been used to characterize M. pneumoniae clinical isolates (117–121). Most evaluations have determined that there are two major genomic groups or subtypes distinguishable by analysis of the P1 adhesin gene, ORF6 gene, P65 gene, and typical DNA restriction fragment patterns. In view of the recent findings of extensive horizontal gene transfer among Ureaplasma serotypes and lack of association at the serovar level with any disease condition, serotyping is not recommended for diagnostic purposes (27). Facilities for typing of human mycoplasmas or ureaplasmas for epidemiological purposes are generally unavailable except in specialized research or reference laboratories.

**SEROLOGIC TESTS**

*M. pneumoniae* Respiratory Disease

Historically, serology has been the most common laboratory means for diagnosis of *M. pneumoniae* respiratory tract infections. Although culture and PCR are also used to detect the presence of *M. pneumoniae* in respiratory specimens, persistence of the organism for variable lengths of time following acute infection makes it difficult in some cases to assess the significance of a positive culture or PCR assay without additional confirmatory tests such as seroconversion.

*M. pneumoniae* has both lipid and protein antigens that elicit antibody responses that can be detected after about 1 week of illness, peaking at 3 to 6 weeks, followed by a gradual decline, allowing several different types of serological assays based on different antigens and technologies. Serology is a very useful epidemiologic tool in circumstances where the likelihood of mycoplasmal disease is high, but it is less suited for assessment of individual patients in a timely manner. Its main disadvantage is the need for both acute- and convalescent-phase sera has limited their utility for prompt point-of-care diagnosis. A membrane-based ELISA specific for IgM, the ImmunoCard (Meridian Bioscience), was developed for rapid detection of acute *M. pneumoniae* infection using a single serum specimen. However, in one study this ELIA had a sensitivity of only 31.8% when a single serum was analyzed from seropositive children with pneumonia, increasing to 88% when paired sera were analyzed (125). The Remel ELIA (Thermo Fisher) is another rapid point-of-care qualitative serologic assay that detects both IgM and IgG simultaneously in an easy-to-read format without the need for instrumentation. This test has shown good sensitivity and specificity compared to other EIAs, IFAs, and CF tests. Several comparison studies have been performed, evaluating each of the ELIA kits listed in Table 3 and various others (122–124, 126–131). A comprehensive evaluation of 12 commercial EIAs and PAs was performed in the Netherlands using PCR as a reference standard. The authors found that most assays had problems with sensitivity and specificity, indicating limitations for their use in diagnosis of acute infections, reaffirming the necessity of testing both IgM and IgG in paired sera from adults, and suggested that the PCR assay is a better diagnostic approach (129). In another study (132), sera from a substantial proportion of healthy blood donors had measurable antibody against *M. pneumoniae*, suggesting cross-reactivity of the antigens used in some of the commercial EIAs and the likelihood that their use results in overdiagnosis of mycoplasmal infections. Selection of the best commercial
EIA for individual patient diagnosis depends on the age of the patient being tested, the timing of serum collection, the availability of paired sera, the equipment available, and the experience of the laboratory personnel who perform the test. However, maintaining a large variety of different assays within one laboratory is not practical or cost-effective. A combination of IgM or IgA serology and PCR might be an optimum diagnostic approach, but it could be less useful for adults who do not mount an IgM response and would add considerable cost to laboratory testing. Cold agglutinins, detected by agglutination of type O rhesus (Rh)-negative erythrocytes at 4°C, occur in association with M. pneumoniae infection, but only in about 50% of cases. Titers of 64 to 128 or a 4-fold or greater rise in titer suggests a recent infection, but only in about 50% of cases. Titers of 64 to 128 or a 4-fold or greater rise in titer suggests a recent infection. However, maintaining a large variety of different assays within one laboratory is not practical or cost-effective. A combination of IgM or IgA serology and PCR might be an optimum diagnostic approach, but it could be less useful for adults who do not mount an IgM response and would add considerable cost to laboratory testing. Cold agglutinins, detected by agglutination of type O rhesus (Rh)-negative erythrocytes at 4°C, occur in association with M. pneumoniae infection, but only in about 50% of cases. Therefore, detection of cold agglutinins is not recommended for serologic diagnosis of M. pneumoniae infection.

**Antimicrobial Susceptibilities**

**Methods Used**

Several methods of susceptibility testing have been employed for testing mycoplasmas. Agar dilution has been used as a reference method (139). It has the advantages of a relatively stable endpoint over time, the inoculum size does not have a great effect, and it allows detection of mixed cultures readily. However, this technique is not practical for testing small numbers of strains or occasional isolates encountered in diagnostic laboratories. Agar disk diffusion is not useful for testing mycoplasmas, since there has been no correlation between inhibitory zones and MICs, and the relatively slow growth of some of these bacteria.

**Infections Due to Genital Mycoplasmas**

Serologic tests for M. hominis and Ureaplasma spp. using the techniques of microimmunofluorescence, metabolism inhibition, and EIA have been described (133–135). A microimmunofluorescence assay for M. genitalium has also been developed (136) and shown to detect antibody responses in men with NGU (137) and women with salpingitis (138). This method is rapid, reproducible, and quite sensitive and specific, there being less cross-reactivity with M. pneumoniae than is seen with other methods. A sensitive and specific serological assay for M. genitalium using lipid-associated membrane proteins as antigens has also been developed, and this technique has been used in combination with Western immunoblotting to assess the immunoreactivity of women who were regarded as culture positive for M. genitalium (86). No serologic tests for genital mycoplasmas have been standardized and made commercially available for diagnostic use in the United States. Therefore, they cannot be recommended for routine diagnostic purposes.
organisms further limits application of this technology. Studies using the agar gradient diffusion technique (Etest; bioMérieux) for detection of tetracycline and fluoroquinolone susceptibilities in *M. hominis* and *Ureaplasma* spp. yielded results comparable to both broth microdilution and agar dilution, although the procedures for performing the Etest MIC are not standardized (140–142). Staining plates with Dienes’ stain helps visualize the ellipse on the agar plate. Etest advantages include the simplicity of agar-based testing, an endpoint that does not shift over time, absence of large inoculum effect, and its easy adaptability for testing single isolates. This technique is adaptable for laboratories not specializing in mycoplasma diagnosis that encounter isolates needing susceptibility tests only on an occasional basis. Etests are commercially available, can be maintained frozen for 3 to 5 years, and work well with commercial SP4 broth and agar. Broth microdilution is the most practical and widely used method to determine MICs. It is economical and allows several antimicrobials to be tested in the same microtiter plate but has some disadvantages in that preparation of antimicrobial dilutions is labor-intensive and the endpoint tends to shift over time (110).

Standardized consensus-based methods, designated quality control reference strains with defined MIC ranges, medium formulations for broth microdilution and agar dilution, as well as MIC breakpoints for selected antimicrobial agents have now been published for human mycoplasmas and ureaplasmas by the Clinical and Laboratory Standards Institute (CLSI) (143). Since standardized methods for MIC determination and quality control are now available, these procedures should be used whenever MIC testing is needed. Bactericidal activity can be tested directly from the wells in broth microdilution MIC assays that have not changed color by removing the mixture of organisms and antibiotic, diluting it to subinhibitory concentrations in fresh medium, and observing for a color change as evidence of growth. This method is described in more detail in another publication (110).

Susceptibility testing kits using the broth microdilution technique, such as Mycoplasma IST2 (bioMérieux, Marcy-l’Etoile, France), SIR Mycoplasma (Bio-Rad, Hercules, CA), MYCOFAST Evolution2, Evolution3, and RevolutioN (ELItech, Puteaux, France), and Myco-Kit-ATB (Eurobio, Courtabeuf, France), are sold in Europe but not in the United States. Some of these kits combine detection and identification in the same product. They consist of microtiter wells containing dried antimicrobials, generally in one or two concentrations corresponding to the thresholds proposed for conventional bacteria to classify the strains as susceptible, intermediate, or resistant. To date, only the RevolutioN kit has adapted the antibiotics tested and their concentrations to the new mycoplasma susceptibility testing guidelines published by the CLSI, which include the designations for susceptibility and resistance.

### Susceptibility Profiles and Treatment

A comparison of MICs for several antimicrobial agents is shown in Table 4. Mollicutes are intrinsically resistant to all beta-lactams, sulfonamides, trimethoprim, and rifampin. Resistance to macrolides and lincosamides is variable according to

*Data were compiled from multiple published studies in which different methodologies and often different antimicrobial concentrations were used. ND, no data available.

1. Tetracycline-susceptible isolates only. Tetracycline MICs for resistant isolates containing tetrA are 2 to >64 μg/ml.

2. Macrolide-susceptible isolates only. Erythromycin MICs for resistant isolates containing mutations in domain V of 23S rRNA are ≥32 μg/ml.

3. Macrolide-susceptible isolates only. Erythromycin MICs for resistant isolates containing 23S rRNA mutations or mutations and/or deletions in L4 ribosomal proteins are usually ≥32 μg/ml.

4. Data include only macrolide-resistant strains with MICs of 0.5 μg/ml. Corresponding azithromycin MICs were >12 μg/ml.

5. Macrolide-resistant strains only. Levofloxacin MICs for resistant isolates containing gyrA and/or parC mutations are 4 to 32 μg/ml.
to species, with M. hominis being resistant to erythromycin and other 14- and 15-membered macrolides but susceptible to clindamycin. For Ureaplasma spp., the reverse is true. Newer macrolides and ketolides have shown in vitro activity comparable to or better than that of erythromycin for M. pneumoniae.

M. pneumoniae has historically been predictably susceptible to fluoroquinolones, tetracyclines, and macrolides, so that susceptibility testing has not been recommended except for the in vitro evaluation of new and previously untested agents. However, studies from Japan, China, Europe, and the United States found that high-level macrolide resistance in M. pneumoniae due to mutations in domain V on the 23S rRNA gene is increasing in children and adults with acute respiratory infections (144). This resistance is greatest in China, where the percentage of resistant organisms has exceeded 90%. This high-level resistance can be clinically significant, sometimes necessitating changes to alternative treatments such as fluoroquinolones (145, 146). Molecular methods to detect mutations in rRNA directly in clinical specimens by PCR enable monitoring resistance trends without having to isolate M. pneumoniae in culture and can provide rapid diagnostic information (145, 147, 148). Tetracycline resistance has been well documented in both M. hominis and Ureaplasma spp. since the mid-1980s, mediated by the tetM determinant, which codes for a protein that binds to the ribosomes, protecting them from the actions of these drugs. The extent to which tetracycline resistance occurs in M. hominis and Ureaplasma species varies geographically and according to prior antimicrobial exposure in different populations but may approach 40 to 50% in some locations (11). In recent studies, some isolates of Ureaplasma spp. that contain ribosomal mutations conferring high-level macrolide resistance have been found (149, 150). However, such resistance remains uncommon in the United States. M. genitalium-positive NGU or women with cervicitis respond better to azithromycin than they do to a tetracycline, possibly because of the lower MICs. However, there has been documentation of clinically significant macrolide-resistant M. genitalium due to rRNA mutations (151).

Fluoroquinolones such as levofloxacin and moxifloxacin are usually active against all human mycoplasmal and ureaplasmal species. However, fluoroquinolone-resistant strains of M. hominis, Ureaplasma spp., and M. genitalium with mutations in the DNA gyrase and/or topoisomerase IV genes have been reported (150, 152–156). Other agents such as streptogramins, aminoglycosides, and chloramphenicol can show in vitro inhibitory activity against some mollicute species, but these agents are rarely used to treat infections caused by these organisms. Oxaquinolones such as linezolid are inactive in vitro against mycoplasmas.

Extragenital infections, often in immunocompromised hosts, can be caused by multidrug-resistant mycoplasmas and ureaplasmas, making guidance of chemotheraphy by in vitro susceptibility tests important in this clinical setting. Eradication of infection under these circumstances can be extremely difficult, requiring prolonged therapy, even when the organisms are susceptible to the expected agents. This difficulty highlights the facts that macrolides are inhibited but not killed by most commonly used bacteriostatic antimicrobial agents in concentrations achievable in vitro and that a functioning immune system plays an integral part in their eradication. Treatment of mycoplasmal and ureaplasmal infections has been described elsewhere (157).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Tests offered through diagnostic microbiology laboratories should focus on the species known to cause human disease and for which cultivation techniques are best defined. Unusual organisms or those for which cultivation conditions are not established may be detectable by PCR technology offered through a few specialized research or reference laboratories. Such organisms should be sought only after consultation with clinicians and personnel from the reference laboratory. Except for Ureaplasma spp., which can be identified by urease production and distinct colonial morphology, until species identification can be confirmed, a preliminary report of “large-colony Mycoplasma species” is appropriate.

M. pneumoniae

Detection of M. pneumoniae in culture is time-consuming and not overly sensitive. However, isolation of the organism from respiratory tract specimens is clinically significant in most instances and should be correlated with the presence of clinical respiratory disease, since a small proportion of asymptomatic carriers exist. A mycoplasma isolated by culture from the respiratory tract or from a sterile site that is suspected of being M. pneumoniae should always have species identification confirmed due to the possibility that one of several commensal species inhabiting the upper respiratory tract could also be present. Detection of M. pneumoniae by the PCR assay or other molecular method is becoming more widely available through reference laboratories, but a positive result must still be correlated with clinical events. A 4-fold rise in antibody titer between acute-phase and convalescent-phase sera is considered diagnostic of acute infection. In children, adolescents, and young adults, a single positive IgM result using appropriate immunoglobulin class-specific reagents can be considered diagnostic of acute infection in some, but not necessarily all, cases because of the possibility of prolonged IgM elevation that sometimes occurs. Mild respiratory infections due to M. pneumoniae may not merit a costly and time-consuming microbiological workup since empiric treatment is effective in most instances. However, the emergence of clinically significant macrolide resistance may influence choices of empiric antimicrobial agents.

M. hominis

M. hominis can be detected in culture within a few days. It may occasionally be discovered in routine bacteriologic media from appropriate clinical material, but this should not be relied upon. Its isolation in any quantity from normally sterile body fluids or tissues is significantly associated with disease, and complete species identification is necessary. Quantitation of organisms could also be of value. When mycoplasmas are detected in nonsterile sites such as the female lower genital tract in numbers exceeding 10^9 organisms, they are most likely to be associated with BV.

Ureaplasma Species

Ureaplasmas can be detected in culture within 24 to 48 hours. The characteristic colony morphology and urease production are sufficient for identification at the genus level. Isolation in any quantity from normally sterile body fluids or tissues is significantly associated with disease and can result in a serious infection in neonates or other immunosuppressed persons. Detection of fewer than 10^4 organisms in the male urethra is unlikely to be significant. Distinguishing between the 2 species of Ureaplasma, U. urealyticum and
U. parvum, by the PCR assay could become more important in view of possible differences in pathogenicity in some circumstances, but currently this is not recommended for routine diagnostic purposes.

**M. genitalium**

Growing evidence for the role of *M. genitalium* as a urogenital pathogen has generated interest in the development of diagnostic methods for its detection, though no molecular assays for direct detection or serology test kits have been sold commercially in the United States thus far. Even though cultivation techniques for *M. genitalium* have been described (4, 86, 158), relatively few clinical isolates have actually been attained since the initial description of this mycoplasma in the early 1980s. The slow growth, requiring 6 weeks or longer even in enriched SP4 media, and poor sensitivity make culture impractical. The potential importance of this organism in sexually transmitted urogenital infections underscores the need for improved and standardized methods for its detection. At present, noncommercially, nonstandardized PCR-based assays are available in the United States through reference laboratories. Results of these assays should be used with caution if they are adapted and employed for diagnostic purposes. When *M. genitalium* is detected in clinical specimens from the urogenital tract such as the male urethra or female cervix in persons with clinical evidence of urethritis or cervicitis, it should be considered medically significant.

BACTERIOLOGY

TAXONOMY

Members of the Chlamydiaceae are nonmotile, obligate intracellular prokaryotic bacteria characterized by a unique biphasic developmental cycle bearing two chlamydial forms that differ essentially in terms of morphology and function. According to the Approved List of Bacterial Names, published in 1980, the Chlamydiaceae contained one genus with just two species, Chlamydia trachomatis and Chlamydia psittaci, which were separated by their capability to accumulate glycogen inclusions (Fig. 1A) and their susceptibility to sulfadiazine. In the 1990s, the application of DNA-based classification methods contributed to the recognition of the emerging human pathogen Chlamydia pneumoniae (1) and of Chlamydia pecorum (2), a pathogen of ruminants, as new species of the Chlamydiaceae. Phylogenetic analyses of the 16S and 23S rRNA genes were the rationale for the proposal of an emended description of the order Chlamydiaceae and a revised taxonomy of the family Chlamydiaceae in 1999 (3). According to this proposal, members of the order Chlamydiaceae are obligately intracellular bacteria that have the unique chlamydial-like developmental cycle and more than 80% sequence identity with chlamydial 16S rRNA genes and/or 23S rRNA genes. The emended order now includes four families: Chlamydiaceae, Parachlamydiaceae, Simkaniaaeae (4), and Waddliaceae (5).

Early divergence of C. trachomatis-like strains in the Chlamydiaceae was postulated on the basis of sequence data from the rRNA genes and supported by other data such as genome size, glycogen production, and ompA sequence analysis. This led to the proposal to divide the family Chlamydiaceae into two genera, Chlamydia and Chlamydophila (3). As a consequence, Chlamydia psittaci, Chlamydia trachomatis, and Chlamydia pecorum were proposed to be placed into the new genus Chlamydophila. However, the newly proposed nomenclature was controversial. The division into two genera was especially objected to by experts in the field, who argued that the new genus designations ignore the unique, highly conserved biology shared by these organisms that was recognized when they were in a single genus (6). Although the new taxonomy was validly published, the scientific chlamydia community has consistently rejected the use of the term Chlamydophila, and its use has been abandoned (7).

DESCRIPTION OF THE FAMILY

The Chlamydiaceae contain the known human pathogens C. trachomatis, C. pneumoniae, and C. psittaci as well as organisms such as C. abortus and C. felis that have been rarely associated with human infections. Members of the Chlamydiaceae show less than 10% overall 16S rRNA gene diversity and less than 10% overall 23S rRNA gene diversity. The genome sizes of the Chlamydiaceae range from 1.0 to 1.24 Mbp with a G+C content of about 40%.

The cell wall harbors a common lipopolysaccharide (LPS) that differs from LPS of other bacteria in its relatively low endotoxic activity. Accounting for about 60% of the protein mass, the 40-kDa chlamydial major outer membrane protein (MOMP), encoded by the ompA gene, is an important structural component of the organisms’ outer membrane. The variable domains 1 through 4 (VD1 through 4) lead to multiple C. trachomatis serovars associated with different clinical manifestations of oculargential infections. In contrast, C. pneumoniae isolates possess a strikingly high MOMP homology and serovars of C. pneumoniae have not been described.

Members of the Chlamydiaceae share a unique biphasic developmental cycle leading to important consequences in laboratory diagnosis, clinical course, and antibiotic therapy. The elementary body (EB) of chlamydiae infects eukaryotic host cells and can survive for only a limited period of time outside the host cell. Once inside the host cell, EBs differentiate to metabolically active reticulate bodies (RB) that multiply by binary fission (Fig. 1D) within vacuoles that are continuously growing and that develop into large intracytoplasmic inclusions (Fig. 1C). Reticulate bodies reorganize back to EBs at the end of the chlamydial developmental cycle (Fig. 1D). After 48 to 72 h, hundreds of EBs are released from the host cell, using two mutually exclusive pathways to perpetuate the infectious cycle (8). Genomic transcriptional analysis of the chlamydial developmental cycle reveals a small subset of genes that control the differentiation stages of the cycle and have evolutionary origins in eukaryotic lineages (9).

There is accumulating evidence that factors including gamma interferon, antibiotics, and nutrient deprivation may drive chlamydiae into a state of persistence. Persistent chlamydial forms are morphologically characterized by aberrantly enlarged RBs located within small intracellular inclusions that are arrested in a viable but noninfectious state. It was proposed that persistence is an alternative life cycle.
FIGURE 1  Identification of C. trachomatis by staining intracytoplasmic inclusions with iodine (A) and FITC-conjugated monoclonal antibody directed at the MOMP (B). Transmission electron microscopy of a C. pneumoniae-infected cell shows an intracytoplasmic inclusion impressing the cell nucleus (C) and filled with EBs and RBs (D) at 60 h postinfection; the arrowhead shows a dividing RB. (E) Identification of culture-grown C. pneumoniae by fluorescence in situ hybridization using rRNA-targeted oligonucleotide probes. Simultaneous use of a Cy5-labeled probe that targets a chlamydial 16S rRNA sequence common to all members of the Chlamydiaceae (blue) and a Cy3-labeled probe specific for C. pneumoniae (red). Due to the overlap of colors, C. pneumoniae appears purple in the composite image; host cells are counterstained by a 5(6)-carboxyfluorescein-N-hydroxysuccinimide ester (FLUOS)-labeled eukaryotic probe (green). (F) IgG-MIF image (magnification, ×400) showing bright homogeneous fluorescence of C. pneumoniae EBs at a serum dilution of 1:512. (Photographs courtesy of Sonja Maier, Sven Poppert, and Ulrike Simnacher, Department of Medical Microbiology and Hygiene, University of Ulm; and Matthias Horn, Division of Microbial Ecology, University of Vienna.) doi:10.1128/9781555817381.ch63.f1
used by chlamydiae to avoid the host immune response. As a consequence, chronic infections have been attributed to chlamydial persistence (10). However, the clinical significance of chlamydial persistence is still a matter of debate because diagnostic tools to detect persistence in the human host are lacking.

The chlamydiae can elicit the induction of host cell apoptosis under some circumstances and actively inhibit apoptosis under others (11). This illustrates an important strategy that chlamydiae have evolved to promote their survival through the modulation of programmed cell death pathways in infected host cells.

Sequence information is available for C. trachomatis including lymphogranuloma venereum (LGV) isolates (12, 13), C. psittaci (14), C. pneumoniae (15), C. caviae (16), C. abortus (17), C. felis (18), and C. muridarum (19). Comparative analyses of chlamydial genomes have provided a novel understanding of the common biological processes required for infection and survival in mammalian cells and allowed new insights in evolutionary dynamics, host and tissue tropism, and virulence determinants of the chlamydiae (15, 20–23). Genome analysis of a Chlamydia-like endosymbiont of Acanthamoeba showed that about 700 million years ago the last common ancestor of pathogenic and symbiotic chlamydiae was already adapted to intracellular survival in early eukaryotes and contained many virulence factors found in modern pathogenic chlamydiae, including a type III secretion system (24).

CLINICAL SIGNIFICANCE, EPIDEMIOLOGY, AND TRANSMISSION

C. trachomatis

Based on the antigenic reactivity of the MOMP, C. trachomatis is currently divided into 18 serovars. Serovars A, B, Ba, and C can be isolated from patients with clinical trachoma in areas of endemicity in poor countries in Africa, the Middle East, Asia, and South America. Acute manifestations of trachoma primarily include a follicular keratoconjunctivitis, while late-stage manifestations include tarsalconjunctival scarring with trichiasis, entropion, and subsequent loss of vision (25). According to estimates of the World Health Organization (WHO), approximately 1.3 million people in the world suffer from preventable blindness due to trachoma. Trachoma is transmitted under poor hygienic conditions between members of the same family or between families with shared facilities via discharges from the eyes of infected patients. Flies feeding from the mucopurulent eye discharges of infected and weakened humans may carry the organisms on their legs from one person to another across relatively long distances. A WHO Global Initiative aims to eliminate blinding trachoma by 2020.

The C. trachomatis serovars D through K, including the serovars Da and Ia and the genovariant Ja, are associated with genital tract disease and are among the most common sexually transmitted bacterial organisms in industrialized countries. According to surveillance data of the Centers for Disease Control and Prevention (CDC), these organisms are responsible for an estimated 2 to 3 million new cases every year in the United States, with 1.4 million cases reported in 2012 in the United States (26). In Europe, more than 300,000 cases were reported in 2011, basically by the United Kingdom and the Scandinavian countries. The C. trachomatis serovars D through K typically cause nongonococcal urethritis in men and cervicitis in women. Infection of the urethra and the lower genital tract may cause dysuria, whitish or clear urethral or mucopurulent vaginal discharge, and postcoital bleeding. Urethritis and the rarer manifestations proctitis and conjunctivitis are observed in both men and women. The majority of infections are asymptomatic and therefore remain undetected (27). This can result in ascending infections such as epididymitis in men and endometritis, salpingitis, pelvic inflammatory disease, and perihepatitis (Fitz–Hugh–Curtis syndrome) in women. Manifestations of upper genital infection in women are irregular uterine bleeding, pelvic discomfort, or chronic abdominal pain. Salpingitis may lead to tubal scarring and severe reproductive complications such as tubal factor infertility and ectopic pregnancy. Tubal factor infertility attributable to C. trachomatis is the most frequent form of infection-induced infertility. C. trachomatis-infected pregnant women may transmit the organisms during delivery to the infants, who are therefore at risk to develop neonatal conjunctivitis and/or pneumonia (28, 29). To prevent chlamydial infection in the infant, pregnant women should be routinely screened for Chlamydia trachomatis (30).

Sequelae of C. trachomatis infection in both men and women can involve HLA-B27-associated reactive arthritis, presenting most frequently as an acute asymmetric oligoarthritis with or without enthesopathic and extramusculoskeletal symptoms (31). Among sexually active people, young age is strongly associated with infection, with the highest prevalence in those aged 25 years or less. Additionally, sex workers, persons with a new sex partner, or persons who have had several sex partners are at increased risk of infection. In one study, high prevalence rates were found among incarcerated females entering juvenile and adult correctional facilities (32). Screening women who are at risk for C. trachomatis infection can prevent serious complications such as pelvic inflammatory disease (27). Consequently, female screening programs have been established in some European countries and the United States to identify and treat infections of asymptomatic individuals and their partners. Screening asymptomatic men has been discussed; however, up to now there is insufficient evidence to recommend routine chlamydia screening in men in the general population (33).

The C. trachomatis serovars L1, L2, L2a, and L3 cause lymphogranuloma venereum, a systemic sexually transmitted disease that is endemic in parts of Africa, Asia, South America, and the Caribbean but is rare in industrialized countries. However, ongoing reports about outbreaks with the newly identified variant L2b in Europe, Australia, and the United States show that health care providers should be vigilant for LGV especially among men who have sex with men (MSM) (34–37). The primary lesion, a small, painless papule that tends to ulcerate at the site of inoculation, often escapes attention. Proctitis is more common in people who practice receptive anal intercourse, and abundance of white blood cells in anorectal smear specimens may predict LGV in these patients (38). Ulcer formation favors transmission of HIV and other sexually transmitted and bloodborne diseases. The cardinal feature of LGV is the presence of painful inguinal and/or femoral lymphadenopathy. Complications of LGV include development of coalescing fluctuant lymph nodes (buboes) that result in discharging sinuses and fistula formation. If untreated, fibrosis can lead to lymphatic obstruction, causing elephantiasis of the genitalia.

C. pneumoniae

C. pneumoniae causes infections of the upper and lower respiratory tract such as sinusitis, pharyngitis, bronchitis,
and pneumonia (39). C. pneumoniae was identified as the causative agent in 10 to 15% of cases of community-acquired pneumonia in adults (40) as well as in children (41). However, data from studies yielding prevalence rates under 1% for C. pneumoniae pose the question whether its role in community-acquired pneumonia is overestimated (42, 43). Severe and life-threatening C. pneumoniae infections have been described in patients with acute leukemia and treatment-induced neutropenia (44). Respiratory outbreaks due to C. pneumoniae were observed in military barracks, long-term care facilities, and a federal correctional facility (45). Chronic infection with C. pneumoniae was reported among patients with chronic obstructive pulmonary disease and could also play a role in the natural history of asthma, including exacerbations. The clinical symptoms of C. pneumoniae infection are nonspecific and do not differ significantly from those caused by respiratory viruses and Mycoplasma pneumoniae. Persistent cough does not seem to be strongly associated with C. pneumoniae. Primary infection occurs mainly in school-age children, while reinfection has been observed in adults. Seroprevalence rates from 40 to 70% show that C. pneumoniae is a widely spread organism in industrialized as well as developing countries.

The role of C. pneumoniae in the etiology of atherosclerosis, a chronic inflammatory disease of the artery vessel wall, has been discussed since 1988, when Saikku and coworkers presented serological evidence of an association of C. pneumoniae with coronary heart disease and acute myocardial infarction (47). In subsequent studies, the organisms were identified in atherosclerotic lesions of patients by culture, PCR, immunohistochemistry, and transmission electron microscopy; however, the discrepancies of study results (48), including those of animal studies, and the failure of large-scale treatment studies (49) have raised skepticism about the organism’s causative role in atherosclerosis (50). In addition, a heterogeneous spectrum of extrapulmonary diseases has been linked to C. pneumoniae, including multiple sclerosis, Alzheimer’s disease, and chronic fatigue syndrome; however, a causal relationship between these diseases and C. pneumoniae infection has not been substantiated.

C. psittaci

Psittacine birds and a wide range of other avian species can act as natural reservoirs for C. psittaci. In addition, a variety of mammalian species may host C. psittaci (3, 51). Based on the ompA sequence, Chlamydia psittaci harbors 9 genotypes (14). Some strains previously designated as belonging to the C. psittaci species have been placed into several animal species such as C. abortus, C. muridarum, C. suis, C. felis, and C. caviae. All birds are susceptible; however, pet birds (parrots, parakeets, macaws, and cockatiels) and poultry (turkeys and ducks) are most frequently involved in C. psittaci transmission to humans. Exposure is greatest in poultry breeders and processing workers, as well as in households with pet birds. Infectious forms of the organisms are shed from symptomatic and from apparently healthy birds and may remain viable for several months. C. psittaci can be readily transmitted to humans either by direct contact with infected birds or following inhalation of aerosols from nasal discharges and from infectious fecal or feather dust. Transmission from person to person has been suggested but has never been proven. Symptomatic C. psittaci infection in humans may present as a severe chronic pneumonia (52), although mild illness and asymptomatic infections in persons exposed to infected birds have also been observed. Typical symptoms include fever, chills, muscular aches and pains, severe headache, hepato- and/or splenomegaly, and gastrointestinal symptoms. Cardiac complications may involve endocarditis and myocarditis. Fatal cases were common in the preantibiotic era. Due to the quarantine of imported birds and improved veterinary-hygienic measures, outbreaks and sporadic cases of psittacosis are rarely observed nowadays. Since 1996, fewer than 50 confirmed cases have been reported in the United States each year.

C. abortus

Chlamydiae associated with ruminant abortion and formerly contained within the Chlamydia psittaci taxon were transferred to a new species: C. abortus (53). C. abortus has been acknowledged as a cause of abortion and fetal loss in sheep and has also been broadly detected in calves. There are a number of reports of pregnant women who have had spontaneous abortions following exposure to animals infected with C. abortus (54, 55). The incidence of this animal-acquired infection is not known, but sheep and goats during the birthing season represent a potential risk to pregnant women. Obstetricians should consider this diagnosis along with early antibiotic treatment and cesarean section delivery in the context of the patient’s case history.

Environmental Chlamydiae

The host range of chlamydiae was further broadened with the discovery of Chlamydia-related endosymbionts in free-living amoebae. The so-called environmental chlamydiae that have been placed in the family Parachlamydiaceae share the chlamydial developmental cycle and represent evolutionary early-diverging sisters of the pathogenic chlamydiae (24). Environmental chlamydiae were discussed as potential emerging pathogens (56); however, clinical evidence for their importance in human infection is still pending. Simkania negevensis, currently the only member of the Simkaniaeae, is a recently discovered Chlamydia-like intracellular agent that has been associated with respiratory infections in infants (4). The natural host of Simkania is not known; however, the organism was successfully grown in various cell lines as well as in free-living amoebae and was identified in drinking water and in reclaimed wastewater.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

General Comments

Since chlamydiae are obligate intracellular pathogens, the objective of specimen collection should be to include the host cells that harbor the organisms. Outside their host, chlamydiae survive only briefly, and efforts must be undertaken to maintain the organisms’ viability for successful culture. Commercial diagnostic nonculture assays do not require the presence of viable chlamydiae in the specimen; nevertheless, the instructions of the manufacturers given in the package insert should be followed for appropriate collection, transport, and storage of specimens. This includes the use of swabs and transport media specified by the manufacturer.

For successful culture of chlamydiae, the time between collection and processing of the specimens in the laboratory should be minimized and specimens should be kept cold (4 to 8°C). Specimens should be forwarded to the laboratory within 24 h in a special chlamydial transport medium such as 2-sucrose phosphate or sucrose phosphate glutamate supplemented with fetal bovine serum (5 to 10%), gentamicin (10 μg/ml), vancomycin (25 to 100 μg/ml), and amphotericin B (2 μg/ml) or nystatin (25 U/ml). Tetracyclines, macrolides,
and penicillins cannot be used in the transport medium since they have activity against chlamydiae. If specimens cannot be processed within 24 h, storage at −70°C in transport medium is acceptable. Specimens for culture should not be stored at −20°C or in frost-free freezers. Swab specimens should be collected on swabs with a Dacron tip and an aluminum or plastic shaft. Swab tips made of calcium alginate and swabs with wooden shafts may inhibit the growth of chlamydiae. It is recommended to check new lots of swabs that are used to collect specimens for culture of chlamydiae for possible inhibition of chlamydial growth (57).

C. trachomatis

The type and anatomical site of specimen collection for laboratory diagnosis of C. trachomatis infection depend on both the clinical picture and the laboratory test selection, as comprehensively reviewed elsewhere (25, 58, 59). Table 1 gives an overview of the ranges of sensitivity and specificity for common diagnostic tests for Chlamydia trachomatis in urogenital specimens.

</table>

<sup>a</sup>Sensitivities and specificities are adapted from published clinical trial data (72, 73, 76–80) and are published in package inserts.
<sup>b</sup>Asymptomatic and symptomatic patient results.
<sup>c</sup>Clinician-collected and self-collected vaginal swabs.
<sup>d</sup>All patient-collected vaginal swabs.

Traditional sites for specimen collection in C. trachomatis genital tract infection have involved the endocervix in females and the urethra in males, especially for symptomatic patients. The newly recommended specimen additions include so-called noninvasive specimens such as vaginal samples for women and first-void urines (FVU; the first 10 to 30 ml of urine) for men, but only when highly sensitive nucleic acid amplification tests (NAATs) are used (59, 60). Urine or vaginal specimens are specifically not recommended by the CDC for testing by culture and nonamplification tests such as enzyme immunoassay (EIA), direct fluorescence antibody assays (DFA), and nucleic acid hybridization (NAH) because of their very low sensitivity (58).

The noninvasive specimens are ideal for screening asymptomatic patients but can also be used for symptomatic patients. Sensitivity and specificity of NAATs for C. trachomatis on noninvasively collected specimens are similar to those obtained with samples collected directly from the cervix or urethra (61, 62). FVU specimens should be obtained at least 2 h after the last micturition. Ambient-
temperature storage of fresh unprocessed urine should not exceed 24 h to avoid denaturation of chlamydial DNA. Subsequent processing of the urine specimens for NAAT varies depending on the manufacturers’ instructions. Since culture and older, less sensitive tests are falling into disuse, the preferred samples recommended for screening asymptomatic women are vaginal swabs, which can be self-collected for some assays. Self-obtained vaginal swabs are gaining in practical use (63) and have been recommended again in new CDC laboratory guidelines as highly accurate and acceptable samples (64). It was shown that for women, self-collected vaginal swabs had a higher mean chlamydial load than did first-void urines (65).

In cases where culture is performed, although rare today, proficient specimen collection including speculum examination in females is required to obtain appropriate samples that contain sufficient columnar or squamocolumnar epithelial cells. Purulent discharges have to be cleaned before a swab is inserted 1 to 2 cm into the cervical os past the squamocolumnar junction, rotated more than two times, and removed without touching the vaginal mucosa. Urethral specimens from males are collected by placing a dry swab 3 to 4 cm into the urethra and rotating prior to removal. Urination prior to specimen collection may reduce test sensitivity by washing out infected columnar epithelial cells. In women with salpingitis, samples may be collected by needle aspiration of the involved fallopian tube. Endometrial specimens have also yielded chlamydiae. Further appropriate sites include the conjunctiva in chlamydial eye infection (trachoma, inclusion conjunctivitis, and newborn conjunctivitis) and the nasopharynx and deeper respiratory tract of infants in newborn pneumonia. For men who have sex with men, screening of rectal and pharyngeal specimens is recommended since some reports support the utility of commercial NAATs as a screening test for this population (66, 67). In cases of suspected LGV, ulcer swabs, aspirates of bubo fluid, and rectal or urethral swabs should be collected in transport medium. Buboes of LGV may contain only small amounts of a thin milky fluid, and it may be necessary to inject 2 to 5 ml of sterile saline to obtain any fluid by aspiration.

C. pneumoniae

The optimal sites for specimen collection in C. pneumoniae infection are poorly defined. Respiratory specimens from which the organisms were cultured include sputum, bronchoalveolar lavage fluids, nasopharyngeal aspirates, throat washings, and throat swabs (tonsil area). Swab specimens should be collected using a Dacron tip and a plastic shaft (57) and placed immediately in transport medium. Specimens need to be kept at 4 to 8°C in chlamydial transport medium, since the organisms are inactivated rapidly at room temperature. Rapid freezing or freezing and thawing of specimens should be avoided (39). Liquid specimens are collected in transport medium at a specimen-to-medium ratio of 1:2 (57). Testing of vascular tissue specimens and blood samples is of questionable value.

C. psittaci

C. psittaci strains seem to be the most stable organisms among the pathogenic chlamydiae. Nevertheless, specimens should be collected in chlamydial transport medium. Appropriate specimens include sputum, bronchoalveolar lavage fluid, pleural fluid, blood, and tissue biopsy specimens from various anatomical sites. Culture is no longer recommended because of the potential for laboratory-acquired infections.

DIRECT EXAMINATION

Nucleic Acid Amplification Tests

C. trachomatis

Due to their high sensitivity and specificity, NAATs are the tests of choice for the diagnosis of genital C. trachomatis infections in routine clinical laboratories. NAATs can be used to detect C. trachomatis without a pelvic examination or intraurethral swab specimen by testing self- or clinician-collected vaginal swabs or urine, respectively (60, 68). This facilitates the establishment of screening programs in asymptomatic individuals and may enhance the compliance for testing asymptomatic contact persons of infected individuals. NAATs on urine, with confirmation, were shown to be adequate for use as a new forensic standard for diagnosis of CT and NG in children suspected of being sexually abused (69). Increasing experience is available for the use of NAATs in conjunctival, oropharyngeal, and rectal samples (66, 67) and in LGV (70, 71). All commercial NAATs detect LGV serovars as C. trachomatis, but none can differentiate them as LGV. Only research PCR assays have this ability. Thus far, no commercial company has an FDA-cleared test for alternative sample types from extragenital sites, but it is possible for laboratories to use these samples for testing by NAATs if they perform a verification study to indicate their performance. If such verification is performed, Clinical Laboratory Improvement Amendments (CLIA) compliance can be demonstrated (58). Commercial NAATs seem to work in cases of newborn conjunctivitis (28), but no company has an FDA claim. For research studies of trachoma patients, NAATs have been recommended and are now being used by trachoma researchers as the “gold standard” (72). However, the available commercial assays may be too expensive and too complex for use in some national trachoma programs (25). In many evaluations, NAATs detected 20 to 30% more positive specimens than could be detected by earlier technologies.

Licensed NAATs for detection of C. trachomatis include (in the order of their introduction) the PCR-based Roche Amplicor (Roche Diagnostics, Basel, Switzerland), the Aptima transcription-mediated amplification (Gen-Probe/Hologic, Inc., San Diego, CA), the BD ProbeTec strand displacement amplification (SDA; Becton Dickinson and Company, Diagnostic Systems, Franklin Lakes, NJ), the m2000 real-time PCR (Abbott Molecular, Des Plaines, IL), and the GeneXpert CT/NG real-time PCR assay (Cepheid, San Jose, CA). The GeneXpert is a modular cartridge-based platform that allows molecular point-of-care testing (POCT) because it can be performed in on-site laboratories and may provide results at the time of patient visits (73). Licensed assays working on fully automated platforms for use in high-volume laboratories include the Roche Cobas Taqman, Cobas c4800, Abbott m2000, BD ProbeTec (Viper), and Aptima (Tigris and Panther) (61, 73–80).

Both the PCR and SDA assays amplify nucleotide sequences of the 7.5-kb cryptic plasmid of C. trachomatis, which is present in an average copy number of about four plasmids per chromosome in EBs and up to seven plasmids per chromosome in replicating RBs (81). C. trachomatis strains that do not harbor the cryptic plasmid have been sporadically isolated from urethral specimens. A new variant of C. trachomatis was discovered in Sweden but did not gain
substantial clinical and epidemiological relevance outside Sweden. Due to a 377-bp deletion in the target sequence for nucleic acid amplification, this strain had initially escaped detection by some of the licensed NAATs (82, 83), but manufacturers affected by this discovery moved quickly to modify their primers to enable this variant’s detection. The transcription-mediated amplification-based assays target specific sequences of the 23S rRNA, which is also present in multiple copies. Each of the five commercially available NAAT systems offers the option for combination testing of C. trachomatis and Neisseria gonorrhoeae in the same specimen. The transcription-mediated amplification platform is also offered as individual assays for chlamydia infection or gonorrhea.

Considering the multiplicity of target sites for the amplification procedures being used, NAATs should be able to produce a positive signal from less than one EB; however, the actual sensitivity in clinical specimens is lower because of sampling variability due to Poisson distribution and inefficient nucleic acid isolation. Since inhibitor problems of NAATs can be reduced by dilution of specimens, heating, freeze-thaw cycles, or overnight storage at 4°C, the use of internal inhibition controls of the amplification assays (as supplied by the manufacturers of PCR and SDA) is helpful for identification of clinical specimens containing inhibitory factors. Extraction of nucleic acids by target capture and magnetic bead procedures in second-generation NAATs has almost completely eliminated the presence of inhibitors in processed clinical samples. All of these NAATs are highly specific for chlamydia if problems with cross-contamination, labeling errors, and mistakes in specimen collection can be avoided (Table 1). Confirmatory testing of positive specimens was once recommended by CDC if a low positive predictive value was expected (≤90%) or if a false-positive result would have serious psychosocial or legal consequences. However, supplemental testing is no longer recommended for chlamydia or for diagnosis of C. trachomatis or N. gonorrhoeae infection in children suspected of being sexually abused (58, 69, 84).

In settings where resources are limited, including developing countries, the concept of pooling to detect C. trachomatis by NAATs has proved to be a simple, accurate, and cost-effective procedure compared to individual testing (85, 86). Specimen pools may consist of aliquots from 4 to 10 processed specimens (FVU or genital swab) combined into one amplification tube. Subsequent testing of individual samples is required only if the pooled sample gives a positive result. Following this strategy, considerable savings of reagent costs can be obtained, especially in low-prevalence populations.

C. pneumoniae

A vast number of PCR-based protocols using different formats and target genes have been developed in research laboratories for detection of C. pneumoniae in both respiratory and nonrespiratory samples (87). However, the lack of a reliable gold standard for C. pneumoniae infection has made it difficult to evaluate the published protocols thoroughly. Broad applicability of NAATs for diagnosis of C. pneumoniae infection has been hampered because many PCR protocols are not reliable or robust enough to provide reproducible results in routine clinical laboratories. Even in specialized laboratories, there seems to be a substantial interlaboratory variation in the performance of C. pneumoniae NAATs, and the need for quality control and standardization of these assays has been recognized (57, 87). Subsequently, specific recommendations for standardizing C. pneumoniae PCR assays were made, and it was suggested to compare the performance of newly developed PCR protocols with at least one of four recommended assays that target the PSTI fragment (88), the ompA gene (89), or the 16S rRNA gene (90, 91). However, all of these assays must be considered research tools (57), because commercial FDA-cleared assays are currently not available. Real-time PCR technology provides promising results that warrant further evaluation of this approach for detection of C. pneumoniae infection (92–94). A recent review again stated that standardization and validation particularly of PCR assays are urgently needed because the true role of the organism in respiratory infections as well as in extrapulmonary diseases cannot be ascertained at the moment (87).

C. psittaci

NAATs could be helpful for detection of avian C. psittaci strains from clinical samples since culture of these organisms is dangerous, requires biosafety level 3 (BSL-3) facilities, and is not recommended. Some PCR-based assays (82, 89, 90), including a DNA microarray assay (95), have been developed in research laboratories for diagnosis of human ornithosis. Due to the rarity of the disease, the performance characteristics of these assays have been poorly evaluated in clinical specimens.

Nucleic Acid Hybridization Tests

Two NAH tests were previously commercially available for detection of C. trachomatis: the Gen-Probe PACE 2 test and the Digene Hybrid Capture II (Digene Corp., Gaithersburg, MD). The PACE 2 test is no longer commercially available. The use of NAH tests has been replaced by NAATs.

Antigen Detection Assays

Direct Fluorescent Antibody Tests

The presence of typical intracytoplasmic inclusions in columnar epithelial cells of the conjunctiva, urethra, or cervix of infected patients can be demonstrated when air-dried smears are fixed on a slide with absolute methanol and stained with Giemsa. Cytological testing was particularly useful in diagnosing acute inclusion conjunctivitis of the newborn, but the more-sensitive immunofluorescence procedures have largely replaced this method. DFAs use fluorescein isothiocyanate (FITC)-conjugated monoclonal antibodies directed at a C. trachomatis-specific epitope of the MOMP (Chlamydia CEL, from Cellabs, Brookvale, Australia; Pathfinder, from Bio-Rad Laboratories, Redmond, WA). DFAs are based on detecting EBs in smears, although staining of inclusions can also succeed if intact infected host cells are collected. Checking for the presence of columnar cells allows assessment of the adequacy of the sample. The procedure offers rapid diagnosis, taking only 30 min to perform, making DFA tests useful especially for laboratories that test only a limited number of specimens. However, this method requires an experienced microscopist who can distinguish between fluorescing chlamydial particles and nonspecific fluorescence. The DFA test has approximately 75 to 85% sensitivity and 98 to 99% specificity compared with culture and a lower sensitivity than NAATs (96, 97). DFA tests can be another alternative for testing endocervical swabs from females or urethral swabs from males when a NAAT is not available or not economical. In addition, DFAs have been recommended for use with conjunctival specimens and for testing of individuals with possible rectal and pharyngeal exposure to C. trachomatis, if a C. trachomatis
MOMP-specific antibody is used. Nontrachomatis chlamydial conjunctivitis should be considered if DFA testing reveals the presence of chlamydial LPS but not C. trachomatis-specific MOMP.

Enzyme Immunoassays
EIA-based tests for detection of C. trachomatis use either monoclonal or polyclonal antibodies to detect chlamydial LPS, which is more soluble than MOMP. Although they can theoretically detect all chlamydiae, EIAs have not been well evaluated for the diagnosis of infections with C. pneumoniae or C. psittaci. Using cultures as reference standards, the sensitivities of EIAs applied to endocervical swabs were in a range from 62 to 72% (97). EIAs are never recommended for testing of noninvasively collected specimens such as urine and vaginal swabs. EIAs are now considered substandard and are not recommended for use as a diagnostic platform by the CDC.

Point-of-Care Tests
Rapid or point-of-care tests designed for office- or clinic-based settings that provide test results in less than 30 min for C. trachomatis infection in women have been developed. Similar to EIAs, they also use antibodies against chlamydial LPS with the potential to yield false-positive results due to cross-reaction with other Gram-negative bacteria. Current POCTs are not recommended in laboratory settings because sensitivity and specificity are lower, quality controls are less rigorous, and costs are higher than for tests designed for laboratory use. Although some POCTs are FDA cleared, they were compared to culture as the gold standard and now that the new gold standard is NAATs, the package inserts often overstate performance. When compared to PCR, the Clearview POCT demonstrated a sensitivity of 32.8% for vaginal swabs and 49.7% for cervical swabs (98). New POCTs are highly desirable and are being developed. Technologies such as microfluidics and biosensors appear promising but are not yet FDA cleared (99).

ISOILATION

Biosafety Considerations
C. pneumoniae and C. trachomatis are BSL-2 organisms, whereas C. psittaci is a BSL-3 organism. Transmission of the organisms from patient specimens or infected cell cultures can occur through aerosols, splashes onto the mucous membranes of the eyes, and hand-to-face actions. In recent years, fewer laboratory-acquired infections have been reported, probably due to the common usage of class II biosafety cabinets in laboratories that work with Chlamydia-infected cell cultures. Use of a class II biosafety cabinet protects laboratory staff from exposure to aerosols as well as specimens and cell cultures from contamination. Additional means of preventing laboratory-acquired infection include the use of gloves, alcohol-based hand disinfectants, safety centrifuge caps, and face protection, if appropriate. Laboratory infections with C. trachomatis usually manifest as follicular conjunctivitis. The LGV strains are more invasive, and severe cases of laboratory-associated pneumonia and lymphadenitis are reported. C. psittaci must be considered a potentially dangerous organism, requiring appropriate BSL-3 facilities. Laboratory-acquired C. pneumoniae infections might be underestimated, since the mild clinical course may not prompt infected laboratory workers to seek medical attention.

Specimen Processing

Ocular and Genital Tract Specimens
For culture of chlamydiae from ocular and genital tract sites, only swabs that are rapidly forwarded to the laboratory in a special chlamydial transport medium are acceptable (see above). Specimens to be assayed by commercial ELA, DFA, NAATs should be processed as directed by the manufacturer.

Bubo Pus
To prepare bubo pus, the aspirate fluid of fluctuant lymph nodes is ground and then suspended in nutrient broth or cell culture medium to at least 20% by weight. Even when the pus is not viscous, dilution is advisable. The material should be tested for bacterial contaminants and inoculated onto monolayer cultures of McCoy or HeLa 229 cells.

Blood
Blood samples from clotted blood tubes have been used in the past for diagnosis of C. psittaci endocarditis. The blood clot was ground, and cell culture medium was added to make a 10% solution. However, culture is no longer recommended for C. psittaci due to the possibility of laboratory-acquired infections, so this method is reserved for specialized public health and research laboratories.

Sputum, Throat Washings, and Other Secretions from the Respiratory Tract
Sputum and other respiratory samples are suspended in antibiotic-containing transport medium or cell culture medium at a 1:2 to 1:10 ratio of specimen to medium depending on specimen consistency. Specimens are homogenized by adding sterile glass beads to the sample and vigorously vortexing for 1 to 2 min in a tightly stoppered container. Extracts should be centrifuged for 20 to 30 min at 100 × g to remove coarse material before the supernatant fluid is inoculated onto cell monolayers. Serial dilutions may be required if the inoculum is toxic to cells.

Fecal Samples
Human rectal swabs for C. trachomatis and avian material for C. psittaci are suspended in chlamydial transport medium or antibiotic-containing cell culture medium. The suspension is shaken thoroughly and centrifuged at 300 × g for 10 min, and the supernatant is removed. It may be further diluted (1:2 and 1:20) with medium before being inoculated into cell culture. Rectal swabs for commercial NAATs are processed in accordance with the corresponding protocol of the manufacturer.

Tissue Samples
Frozen tissue is thawed in a refrigerator at 4°C. The specimen is weighed, minced with sterile scissors or a scalpel, and ground with a mortar and pestle or homogenizer. A volume of cell culture medium required to make a 10 to 20% suspension is added, and the suspension is thoroughly mixed. For tissue specimens, serial dilutions (1:10 to 1:100) are often required for inoculation to prevent toxicity.

Isolation Procedures
Cell culture was considered the gold standard for diagnosis of genital C. trachomatis infection because its sensitivity and specificity were thought to be close to 100%. Problems associated with cell culture isolation of chlamydiae, including technical complexity, long turnaround time, and strin-
gent requirements related to collection, transport, and storage of specimens, have driven the development of commercially available nonculture methods, which have few requirements and are inoculated in many routine laboratories. With the advent of NAAT detection methods, it became clear that the sensitivity of culture was substantially lower than previously thought, most probably due to the presence of nonviable chlamydiae that died during transport and processing. For detection of chlamydiae in clinical specimens is generally now performed only in specialized laboratories. Culture is recommended in treatment failures (when a viable isolate is needed for susceptibility testing) and in cases related to possible sexual assault for medicolegal reasons, although NAATs on urine have been shown to be adequate for children suspected of being sexually abused (69).

Historically, chlamydiae were cultivated in the yolk sac of embryonated eggs. The yolk sac method (for details, see reference 100) is still used for preparing antigens for the microimmunofluorescence (MIF) test. The ability to propagate chlamydiae in the laboratory has greatly increased the understanding of diagnosis and pathogenesis of chlamydial infections (101). For isolation of chlamydiae from clinical specimens, appropriately collected and transported samples are inoculated onto preformed cell monolayers. A number of susceptible permanent cell lines, including McCoy, HeLa 229, HEp-2, HL, BGMK, Vero, and L cells, have been used. Clinical samples are centrifuged onto monolayers to enhance infection. Strains of C. psittaci and LGV biovars are capable of serial growth in cell culture without centrifugation. Cultures are incubated for 48 to 72 h in the presence of the host cell protein synthesis inhibitor cycloheximide. McCoy and HeLa 229 cells are most commonly used for C. trachomatis. HL and HEp-2 cells seem to be more sensitive for recovery of the fastidious C. pneumoniae from clinical specimens. Visualization of cell culture-grown chlamydiae is achieved by immunostaining of inoculated cell monolayers for intracytoplasmic inclusions. A positive culture shows one or more typical intracellular inclusions (Fig. 1B).

Cell culture methods can vary among laboratories. Host cells are plated either onto 12-mm glass coverslips contained in 15-mm-diameter (1 dram [1 dram = 3.697 ml]) disposable glass vials (shell vial method) or in 6-, 12-, or 24-well tissue culture plates. The cells are seeded in concentrations of 1 × 10^5 to 2 × 10^5 cells/ml to give a healthy and confluent monolayer after 24 to 48 h of incubation. For optimal results, cell monolayers should be inoculated with patient specimens within 24 h after reaching confluence. Clinical specimens are thoroughly vortexed with glass beads in tightly closed screw-cap vials to facilitate release of chlamydiae before inoculation. The cell culture medium of the cell monolayers to be inoculated is discarded and replaced by a volume of 0.2 to 2 ml of the vortexed specimen. The inoculated specimen is centrifuged onto the cell monolayers at 900 to 3,000 × g for 1 h at 22 to 35°C. Cells are incubated at 35°C for 1 to 2 h to allow uptake of chlamydiae before the medium is replaced with chlamydia-free culture medium, consisting of the cell culture medium supplemented with fetal calf serum (10%), L-glutamine (2 mM), cycloheximide (1 to 2 μg/ml), gentamicin (10 μg/ml), vancomycin (25 μg/ml), and amphotericin B (2 μg/ml). Cultures are incubated at 35°C in 5% CO_2 for 48 to 72 h. Then, one coverslip per specimen is removed for immunostaining of inoculated monolayers. Both cell debris and toxic effects of the inoculum may make it difficult to read slides. Dilution of cell-rich material (bubo pus, sputum, tissue samples, and rectal swabs) and blind performance of subpassages can be helpful for microscopic interpretation of slides.

If a blind subpassage or passage of positive material is to be performed, the corresponding cell monolayers of duplicate wells are scraped and disrupted by vortexing with glass beads. Cell debris of harvested material is removed by low-speed centrifugation (300 × g) for 10 min, and the supernatant is passed onto preformed cell monolayers as described above. For C. pneumoniae, most laboratories agree that at least two passages are needed to maximize the recovery of the organisms from respiratory specimens. Modifications of the standard procedure, including use of serum-free culture medium, pretreatment of cell monolayers with polyethylene glycol or diethylaminoethyl-dextran, and extension of culture times, have not been sufficiently tested to warrant their routine recommendation (57). Laboratories processing large numbers of specimens may use flat-bottom 48- or 96-well microtiter plates onto which cells are plated directly. Processing and incubation are as described above, but microscopy is modified because cells are stained directly in the well, requiring use of inverted microscopes and long working objectives.

Continuous quality control is important for maintaining a sensitive and specific culture system. Because of its technical complexity, there are multiple opportunities to modify factors in the culture system that may impact the isolation efficiency (25, 101). Therefore, positive controls with a known number of inclusion-forming units should be run routinely to check the sensitivity of the culture system. Negative controls with uninfected human cells may help to evaluate episodes of cross-contamination as a result of handling positive patient specimens or positive controls. Routine testing of cell culture systems for Mycoplasma contamination has been recommended because Mycoplasma contamination may impair the growth of chlamydiae and may decrease the sensitivity of the culture system (57).

**IDENTIFICATION**

The basic procedure for detection of isolated chlamydiae involves demonstration of intracytoplasmic inclusions by fluorescent-antibody staining that provides both morphological and immunological identification of chlamydiae. Screening of cultures can be performed with a commercially available FITC-conjugated monoclonal anti-LPS antibody (Pathfinder Bio-Rad), which recognizes all chlamydiae known to cause infections in humans. Confirmation of positive genital cultures can be done by the use of a C. trachomatis MOMP-specific monoclonal antibody (Fig. 1B). For respiratory cultures, a C. pneumoniae-specific monoclonal antibody may additionally be appropriate. Monoclonal antibodies specific for C. psittaci are not commercially available. Using DFA procedures, inclusions of C. trachomatis-infected cells are visible at 24 h postinfection. Less expensive but also less sensitive methods that were commonly used before the advent of monoclonal antibodies include Giemsa staining (which needs an experienced and well-trained microscopist for interpretation) and iodine staining for identification of glycoprotein-containing inclusions, which are produced by C. trachomatis but not by C. psittaci or C. pneumoniae (Fig. 1A). Identification of replicating chlamydiae can also be done by fluorescence in situ hybridization using fluorescently labeled oligonucleotide probes complementary to order-, genus-, and species-specific target sites on the chlamydial 16S rRNA molecules (102). The risk of false-positive signals caused by nonspecific binding of the fluorescent dyes to
nontarget organisms or structures of the host cells can be
minimized by the simultaneous application of multiple
probes with hierarchical specificity labeled with different
dyes leading to a characteristic hybridization pattern (Fig.
1E).

**TYPING SYSTEMS**

Serotyping and genotyping procedures are important tools
for epidemiological studies. They are of clinical use if medi-
colegal issues are involved or if lymphogranuloma venereum
is suspected. The most convenient method for serotyping
of *C. trachomatis* isolates appears to be the microwell typing
system (103), in which inclusions in microtiter plates are
stained with pools of monoclonal antibodies (available at
Washington Research Foundation, Seattle, WA) that rec-
ognize serovar- and subspecies-specific epitopes of the
MOMP. Genotyping of *C. trachomatis* isolates usually in-
volves either restriction fragment length polymorphism
analysis of the MOMP-encoding *ompA* gene or sequence
analysis of the variable domains in the *ompA* gene. These
variable regions include the peptides responsible for species,
serovar, and serogroup specificities. PCR amplification and
sequencing of *ompA* using extracted DNA from patient
specimens such as urine or genital samples allow direct
genotyping from *C. trachomatis*-positive individuals without
isolation of the organisms. In addition, new high-resolution
genotyping methods applying a multilocus variable number
tandem repeat assay (MLVA) or multilocus sequence typing
(MLST) have been introduced (104). *ompA*-based proce-
dures (105), including real-time PCR with high-resolution
melt analysis (106) and DNA microarray technology (107),
are used to identify all known and additional new genotypes
of avian *C. psittaci* strains. Different serotypes or genotypes
of *C. pneumoniae* have not been described.

**SEROLOGIC TESTS**

Serological testing may be helpful in the diagnosis of human
ornithosis, lymphogranuloma venereum, neonatal pneumo-
nia caused by *C. trachomatis*, and respiratory *C. pneu-
moniae* infections. Serological testing for diagnosis of uncompli-
cated genital infections of the urethra and the lower genital
tract as well as for *C. trachomatis* screening in asymptomatic
individuals is not recommended. *C. trachomatis* antibody
testing has been proposed as the first screening test for tubal
factor subfertility (108). Antibodies to *C. trachomatis* were
independently associated with reduced rates of pregnancy
and elevated rates of recurrent pelvic inflammatory disease
(PID) (109).

Since a reference standard has not been defined, the
diagnostic value of some serological assays for detection of
chronic or persistent chlamydial infections is difficult to
estimate. General problems of chlamydial serodiagnosis arise
from the difficulty in obtaining paired serum samples, the
high seroprevalence of *C. pneumoniae* in adult populations,
and the lack of standardized species-specific test methods.
The most commonly used serological assay formats include
the complement fixation (CF) test, the MIF test, and the
EIA to detect immunoglobulin M (IgM), IgA, IgG, or total
classes of antibodies with either family, species, or serotype
specificity. Some of these assays have been commercialized
and are being used by clinical laboratories, although their
performance characteristics have been evaluated only in
a limited number of studies.

**CF Test**

The complement fixation test is based on antibody reactivity
to the chlamydial LPS antigen common to all members of the
*Chlamydiaceae*. The CF test may be useful in diagnosing
LGV in patients who present compatible clinical symptoms.
A titer of ≥256 strongly supports the clinical diagnosis, while
a titer of <32 rules it out except in the very early stages of
the disease. In addition, the CF test is useful for diagnosis
of psittacosis; however, in the absence of a typical patient
history (exposure to birds), *C. pneumoniae* infection might
be considered in patients with positive test results. However,
due to its potential for cross-reactivity and its low sensitivity
for reinfection, CF is not recommended for serodiagnosis
of *C. pneumoniae* infections (57). The CF test also lacks
sensitivity for the diagnosis of trachoma, inclusion conjunc-
tivitis, and uncomplicated genital infections caused by *C.
trachomatis*. The CF test is becoming unavailable in many
laboratories, which may limit its usefulness in the near
future.

**MIF Test**

The MIF test developed by Wang and Grayston in the
early 1970s is still considered the method of choice for
serodiagnosis of chlamydial infections. With this procedure,
species- and serovar-specific antibody responses in human
chlamydial infection can be detected. The MIF test allows
quantitative detection of IgM and IgG antibodies that may
be helpful in distinguishing recent from past infections.

The MIF is the diagnostic test of choice for *C. trachomatis*
pneumonitis in infants because elevated levels of IgM anti-
body are regularly associated with disease. A single IgM
titer of ≥32 may support the diagnosis of neonatal pneumo-
nia caused by *C. trachomatis*. IgG antibodies are less useful
because infants may present with typical symptoms when
they still have a high level of maternal IgG. In LGV-infected
individuals, an MIF IgG titer of ≥128 strongly supports the
clinical diagnosis, although invasive genital infection with
*C. trachomatis* serovars D through K, such as pelvic inflam-
matory disease, salpingitis, or epididymitis, can also give
rise to high titers of antichlamydial antibody in serum. The
MIF test may be useful in the diagnosis of psittacosis and
is the serological testing method of choice for diagnosis of
acute *C. pneumoniae* infection. Criteria for acute infection
of *C. pneumoniae* generally include paired sera demonstrat-
ing at least a 4-fold rise in titer and single serum samples
with IgM titers of ≥16 and/or IgG titers of ≥512. However,
single IgG titers of ≥512 should be interpreted with caution
because elevated IgG titers may persist for several years in
the absence of clinically apparent disease (57). IgG titers
in the range of 16 to 256 are suggestive of past infection.
The usefulness of IgA as a diagnostic marker in acute or
chronic *C. pneumoniae* infections has not been substantiated
(57).

The MIF assay is performed using purified formalinized
EBs of representative strains or serovars of *C. trachomatis,
*C. psittaci*, and *C. pneumoniae* that are dotted in a specific
pattern onto glass slides. MIF antigens are commercially
available from the Washington Research Foundation. Serial
dilutions of patient sera are placed over the fixed antigen
dots and incubated, and bound antibody is detected with
fluorescein-conjugated anti-IgG or anti-IgM antibody (Fig.
1F). A more detailed description of the MIF procedure has
been summarized elsewhere (110). In addition, recommenda-
dations for standardizing the MIF assay in terms of antigen
preparation, testing, interpretation of results, and quality
assurance should be followed (57).
The MIF assay format is technically demanding, time-consuming, and less useful for higher volume testing. In addition, subjectivity in reading of titers may contribute to intra- and interlaboratory variation in MIF assay results (111). For these reasons, a well-trained and experienced laboratory staff is required. A few standardized kits based on the MIF format have been developed and marketed (Focus Diagnostics, Cypress, CA; Labsystems OY, Helsinki, Finland; Savyon Diagnostics Ltd., Ashdod, Israel). Initial studies suggest that their performance characteristics are similar and seem to correspond well to those of the classical MIF method (112). However, at the time of this writing, none of these assays are cleared by the FDA for use in the United States for the diagnosis of C. pneumoniae or C. trachomatis infections.

Enzyme Immunoassay

To overcome the problems associated with MIF testing, EIAs that offer a more automated workflow and objective endpoints for serodiagnosis of chlamydial infections have been developed. EIAs based on synthetic peptides from the variable domain 4 (VD4) of the C. trachomatis MOMP have been marketed for detection of C. trachomatis-specific IgG and IgA antibodies (CT-ELA [Labsystems OY]; Sero-CT [Savyon Diagnostics Ltd.]; CT pELISA [Medac, Wedel, Germany]). These assays performed as well as the MIF assay in a few studies (113); however, little is known regarding how long specific antibodies may persist in individuals with resolved infections. For this reason, they cannot reliably differentiate current and past infections. They are not useful in C. trachomatis infections of the lower genital tract, for which adequate specimens for direct detection of the organisms can be noninvasively obtained. Further studies are needed to clarify if C. trachomatis species-specific antibody tests based on recombinant antigens are convenient tools for diagnosis of upper genital tract infections (114) and tubal factor infertility (115).

The major antigenic determinants of C. pneumoniae that are broadly immunodominant among infected individuals are elusive. Commercial assays designed for specific diagnosis of C. pneumoniae infection are based on either whole elementary bodies (Savvyon Diagnostics Ltd.) or (to obtain more specificity) on LPS-extracted EB preparations (Labsystems OY and Medac). Most kits have been compared only to MIF tests (116), but none has been evaluated adequately with sera from culture- or PCR-positive patients. Thus, their diagnostic value for acute C. pneumoniae infections remains to be determined (57).

ANTIMICROBIAL SUSCEPTIBILITIES

Evaluation of antimicrobial resistance and potential clinical treatment failure in chlamydial infection is hampered by the lack of standardized antimicrobial susceptibility tests and the fact that in vitro resistance does not correlate with the patient’s clinical outcome (117). For these reasons, antimicrobial susceptibility testing of Chlamydia organisms has little clinical utility and is currently performed only in some research laboratories. Antimicrobial susceptibility testing in chlamydiae requires growing the organisms in epithelial cells cultured in medium containing increasing concentrations of antibiotics. Cells are stained with an FITC-labeled anti-chlamydial antibody, and the lowest concentration of antibiotic that inhibits inclusion formation after 48 h of incubation is reported as the MIC (117, 118). The minimum chlamydialcidal concentration has been defined as the lowest concentration of antibiotic producing no viable bacterial progeny as determined after passage from antimicrobial-containing medium to antimicrobial-free medium. However, variation of antimicrobial susceptibility results is common because they depend on many factors including the cell type used, the inoculum size, and the time between infection and the addition of an antimicrobial.

Tetracyclines, macrolides, fluoroquinolones, and rifampin are commonly used for antibiotic treatment of chlamydial infections. A single 1-gram dose of azithromycin has been shown to be as effective for the treatment of uncomplicated genital C. trachomatis infections in adults as a standard 7-day course of doxycycline (33, 119). Alternative regimens include a 7-day course of erythromycin, ofloxacin, or levofloxacin. More data and clinical experience are available to support the efficacy and safety of azithromycin in pregnant women (30, 33). Cotreatment or testing for chlamydiae should be considered among gonorrhea-infected patients because of the frequency of coinfection. Systemic treatment with erythromycin has been recommended for opthalmia neonatorum as well as for infant pneumonia caused by C. trachomatis. In the treatment of adult inclusion conjunctivitis, a single azithromycin dose was as effective as a standard 10-day treatment with doxycycline (120). Doxycycline for 21 days is the antibiotic treatment of choice for both bubonic and anogenital LGV (121). Doxycycline, azithromycin, erythromycin, levofloxacin, and newer macrolides such as clarithromycin and roxithromycin have been recommended for treatment of C. pneumoniae infection; however, evidence from clinical trials supporting their use is limited.

Chlamydial resistance to recommended antimicrobial agents appears to be rare and confined to only a few clinical isolates of C. trachomatis and has not yet been reported for C. pneumoniae or C. psittaci infections. Nevertheless, concern has been raised about resistance because recurrent or persistent chlamydial infections were observed in women adequately treated for C. trachomatis infection and in a few cases of C. pneumoniae infections.

In vitro, chlamydial resistance to fluoroquinolones, macrolides, tetracyclines, and rifampin can be induced with large numbers of organisms cultured in the presence of antimicrobials. In an animal model, persistence of C. pneumoniae after antimicrobial therapy has been demonstrated. The emergence of Chlamydia suis strains isolated from livestock and displaying a chromosomally stable tet(C) resistance gene raises concern about the issue of antibiotic use in animal feeds.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Licensed commercially available NAATs enable the reliable detection of uncomplicated genital C. trachomatis infection even from noninvasively obtained specimens such as first-void urine and (self-collected or clinician-collected) vaginal swabs. These specimens are also recommended for screening asymptomatic individuals. Reporting of test results for chlamydiae should include the type of test used and a clinical interpretation if possible. Sexual partners of infected patients should be notified, examined, and treated for C. trachomatis. Patients and their partners should be instructed to abstain from sexual intercourse until therapy is completed. Due to the presence of nonviable bacteria, nonculture tests for C. trachomatis, especially NAATs, may remain positive when performed ≤3 weeks after completion of therapy (122). Repeat C. trachomatis testing of recently infected women and men should be performed approximately 3 months after treatment (30) because recurrent chlamydial infections are common in women and men even after treat-
ment. The use of ELAs, DFAs, and NAH-based assays are increasingly discouraged due to their relatively low sensitivity compared to that of NAATs. In cases of repeated treatment failure, isolation should be attempted and specimens should be forwarded to a specialized reference laboratory.

NAATs could also be helpful for diagnosis of C. pneumoniae and C. psittaci infections. However, commercial FDA-cleared assays are currently not available. Therefore, respiratory specimens of patients with clinical suspicion of orornithosis or C. pneumoniae infection should be directed to a specialized laboratory.

Interpretation of serologic results is particularly challenging in chlamydial infections. Serologic testing may be helpful for screening of chlamydial tubal factor infertility and diagnosis of human ornithosis, lymphogranuloma veneruem, neonatal pneumonia, and respiratory C. pneumoniae infections. A reliable serologic marker for chronic or persistent chlamydial infection is not available. Especially in C. pneumoniae, there is poor agreement between the presence of chlamydial antibody and direct markers of current infection, such as culture or PCR (123). Single-point serology for diagnosis of C. pneumoniae infection is discouraged, except when specific IgM antibodies are positive. Paired sera should be tested in the same assay on the same day, and seroconversion or a 4-fold rise or fall in titer is diagnostic for a recent infection. Obviously, there is a general lack of reliable and standardized assays for laboratory diagnosis of C. pneumoniae, and this basically hampers the current understanding of the organism’s true prevalence and role in respiratory infections as well as in extrapulmonary diseases.

**Rickettsia and Orientia**

DAVID H. WALKER AND DONALD H. BOUYER

---

**TAXONOMY**

The family *Rickettsiaceae* comprises two genera of small, obligately intracellular bacteria that reside freely within the host cell cytosol, namely, *Rickettsia* and *Orientia*. Although the numbers and diversities of pathogenic strains in these genera are similar, the practices of species designation differ remarkably. The second edition of Bergey’s Manual of Systematic Bacteriology lists 20 validated names of *Rickettsia* species, and others have been proposed (1). Strains of *Orientia tsutsugamushi* have 0.8% divergence of the *rrs* (16S rRNA) gene. Similarly, other obligately intracellular bacteria have 0.5% *rrs* divergence within a species (e.g., *Ehrlichia chaffeensis*, *Coxiella burnetii*, and *Chlamydia trachomatis*). A proposal of criteria for the limits of divergence of *Rickettsia* species based upon the unacceptable criteria of historical designations would allow different species to be as closely related as having a 0.2% divergence for *rrs*, 0.8% for citrate synthase (*gltA*), 1.2% for outer membrane protein A (*ompA*), 0.8% for outer membrane protein B (*ompB*), and 0.7% for *scn* (2, 3). There are no common or universal concepts that can be utilized to delineate prokaryotic species as there are with eukaryotes. However, among prokaryotes, 1% divergence of the *rrs* gene is considered to indicate a natural separation between species. Thus, the genus *Rickettsia* has a disproportionate number of designated species relative to the genetic divergence of the relevant bacteria.

The genus is divided by phylogenetic clustering into the typhus group (TG) and the spotted fever group (SFG), defined originally by their distinctive lipopolysaccharide antigens, as well as the transitional group and other basal groups that are widely distributed in arthropods (4). The TG consists of only two members, *Rickettsia prowazekii* and *R. typhi*, whereas the SFG contains bacteria that are generally recognized as human pathogens (*R. rickettsii*, *R. conorii*, *R. africae*, *R. sibirica*, *R. japonica*, *R. honei*, *R. parkeri*, *R. massiliae*, *R. monacensis*, *R. slovaca*, *R. aeschlimanni*, and *R. helvetica*), as well as others that have been identified only in arthropods (1, 4–9). The transitional group, a clade between the TG and SFG, contains the pathogens *R. akari*, *R. australis*, and *R. felis* (10). Most *Rickettsia* spp. of undetermined pathogenicity, including *R. montanensis*, *R. bellii*, *R. peacockii*, and *R. rhipicephali*, are much more prevalent in U.S. ticks than is pathogenic *R. rickettsii*. SFG isolates from patients infected with *Orientia tsutsugamushi*, which was once considered to be the only species in the *Orientia* genus, diverges from *Rickettsia* by approximately 10% in the *rrs* gene and differs greatly in its cell wall structure, containing completely unrelated proteins and lacking lipopolysaccharide (Table 1). Phylogeny based upon *groEL*, encoding a member of the molecular chaperone family, reveals genetic diversity for the genus *Orientia* similar to that for SFG *Rickettsia*, for which it may be that too many species have been named (Fig. 1) (13, 14). *O. tsutsugamushi*, originally classified serologically, was subsequently analyzed genetically (15). There are several genetic variants in each geographic area. Phylogeny reveals nine genetic clusters that are not identical with serotypes. The genotypes do not have strong evidence of geographic differentiation (15). Genetic variants of *O. tsutsugamushi* appear to correspond to particular arthropod hosts in which divergence most likely occurred. However, a recent change in the *Orientia* genus was the addition of a newly validated species, *Orientia chuto* sp. nov., that was isolated from a patient infected in Dubai (16). This new species has 98.5% homology in *rrs* to *O. tsutsugamushi* strains Ikeda, Kato, and Karp, with only 84.1 to 84.6% identity in the 47-kDa protein gene (16, 17). There is also genetic evidence of a potential third member of the genus in Chile, which was detected in an eschar from a man who was suffering a scrub typhus-like illness (18). Analysis of *rrs* showed 97% sequence similarity to isolates of *O. tsutsugamushi* and a similar difference from *O. chuto* sp. nov. The 47-kDa protein gene could not be amplified, indicating that the genetic sequence for the Chilian agent may be substantially divergent from that of *O. tsutsugamushi*.

**DESCRIPTION OF THE GENERA**

*Rickettsia* spp. are small (0.3 to 0.5 μm by 1 to 2 μm), obligately intracellular bacteria of the *Alphaproteobacteria* with a Gram-negative cell wall structure that contains lipopolysaccharide, peptidoglycan, a major 135-kDa S-layer protein (*OmpB*), a 17-kDa lipoprotein, and, for SFG rickettsiae, a surface-exposed protein (*OmpA*) containing different numbers of nearly identical tandem repeat units (19, 20). *Rickettsia* organisms have small (1.1 to 1.5 Mb), AT-rich genomes resulting from reductive evolution, with a large proportion (19 to 24%) of noncoding sequence. Among SFG and TG rickettsiae, the genomes have remarkable synteny (21). *Rickettsia* organisms lack genes for enzymes for sugar metabolism, lipid biosynthesis, nucleotide synthe-

sis, and amino acid synthesis and possess genes encoding enzymes for the complete tricarboxylic acid cycle and several copies of ATP/ADP translocase. These facts suggest both independent synthesis of ATP and acquisition of host ATP, as well as rickettsial utilization of host sources for nutrition and building blocks. Rickettsiae adhere to the host cell receptor Ku70 by OmpB, to an integrin receptor by OmpA, and to unknown receptors for SFG rickettsiae by Sca1 and Sca2. Adhesion triggers signaling pathways that lead to recruitment and activation of induced phagocytosis and escape from the phagosome by membranolytic activities of rickettsial phospholipase D and hemolysin C (TlyC) (22–28). Orientia tsutsugamushi (0.3 to 0.5 μm by 0.8 to 1.5 μm) has a 2.1-Mb genome with large proportions of mobile genetic elements, identical repeats, and fragmented genes and a low coding capacity (29). This organism has a major surface protein of 54 to 58 kDa as well as 110-, 80-, 47-, 42-, 35-, 28-, and 25-kDa surface proteins but lacks muramic acid, glucosamine, 2-keto-3-deoctulonic acid, and hydroxy fatty acids, suggesting the absence of lipopolysaccharide and peptidoglycan. Compared with Rickettsia, Orientia has a more plastic Gram-negative cell wall, with a thicker outer leaflet and thinner inner leaflet of the outer envelope.

FIGURE 1 Phylogeny of Rickettsia and Orientia as determined by unweighted maximum parsimony analyses of groEL gene sequences, with Escherichia coli as the outgroup (prepared by PAUP 4.0 software). Numerical values on the branches represent quantities of genetic divergence from the nearest nodes. doi:10.1128/9781555817381.ch64.f1

EPIDEMIOLOGY AND TRANSMISSION
Rickettsia spp. reside in an arthropod host (tick, mite, louse, flea, or other insect) for at least a part of their life cycle,
during which they are maintained by transovarian transmission and/or cycles involving horizontal transmission to vertebrate hosts (30–37) (Table 2). Orientia tsutsugamushi resides freely in the cytoplasm and is maintained in nature by transovarian transmission in trombiculid mites whose larval stage transmits the infection to humans during feeding (Table 2). Although unconfirmed as vectors of Orientia species, in the case of the Chilean agent, leeches have been suggested as a possible vector because the patient recalled being bitten by a leech during a field project (18). There is also the possibility that the patient was bitten by mites that were not detected (18).

**CLINICAL SIGNIFICANCE**

Rocky Mountain spotted fever (RMSF), rickettsialpox, murine typhus, flying squirrel-associated R. prowazekii infection, flea-borne spotted fever, R. parkeri infection, and “Candidateus Rickettsia philippin” infection are indigenous to the United States. In addition, the potential for imported cases is significant for African tick bite fever, boutonneuse fever, murine typhus, and scrub typhus (Table 2) (38–47). Other rickettsioses, either because of their geographic distribution and the infrequency of travelers’ exposure to them or because of their incidence, are unlikely to be imported. RMSF, louse-borne typhus, and scrub typhus are life-threatening illnesses even for young, previously healthy persons. Murine typhus and boutonneuse fever can have a fatal outcome in patients who are elderly or have underlying diseases or other risk factors. A recent study of 140 patients infected with R. conorii that were admitted to Portuguese hospitals indicated that alcoholism and infection with the Israeli strain are risk factors for a fatal outcome. Patients with fatal cases more frequently have acute renal failure, hyperbilirubinemia, obtundation, tachypnea, petechial rash, gastrointestinal symptoms, and coagulopathy (48).

An average of 7 days after tick bite inoculation of rickettsiae, patients with RMSF develop fever, severe headache, malaise, and myalgia, frequently accompanied by nausea, vomiting, and abdominal pain, and sometimes cough (40). A rash typically appears only after 3 to 5 days of illness. Rickettsiae infect endothelial cells, frequently leading to increased vascular permeability and focal hemorrhages. In severe cases, noncardiogenic pulmonary edema and rickettsial encephalitis with coma and seizures are grave conditions that often presage death (49, 50).

*Rickettsia parkeri* causes a milder illness, with tick inoculation site eschar, fever, headache, and myalgia, usually a maculopapular or vesiculopapular rash, occasionally tender regional lymphadenopathy, and no reported deaths (51). Rickettsialpox has been recognized mainly as a nonfatal urban disease with disseminated vesicular rash and an eschar at the location of rickettsial inoculation by the feeding mite (41). The complete spectrum of clinical manifestations of *R. felis* infections has yet to be determined. This disease suffers from diagnostic neglect despite its widening recognized geographic distribution and the prevalence of cat flea exposure (44, 52–55).

Murine typhus causes a rash in only slightly more than one-half of patients, cough and chest radiographic infiltrates suggesting pneumonia in many patients, and severe illness in some patients, with seizures, coma, and renal and respiratory failure necessitating intensive care unit admission in 10% of hospitalized patients (39).

Travelers who have returned from Africa and develop fever, one or more eschars, and, in some cases, regional lymphadenopathy and a maculopapular or vesicular rash are very likely infected with *R. africanum* (43).

Rickettsia prowazekii, R. rickettsii, R. typhi, and R. conorii are bioterror threats via aerosol exposure to organisms that are infectious at a low dose (56). Only *R. prowazekii* is classified as a select agent, with restrictions on its possession and biosecurity.

Scrub typhus caused by *O. tsutsugamushi* occurs in the geographic area that is bordered by Japan, Korea, and Russia on the north, Australia and Indonesia on the south, Pakistan and Afghanistan on the west, and the Philippines and Micronesia on the east (57). Clinical signs and symptoms of the disease include fever, headache, maculopapular rash, eschar, interstitial pneumonia, temporary deafness, lymphadenopathy, and central nervous system involvement (57–61). In a study of 191 confirmed scrub typhus patients, differences in clinical manifestations were observed between the *O. tsutsugamushi* Boryong and Karp genotypes: weakness (91% versus 61.1%), eschar (97% versus 73.7%), skin rash (94% versus 68.4%), and conjunctival injection (45.1% versus 3%) occurred with increased frequency with the Boryong genotype (62). Without treatment, mortality can reach 30% (58, 61, 63, 64). The index case of *O. tsutsugamushi* infection was characterized by an eschar, lymphadenopathy, and generalized myalgia followed by fever, lethargy, and rash (16).

**COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS**

Blood should be collected as early as possible in the course of illness. For the isolation of rickettsiae, blood should be obtained in a sterile heparin-containing vial prior to the administration of antimicrobial agents that are active against rickettsiae (40, 65). For isolation and immunocytologic diagnosis, blood can be stored temporarily at 4°C and should be processed as promptly as possible. If inoculation of cell culture or animals must be delayed for more than 24 h, plasma, Buffy coat, whole blood, or biopsied tissue should be frozen rapidly and stored at −70°C or in liquid nitrogen. EDTA- or sodium citrate-anticoagulated blood collected in the acute state has been used effectively for the diagnosis of boutonneuse fever, murine typhus, epidemic typhus, Japanese spotted fever, and scrub typhus, and, with a lower sensitivity, RMSF and African tick bite fever, by PCR (43, 44, 66–69). PCR provides a higher diagnostic yield when applied to biopsy specimens of rickettsia-infected lesions, particularly eschars (48, 70–73). If whole blood, plasma, Buffy coat, or tissue cannot be processed for PCR within several days, it should be stored at −20°C or lower. Serum has a lower sensitivity in PCR but is often diagnostic in fatal cases (74, 75). Overall, PCR has poor sensitivity for diagnosis of rickettsioses owing to the presence of organisms in tissue rather than blood until near death.

For serologic diagnosis, blood is collected as early in the course of disease as possible, a second sample is collected after 1 or 2 weeks, and if a 4-fold rise in antibody titer has not occurred, a third sample is collected 3 or 4 weeks after onset. The serum can be stored for several days at 4°C but should be stored frozen at −20°C or lower for longer periods to avoid degradation of the antibodies. However, blood samples collected by finger stick on appropriate blotting paper in remote areas and sent by ordinary mail can be used for serologic diagnosis (76, 77). Even after transport at ambient temperature, this collection method yields a serologic sensitivity similar to that of testing of fresh serum for immunofluorescence assay (IFA) diagnosis of scrub typhus (77).

</table>
A 3-mm-diameter punch biopsy specimen of a skin lesion, preferably a maculopapule containing a petechia or the margin of an eschar, should be collected as soon as possible (78, 79). Although treatment should not be delayed, it is best to perform the biopsy prior to the completion of 24 h of treatment with a tetracycline or chloramphenicol. For immunohistologic detection of rickettsiae, the specimen can be snap-frozen for frozen sectioning or fixed in neutral buffered formalin for the preparation of paraffin-embedded sections (40, 41, 45, 78–81). The former approach yields an answer more rapidly, but freezing artifacts distort the architecture of the tissue, and fixed tissue is more convenient for shipping to a reference laboratory. Aseptically collected autopsy tissues, e.g., spleen and lung, are useful for rickettsial isolation. Ideally, these are inoculated fresh, held for 24 h at 4°C, or stored frozen at −70°C for longer periods if the specimen must be shipped to a public health or reference laboratory. Autopsy tissues can also be examined for rickettsiae by use of immunohistochemistry or PCR.

Body lice (Pediculus humanus corporis) removed from the clothing of patients with suspected epidemic typhus can be examined for the presence of rickettsiae. Body lice acquire rickettsiae and remain infected for life, thus providing a useful specimen for PCR diagnosis even after a prolonged period of shipping at ambient temperature and humidity, which do not ensure survival of the lice (82).

DIRECT DETECTION

General Considerations

At this time, to the best of our knowledge, molecular and immunohistochemical diagnostic testing, the most useful methods for establishing a diagnosis during the acute stage of illness, when therapeutic decisions are critical, are available in only a few reference laboratories, including ours. Individual cases for immunohistochemistry can be referred to the following laboratories after contacting the directors for consultation: David H. Walker, Department of Pathology, University of Texas Medical Branch, 301 University Boulevard, Keiller Building, Room 1.104, Galveston, TX 77555-0609 [telephone, (409) 747-3990; fax, (409) 772-1850; e-mail, dwalker@utmb.edu]; Sherif Zaki, Department of Pathology, Centers for Disease Control and Prevention, 1600 Clifton Road, Mail Stop G32, Atlanta, GA 30333 [telephone, (404) 639-3133; e-mail, sxz1@cdc.gov]; and Robert Massung, Rickettsial Zoonosis Branch, Centers for Disease Control and Prevention, 1600 Clifton Road, Mail Stop G-13, Atlanta, GA 30333 [telephone, (404) 639-1082; e-mail, rmassung@cdc.gov].

Immunologic Detection

The diagnoses of RMSF, *R. parkeri* infection, boutonneuse fever, African tick bite fever, murine typhus, louse-borne typhus, and rickettsialpox have been established by immunohistochemical detection of rickettsiae in formalin-fixed, paraffin-embedded sections of biopsy specimens of rash and eschar lesions (40, 45, 49, 72, 79, 81) (Fig. 2, left panel). Monoclonal antibodies that are specific for lipopolysaccharides of either SFG or TG rickettsiae can be used to detect rickettsiae by immunohistochemical staining (Fig. 2, right panel) (45, 80). There is no antibody commercially available. The sensitivity and specificity of immunohistochemical detection of *R. rickettsii* in cutaneous biopsy specimens are 70 and 100%, respectively (40, 79). Eschar biopsies yield sensitive specimens for the diagnosis of SFG rickettsioses that manifest those lesions and should be considered for diagnostic evaluation for patients suspected of having rickettsialpox, *R. parkeri* infection, boutonneuse fever, or Afri-
can tick bite fever. Because histologic processing results in heat denaturation of species-specific antigens, immunohistochemistry distinguishes Rickettsia organisms only at the SFG or TG level.

Immunocytochemical detection of R. conorii in circulating endothelial cells has been accomplished by capture of endothelial cells from blood samples by use of magnetic beads coated with a monoclonal antibody specific for a human endothelial cell surface antigen followed by immunofluorescence staining of the intracellular rickettsiae (65). This method has a sensitivity of 50% and a specificity of 94%. Rickettsiae are detected in 56% of untreated patients and in 29% of patients receiving antirickettsial treatment. O. tsutsugamushi has been identified in human endothelial cells, dendritic cells, macrophages, and cardiac myocytes by use of immunohistochemistry (83). The technique of in situ hybridization has been developed but has not been reported for the detection of rickettsiae in clinical samples.

Skin biopsy specimens can also be utilized for the diagnosis of scrub typhus (84). Immunohistochemical staining of maculopapular skin rash samples using a mouse polyclonal antibody against endothelial cells from blood samples by use of magnetic beads coated with a monoclonal antibody specific for a human endothelial cell surface antigen followed by immunofluorescence staining of the intracellular rickettsiae (65). This method has a sensitivity of 50% and a specificity of 94%. Rickettsiae are detected in 56% of untreated patients and in 29% of patients receiving antirickettsial treatment. O. tsutsugamushi has been identified in human endothelial cells, dendritic cells, macrophages, and cardiac myocytes by use of immunohistochemistry (83). The technique of in situ hybridization has been developed but has not been reported for the detection of rickettsiae in clinical samples.

Molecular Detection

PCR has been applied for the amplification of DNA of R. rickettsii, R. parkeri, R. conorii, R. japonica, R. typhi, R. prowazekii, R. africae, R. sibirica, R. felis, R. akari, R. slovaca, and O. tsutsugamushi, usually from peripheral blood,uffy coat, or plasma but occasionally from fresh, frozen, or paraffin-embedded tissue or arthropod vectors from patients (43, 44, 66, 67, 73, 82, 85–88). Nested PCR applied to skin biopsy specimens, particularly of eschars prior to treatment, has a sensitivity of 78% (89). For all pathogenic Rickettsia spp., the 17-kDa lipoprotein gene is a target, amplified by employing the primers 5′-CATTACTGGTCTCAGTTG-3′ and 5′-GGTCTTTATTAGTGGTGCTAA-3′, which amplify a 231-bp DNA fragment (44). The gltA, rrs, groEL, ompA, and ompB genes have also been amplified diagnostically, with the Rickettsia spp. being identified through either restriction fragment length polymorphism analysis using Alul and XbaI or sequencing of the PCR product. The primer set RP.330(2) Fw (5′-ATGGCC TCAAAAACCAAAATTTTCTAA-3′) and RP.330(2) Rev (5′-AGCTTCTACCTGCCCATTATGTTAC-3′), which targets the ompB gene, amplifies a 990- to 1,000-bp PCR product (length is species dependent) that, when digested with Alul, discriminates among 11 different rickettsial species (90). The availability of rickettsial genome sequences offers the possible design of an enormous number of primer sets. The approach of using primer sets on a single occasion to reduce the chances of amplicon contamination and false-positive results seems impractical. With batch processing, the delay in laboratory results reduces the clinical value (89). The single use of primers requires that their utility and sensitivity be unknown. The potential for amplicon contamination originating from a positive patient sample remains even if there is no positive control. Recent advances in technology, such as real-time PCR, allow for increased sensitivity in the detection of rickettsiae (91–98). The advantage of real-time PCR is detection of rickettsial organisms during the early or acute stage of disease, before the generation of antibody. The targets for primer design have ranged from housekeeping genes (gltA) to antigenic genes (ompA and ompB). The sensitivities for detection vary among primer sets. For example, real-time assays utilizing the primer set BR.190.547F (5′-CTCTTCGTATAATTA TACAGGTTTA-3′) and BR.190.701R (5′-GTCCGTTT AATGCGACTCAT-3′), generating a product of 154 bp, can detect five copies of rickettsial DNA. The primer set CS-5 and CS-6 detects 1 copy of R. rickettsii DNA and 10 copies of R. bellii DNA. Perhaps the best potential demonstration of real-time PCR as a diagnostic assay was observed in a recent study that compared real-time PCR evaluation with serology (98). In that study, the primer set PanRick_2-for (5′-ATAGGACACCGTTATTTTT-3′) and PanRick_2_rev (5′-CAAAACATCATATGCCAGAAA-3′) and the probe PanRick_3-taq (5′-6-carboxyfluoresce n-CCTGA TATTGCTTAGTATTTACG-TMR-3′), targeting a 70-bp region of the rickettsial gltA gene, were utilized for diagnosis of a febrile returned traveler who presented with a macular rash and an eschar on his leg. DNAs were extracted from a small sample of the eschar biopsy and from the leukocyte layer of the EDTA-treated blood sample collected from the patient and analyzed by real-time PCR. The assay was able to detect 1,476 copies of PCR target per ml (1.4 copies per μl) from the initial patient sample. The acute-phase serum of the patient had a positive IFA titer for SFG rickettsial IgM antibodies of 64 and no IgG antibodies. Intracellular bacterial growth was observed in Gimenez-stained Vero cells on day 5 after inoculation. IgG seroconversion was detected using convalescent-phase sera obtained 4 weeks later. This rapid (total processing time is 3 to 4 h) molecular approach is currently being evaluated further for its effectiveness as a timely diagnostic tool (98).

Utilization of group- and species-specific primers in real-time PCR analysis of banked blood and tissue samples by both the CDC and a laboratory in France has shown that real-time PCR analysis is more sensitive than nested PCR assays and can identify the rickettsial agent at the group or species level (99, 100). For patients who have been treated empirically with antibiotics before diagnosis, real-time quantitative PCR is slightly more sensitive (28%) than rickettsial isolation and cultivation (19%) (101). For O. tsutsugamushi, the 56-kDa protein gene is the usual target of diagnostic PCR. The nested 56-kDa protein gene PCR assay is useful for the diagnosis of O. tsutsugamushi infections during the acute phase of the disease (67). PCR amplification of DNA from blood samples by using primers p34 (5′-TCAAGGCTTATGCTCAGTGCAT TCCTGC-3′) and p55 (5′-AGGGATTCCTGCTGTG CATTGCGG-3′), which generate a 1,003-bp product, followed by nested PCR with primers p10 (5′-GATCAA GCTCCCTACCTACTAATGCC-3′) and p11 (5′- CAGGATCCGAAGCTGATATGCTGG-3′), amplifies a 483-bp product. This assay detects 10 prototype strains of O. tsutsugamushi and does not amplify R. typhi or R. honei. Real-time PCR assays targeting the Orientia htrA gene have been applied to diagnosis with clinical samples (88, 102, 103). The greatest analytical sensitivity level of detection (2 copies per μl of DNA extracted from buffy coat) was observed when genoEL was the target for analysis in blood collected from 61 Thai patients at the time of clinical admission (94). In this assay, a set of primers (forward primer, 5′-TGCAACRAATCCTGAAAAG-3′; and reverse primer, 5′-TCTCGCTCTACCTATCATGCA-3′) was used to amplify a 459-bp fragment of the gene. This quantitative PCR method is the preferred molecular method as a diagnostic tool for the acute stage of scrub typhus and
is more sensitive than conventional or nested PCR (103). The development of a loop-mediated isothermal PCR assay targeting O. tsutsugamushi groEL offers the possibility of a simple method that can be used in locations lacking costly infrastructure (95).

**ISOLATION PROCEDURES**

Due to high infectivity at a low dose, rickettsial isolation is performed in biosafety level 3 laboratories. Cumbersome historic methods, such as inoculation of adult male guinea pigs, mice, or yolk sacs of embryonated chicken eggs, have been supplanted by cell culture methods, except for isolation of O. tsutsugamushi, which is often achieved by intraperitoneal inoculation of mice (40, 65). Vero, L-929, HEL, and MRC5 cells have been used in antibiotic-free media to isolate rickettsiae. The best results reported were achieved with heparin-anticoagulated plasma, buffy coat, or skin lesion biopsy specimens collected prior to administration of antibiotic treatment. This method yields a diagnosis in convalescence with group-, species-, and strain-specific monoclonal antibodies. There is no current commercial kit or in reference laboratories, and not for all rickettsial diseases. Other serologic tests, such as indirect hemagglutination, microagglutination, and complement fixation, are no longer in general use.

Rickettsiae were detected at 48 h of growth in 82% of the positive samples. Universal precautions should be exercised, and work should be performed in a laminar flow biosafety hood with use of gloves, mask, and gown. Although the quantity of rickettsiae in the cell culture is relatively small, avoidance of aerosol, internal, or contact exposure should be taken as for mycobacteria, fungi, and viruses.

**IDENTIFICATION OF RICKETTSIA AND ORIENTIA ISOLATES**

Rickettsiae isolated in cell culture can be identified by indirect immunofluorescence with group-, species-, and strain-specific monoclonal antibodies. There is no current commercial source for these reagents. Thus, rickettsial isolates are frequently identified by molecular methods, such as PCR amplification of genes that are genus specific (17-kDa protein, citrate synthase [gta], or ompB) or SFG specific (ompA) (105). Orientia tsutsugamushi, being more distantly related to Rickettsia spp., lacks the above cell wall genes but can be identified by PCR amplification of the gene encoding the major immunodominant 56-kDa surface protein, groEL, or rrs (71, 95).

Identifying the species of rickettsial isolates by microimmunofluorescence serotyping requires intravenous inoculation of mice with large doses of rickettsiae on days 0 and 7 and collection of sera on day 10. The resultant high-titer antibodies react with conformational species-specific epitopes of OmpA and OmpB. Antibodies against group-specific lipopolysaccharide develop later in the murine immune response to high doses of Rickettsia spp. This rather cumbersome and expensive method requires propagation of large quantities of the isolate and of the prototype strains for immunofluorescence titration as well as for development of the typing sera. As a result, genetic analysis is currently favored for identification of isolates. An isolate that is known to be a Rickettsia spp., should be identified in a biosafety level 3 laboratory, and isolates of R. prowazekii must be handled as required by U.S. federal regulations for select agents.

**SEROLOGIC TESTS**

For most clinical microbiology laboratories, assays for antibodies to rickettsiae are the only tests performed. This situation is unfortunate for patients with life-threatening, acutely incapacitating rickettsial disease because these assays are useful principally for serologic confirmation of the diagnosis in convalescence and usually do not provide information that is helpful in making critical therapeutic decisions during the acute stage of illness. Patients who die of rickettsial infections usually have received many antibiotics, none of which have antirickettsial activity, owing in part to the lack of laboratory data providing clinical guidance for a rickettsial diagnosis. The earlier a diagnosis is established, the shorter the course of rickettsial illness will be after an appropriate antibiotic is administered.

Serologic assays for the diagnosis of rickettsial infections focus on the "gold standard," the indirect IFA. Other approaches include indirect immunoperoxidase assay, latex agglutination, enzyme immunoassay (EIA), Proteus vulgaris OX-19 and OX-2 and Proteus mirabilis OX-K agglutination (Weil-Felix febrile agglutinins), line blotting, Western immunoblotting, and rapid lateral flow assays (39–41, 77, 79, 106–117). Only some of these assays are available as commercial kits or in reference laboratories, and not for all rickettsial diseases. Other serologic tests, such as indirect hemagglutination, microagglutination, and complement fixation, are no longer in general use.

The IFA contains all the rickettsial heat-labile protein antigens and group-shared lipopolysaccharide antigen and thus provides group-reactive serology. IFA reagents for SFG and TG rickettsiae are available commercially from Scimedx Corp., Denville, NJ; Focus Technologies, Cypress, CA; and Fuller Laboratories, Fullerton, CA. They are also available for O. tsutsugamushi from Scimedx Corp. and Fuller Laboratories. In cases of RMSF, IFA detects antibodies at titers of ≥64, usually in the second week of illness. Effective antirickettsial treatment of RMSF must be initiated by day 5 of illness to avoid a potentially fatal outcome. For boutonneuse fever, an IFA titer of ≥40 occurs in 46% of patients between days 5 and 9 of illness, in 90% of patients between 20 and 29 days, and in 100% of patients thereafter. For murine typhus, diagnostic IFA titers are present in 50% of cases by the end of the first week of illness and in nearly all cases by 15 days after onset. In areas where particular rickettsial diseases are endemic, a higher diagnostic cutoff titer is required. For example, for the IFA diagnosis of scrub typhus in patients residing in zones of endemicity, an IFA titer to O. tsutsugamushi of ≥400 is 96% specific and 48% sensitive, with sensitivity rising from 29% in the first week to 56% in the second week (118). Lowering the diagnostic cutoff titer to 100 raises the sensitivity only to 84% and reduces the specificity to 78%. These considerations are not as important for testing patients who have visited regions of endemicity for only a short period. Each laboratory performing the test should establish its own cutoff titers for the
patient population, the microscope and reagents used, and the laboratorian’s judgment of the minimal positive signal. Meta-analysis of IFA serology for the diagnosis of scrub typhus led to recommendations that diagnosis be based on a 4-fold or greater rise in titer and that diagnosis not be based on a single antibody titer, unless previous studies had determined a seroprevalence in the local population that justified the cutoff titer (118).

Indirect immunoperoxidase assays for scrub typhus, murine typhus, boutonneuse fever, and presumably other rickettsioses yield results similar to those of IFA when the IgG diagnostic titer is set at 128 and that of IgM is set at 32 (115). Advantages include the use of a light microscope rather than a fluorescence microscope and the production of a permanent slide result. Latex agglutination test reagents are available commercially from Scimedx Corp. only for R. rickettsii in the United States. Latex beads coated with an extracted rickettsial protein-carbohydrate complex containing rickettsial lipopolysaccharide are agglutinated mainly by IgM antibodies, with reports of a sensitivity of 71 to 94% and a specificity of 96 to 99% (110). A diagnostic titer of 128 is often detected early in the first week of illness (111). The utilization of these tests is especially useful in situations with limited laboratory facilities and a small number of specimens, is available from Panbio Ltd., Brisbane, Australia.

The assays that were historically most widely used for the diagnosis of rickettsial diseases were the Weil-Felix febrile agglutination tests, using the OX-19 and OX-2 strains of Proteus vulgaris for TG and SFG rickettsioses and the OX-K strain of Proteus mirabilis for O. tsutsugamushi infections. These assays have poor sensitivity and specificity (79, 113), and they should be replaced by more accurate serologic methods, such as IFA or ELISA. However, there are situations in developing countries where the choice is between the Proteus agglutination tests and none at all for the detection of important public health problems, such as outbreaks of louse-borne typhus (121). In fact, the evidence leading to the discovery of Japanese spotted fever and Flinders Island spotted fever included Proteus agglutinating antibodies.

Shared antigens of OmpA, OmpB, and group-specific lipopolysaccharide impede establishment of a species-specific diagnosis by serologic methods. The criterion of a 4-fold or greater difference in IFA titers between the two suspected agents distinguished infections by R. prowazekii and R. typhi in only 34% of cases and infections by R. africae and R. conorii in only 26% of cases (43, 122). Western immunoblot detection of antibodies against OmpA or OmpB of only one Rickettsia species has also been proposed as a criterion for species-specific diagnosis. However, it was effective in distinguishing R. prowazekii and R. typhi infections or R. africae and R. conorii infections in only half of the cases (43, 122, 123). Cumbersome, expensive cross-absorption of sera prior to IFA or Western immunoblotting is more effective in establishing a species-specific diagnosis. However, interpretation of these results requires careful evaluation of the performance of valid controls, the quality and quantity of each antigen preparation, and the potential for the occurrence of infection by an untested or even undiscovered agent. In the past, knowledge of the geographic origin of the case was thought to suffice to designate the specific diagnosis. However, the increasing number and geographic overlap of rickettsioses challenge old assumptions. The report of the reactivity of sera from patients with flea-borne spotted fever but not of those from patients with RMSF, rickettsialpox, or murine typhus with a recombinant fragment of R. felis OmpA suggests that species-specific peptide antigens may be identified and incorporated into assays that identify the disease more precisely (124).

ANTIMICROBIAL SUSCEPTIBILITIES

Data supporting the use of doxycycline or another tetracycline antibiotic as the drug of choice for the treatment of infections caused by Rickettsia spp. and O. tsutsugamushi and the use of chloramphenicol as an alternative drug have been derived principally by empirical experience, retrospective case studies, and a few prospective studies (125–134). In addition to historic studies of the activity of antimicrobial agents against these obligately intracellular bacteria in infected animals and embryonated eggs, studies of the effects of antimicrobial agents in cell culture have supported the consideration of alternative drugs, such as fluoroquinolones, josamycin, azithromycin, and clarithromycin. Indeed, several fluoroquinolones, josamycin, and azithromycin have been used successfully for the treatment of boutonneuse fever under certain circumstances but cannot be recommended for more pathogenic rickettsioses (125, 126, 130, 131). Mediterranean spotted fever has also been treated effectively in clinical trials by use of fluoroquinolones such as ciprofloxacin, azithromycin, and clarithromycin. A retrospective study of patients with
murine typhus demonstrated that ciprofloxacin is an effective drug. Evidence for a toxic effect of fluoroquinolones led to concern about these infections (135,136). During pregnancy, chloramphenicol has been used to treat RMSF, and josamycin has been used for boutonneuse fever. Except for cases of scrub typhus in Thailand, which responded poorly to doxycycline or chloramphenicol, but for which azithromycin has been reported to be effective, there is little concern regarding rickettsial development of antimicrobial resistance (129,134,137). Thus, antimicrobial susceptibility studies of rickettsiae are not routinely performed clinical laboratory tests. However, it has been reported that fluoroquinolones may exacerbate rickettsial effects (135).

INTERPRETATION AND REPORTING OF RESULTS

In reporting the results of an assay for antibodies in a single serum sample, the laboratorian seldom knows the duration of illness and whether the serum sample is from the acute or convalescent phase of the disease. For sera that are nonreactive by dot-ELISA, by IFA at a dilution of 1:64, by indirect immunoperoxidase assay at a dilution of 1:128, by latex agglutination at a dilution of 1:64, or by Weil-Felix Proteus agglutination at a titer of 1:160, the laboratory report should state that no antibodies were detected at the particular cutoff dilution. In addition, the report should indicate that this may differ among laboratories and patient populations, that negative results are expected in the acute stage of rickettsial illness, and that a second sample should be submitted to evaluate the possibility of seroconversion if no alternative diagnosis has been established. If paired acute- and convalescent-phase sera separated by an appropriate interval are available, they should be tested simultaneously. It is wise to test for all the rickettsial and ehrlichial agents to which the patient is likely to have been exposed in the United States. SFG rickettsiae, Ehrlichia chaffeensis, Anaplasma phagocytophilum, and R. typhi are the likely agents, unless travel to an area where scrub typhus is endemic has occurred. If the paired sera contain no antibodies against rickettsiae at the cutoff dilution, the report should state that the results do not support the diagnosis of rickettsial infection but that occasionally antibody synthesis is delayed, particularly in cases with early antirickettsial therapy. If a single serum sample contains an IFA antibody titer of ≥64, an IFA IgM titer of ≥32, an indirect immunoperoxidase antibody titer of ≥128, a latex agglutination titer of ≥64, or a Weil-Felix titer of ≥320, the laboratory report should state (i) that antibodies reactive with the particular rickettsial antigen were detected at the measured titer, (ii) that the result provides supportive evidence for the diagnosis of the rickettsial disease, and (iii) that a convalescent-phase sample should be submitted to assess the possibility of a diagnostic rise in titer. If paired sera measured simultaneously show a 4-fold or greater rise in titer, the interpretation should state that the results strongly support the rickettsial diagnosis indicated by the tested antigen. If a significant titer was detected in the acute-phase sample but no rise or only a single doubling dilution rise was measured, it should be stated that an additional later sample should be tested to evaluate a 4-fold rise or fall in titer. The concept that recrudescent typhus may be distinguished from primary louse-borne typhus by the absence of IgM antibodies to R. prowazekii and of Proteus OX-19 agglutinating antibodies has been challenged (109). The manufacturers of the dot-ELISA have recommended the interpretation that strongly reactive samples (three or four dots) may indicate the presence of a specific antibody response and that weakly reactive samples (one or two dots) are infrequent but possible in normal populations. Retesting 2 to 3 weeks later would establish the diagnosis if three or four dots developed in the convalescent-phase serology and should always be performed.

Isolation of a rickettsia from blood or tissue may be interpreted as indicating an etiologic role. The level of identification of the isolate should be stated, whether it is identified only to the level of a group containing particular organisms or to the species level.

Immunohistologic and immunocytologic diagnostic interpretations should state the method, reactivity of the method (e.g., antibody reactive with SFG rickettsiae), and location of the antigen (e.g., vascular endothelium and, frequently, adjacent vascular smooth muscle for R. rickettsii). Detection of three or more rickettsiae in vascular endothelium in biopsy specimens or four or more rickettsiae in captured circulating endothelial cells is diagnostic of rickettsial infection.

Interpretation of PCR results should state the target gene, the organisms that would be detected, and the presence or absence of a DNA product. If a specific oligonucleotide probe or DNA sequence confirmed the specificity of the identification, this result should be stated. For negative immunohistologic, immunocytoologic, and PCR results, it should always be stated that the failure to detect the agent does not exclude the diagnosis, along with data regarding the sensitivity and specificity of the assay in the particular laboratory and the effects of antirickettsial treatment on the sensitivity.

Special efforts should be made to establish the diagnosis of fatal cases, including rickettsial isolation, immunohistology, PCR, and serology on samples collected at necropsy.

**Ehrlichia, Anaplasma, and Related Intracellular Bacteria**

Megan E. Reller and J. Stephen Dumluer

---

**TAXONOMY**

Members of the genus *Ehrlichia* and *Anaplasma* are now recognized to be important human pathogens. They are obligate intracellular bacteria currently placed in the Proteobacteria phylum, order Rickettsiales, and family *Anaplasmataceae*. Although most closely related to the genera *Rickettsia* and *Orientia*, organisms classically considered ehrlichiae are divided into at least 4 major clades. Taxonomic classification (Fig. 1) is largely based upon sequence analysis of 16S rRNA genes and groEL (heat shock operon) (1) and, increasingly, on fully sequenced genomes (2). Serologic cross-reactions, similarities among major immunodominant surface proteins, and the cellular tropisms of these bacteria further support the phylogenetic approach (3). Recent studies also discern a separate clade of related bacteria, the family “*Candidatus Midichloriaceae,*” that invade eukaryotic, mostly arthropod, mitochondria. Some serologic and molecular evidence suggests human pathogenicity, but this remains to be critically evaluated. Table 1 delineates current names of selected *Ehrlichia* and *Anaplasma* species that are known human and veterinary pathogens. Minor sequence differences in 16S exist that are markers of their biological and ecological differences (5–7). Genetic variants of *Anaplasma phagocytophilum* exist among ticks and mammals in the Northeast United States and Europe, including some that probably do not cause disease in humans (6, 7).

Although *Ehrlichia* species infect predominantly leukocytes of humans and other mammals, individual *Anaplasma* species infect bone marrow-derived cells of each lineage in different animal hosts. *Neorickettsia* species infect predominantly mononuclear phagocytes and occasionally enterocytes in mammalian hosts (8). “*Candidatus Neoehrlichia mikurensis,*” a bacterium in a clade equally distant from the *Ehrlichia* and *Anaplasma* branches and present in Ixodes ticks, is proposed to be a new genus and species, and infections in humans are now documented (9–13). The genus *Aegyptia nella* is currently listed as incerta sedis, most closely related to *Anaplasma* (14). *Wolbachia* spp. are “endosymbionts” of insects, helminths, and crustaceans that are transmitted predominantly by transovarial and transstadial (between stages of development) passage (15), although cell-to-cell transmission into mammalian cells has been demonstrated in vitro.

---

**DESCRIPTION OF THE GENERA**

*Ehrlichia* and *Anaplasma* spp. are Gram-negative obligate intracellular bacteria that reside and propagate within membrane-lined vacuoles found in the cytoplasm of bone marrow-derived cells, such as granulocytes, monocytes, erythrocytes, and platelets. *Ehrlichia ruminantium* and several other species also infect endothelial cells (16, 17). These intracytoplasmic clusters of bacteria resemble elementary bodies of *Chlamydia* as small dense core forms (0.2 to 0.4 μm); larger forms (0.8 to 1.5 μm) resemble reticulate bodies (18). Both are capable of binary fission. Specific ligands associated with cell adhesion are differentially expressed on the infective dense forms but not on the metabolically active reticulate forms. After a few days, the elementary bodies dividing in the phagosome form an inclusion, also called a morula, which can be seen microscopically. *Neorickettsia sennetsu* organisms grow as bacterial cells that can maintain individual vacuolar membranes with binary fission. Cell lysis leads to the release of bacteria that can infect other competent cells (19). Unlike *Rickettsia*, *Ehrlichia* and *Anaplasma* do not have a thickened outer membrane leaflet. The outer membrane appears more ruffled in *A. phagocytophilum* than in *N. sennetsu* or *E. chaffeensis* (20). As observed by transmission electron microscopy, *Ehrlichia* and *Anaplasma* spp. have a very limited region that corresponds to the peptidoglycan layer, and genes necessary for its synthesis and for lipopolysaccharide synthesis are not present within the genomes of *Ehrlichia*, *Anaplasma*, or *Neorickettsia* spp. (21–23).

The family *Anaplasmataceae* contains five genera. The full genome sequences of more than 25 *Anaplasmataceae* members are established and range in length from 860 kb in *N. sennetsu* to 1,176 kb in *Ehrlichia chaffeensis* and 1,471 kb in *A. phagocytophilum*. Genome sequencing identified a low G+C content common to endosymbionts (except for *Anaplasma marginale*) and a large proportion of noncoding sequences. Many of the genes required for glycolysis are absent, but those that are present suggest the ability of these bacteria to use simple substrates such as glyceraldehyde 3-phosphate and phosphoenolpyruvate for biosynthesis of phospholipids and nucleotides (22). Carbon sources are proline and glutamine. In contrast to the case with *Rickettsiaceae*, all enzymes necessary for the Krebs cycle and for metabolism of purine and pyrimidine are present. All other
amino acids must be imported from the host by membrane transporters. ATP synthesis is possible, since these organisms possess the ATP synthase complex and other enzymes required for aerobic respiration. However, unlike in Rickettsiae, ATP/ADP translocases are absent. Like other Rickettsiales, Anaplasmataceae possess genes that encode an anomalous type IV secretion system that most likely contributes to virulence, perhaps by transport of effectors into the host cell or by DNA uptake or in conjugation (24). In contrast to the reductive evolution seen in other intracellular bacteria, these organisms have many pseudogenes, which document gene duplication events (21, 22). The active duplication of tandemly repeated sequences likely results in new genes, antigenic variation, immune evasion, and thereby enhanced survival.

Anaplasma marginale infects ruminants, and Aegyptianella spp. infect birds, amphibians, and reptiles. These organisms also reside in small membrane-bound inclusions (14, 25) and are not known to cause human disease.

EPIDEMIOLOGY AND TRANSMISSION

Ehrlichia, Anaplasma, and “Candidatus Neoehrlichia” spp. are zoonotic agents transmitted to animals and humans by ticks. Neorickettsia sennetsu rarely causes human disease and is likely acquired by ingestion of fish infested with Neorickettsia-in-

*Modified from Juan P. Olano and Maria E. Aguero-Rosenfeld in chapter 67 of the 9th edition of this Manual (156). EGE, equine granulocytic ehrlichiosis; HGA, human granulocytic anaplasmosis; HME, human monocytic ehrlichiosis; CGE, canine granulocytic ehrlichiosis; CME, canine granulocytic ehrlichiosis; VHE, Venezuelan human ehrlichiosis.*
fected flukes (8). Wolbachia spp. are symbionts of a broad range of arthropods, helminths, and crustaceans (26). Thus, most species can infect vertebrates and invertebrates (Table 1). Transovarial transmission of these organisms in ticks does not occur, but transstadial, interstadial, and intrastadial transmissions do. The bacteria are acquired when a larval or nymphal tick feeds on an infected animal and are transmitted when the next stage (nymph or adult) feeds on another mammalian host. Ticks and mammals, the latter with bacteremia that can persist, serve as reservoirs (27). In contrast, humans are only inadvertently infected and represent an end-stage host. Therefore, maintenance of tick-borne ehrlichiae in nature depends upon the presence of appropriate tick vectors and mammalian hosts in the local environment (28–31).

Recognized natural reservoirs for E. chaffeensis include deer (Odocoileus virginianus and Blastocerus dichotomus), domestic dogs, and perhaps other animals that host Amblyomma ticks (32, 33). Less important reservoirs include opossums, raccoons, voles, coyotes, and goats (34). White-tailed deer (Odocoileus virginianus) also are a reservoir of Ehrlichia ewingii and of the white-tailed deer agent, an ehrlichia closely related to Anaplasma platys that has not yet been associated with human disease (35). E. muris was found in Apodemus mice and Haemaphysalis flavis ticks when first detected in Japan (12). In the Perm region of Russia, E. muris, or a closely related organism, was also detected in Ixodes persulcatus ticks and humans were found to have serologic reactions to this agent (36). In the United States, this organism was isolated from Ixodes scapularis ticks from Wisconsin and Minnesota (37). Further study is needed to identify the major animal reservoirs for E. muris.

Even for A. phagocytophilum, the major reservoirs are incompletely documented. However, small mammals are frequent hosts of the immature stages of I. scapularis, Ixodes ricinus, I. persulcatus, and Haemaphysalis concinna (31, 38). These include white-footed mice (Peromyscus leucopus), chipmunks (Tamias striatus), voles (Clethrionomys gapperi), wild rodents, and other small mammals worldwide. Although white-tailed deer can be persistently infected by A. phagocytophilum, the A. phagocytophilum strains (AP variant 1) that naturally infect deer are not infectious for small mammals, have not been identified in humans, and may represent nonpathogenic variants (39, 40). Persistent or prolonged infection in animal reservoir hosts is essential for maintenance of zoonoses. Mice infected with A. phagocytophilum can remain infected for months, which contributes to transmission to different stages of developing I. scapularis ticks (41). In Europe, red deer, sheep, cattle, and goats are persistently infected and serve as reservoirs of A. phagocytophilum. Cases of “Candidatus Neoehrlichia mikurensis” in humans have now been reported among predominantly immunocompromised patients in Europe (Czech Republic, Germany, Sweden, and Switzerland) and immunocompetent patients in China (12, 13, 42–45); the reservoirs for “Candidatus Neoehrlichia mikurensis” are also small mammals, including field mice and voles, in both Europe and Asia. Although the reservoir for N. sennetsu is also not known, epidemiological data suggest that consumption of raw fish is a risk factor for sennetsu fever (8). Other species of Neorickettsia have complex transmission processes involving trematodes. Neorickettsia risticii, the agent of Potomac horse fever, is transmitted to horses by accidental ingestion of insects carrying N. risticii-infected cercariae (46). Similarly, Neorickettsia helminthoea infects dogs through ingestion of trematode-infested fish.

CLINICAL SIGNIFICANCE

Human Diseases

HME

The causative agent of HME is E. chaffeensis, a monocytotropic ehrlichia first identified as a human pathogen in a patient with a severe febrile illness after tick bites in 1986 (47). More than 8,523 cases of HME were reported to the CDC through 2012; however, data from active surveillance efforts suggest that HME occurs much more frequently than is reported (48, 49). The seroprevalence of E. chaffeensis ranges from 1.3% to 12.5% in regions of Arkansas and Tennessee where it is endemic. In contrast, active surveillance in Tennessee and Missouri identified 330 to 414 cases/100,000 population (48, 49). Most cases are identified in the south central and southeastern United States, but increasingly infections are identified in the mid-Atlantic region. Prospective evaluation of heavily exposed cohorts shows that approximately 75% of seroconversions are subclinical (50). Reports from Latin America, Africa, Europe, and Asia indicate that E. chaffeensis, or closely related microorganisms, could also be found there (51–56).

The median incubation period for HME is 9 days. The median age of HME patients is 51 years, and 60% of patients are males (34, 57). Patients often present with high fever (96%), headache (72%), malaise (77%), myalgia (68%), nausea (57%), and no localizing physical findings (48). Other gastrointestinal (vomiting and diarrhea), respiratory (cough), and osteoarticular (joint pain) symptoms are present in less than 50% of patients. Central nervous system involvement (stiff neck, confusion, and meningitis) is well described (58). Patients with E. chaffeensis can develop hemophagocytic lymphohistocytosis syndrome (59–61). Petechial, macular, and maculopapular rashes occur with varied distribution and onset (34, 62). Rashes are more frequent in children (57% of cases) (63). Abnormal laboratory parameters occur in at least 86% of patients and include thrombocytopenia (68 to 88%), leukopenia (60 to 71%) with lymphopenia and/or neutropenia, and increased serum transaminases (38 to 54%). Severe complications occur in 9 to 17% and include meningoencephalitis and a toxic shock-like syndrome with multiorgan failure, including adult respiratory distress syndrome. Fulminant infections are more common in patients immunocompromised by HIV, high-dose corticosteroids, medications related to organ transplantation, and diabetes (64–70). The case fatality rate is 2 to 3% (71). Male sex, advanced age, immunosuppression, and delayed diagnosis leading to late treatment are independent risk factors for death (57).

HGA

The causative agent of human granulocytic anaplasmosis (HGA) is Anaplasma phagocytophilum. HGA was first identified in 1990 in a patient from Wisconsin who reported tick bites. Tick bite is the most frequent route of transmission; however, there are others (72–74), including perinatal transmission (73), accidental inoculation of infected blood, and blood transfusion (72, 74).

Despite a mandate to report all cases of HGA in the United States, the true incidence and prevalence of the infection are unknown. Passive surveillance in northwestern Wisconsin and Connecticut reveals yearly incidence rates of 24 to 58 cases per 100,000 population (49). As of 2012, 13,151 cases were reported nationwide, with the highest annual incidence rates in the Northeast and upper Midwest. Infected patients are identified in other states, as well as
in Europe and Asia (56, 72, 75–79). Most infections are subclinical or mild, since between 1% and 15% of persons residing in regions of endemicity in Connecticut and northwestern Wisconsin, respectively, are seropositive (80, 81). The tick vectors for HME and HGA coexist in the mid-Atlantic, the southern New England states, and the southern Midwest. Thus, both diseases occur in these areas (57, 78, 82). Furthermore, human ehrlichioses, including HME, HGA, and infections with E. ewingii and an E. muris-like agent, are clinically indistinguishable.

HGA has a median incubation period of 5 to 11 days after the bite of an infected tick (Ixodes or Haemaphysalis spp.). The median age of HGA patients is 53 to 54 years (83 to 85), and the male/female ratio is 1.5:1 (86). Patients most often present with high fever (93%), myalgias (68%), headache (62%), and malaise (93%). Gastrointestinal, respiratory, musculoskeletal, and central nervous system involvement occurs in fewer than half of patients. Rash is observed in 6% of patients, in all cases attributable to erythema migrans with concurrent Lyme disease (87). Leukopenia with lymphopenia, thrombocytopenia, and increased serum aspartate transaminase activity is common early in the disease and may normalize before anamnestic treatment. Lymphocytosis with atypical lymphocytes can occur after the first week of infection (86, 88). Approximately 36% (89) of infections are severe enough to warrant hospitalization, and 3 to 7% of patients have life-threatening complications or require intensive care unit admission (71, 90). The clinical course is worse for patients with cancer, diabetes, immunosuppression related to treatment of rheumatic conditions, or functional or anatomic asplenia. Severe complications of HGA include a septic shock-like illness with multiorgan failure, adult respiratory distress syndrome, and opportunistic infections (85, 88, 91–93). Meningoencephalitis and cerebrospinal fluid (CSF) pleocytosis are rarely documented (0.2% of cases) (71) in HGA; however, other neurologic sequelae can include facial diplegia, brachial plexopathy, and demyelinating polyneuropathy (89). Meningitis has not been documented. Clinical severity can vary. For example, a subset of 16 patients from one region of China had significantly greater disease severity (including multiorgan dysfunction, gastrointestinal, renal, and hemorrhagic manifestations, and worse laboratory features) and a case fatality rate of 16%, whereas the case fatality rate was 2.6% among 46 other patients with HGA in Shandong Province and is 0.6% in the United States (94).

Ehrlichia ewingii Ehrlichiosis

E. ewingii was recognized to cause human infection when its DNA was found in the blood of patients with an HME-like disease in Missouri (95). As with E. chaffeensis, the main vector is the lone star tick (A. americanum); therefore, the distribution of the disease is similar to that of HME. White-tailed deer are also reservoirs, and recent epidemiological studies suggest that dogs may be as well (35, 96). E. ewingii ehrlichiosis seems to affect mostly immunosuppressed patients, including those with HIV, but is clinically milder than coinfection with HIV and E. chaffeensis (68, 95). In dogs, E. ewingii is responsible for canine granulocytotropic ehrlichiosis.

Other Human Ehrlichioses

Venezuelan Human Ehrlichiosis

In 1996, Ehrlichia canis was isolated from the blood of an asymptomatic man from Venezuela. Since then, 6 additional symptomatic patients have been identified as infected by an E. canis strain that differs from canine strains by a single nucleotide polymorphism in rrs (97, 98).

Ehrlichia muris-Like Agent Ehrlichiosis

In 2009, infection with an Ehrlichia muris-like agent was detected and the organism isolated from patients with suspected ehrlichiosis/anaplasmosis in Wisconsin and Minnesota (37). Some patients had strong serologic reactivity in convalescence to E. chaffeensis but not A. phagocytophilum antigens. Since the original report, 44 patients, all from Minnesota and Wisconsin, were diagnosed with Ehrlichia muris-like agent infection (B. Pritt, personal communication). The mean age of patients is 60 years, and >1/3 of patients are immunocompromised. The clinical features mimic HME and HGA.

“Candidatus Neoehrlichia mikurensis” Ehrlichiosis

Seven European patients with “Candidatus Neoehrlichia mikurensis” infection presented with severe sepsis-like syndromes, some lasting weeks, and 1 patient died. In contrast, reported illnesses of 7 patients with “Candidatus Neoehrlichia mikurensis” infection in China were mild (45).

N. sennetsu Ehrlichiosis (Neorickettsiosis)

Named after the Japanese term for glandular fever, Neorickettsia sennetsu was first isolated from patients with suspected infectious mononucleosis in 1953 (99). The organism is rarely identified now. Patients develop a self-limited febrile illness with chills, headache, malaise, sore throat, anorexia, and generalized lymphadenopathy. Cases have been identified in Japan and possibly Malaysia, although at least one case was recognized in the Lao People’s Democratic Republic (8). Laboratory findings include early leukopenia and atypical lymphocytes in the peripheral blood during early convalescence. No fatalities or severe complications have been reported.

Contributions of Wolbachia to Human Disease

Although Wolbachia spp. have not yet been shown to be directly pathogenic for humans or animals, evidence indicates a potential role for release of intracellular Wolbachia components from filarial helminths such as Brugia malayi, Onchocerca volvulus, and Wuchereria bancrofti. In theory, these microbial components act as potentiators of inflammation and contribute to lymphatic obstruction associated with parasitic infections (15, 100). At a minimum, the endosymbionts are mutualists on which the helminths depend to enable survival from stage to stage.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS

Currently, there are 3 methods for diagnosis of active infection with HME or HGA: (i) PCR amplification of nucleic acids from Ehrlichia or Anaplasma species, (ii) detection of morulae in the cytoplasm of infected leukocytes by nonspecific Romanowsky stains (e.g., Giemsa or Wright) or by specific immunocytologic or immunohistologic stains using E. chaffeensis or A. phagocytophilum antibodies, and (iii) culture of Ehrlichia or Anaplasma from blood or CSF. In contrast, testing of single serum samples (acute or convalescent phase) is rarely useful. However, concurrent testing of paired sera (obtained during the acute illness and in convalescence 2 to 4 weeks later) does provide definitive retrospective diagnosis.
EDTA-anticoagulated blood is a useful specimen for most tests (PCR, smears, and culture) and should be obtained during the active phase of illness before treatment (62, 83, 101). Acute-phase peripheral blood buffy coat smears or cytocentrifuged preparations of CSF cells should be prepared within hours of obtaining the samples since leukocytes degenerate rapidly. Once prepared, air-dried blood smears and cytocentrifuged CSF preparations are stable at room temperature for months or years.

Whole blood is the preferred sample for PCR since it contains infected leukocytes; serum should not be used. Samples for PCR should be tested promptly or frozen at −20 to −80°C.

The preferred specimen for culture of *Ehrlichia* and *Anaplasma* is peripheral blood. Samples should be obtained by sterile venipuncture or lumbar puncture and processed as soon as possible. The culture conditions for *Ehrlichia* and *Anaplasma* species are not optimized. Culture is currently performed only in a few public health and research laboratories. Samples should be maintained at 4°C during shipping but not frozen. *A. phagocytophilum* is easier to culture than *E. chaffeensis*, including from EDTA-anticoagulated blood stored for up to 18 days at 4°C (102); however, isolation can take days to weeks. *Ehrlichia*- and *Anaplasma*-infected cells can be stored frozen within infected host cells at −80°C for months. Storage of infected cells is best accomplished when more than 50 to 90% of the host cells are infected, and it is achieved by suspension of at least 10⁶ cells per ml in tissue culture medium that contains 10% dimethyl sulfoxide and at least 30% fetal bovine serum.

**LABORATORY CONFIRMATION OF *EHRlichIA CHAFFEensis***

**Direct Examination**

Microscopy by Romanowsky Staining of Peripheral Blood

Patients with suspected HME should have Giemsa or Wright-stained peripheral blood oruffy coat leukocytes examined for the presence of morulae. However, the sensitivity is low (≤29%) compared to that of culture (58). *E. chaffeensis* is detected predominantly in monocytes and is more frequently detected in severe infection. When present, morulae are small (1- to 3-μm diameter), round to oval clusters of small bacteria that appear as basophilic to amphophilic stippling within cytoplasmic vacuoles (Fig. 2). Detection is accomplished more frequently for immunocompromised patients. Since the percentage of cells infected ranges from 0.2% to 10%, up to 500 cells should be examined.

Antigen Detection by Immunohistology

Immunohistochemistry can identify *E. chaffeensis* in bone marrow, liver, and spleen. However, the sensitivity of detecting active infection with examination of bone marrow is only 40% (103). A monoclonal antibody can specifically detect *E. chaffeensis* in human tissues (104), but most studies use polyclonal antibodies which react with other *Ehrlichia* species. Commercial assays are not currently available.

Nucleic Acid Detection Techniques

There are a large number of potential gene targets for molecular confirmation of infection with *E. chaffeensis*, with sensitivity of PCR ranging from 60% to 100% (58, 62, 105). The most widely used method is PCR amplification of DNA from *E. chaffeensis* in clinical samples using the HE1/HE3 primer set (58, 106, 107). This primer pair amplifies a 389-bp fragment of *rrs* (16S rRNA gene). The product can be detected by simple nucleic acid staining (e.g., ethidium bromide) after agarose gel electrophoresis, by Southern hybridization of the amplified products using an internal probe, or, preferably, by real-time PCR with either 5' nuclelease or molecular beacon probes that increase analytical sensitivity (108). A clinical evaluation of *E. chaffeensis* PCR using the HE1/HE3 system showed a sensitivity of 79 to 100% compared with that of serology; however, nucleic acids from *E. chaffeensis* were frequently detected in patients who never developed antibodies (58, 107). A similar sensitivity was shown with a nested PCR that employs broad-range “*Ehrlichia genus*” primers in an initial step followed by PCR with the HE1/HE3 primer pair (109). A nested PCR assay with broad-range *rrs* primers (8F and 1448R) followed by a second (nested) reaction with primers 15F and 208R on whole blood yielded results similar to those obtained by culture (58). Other targets for PCR that have not been fully evaluated for clinical sensitivity or specificity include the outer-surface variable-length PCR target protein gene present in *E. chaffeensis* (58, 68, 110), the TRP120 gene that encodes an immunodominant antigen with tandemly repeated subunits that vary among *E. chaffeensis* isolates, the quinolinate synthase A gene (*nadA*), the disulfide bond formation protein gene (*dsb*), and the p28 multigene family (3, 68, 111, 112). In a prospective study, the overall sensitivity and specificity of PCR were 56% and 100%, respectively, using the 16S rRNA subunit, *nadA*, and TRP120 genes (62). However, in this study, several samples had high titers of antiehrlichial antibodies by indirect immunofluorescence assay (IFA), suggesting that the pathogen was already cleared. When sensitivity was calculated using seroconversion as the “gold standard,” it increased to 84%. Posttest probabilities for a positive and negative PCR result were 96% and 11.1%, respectively. Posttest probabilities depend critically on prevalence (62).

Real-time multicolor PCR and real-time multiplex reverse transcriptase PCR assays have been developed recently with extremely high analytical sensitivity and specificity comparable to those of nested PCR (3, 113). Advantages include improved specificity (lower risk of contamination), speed, cost, and the detection of multiple ehrlichia pathogens simultaneously. A broad-range real-time PCR assay that targets *groEL* of *E. chaffeensis*, *A. phagocytophilum*, and *E. ewingii* has shown excellent clinical sensitivity and specificity and also detects the *E. maris*-like *ehrlichia* (37, 114).

**Isolation Procedures**

*Ehrlichia chaffeensis* is classified as a biosafety level 2 pathogen. *Ehrlichia chaffeensis* has been isolated from the peripheral blood of a limited number of patients with HME, and an *E. canis*-like organism was recovered only once from an asymptomatic human (58, 67, 98, 115, 116). Culture remains a research tool that employs specialized methods and unique cell lines (58). The most frequently used cell for primary isolation is the canine histiocytic cell line DH82; however, *E. chaffeensis* has been successfully cultivated in other cells, including the human macrophage-like THP-1 cells, the fibroblast-like HEL-22 cells, Vero cells, and HL-60 cells (human promyelocytic cell line differentiated to the monocytic pathway), among others (117). Isolation may be successful even when infected leukocytes are not observed on peripheral blood examination (58). Isolation usually involves direct inoculation of leukocyte fractions or whole blood into flasks with confluent layers of adherent cells or into flasks that contain approximately 2 × 10⁵ to
FIGURE 2  (A and C) Wright stains (original magnification, ×1,000) of E. chaffeensis (A) and A. phagocytophilum (C) in peripheral blood leukocytes. Note that an E. chaffeensis morula (arrowhead) is present in a monocyte (A) and that an A. phagocytophilum morula (arrow) is present in a neutrophil (C). (B) Romanowsky (Leukostat) stain (original magnification, ×1,000) of E. chaffeensis cultured in the canine histiocyte cell line DH82. Note the presence of basophilic, stippled, intracytoplasmic inclusions approximately 2 to 3 μm in diameter (arrows). The smaller intracytoplasmic granules may also be ehrlichial morulae. (D) Wright stain (original magnification, ×1,000) of A. phagocytophilum from the blood of an infected patient cultured in the human promyelocytic cell line HL-60. Note the presence of multiple basophilic, stippled, intracytoplasmic inclusions (arrowheads) in an HL-60 cell. doi:10.1128/9781555817381.ch65.f2

1 × 10^6 cells per ml of tissue culture medium. Macrophage-like cells that are highly phagocytic could be adversely affected by the presence of erythrocytes; thus, it is recommended that either (i) leukocytes be fractionated from erythrocytes by density gradient centrifugation (e.g., Ficoll-Paque), (ii) leukocytes be harvested after erythrocyte lysis (hypotonic lysis, NHCl4 lysis, etc.), or (iii) confluent monolayers be reestablished after cultivation with erythrocyte-containing samples by addition of uninfected cells. Since E. chaffeensis can be present in very few peripheral blood leukocytes, it is advisable to inoculate cultures with as many peripheral blood leukocytes as possible (which may be difficult with leukopenia). Use of 2 to 3 ml of EDTA-anticoagulated blood diluted in 2 volumes of sterile Hanks’ balanced salt solution followed by Histopaque (Sigma, St. Louis, MO) gradient separation of leukocytes has been effective (58).

The blood mononuclear cells are resuspended in a 2-ml volume of tissue culture medium supplemented with 5% fetal bovine serum and allowed to interact with adherent host cells in a 25-cm² flask for 3 h, usually enhanced by incubation with rocking at 37°C in 5% CO₂. The inoculum is removed if significant erythrocyte contamination is present and the monolayer is replenished with 5 ml of fresh tissue culture medium. Since Ehrlichia species are bacteria, antibiotics in the medium must be avoided. The generation time of E. chaffeensis is approximately 19 h (118), and thus, cultures must be maintained to allow a slow logarithmic or stable growth phase to avoid the host cells outgrowing the ehrlichiae.
Identification

The presence of infected cells is determined by sampling the medium (DH82 cells and THP-1 cells) or by lightly scraping part of the monolayer. Aliquots of the culture are cytocentrifuged, followed by Wright or Giemsa or immunofluorescent stains, and cells are examined for the presence of intracytoplasmic morulae or Ehrlichia chaffeensis antigen (Fig. 2). Culture can require 1 month or more but has been achieved in as short as a few days (58, 115, 116). Confirmation of the infectious agent is currently best achieved by PCR amplification using species-specific primers (119).

Serologic Tests

The gold standard for the diagnosis of HME is demonstration of a 4-fold rise in IgG titer or seroconversion by examination of paired (acute- and convalescent-phase) sera. Thus, diagnosis is at best retrospective. The most frequently used serologic method is the IFA. Other methods include enzyme-linked immunosorbent assay (ELISA) or enzyme immunoassay and protein (Western) immunoblotting, but none have been well validated. Ehrlichia antigens can be difficult to prepare. Commercial production and distribution now make these more readily available. Commercial sources of IFA serodiagnostic kits include Focus Technologies (Cypress, CA), Scimedx Corp. (Denville, NJ), and PanBio Diagnostics (not available in the United States).

Currently, there is little standardization for any method of ehrlichia serology, and cutoff titers are dependent upon validation in individual laboratories that perform these assays or are per manufacturer instructions. The algorithm for serologic testing by IFA includes an initial screen at a dilution of 1:64 or 1:80 for IgG antibodies to E. chaffeensis. Reactive samples are then titrated to endpoint. Of note, patients with Ehrlichia muris-like agent have strong serologic reactivity with E. chaffeensis but not A. phagocytophilum antigens. However, when tested, these patients have even stronger reactivity with homologous antigens, although currently Ehrlichia muris-like antigens are not commercially available (37).

Ehrlichia chaffeensis IFA

E. chaffeensis IgG is detected by IFA using E. chaffeensis Arkansas strain-infected DH82 canine macrophage-like cells. Reactive sera are serially diluted starting at a dilution of 1:64. The presence of antibodies is detected after incubation with fluorescein isothiocyanate (FITC)-conjugated antihuman IgG. The test is positive if classic intracytoplasmic morulae are seen. It is important to identify the appropriate proportion of infected cells as determined by a positive control serum and the appropriate morphology for each antigen preparation to preclude false-positive interpretations. Prescreening for autoantibodies or routine removal of rheumatoid factors will lessen the risk of misinterpretation due to antibodies reactive with cellular components, including nuclear or cytoplasmic antigens that could have the morphologic appearance of morulae. A 4-fold increase in IgG antibody titer or seroconversion confirms the diagnosis of HME. A single high specific IgG titer, like identification of morulae in monocytes or macrophages for E. chaffeensis by microscopy, is suggestive of acute infection. However, antibody titers can be detected in a small proportion of subjects without HME owing to the presence of antigens that are highly conserved among bacterial species (120, 121). Acute-phase sera should be obtained at the time of presentation with acute illness, and convalescent-phase sera are best obtained 3 to 6 weeks later (120).

The sensitivity and specificity of IFA for the diagnosis of infection with E. chaffeensis are not known but are assumed to be high because of documented correlation between new or rising antibody titers against E. chaffeensis and characteristic clinical findings (50). In the early phase of infection, IFA testing is not sensitive compared to PCR (105). A systematic evaluation of the usefulness of IgM testing has not been conducted, but a preliminary evaluation based on nine culture-confirmed cases suggests that it might be slightly more sensitive than IgG for the diagnosis of HME during the acute phase (105). Previously, the serologically cross-reactive E. canis was used as a surrogate antigen; however, this serodiagnostic assay has a lower sensitivity than obtained using E. chaffeensis antigen, and its use should be discouraged (106). The role of immunoblots in diagnosis is not well established and cannot be advocated. Alternative methods based on recombinant proteins and synthetic peptides show promise, but these are not commercially available (112). Antibodies to E. chaffeensis can also be detected in patients diagnosed with Rocky Mountain spotted fever, Q fever, brucellosis, Lyme disease, and Epstein-Barr virus infections, suggesting that false-positive reactions do occur (120, 121). Antigen diversity among E. chaffeensis isolates is well described (123) but may not affect the detection of polyclonal antibody responses generated with human infection. Several reports characterized patients with suspected HME who lacked antibody responses, even long after onset of symptoms (58, 107, 124). However, in the few cases in which E. chaffeensis infection was proven by isolation of the agent, patients who survived developed clear convalescent-phase serologic reactions by IFA (58, 68, 115, 116, 123). Hypothetical reasons for false-negative results include infection by antigenically diverse strains (unproven) and abrogation of antibody response by early therapy (58).

LABORATORY CONFIRMATION OF ANAPLASMA PHAGOCYTOSPHILUM

Direct Examination

Microscopy by Romanowsky Staining of Peripheral Blood

Examination of Giemsa- or Wright-stained peripheral blood or buffy coat leukocytes for the presence of morulae is highly valuable in the diagnosis of HGA. Usually, 800 to 1,000 granulocytes are examined under magnifications of ×500 to ×1,000 for the presence of morulae (83–85). Since most patients presenting with positive smears have <1% of infected granulocytes and usually have leukopenia, buffy coat preparations will yield more than peripheral smears. Infection rates as high as 40% of granulocytes are described (123). As for HME, the presence of detectable infected granulocytes in peripheral blood correlates modestly with severity of infection (84, 86, 125). The sensitivity of theuffy coat smear examination in the acute phase of HGA is approximately 60% (86). When present, ehrlichia morulae are small (1- to 3-μm diameter), round to oval clusters of small bacteria that stain basophilic to amorphophilic with Wright and Giemsa stains (Fig. 2). These clusters are present in the cytoplasm of neutrophils or eosinophils and have a stippled appearance owing to individual bacteria within the vacuole.

Immunohistology for Antigen Detection

Immunohistologic methods can also be used to identify A. phagocytophilum within human tissues, including bone
Nucleic Acid Detection Techniques

Multiple PCR assays for detection of *A. phagocytophilum* nucleic acids are published (113, 126–129). PCR is at least as sensitive as blood smear in the first 14 days after onset of illness and is more sensitive longer (>14 to ≤30 days) after illness onset (130). Most protocols utilize amplification of rrs (16S rRNA gene). The most frequently applied and evaluated method employs the primer set ge9f and ge10r, which amplify a 919-bp fragment, usually in a single-stage reaction with or without a hybridization probe to enhance sensitivity (5, 126). A previously popular alternative uses nested PCR with an outer set of primers to amplify eubacterial 16S rRNA genes, followed by PCR with internal nested *A. phagocytophilum*-specific primers (58, 127). PCR amplification of groEL using a nested reaction has also been useful. The size of the amplified product distinguishes *E. chaffeensis* from *A. phagocytophilum* (128). In studies conducted prior to the development of real-time PCR, the analytical sensitivity and specificity of several published primer sets were evaluated using DNA extracted from serial dilutions of *A. phagocytophilum*-infected HL-60 cells (127). Specificity was evaluated using DNA extracted from cultures of *E. chaffeensis*, *Rickettsia rickettsii*, and *Bartonella henselae*. The primer sets with the greatest sensitivity and specificity were those used in nested PCR to amplify rrs, ge9a-ge10 and ge9-ge2, and those amplifying the msp2 gene, msp2-3f-msp2-3r (127). Both PCR assays detected as few as 0.25 infected HL-60 cells. Real-time PCR and 5′ nuclease (TaqMan) assays that target the >100-copy msp2 gene family provide increased sensitivity to as few as 1 infected cell per microliter of blood (131). A multiplex assay to detect *Ehrlichia* and *Anaplasma* spp. by real-time reverse transcriptase PCR was developed and evaluated in peripheral blood of dogs suspected of ehrlichiosis (113). The assay has a sensitivity of 100 rrs transcripts (which corresponds to about 1 infected cell in a test sample), can detect single or multiple infections, and has the potential for automation. A broad-range real-time assay that targets *Anaplasmataceae* groEL can distinguish *E. chaffeensis*, *E. ewingii*, *A. phagocytophilum*, and *E. muris*-like agent when melt-curve analysis is applied, providing excellent clinical sensitivity and specificity (37, 114).

Isolation Procedures

*A. phagocytophilum*, a biosafety level 2 agent, is successfully cultivated more often from human patients than *E. chaffeensis*, *E. canis*, *E. muris*-like agent, or *N. sennetsu*, probably owing to the quantity of organisms present in the peripheral blood of infected patients (83). HGA is described in Europe and Asia, and success at isolating the organism is reported. Isolation is best achieved with the human HL-60 promyelocytic cell line (101) and has been accomplished even when morulae are not observed in peripheral blood smears. Optimal conditions for recovery have not been conclusively determined. Because erythrocytes do not adversely affect HL-60 cells, direct inoculation of EDTA-anticoagulated blood is effective. Fractionation of blood into buffy coat or granulocyte fractions by density gradient centrifugation is also effective (132). Approximately 100 to 500 μl of EDTA-anticoagulated blood, containing 10^2 to 10^4 infected granulocytes, is inoculated into 100-fold-more uninfected HL-60 cells. Cultures are subsequently maintained at a concentration between 2 × 10^5 and 1 × 10^6 cells per ml of tissue culture medium.

Identification

Cultures are examined every 2 to 3 days by Wright or Giemsa staining of cytocentrifuged preparations of 20 to 50 μl of culture suspensions. *Ehrlichia* morulae appear as small aggregates of basophilic bacteria in the cytoplasm of HL-60 cells (Fig. 2). Since HL-60 cells can contain cytoplasmic granules, immunocytochemistry or immunofluorescence is very helpful for inexperienced readers. Unfortunately, immunohistologic reagents are currently not commercially available for tissue sample examination. Cultures usually require between 5 and 10 days before morulae are clearly identified, but infected cells can be detected as early as 3 days postinoculation. Time to detection of organisms in culture correlates with the amount of bacteria present in blood at the time of culture (102). Definitive identification is achieved by PCR amplification using species-specific primers (5, 101) or by sequence analysis of PCR-amplified genes (5). The exact length of incubation before cultures are considered negative has not been determined, but they should be kept for at least 14 days, maintaining the cell density adjusted to about 2 × 10^5/ml.

Serologic Tests

*Anaplasma phagocytophilum* IFA

Although testing can be performed using *A. phagocytophilum* antigens prepared from infected circulating leukocytes of horses, the preferred method for testing human sera is the use of a human isolate propagated in the HL-60 promyelocyte cell line (36, 78, 101, 133–135). It is now well demonstrated that antigenic diversity exists among isolates of *A. phagocytophilum*, but such diversity has heretofore not been shown to affect detection in clinical specimens (135, 136). Recently, in 2 cases of anaplasmosis in humans in Japan, patient blood samples contained unique p44/msp2 and antibodies bound to *A. phagocytophilum* antigens propagated in THP-1 rather than HL-60 cells, indicating that cases could go undetected if both cell lines are not used for serodiagnosis (137). Interpretation of immunofluorescent patterns is similar to that for *E. chaffeensis* and requires an experienced microscopist. Commercial sources of IFA serodiagnostic kits include Focus Technologies (Cypress, CA), Scimedx Corp. (Denville, NJ), and PanBio Diagnostics (not available in the United States).

Sera should be screened at a single dilution (1:64 or 1:80), and the presence of antibodies is determined after incubation with FITC-conjugated anti-human IgG. If specimens are reactive, they are serially diluted to determine the endpoint titer. A serologic confirmation diagnosis is achieved when a 4-fold rise in titer is demonstrated in convalescence with a minimum IgG titer of 80, or when a single high antibody titer is demonstrated for a patient with typical clinical features of HGA (84, 85, 138). Approximately 25 to 45% of infected patients have antibodies at the time of presentation (84, 85, 133, 138); however, in regions where HGA is endemic, up to 11 to 14% of the population possess antibodies, rendering a single serologic test less useful (80, 139). The typical response during acute infection is a rapid rise (within 2 weeks of onset) in antibody levels, reaching high titers (≥640) within the first month (133, 138). In treated patients whose diagnosis was confirmed by culture, antibody titers declined gradually over the several months, and about half had antibodies detectable by IFA 1 year after infection. However, many patients have antibodies detectable for months to years after initial infection (138).
The sensitivity and specificity of the HGA serologic tests are both believed to be high because of good correlation between typical clinical cases and serologic reactions to A. phagocytophilum group antigens (84, 133, 138). Seroconversion was documented for 21 of 23 patients (91.3%) with culture-confirmed HGA from whom a convalescent-phase sample was available (133). In an inter- and intralaboratory evaluation, paired serology had a median sensitivity of 95% for the detection of acute HGA in a group of 28 patients diagnosed by culture, PCR, or the presence of morulae in blood smears (135). IgM testing appears to be a useful tool for identification of recent infection, but neither the sensitivity nor the specificity is as high as that for testing paired sera for IgG (135). Although ELISA and immunoblots are described (36, 134, 140), they are not routinely used for the serodiagnosis of HGA. Patients with HGA have serologic reactions to E. chaffeensis in up to 15% of cases but often show higher titers with homologous antigens (84, 135). Thus, when ehrlichiosis is clinically suspected, screening for antibodies against E. chaffeensis and A. phagocytophilum is recommended (141). Immunoblots can be used to differentiate among A. phagocytophilum and E. chaffeensis infections (121, 134, 140).

False-positive reactions can be observed in patients infected with other rickettsiae, the Q fever agent, and Epstein-Barr virus. Many patients with HGA develop antibodies that react with B. burgdorferi by ELISA and demonstrate diagnostic B. burgdorferi IgG or IgM immunoblots (142). Most of these likely represent false positives for B. burgdorferi, although some patients have been confirmed by culture to have concurrent infection with A. phagocytophilum and B. burgdorferi (121, 143). Another explanation is previous exposure to another tick-borne agent (sequential tick bites). Indeed, antibodies to multiple agents are common in individuals living in areas of high endemicity (80, 144). Autoantibodies to platelets and other leukocyte components also can cause false-positive IFA tests (145).

Technologies that use Western immunoblot confirmation or commercially prepared recombinant A. phagocytophilum mp2 proteins or peptides in devices that enable rapid detection have been employed for serologic diagnosis in veterinary laboratories, but they have not been evaluated for diagnosis of human infections (146, 147).

**ANTIMICROBIAL SUSCEPTIBILITIES**

No prospective controlled treatment trials to determine antimicrobial effectiveness for ehrlichioses or anaplasmosis have been conducted. In retrospective studies and routine clinical practice, patients with either HME or HGA defer-vene within 48 h of therapy with doxycycline, the drug of choice (50, 87). Tetracyclines are uniformly bactericidal for *Ehrlichia* and *Anaplasm* species, whereas the MICs of chloramphenicol cannot be safely achieved in humans with HME or HGA (118, 148–151). In contrast, many antibiotics prescribed for undifferentiated fever, such as penicillins, cephalosporins, aminoglycosides, and macrolides, do not inhibit the growth of ehrlichiae in vitro. The rifamycins (rifampin and rifabutin) can achieve effective inhibition of *Ehrlichia* and *Anaplasm* species in vitro, and the fluoroquinolones (ofloxacin and levofloxacin) have very low MICs for human isolates of *A. phagocytophilum* (149, 151). However, at least one report documents recrudescence of infection with *A. phagocytophilum* after levofloxacin was discontinued and subsequent clinical response to doxycycline (152). Rifampin has been used successfully in patients who cannot receive tetracyclines (153, 154). *In vitro* susceptibility testing by real-time PCR found that *E. chaffeensis* was susceptible to doxycycline and rifampin and was partially susceptible to the fluoroquinolones. Resistance to macrolides, co-trimoxazole, and beta-lactam compounds was confirmed (118).

Whereas persistent infections with *Ehrlichia* and *Anaplasm* species can occur in naturally and experimentally infected animals even after treatment with tetracycline, persistence of ehrlichiae in humans is rarely documented and is not believed to have any clinical importance (122, 124, 155). Therapy is usually highly effective at eliminating ehrlichiae from the blood of infected humans.

**EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS**

Identification of infections with *Ehrlichia* and *Anaplasm* species requires clinical suspicion followed by laboratory confirmation. Since rapid specific diagnosis is infrequently possible, empirical therapy should be initiated when the diagnosis is suspected, since delays may lead to increased morbidity and perhaps mortality. Collection of diagnostic samples should ideally occur before therapy is initiated, and patients should be encouraged to return for clinical and serologic follow-up 2 to 4 weeks later.

The presence of intracytoplasmic inclusions within a leukocyte in peripheral blood is helpful when present but can be difficult to distinguish from overlying platelets, Döhle bodies, toxic granulation, nuclear fragments, Auer rods, other bacteria, yeasts, inorganic materials, or normal granules. If the typical morphology of an *Ehrlichia* or *Anaplasm* morula is observed, an assessment as to the hematopoietic lineage and the percentage of cells that contain morulae should be made and reported. A positive PCR result should be reported as such, indicating the presence of *E. chaffeensis* or *A. phagocytophilum* DNA present, and it should be made clear that a positive PCR is not equivalent to the culture of ehrlichiae from blood. Laboratories that use a broad-range PCR to identify *Ehrlichia* or *Anaplasm* DNA in blood can also detect *E. ewingii* and *E. chaffeensis*–like agent infection that may mimic either HME or HGA (95). Broad-range PCR assays targeting 16S rRNA genes or groEL have also identified infection with *Candidatus Neoehrlichia mikurensis* in Europe (42).

*IFA* serologic results should be reported as the titer of antibodies determined to be reactive with *E. chaffeensis* or *A. phagocytophilum*, including the positive cutoff values determined in the laboratory. The gold standard for the diagnosis of *E. chaffeensis* or *A. phagocytophilum* infection by serology is a 4-fold increase in IgG titer or documentation of seroconversion. An interpretation should indicate whether the titers are considered “significant” or “positive” based upon a 4-fold increase or 4-fold decrease or only as a single high serum IgG titer. The use of IgM titer is not advocated to establish a diagnosis, since it is not as sensitive as IgG alone. It should be remembered that infections with *E. ewingii* yield serologic patterns considered diagnostic for *E. chaffeensis*.

Cases of ehrlichiosis and anaplasmosis should be reported using the CDC’s Tick-Borne Rickettsial Disease Case Report form (http://www.cdc.gov/ticks/forms/2010_tbrd_crf.pdf). For the purpose of surveillance, the Council of State and Territorial Epidemiologists and CDC developed a case definition that was amended in 2008 to include HME, HGA, *E. ewingii* infection, and ehrlichiosis/anaplasmosis—undetermined (http://www.cdc.gov/NNDSS/script/casedef.aspx?CondYrID=667&DatePub=1/1/2008%2000:00:00).
20AM). According to this definition, a clinically compatible case is one in which the patient presents with fever, headache, myalgia, anemia, leukopenia, thrombocytopenia, or hepatic transaminase elevation. Definitive confirmation of a clinically compatible case requires (i) a 4-fold change in titer of IgG antibody to *E. chaffeensis* or *A. phagocytophilum* antigen by IFA in paired serum samples, (ii) positive PCR and confirmation of *E. chaffeensis* or *A. phagocytophilum* DNA, (iii) immunostaining of *E. chaffeensis* or *A. phagocytophilum* antigen in a biopsy or autopsy sample, or (iv) culture of *E. chaffeensis* or *A. phagocytophilum* from a clinical sample. A clinically compatible case with (i) an IFA IgG titer ≥24 to *E. chaffeensis* or *A. phagocytophilum* antigen or (ii) identification of morulae in monocytes (HME) or neutrophils or *E. chaffeensis* or *A. phagocytophilum* of *A. phagocytophilum* or *E. chaffeensis* or *A. phagocytophilum* or *E. rouxi* or *A. phagocytophilum* or *E. chaffeensis* or *A. phagocytophilum* or *E. rouxi*. 2002. According to this definition, a clinically compatible case is one in which the patient presents with fever, headache, myalgia, anemia, leukopenia, thrombocytopenia, or hepatic transaminase elevation. Definitive confirmation of a clinically compatible case requires (i) a 4-fold change in titer of IgG antibody to *E. chaffeensis* or *A. phagocytophilum* antigen by IFA in paired serum samples, (ii) positive PCR and confirmation of *E. chaffeensis* or *A. phagocytophilum* DNA, (iii) immunostaining of *E. chaffeensis* or *A. phagocytophilum* antigen in a biopsy or autopsy sample, or (iv) culture of *E. chaffeensis* or *A. phagocytophilum* from a clinical sample. A clinically compatible case with (i) an IFA IgG titer ≥24 to *E. chaffeensis* or *A. phagocytophilum* antigen or (ii) identification of morulae in monocytes (HME) or neutrophils or *E. chaffeensis* or *A. phagocytophilum* or *E. chaffeensis* or *A. phagocytophilum* or *E. rouxi* or *A. phagocytophilum* or *E. chaffeensis* or *A. phagocytophilum* or *E. rouxi* or *A. phagocytophilum* or *E. chaffeensis* or *A. phagocytophilum* or *E. rouxi* of *A. phagocytophilum* or *E. chaffeensis* or *A. phagocytophilum* or *E. rouxi**.

REFERENCES

Coxiella

STEPHEN R. GRAVES AND ROBERT F. MASSUNG

TAXONOMY

Coxiella burnetii is a small, Gram-negative rod that grows within a parasitophorous vacuole located in the cytoplasm of a host eukaryotic cell (invertebrate or vertebrate animal). It is a member of the Gammaproteobacteria. The closest related bacterium is in the genus Legionella. Bergey’s Manual of Systematic Microbiology (2005) classifies it under the order Legionellales, family Coxiellaceae (1). The only other member of the genus Coxiella is the proposed bacterium “C. cheraxi,” a pathogen of the Australian freshwater crayfish Cherax quadricarinatus (2).

DESCRIPTION OF THE AGENT

C. burnetii consists of different morphological forms, depending on the stage of its life cycle. Large-cell variants (LCV) (0.4 to 1.5 µm by 0.2 to 0.5 µm) are metabolically active and divide by binary fission inside the parasitophorous vacuole of the host eukaryotic cell (Fig. 1). Small-cell variants (SCV) (0.5 µm by 0.2 µm) are electron dense and form when conditions are no longer conducive to active growth (3). SCV are filterable (0.22 µm), and this quiescent form of the cell differentially expresses certain proteins compared to LCV (4–7). SCV are functionally spores, although they are chemically different from Gram-positive bacterial spores in that they lack dianaminopimelic acid. They act as the survival and transmissible form of the bacterium when it is extracellular and in the environment. However, they are not as heat stable as typical bacterial spores and can be inactivated by incubation at 63°C for 40 min. The cell wall, although Gram negative, stains poorly by Gram stain and better by Gimenez stain.

The complete genome sequences of Nine Mile and other strains of C. burnetii demonstrate a circular genome with approximately 2 million base pairs, including many insertion sequences; a single plasmid is found in most strains (8). The presence of many pseudogenes implies a process of ongoing gene degradation, presumably associated with a recent evolutionary adaptation to an intracellular lifestyle. Unlike the Rickettsiaceae, C. burnetii does not transport ATP across its cell membrane and has almost full biosynthetic capabilities. It is metabolically active in the extracellular phase, utilizes glucose and glutamate at low pH, and was recently grown in cell-free medium (9). Using microarray and whole-genome sequence analyses, variability in open reading frames and transposon-mediated genomic plasticity have been demonstrated (10).

The virulent form of C. burnetii is referred to as “phase I,” because it is first isolated from humans with Q fever, infected vertebrate animals (especially cattle, sheep, and goats), and ticks. When these isolates are grown for an extended period in the laboratory in tissue culture or embryonated eggs, the population of bacteria can gradually change to a second period (phase II) and become avirulent. This population change can involve loss of genetic material (11) such that the microbe cannot synthesize a full-length polysaccharide, lacking a terminal sugar chain as part of its cell wall lipopolysaccharide (LPS) (12). However, in some strains, loss of virulence does not seem to involve genomic changes (13), presumably due to changes in the expression of genes coding for virulence determinants. The in vitro change from virulent phase I to avirulent phase II is analogous to the smooth-to-rough transition that occurs in bacteria of the Enterobacteriaceae group. In phase I cells, the terminal glycan chain of the LPS contains three unique sugars, L-ribose, dihydroxyacetone, and galactosaminuronic-α(1, 6)-glucosamine, that are not present in phase II LPS (14). Phase I LPS appears to be a key virulence determinant of C. burnetii.

EPIDEMIOLOGY AND TRANSMISSION

Coxiella burnetii is associated with vertebrate animals, especially cattle, sheep, and goats. At parturition, when large concentrations of C. burnetii are present in the placenta, fetus, and associated membranes and fluids, the microbe readily contaminates the animal’s environment. It can remain viable in soil, hay, etc., for many years (possibly decades), presumably in its “spore-like” form (15). Milk from infected cows and other lactating animals can contain C. burnetii (16), which is destroyed by the temperature reached during pasteurization.

A number of other vertebrate animals can be hosts for C. burnetii, especially native animals, for example, native rats, wombats, bandicoots, and kangaroos in Australia. Infections have been described for cats and dogs, with human outbreaks in North America linked to parturition by these animals (17–19). Birds are also hosts, and various other domestic and wildlife species, including
The epidemiology of human Q fever is a combination of the worldwide ubiquitous distribution of \textit{C. burnetii}; the extremely low infectious dose required for human infection (probably between 1 and 10 viable \textit{C. burnetii} cells) (32); the environmental conditions favoring transmission, such as high concentrations of infected animals, high pregnancy rates, appropriate environmental conditions (transmission is greater under dry conditions), and the strength and direction of prevailing winds (28); differences between strains of \textit{C. burnetii} (33–35); and the inherent variability in human susceptibility to \textit{C. burnetii}. While some people are exposed and become sick, others are exposed and seroconvert asymptptomatically or have only mild symptoms that are not sufficient to lead them to seek medical assistance. The proportion of persons that become ill after natural exposure can be as low as 50% (36).

The largest known outbreak of Q fever occurred in the Netherlands between 2007 and 2010 and was associated with dairy goat farming (37). Over 4,000 cases were recorded. Although multiple \textit{C. burnetii} genotypes were identified among human and livestock samples (38), one founder genotype appears to have become established and diversified over time, eventually spreading from animals to humans due to intensive goat farming (39).

**CLINICAL SIGNIFICANCE**

Q fever can present in many forms: (i) as an acute, undifferentiated febrile illness; (ii) as a chronic infection, usually involving the cardiovascular system; or (iii) as a postinfection chronic fatigue syndrome. Q fever can be latent and recrudesce during periods of relative immunosuppression, such as late pregnancy, causing fetal infection. Infection can also result in asymptomatic seroconversion and complete clearance of the microbe, with the patient being unaware of infection or being only mildly ill.

Other features of Q fever include a higher incidence of symptomatic disease in men than in women and a higher incidence in middle-aged men than in those of other age groups. Although it is claimed that occupational and exposure differences explain the gender differences, this is probably not the complete picture. For example, female hormones appear to be protective in mice (40), and 86% of mouse genes modulated by \textit{C. burnetii} infection were differentially expressed in males and females, with genes controlling circadian rhythm probably being protective in females (41).

Information on the diagnosis and management of Q fever in the United States has been published by the CDC and its Q fever working group (42).

**Pathogenesis**

Because \textit{C. burnetii} is an intracellular pathogen, growing in a membrane-bound vacuole in the cytoplasm of a host cell, its survival in the host animal (or patient) depends on its ability to survive and grow intracellularly in the host cell (43). This in turn depends on its ability to keep the host cell alive, and this requires microbe-directed immunomodulation of the host (44). Normally a host cell deals with an invasion by an intracellular microbe by activating the host cell’s self-destructing apoptotic process. Indeed, this is what happens in phase II (avirulent) \textit{C. burnetii} infection. The microbe is rapidly internalized (involving receptor \(\alpha V \beta 3\) integrin and complement receptor 3) (45), and it grows until the host’s cell-mediated immune response, involving gamma interferon and other molecules, induces apoptosis and the infected host cell is destroyed, along with the microbe. Toll-like receptors, including Toll-like receptor 2, are involved in the initial microbe-host cell interaction (46). The silencing of certain host genes by small interfering RNAs increased the size and number of membrane-bound vesicles within \textit{C. burnetii}-infected Vero cells (47).

However, in the case of phase I (virulent) \textit{C. burnetii} infection, a different sequence of events occurs, leading

---

**FIGURE 1** Scanning electron micrograph of \textit{C. burnetii} (orange) in the parasitophorous vacuole of a cryo-prepared Vero cell infected with phase II \textit{C. burnetii} strain Nine Mile. (Courtesy of Beth Fischer and Robert Heinzen, Rocky Mountain Laboratories, NIAID, NIH.)

doi:10.1128/9781555817381.ch66.1
leads to a different sequence of intracellular events. Genes of a type IV secretion system, similar to the Dot/Icm system of Legionella pneumophila, are expressed, leading to secretion of bacterial proteins into the cytoplasm of the host cell. These proteins divert the normal intracellular autophagy pathway, which results in the formation of a parasitophorous vacuole. This vacuole gradually enlarges by incorporating recycled endoplasmic reticulum membrane into its own vesicular membrane, allowing C. burnetii to grow. The inhibition of apoptosis is mediated by host kinases (53), which allow the microbe to survive in the absence of any effective host immune response, despite the presence of circulating antibodies and T lymphocyte-mediated immunity. Eventually the conditions inside the parasitophorous vacuole become unsuitable for ongoing logarithmic-phase bacterial growth, presumably due to nutrient depletion, and C. burnetii converts to the SCV, the nonreplicating survival form. Even then, the host cell may not be destroyed, leading to a state of chronicity or latent infection. Host responses keep the microbe in check, but should immunosuppression develop, such as during pregnancy, the bacterium starts to grow again, causing a Q fever relapse. This is well recognized during the third trimester of pregnancy. In patients with chronic Q fever, there is an impaired maturation of phagolysosomes, permitting ongoing survival of C. burnetii (54). Pathogenesis and immunity in regard to Q fever were reviewed recently (55, 56).

Acute Q Fever

Q fever is a difficult disease to diagnose, as there are no pathognomonic symptoms or signs that give health care providers a clue to the etiology. Many doctors rarely consider Q fever in the differential diagnosis of an acute febrile illness unless a link with animal contact is established from the patient’s history. In fact, many patients without any significant animal contact or tick bite develop Q fever, due to its dispersal by wind (28). Living downwind of a herd of parturient animals, an animal holding yard, or an abattoir is a risk for Q fever. Presenting features can include fever, headache, myalgia, elevated liver transaminases, and interstitial pneumonia.

The great diversity in acute symptoms is probably due to differences in (i) strains of C. burnetii, (ii) human immune response genes and how they process and eliminate C. burnetii (57), (iii) the route of infection (patients infected by the respiratory route [the most common route] are more likely to develop pneumonia, and patients infected by other routes [e.g., tick bite, oral route, sexually transmitted route, or needle stick accident] can manifest the illness differently), and (iv) the infecting dose. An increased dose leads to a reduced incubation period (32). The infecting dose is likely to influence the symptoms and clinical course of the illness. Those with higher infecting doses are more likely to have severe symptoms. Reviews of Q fever from Australia (23, 58) and elsewhere (20, 59, 60) show the diverse symptoms of this disease.

Occasionally, acute Q fever can be fulminant (61). However, most patients survive acute Q fever and defervesce in about 10 to 14 days, at which time they develop either sterilizing or nonsterilizing immunity. It is the latter patients who can go on to develop chronic Q fever.

Chronic Q Fever

As a result of the early dissemination of C. burnetii, many organ systems are exposed and can become chronically infected. The cardiovascular system is particularly susceptible. Most cases of chronic Q fever involve endocarditis (62, 63), including infection of congenitally abnormal (e.g., bicuspid) or previously damaged aortic and mitral valves, aneurysms, and vascular grafts. Pericarditis, myocarditis, and splenic rupture have been reported. Other systems that are often involved in chronic Q fever include the gastrointestinal tract, with chronic granulomatous hepatitis (Fig. 2), acalculous cholecystitis, and diarrhea; the central nervous system, characterized by meningitis and meningoencephalitis; and bones and tendons. Many of these pathogenic features appear to involve autoimmunity, and the presence of autoantibodies is a feature of chronic Q fever (64, 65).

Chronic Q fever cases occurring in the Netherlands outbreak showed a significant risk for patients having had vascular surgery or with a vascular prosthesis or an aneurysm (66). In this series, patients who did not receive antibiotics for acute Q fever (due to mild symptoms) had an increased risk of developing chronic Q fever, indicating the importance of antibiotic treatment of acute Q fever. New diagnostic criteria have been proposed for chronic Q fever, with categories of “proven,” “possible,” and “probable” based on serology, PCR, clinical features, risk factors, and radiology (67).

Pregnancy and Q Fever

Q fever in pregnancy is an underrecognized problem rarely mentioned as a cause of congenital infection, yet it is clearly a problem in some countries where Q fever is significant. The impact of Q fever on pregnancy may well be dependent on the virulence of the circulating C. burnetii strain. In France (68) and Spain (69), it is significant, while in Germany (70), Denmark (71), and the Netherlands (72), it appears not to be so. As pregnancy develops, latent, viable C. burnetii starts to grow in the placenta and the fetus, leading to infection and fetal death. While not recognized as one of the classical

![FIGURE 2 Hematoxylin and eosin stain of a liver biopsy specimen from a patient with acute Q fever. A doughnut ring granuloma is shown. Original magnification, ×400. (Courtesy of H. Lepidi, Marseille, France.)](https://doi.org/10.1128/9781555817381.ch66.f2)
"TORCH" agents of congenital infection, it should be included under “O” (for “other”).

Q Fever in Children
Children appear to be less susceptible than adults to symptomatic Q fever, as are young mice compared to older mice (73). Nevertheless, infections, mainly febrile, influenza-like illnesses or osteomyelitis, have been reported (74, 75).

Post-Q Fever Fatigue Syndrome
A postinfection fatigue syndrome lasting weeks to months after Q fever is now recognized. First described in 1996 (76, 77) in the United Kingdom and Australia, post-Q fever fatigue syndrome is defined as fatigue persisting for more than 12 months after the onset of acute Q fever.

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS
Specimens for the diagnosis of Q fever in humans include blood and tissue, the latter mostly commonly from heart valves following valve replacement surgery. The sample collected depends on the diagnostic test(s) available. Whole blood can be used for isolation and nucleic acid detection methods, and serum or plasma can be used for serologic methods. Tissue samples are most commonly used for isolation, PCR, and immunohistochemistry (IHC). Whole blood should be collected in sodium citrate or EDTA tubes. Samples to be used for isolation should be collected aseptically and shipped promptly, while maintaining refrigeration. If storage of specimens prior to culture is necessary, samples should be kept frozen before and during shipment (to at least −20°C; −80°C is preferable). Blood or tissue samples to be tested by PCR or IHC should be frozen (−20°C) prior to and during shipment, although tissues fixed by the diagnostic laboratory for IHC may be shipped at room temperature.

For the diagnosis of a suspected acute infection by molecular methods or isolation, whole blood should be collected during the acute phase, preferably prior to antibiotic therapy. For serologic diagnosis of an acute infection, a serum sample should be collected during the acute phase, with a second sample collected 3 or 4 weeks after onset. While the same types of specimens can be used for the diagnosis of chronic infection and acute infection, the timing of collection is not as critical for chronic infection. Blood and tissue samples can be persistently positive by culture and/or PCR for chronic infections, and serum antibody levels are typically elevated (phase I and phase II immunoglobulin G [IgG] titers of >1,000) and sustained relative to those with acute infections, which generally have lower peak titers that decrease postinfection.

C. burnetii can be isolated from blood or tissue samples, and this has traditionally been done in cell culture or embryonated chicken eggs or by animal inoculation. However, the recent development of an axenic culture method may allow for isolation of C. burnetii without the use of host cells (78). Isolation must currently be performed in specialized high-containment biosafety level 3 (BSL-3) facilities, as the agent is highly infectious and classified as a U.S. Department of Health and Human Services select agent (79; http://www.selectagents.gov/SelectAgentsandToxinsList.html). If an isolate is propagated by a diagnostic laboratory, U.S. federal regulations require that it be reported to the Federal Select Agent Program within 7 days (http://www.selectagents.gov/form4.html). Diagnostic samples can be evaluated by PCR and serologic methods in BSL-2 facilities with the use of appropriate personal protective equipment.

DIRECT EXAMINATION
Microscopy and Antigen Detection
IHC is an excellent method for the detection of C. burnetii antigens in tissue samples (Fig. 3), particularly cardiac valve tissues that are colonized during chronic Q fever. Organisms in heart valve tissues have also been demonstrated by direct immunofluorescence methods or visualized by electron microscopy (Fig. 1). However, these methods are rarely used for the diagnosis of acute Q fever, as the appropriate tissue samples are not often collected and vary among patients and because other methods (PCR and serology) that are simpler to perform on blood samples are available.

Nucleic Acid Detection
PCR can be a useful diagnostic tool for acute and chronic Q fever infections (80). It is important that the sample be collected during the early period of an acute infection, while the patient is bacteremic, optimally within 4 weeks of onset of symptoms. A recent study showed that PCR can be more sensitive than serology during the first 2 weeks after the onset of symptoms and can provide an earlier diagnosis than that with serology alone (81). Whole blood is most commonly used for the analysis of acute infections, although enrichment of the white blood cell fraction (buffy coat) may increase sensitivity. Serum can be used if whole blood is not available, although it is less likely to be positive due to the lack of infected cells. For chronic Q fever with endocarditis, the valve tissue is typically positive, while blood can be positive or negative. It has been reported that PCR is generally positive for chronically infected patients with phase I IgG antibody titers between 800 and 6,400, but PCR is often negative for those with higher titers. A number of PCR assays have been described that amplify the multicopy IS1111 insertion sequence (82), and these generally provide increased sensitivity compared to assays that amplify single-copy genes (com1, the 16S rRNA or 23S rRNA gene, etc.). However, the potential for false-positive

FIGURE 3  Alkaline phosphatase IHC on a heart valve from a patient with chronic Q fever endocarditis. C. burnetii microorganisms are stained pink within mononuclear cells. Original magnification, ×400. doi:10.1128/9781555817381.ch66.f3
results with PCR makes it imperative that these results be interpreted relative to those of other diagnostic assays, such as serology, and other clinical data.

ISOLATION PROCEDURES

Isolation of *C. burnetii* from human blood or tissue must be performed in a BSL-3 containment facility due to the low infectious dose of the agent and the potential for generating aerosols. Isolation can be accomplished in tissue culture cells or embryonated chicken eggs or by inoculation into animals, such as mice or guinea pigs. Any infected tissue sample can be used for isolation, and PCR assays are quite useful for screening tissue samples prior to isolation to determine those potentially containing organisms. The organism can be stable in tissue samples for months before isolation attempts. Animal inoculation is the most sensitive method for isolation. A mouse can be injected intraperitoneally with up to 0.5 ml of inoculum, and the spleen is then harvested at 10 to 14 days postinjection. The spleen is homogenized and injected into another mouse, inoculated onto uninfected tissue culture cells, or used to infect embryonated eggs for further propagation. Isolation by animal inoculation is particularly useful for tissue or environmental samples that may be contaminated with organisms other than *C. burnetii*, as the animal serves to amplify *Coxiella* while eliminating other agents. Aseptically collected tissues that likely contain only *C. burnetii* can be inoculated directly onto tissue culture cells or embryonated chicken eggs. A shell vial method that works well has been described for isolation in human embryonic lung fibroblast tissue culture cells (83) and can be used with many commonly available cell lines (e.g., Vero, RK13, THP1, and A549) susceptible to infection by *C. burnetii*. Egg inoculations work particularly well for propagating large amounts of *C. burnetii* for antigen preparation.

*C. burnetii* has now been cultivated in a cell-free liquid medium, as its metabolic pathways are largely intact. It generates ATP by substrate-level phosphorylation, has an oxidative capacity (is microaerophilic), and has oxygen-protective enzymes, such as peroxidases and superoxide dismutases. It should now be considered a facultative intracellular bacterium (84). It will also grow on agar and can be transformed genetically (78). It retains its phase I (virulent) character for 8 subcultures in *vitro*, and some strains grow to a concentration of 10⁶/ml, reaching stationary phase by day 6 of culture (85).

IDENTIFICATION

Only reference laboratories are likely to isolate *C. burnetii* in pure culture and be required to confirm its identification by classical means. In recent years, identification has more often been accomplished by amplifying and sequencing key genes or sequences (e.g., coml and IS1111). A routine diagnostic laboratory that inadvertently isolates *C. burnetii* in tissue culture may identify it by a direct fluorescent-antibody assay (Fig. 4), although specific antisera would need to be obtained from a reference laboratory.

TYPING SYSTEMS

Typing systems based on genetic differences between isolates are not standardized and are still undergoing development. While no typing scheme is universally accepted, it is clear that there is considerable strain/isolate variability within the species *C. burnetii*. Restriction endonuclease-digested DNAs separated by SDS-PAGE yielded 6 groups from 32 isolates (33), while multispacer sequence typing of intergenic regions produced 30 different allelic combinations that grouped into 3 major clusters (86). Single nucleotide polymorphism analysis methods, developed for typing of *C. burnetii* based on data from genome sequences and multispacer sequence typing, showed good correlation with the 6 genomic groups and 35 multispacer sequence typing genotypes previously identified (34). Use of microarrays yielded 10 genomotypes organized into 3 groups; some genomotypes were associated with acute human disease, all were associated with chronic human disease, and one was associated with hard tick isolates (35).

SEROLOGIC TESTS

The detection of antibodies to *C. burnetii* is the most commonly used and effective method for the diagnosis of Q fever. The primary serologic assays in use today are indirect immunofluorescent-antibody (IFA) assay, the complement fixation (CF) test, and enzyme-linked immunosorbent assay (ELISA) (87), with the IFA assay being the gold standard and most commonly used method. CF methods generally lack sensitivity and are used less commonly today, while ELISAs are growing in use and availability. The diagnosis of infection by any serologic assay can be complicated by the facts that *C. burnetii* has a worldwide distribution in nature, so that many humans have been exposed and may be seropositive. Most serologic methods make use of *C. burnetii* antigen grown in either tissue culture cells or embryonated chicken eggs. Serologic methods also take advantage of the antigenic differences between naturally occurring virulent phase I *C. burnetii* and attenuated phase II isolates (88). Phase I strains contain intact LPS antigens, while phase II strains lack complete LPS antigens. The antibodies produced during natural human infection respond in a unique time sequence to the phase I and phase II forms, with the acute response directed primarily to phase II antigens, while the response in chronic infections is a mixture of phase I and phase II antibodies.

IFA Test

IFA tests detect IgG, IgM, and IgA antibodies for both phase I and phase II antigens and are useful for the detection of and discrimination between acute and chronic infections.
(89). The IFA test has excellent specificity and sensitivity for the diagnosis of Q fever if the appropriate samples are available. The diagnosis of acute Q fever is dependent on seroconversion, defined as a fourfold increase in the IgG titer for phase II antigens between acute- and convalescent-phase samples. The diagnosis of chronic Q fever should not be based solely on an antibody titer. While earlier studies (20, 90) showed high phase I IgG levels in chronic Q fever, recent studies often regard this phenomenon as normal seroprogression (91, 92). Clinical features consistent with chronic Q fever and a high phase I IgG titer (e.g., >1,024) are necessary to make a diagnosis of chronic Q fever (42, 63, 67). However, the choice of cutoff titer for acute or chronic disease should be determined in each laboratory, as methods for antigen preparation, assays, and interpretation can vary. Ideally, reference laboratories should provide controls with known positive and negative samples that may be used for in-laboratory assay validation and cutoff determination. FDA-approved, commercial C. burnetii IFA tests are available for the diagnosis of acute Q fever (IgG and IgM assays for phase II antigens) and provide the best source for laboratories not equipped to prepare their own antigens (Focus Diagnostics, Cypress, CA). The diagnosis of chronic Q fever is best performed at reference laboratories that have BSL-3 facilities for the propagation and storage of phase I organisms, since C. burnetii is classified as a select agent.

Enzyme-Linked Immunosorbent Assay
ELISAs have been reported to be as sensitive and specific as IFA tests (93). FDA-approved, commercial ELISAs that detect IgG or IgM antibodies to phase II antigens are available (Inverness, Brisbane, Australia) and are useful for detection of IgM antibodies (94), although they are not currently marketed in the United States. A number of reference laboratories and research institutions have also developed in-house ELISAs. In general, ELISAs are qualitative and have not been evaluated as thoroughly as IFA tests. Commercial and in-house ELISAs can be automated to require minimal interpretation and are particularly useful for the detection of IgG antibodies to phase II antigens when employed in seroprevalence studies. However, their lack of standardization and quantification makes them less than ideal for the diagnosis of acute Q fever, and the lack of phase I antigens in commercial assays limits their use for the diagnosis of chronic Q fever.

CF Test
Whereas the CF test is still commonly used as a diagnostic assay for veterinary testing, the assay is rarely used for human diagnostics due to advances in IFA and ELISA methods and the demonstration that the CF test has a lower sensitivity, is more time-consuming, and detects seroconversion at a later date than the other assays. False-negative results with the CF assay have also been described for chronic infections with high titers, due to a prozone effect.

ANTIMICROBIAL SUSCEPTIBILITIES, TREATMENT, AND PREVENTION

In vitro antimicrobial susceptibility testing is not routinely performed. C. burnetii is an intracellular pathogen, and correlations between in vitro MICs of antibiotics in an infected tissue culture system and antibiotic activities in infected patients are uncertain. The recommended treatment for acute Q fever is doxycycline, although strains with partial doxycycline resistance have been reported. Erythromycin and azithromycin are not recommended, as in vitro testing suggests that some strains are resistant (MICs >8 μg/ml) (95, 96). Neither ciprofloxacin nor chloramphenicol is recommended, as these drugs do not inhibit in vitro growth (83, 97). Rifampin can be used, although it is not recommended in the United States. Treatment with cotrimoxazole during pregnancy is recommended, as infection adversely affects pregnancy outcomes (98).

Chronic Q fever, especially Q fever endocarditis, requires long-term antibiotics and often requires valve replacement. Dual therapy with doxycycline and hydroxychloroquine is recommended for a minimum of 1 year, and possibly longer. Hydroxychloroquine increases the pH of the phagolysosome from 4.8 to 5.7 and renders doxycycline bactericidal rather than bacteriostatic (99).

A human Q fever vaccine (QVAX) has been developed and shown to be efficacious (100, 101). Although the vaccine is commercially available only in Australia, it was used in the Netherlands outbreak in 2011 to prevent chronic Q fever in predisposed individuals.

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS
Serological and nucleic acid amplification (PCR) reports for a patient evaluated for Q fever can be difficult to understand. Interpretation should always be provided and should include the following: (i) the significance of the antibody titer, particularly the difference between antibodies to phase I and phase II C. burnetii and the different antibody classes detected (IgM, IgG, and IgA); (ii) whether the serologic result supports recent Q fever (high phase II IgM titer), past Q fever (high phase II IgG titer), or chronic Q fever (high phase I IgG and IgA titers); (iii) the limitations if there is only one serum sample available for testing and the importance of receiving a second serum sample to detect a fourfold increase in antibody titer (for example, a raised phase II IgM titer in one serum sample may represent very early acute Q fever or a false-positive result); (iv) in locales where vaccination occurs or where post-Q fever fatigue syndrome is considered, a comment stating that no antibody pattern can currently define either condition; and (v) an indication that detection of C. burnetii DNA in blood usually indicates acute, very early Q fever, often before seroconversion. Tissue specimens (e.g., heart valve, liver, and bone marrow) are most often positive in chronic Q fever, although peripheral blood leukocytes from such patients can be positive.

REFERENCES

**Tropheryma whipplei**

WALTER GEİBDÖRFER, ANNETTE MOTER, AND CHRISTIAN BOGDAN

*Tropheryma whipplei* is the agent of classical Whipple's disease, a systemic infection originally described by the American pathologist George Hoyt Whipple in 1907 as intestinal lipodystrophy (1–4). Since then, *T. whipplei* has also been implicated in isolated infections of the central nervous system, the heart valves, joints, or other organs. A remarkable amount of research during the past 20 years has yielded new insights into the epidemiology, biology, pathogenicity, and immunological control of this Gram-positive bacterium. However, the early diagnosis of infections with *T. whipplei* still remains a challenge for physicians and microbiological laboratories due to the rarity of the disease, the diversity and nonspecificity of symptoms, the fastidious nature of the pathogen, and the lack of noninvasive serological tests (3).

**TAXONOMY**

In 1991, Wilson et al. identified the “Whipple's disease-associated bacterium” by amplification of a 16S rRNA gene fragment from a small-bowel biopsy specimen and sequence analysis (5). The preliminary name “Trophyernya whippeii” was derived from “trophe” and “eryma” (Greek words for nourishment and barrier) and was changed to *T. whipplei* in 2001 (6). *T. whipplei* is a member of the family of Cellulomonadaceae, which belongs to the phylogenetic subdivision of Gram-positive bacteria with high GC content (Class Actinobacteria, Order Actinomycetales). However, *T. whipplei* has an exceptional status within the Actinobacteria, owing to the low homology of its 16S rRNA gene sequence to other Actinobacteria (<92%), small genome size (approximately 930 kbp), and low GC content (46.3%) (7).

**DESCRIPTION OF THE AGENT**

**Morphology**

Although *T. whipplei* is categorized as a Gram-positive actinobacterium, it nevertheless stains poorly with Gram's method and is negative in acid-fast staining. *T. whipplei* can be detected as intracellular clusters within phagocytic vacuoles or as extracellular bacteria (8). It forms slender rods that react well to periodic acid-Schiff (PAS) staining due to glycoproteins in its unique trilaminar envelope (6, 9). After degradation of the bacteria by macrophages, remnants of the cell envelope are left as intracellular PAS-positive inclusions (9).

**Culture**

Since the first anecdotal report on the growth of *T. whipplei* in human macrophages deactivated by interleukin-4 (10) and the later documented culture and isolation of *T. whipplei* in a human fibroblast cell line (8), *T. whipplei* strains could be isolated from various clinical samples, including heart valves, blood, duodenal biopsy specimens (11), cerebrospinal fluid (7), synovial fluid (12), vitreous fluid (13), skin (14), saliva (15), and stool specimens (16). After genomic data revealed the absence of most genes necessary for amino acid synthesis, a cell-free culture method was developed using a medium supplemented with the missing amino acids (17). However, even optimized and standardized culture protocols of *T. whipplei* culture are insensitive, laborious, and slow and are therefore not applicable as routine methods for the diagnosis of *T. whipplei* infection.

**Genome**

Data from two sequenced *T. whipplei* genomes revealed a reduced genome (<1 Mbp) lacking key biosynthetic pathways. On the other hand, cell surface proteins seem to be abundant, including a new family of *T. whipplei* surface proteins (WiSP). Repetitive sequence elements may play a role in genetic and antigenic variation, suggesting host-dependent coevolution of *T. whipplei* (7).

**EPIEDEMIology AND TRANSMISSION**

The estimated annual incidence of Whipple's disease is 1 case per 100,000 to 1,000,000 inhabitants (4), which makes Whipple’s disease a rare condition. Infections with *T. whipplei* are mainly restricted to white Caucasians in Europe and North America (4) and primarily affect middle-aged (average age, 56 years) males (73%) (18).

*T. whipplei* DNA can be detected in wastewater from sewage plants, indicating an environmental occurrence of this bacterium (19, 20). *T. whipplei* can also be found in asymptomatic, healthy humans, suggesting that it can be a commensal bacterium and that human carriers may represent one of its reservoirs (2). Genotyping studies suggest interhuman transmission of *T. whipplei* (probably via fecal-oral or oral-oral routes), as the same strains have predominantly been found within families or contact persons in France (21) or rural villages in Senegal (2).
FIGURE 1 PAS staining of a duodenal biopsy specimen shows lymphangiectasia and massive infiltration of the lamina propria by strongly PAS-positive foamy macrophages containing *T. whipplei* (image kindly provided by Christoph Loddenkemper, Pathotres, Berlin, Germany).

doi:10.1128/9781555817381.ch67.f1

**CLINICAL SIGNIFICANCE**

**Pathogenesis and Immunology**

Local or systemic disease following *T. whipplei* infection is rare despite an abundance of this microbe in the environment and a high rate of human colonization. Thus, manifestations of clinical disease might require an immunological predisposition. According to the current model (2–4, 22), *T. whipplei* is taken up orally, primarily in early childhood, leading to temporary asymptomatic carriage, self-limiting gastroenteritis, fever, or cough. Usually, a protective humoral and cellular immune response will develop, resulting in the clearance of *T. whipplei*. In predisposed persons, *T. whipplei* may persist and spread systemically over the years, resulting in classical Whipple’s disease with infiltration of the lamina propria by alternatively activated macrophages (Fig. 1 and 2), which cannot efficiently kill *T. whipplei* (23). In addition to a shift of T-cell subsets from Th1 and Th17 cells toward Th2 and regulatory T cells (24), there is also evidence for a reduced number of immunoglobulin-positive plasma cells and an impaired secretion of immunoglobulins in the duodenal lesions of Whipple’s disease patients (25). The characterization of bacterial factors involved in disease pathogenesis and the modulation of immune response, as well as identification of host factors predisposing to symptomatic *T. whipplei* infections, are themes of current research.

**Classical (Systemic) Whipple’s Disease**

In classical Whipple’s disease, the infection with *T. whipplei* probably occurs years before clinical symptoms point to the diagnosis. Chronic diarrhea, as one of the leading signs, can start mildly; often migratory arthralgias of large joints are the prominent findings. After the prodromal state that can last for years, the condition of the patients may worsen rapidly with aggravated diarrhea, malabsorption, weight loss, abdominal pain, and lymphadenopathy, leading to the full picture of a wasting syndrome. Nonspecific symptoms like fever, (night) sweats, and asthenia may be present. Depending on the organ systems affected by the disease, a multitude of symptoms can emerge (Table 1). Involvement of the central nervous system is a serious complication of classical Whipple’s disease that occurs in approximately one-fifth of patients (18). The prognosis is unfavorable because irreversible damage may occur, and antibiotic treatment failure has been described. In patients newly diagnosed with Whipple’s disease, cerebrospinal fluid for PCR diagnosis should be obtained.

**Isolated Organ Manifestations**

**Joints**

Whereas arthropathy is the most common symptom in classical Whipple’s disease, it may also be the only clinical manifestation (Table 1). When it appears as migrating oligo- or polyarthritis, it is often misdiagnosed as rheumatoid arthritis. This may result in erroneous immunosuppressive treatments with corticosteroids or tumor necrosis factor antagonists which then cause a dramatic deterioration of the disease. Therefore, it is prudent to test patients with presumed seronegative rheumatoid arthritis for Whipple’s disease by PCR examination of synovial biopsy specimens or joint aspirates.

Central Nervous System (CNS)
Non-specific neuropsychiatric manifestations can be the only pathological findings of T. whipplei infection, ranging from psychiatric disorders such as depression, personality changes, dementia, or memory impairment to ocular movement disturbances, epileptic seizures, ataxia, and headache. In magnetic resonance imaging or computed tomography scans, solitary or multiple enhancing lesions can be present involving the temporal lobe, midbrain, hypothalamus, and thalamus region (26). Diagnosis is often delayed and is made by PCR detection of T. whipplei in cerebrospinal fluid (CSF) or brain biopsy specimens.

Eyes
Two studies on Whipple’s disease with 696 or 113 patients revealed an ocular involvement in 2.7 or 6% of the cases, respectively (18, 27). Symptoms may be non-specific, occurring bi- or unilaterally, and include mild vision loss or blurry vision, diplopia, eye floaters, or neuro-ophthalmic findings such as ophthalmoplegia, nystagmus, and papilledema (28, 29). Characteristic ocular findings are intraocular inflammation (uveitis, retinitis, and endophthalmitis) or crystalline keratopathy. In most cases, diagnosis of the typically chronic and corticosteroid-resistant infection is only made years after the onset of symptoms by PCR examination of vitreous humor. In general, ocular infection by T. whipplei points to classical Whipple’s disease and, therefore, can also be diagnosed in other tissues (e.g., small bowel biopsy specimens). However, at the time of presentation, ocular involvement may be the only clinical sign of Whipple’s disease (28, 29).

Endocarditis
Endocarditis (Fig. 3) might be the most frequent manifestation of T. whipplei infection and accounts for 8.5 and 6.3% of culture-negative endocarditis cases in France (Department Rhône-Alpes) (30) and Germany (31), respectively. Endocarditis may occur as a complication of classical Whipple’s disease (6/113 cases in reference 18), but in the majority of cases, it is a localized infection (14/16 cases in reference 31). This suggests that most patients with isolated T. whipplei endocarditis might not exhibit the putative immunodeficiency which predisposes patients to systemic Whipple’s disease. Valvular vegetations are detected by echocardiography in 78% of the patients. Arthralgias are the most frequent (75%) clinical symptom, whereas fever is present in only 39% of the cases. Duke criteria are not helpful in establishing a definitive diagnosis of Whipple’s endocarditis (30, 31). PCR analysis of explanted heart valves is the diagnostic method of choice.

IRIS
Immune reconstitution inflammatory syndrome (IRIS), which was first reported as a complication following treatment of Whipple’s disease in 2009 (32), has been diagnosed in up to 11% of treated patients. Prior immunosuppressive treatment, e.g., for suspected rheumatoid arthritis, is a risk factor for the development of an IRIS. After initial clinical improvement, immune reaction to nonviable T. whipplei antigen results in symptoms including fever, arthralgias, gastrointestinal symptoms, and skin irritation. PCR tests typically remain negative in this situation. After exclusion of opportunistic infections, corticosteroid treatment may be effective (see reference 33 and references therein).

Acute Gastroenteritis
Diarrhea and abdominal pain are frequent symptoms in classical Whipple’s disease and may be a consequence of malabsorption and gut infection. Recently, large quantities of T. whipplei DNA have been detected in children with acute gastroenteritis, raising the question whether T. whipplei may also cause acute gastroenteritis in otherwise healthy people (34). However, it remains unclear whether this unusual finding reflects causality or an accidental association.

Skin
Manifestations like melanoderma, hyperkeratosis, peripheral edema, petechiae, and purpura may be present in late stages of the disease. Interestingly, T. whipplei DNA can often be detected in skin biopsy specimens of patients with Whipple’s disease, even in the absence of cutaneous symptoms (14). Highly sensitive PCR methods may provide a mechanism to screen skin biopsy specimens for T. whipplei DNA, although negative PCR results do not exclude Whipple’s disease (35).

Lungs
Pulmonary involvement (pleural effusion, pulmonary infiltration, and granulomatous mediastinal adenopathy) is estimated to occur in 30 to 40% of patients with classical Whipple’s disease (1). Interstitial lung disease with detection of T. whipplei in biopsy specimens of pulmonary parenchymal nodules has been reported in only a few cases (15, 36). These patients presented usually with dry cough and shortness of breath, mostly accompanied by arthralgias and fever. In the absence of gastrointestinal symptoms, pulmonary manifestations may lead to the primary diagnosis of Whipple’s disease. The relevance of increased T. whipplei colonization in human immunodeficiency virus-positive compared to human immunodeficiency virus-negative individuals (13 versus 1%) needs further investigation (37).

Healthy Carriers
T. whipplei can be detected in saliva, dental plaque, intestinal biopsy, gastric juice, and stool specimens of healthy individuals without signs of Whipple’s disease. Although early reports may have overestimated the prevalence rate because of false-positive PCR results (38), colonization of asymptomatic adults is well established. In stool and saliva specimens, the estimated prevalence rates were 4% and =1%, respectively (39, 40). Higher prevalence rates were found in humans with increased risks for acquisition of T. whipplei (e.g., in sewage workers [40], homeless people [41], and family members of Whipple’s disease patients [21]). As the prevalence and bacterial load is far higher in stool and saliva samples of Whipple’s disease patients, PCR can be used as a diagnostic tool (14, 39). However, positive results are not proof of infection. A very high prevalence of T. whipplei DNA (75%) was reported in stool samples of children under 5 years of age in Senegal (2). As environmental specimens were largely negative for T. whipplei DNA and systemic Whipple’s disease is restricted to Caucasians, this finding most likely reflects a human reservoir of T. whipplei and early colonization due to fecal-oral transmission (42).

COLLECTION, TRANSPORT, AND STORAGE OF SPECIMENS
Small bowel biopsy specimens should be examined by PAS staining and PCR whenever classical Whipple’s disease is suspected (Fig. 4). To avoid sampling errors in cases of sparse or patchy prevalence of PAS-positive macrophages, at least five endoscopic biopsy specimens from the small bowel (distal duodenum and/or jejunum) should be evaluated. In the case of positive results, CSF should be analyzed...
PAS staining with respect to total performance (sensitivity, specificity, time to result, and hands-on time) (43). Laboratories generally use in-house PCR protocols (for examples, see reference 49 and 50) and, therefore, are responsible for validation and accurate quality control procedures. This is important, as PCR is prone to laboratory contamination by PCR to verify or exclude CNS involvement. A recently published alternative workflow proposes the screening of stool, saliva, and skin biopsy specimens using highly sensitive PCR methods as first steps in the diagnosis of classical Whipple’s disease (35). To test for isolated T. whipplei infection, a sample of the affected organ should be examined by PCR and histological methods including PAS staining. When positive results are obtained, gastrointestinal and CNS involvement should be excluded.

Samples for PAS staining, immunohistochemistry (IHC) or fluorescence in situ hybridization (FISH) analysis should be fixed in 10% formalin and transported at room temperature. For PCR, the samples must not be fixed (i.e., no formalin pretreatment) and can usually be transported at room temperature within 1 day. If assays cannot be done within 1 day, fresh samples can be stored for a few days at 4°C and for long-term storage at −80°C. For culture, fresh samples should be frozen at −80°C and transported on dry ice.

DIRECT EXAMINATION

Microscopy

PAS Staining

PAS staining of biopsy specimens from the lower duodenum or jejunum typically shows an infiltration of the lamina propria with macrophages containing PAS-positive, diastase-negative granular inclusions of intracellular or ingested bacteria (Fig. 1). However, PAS staining can be both false-positive due to infection with other agents (e.g., nontuberculous mycobacteria) and false-negative as a consequence of low bacterial load (43). Therefore, every positive PAS result should be confirmed by an independent and specific method (PCR, IHC, or FISH). Similarly, in case of continuing clinical suspicion of Whipple’s disease despite a negative PAS result, PCR should be performed due to its high sensitivity to detect small quantities of T. whipplei (3, 4) (Fig. 4).

In patients without gastrointestinal manifestations, specimens from the clinically affected sites, e.g., explanted heart valves, lymph nodes, synovial tissue, CSF, or brain biopsy specimens, may be PAS positive, whereas duodenal biopsy specimens remain negative (3).

For experienced pathologists, PAS staining is appropriate to assess the success of treatment based on the change of inclusions from intensely PAS-positive granular particles to faintly PAS-positive cytoplasm without granulation (44).

Transmission EM

Transmission electron microscopy (EM) can be used to identify T. whipplei in ultrathin histological sections from infected organs due to its unique trilamellar cell wall (9). As EM is laborious, time-consuming, and available in only a few specialized laboratories, its use is restricted to the analysis of special cases (43).

Antigen Detection

IHC

IHC with polyclonal rabbit anti-T. whipplei antibodies is able to specifically visualize the bacteria in circulating monocytes (45) and in histological slides from various tissues (46). Compared to PAS staining, IHC is more specific and sensitive in untreated Whipple’s disease but less sensitive after treatment (46). As the antiserum is not yet commercially available, this method is restricted to a few specialized laboratories. Like FISH, IHC may be used to confirm positive results obtained by PAS staining.

Nucleic Acid Detection

FISH

FISH is a molecular technique using fluorescently labeled oligonucleotide probes to target T. whipplei 16S rRNA in histological sections. FISH is particularly useful to verify and localize T. whipplei in extraintestinal tissues (31, 47, 48) or to confirm PAS-positive staining of small bowel biopsy specimens (Fig. 2 and 3). FISH probes target the ribosomes which correlate with the activity of bacteria, whereas PAS staining stays positive for prolonged periods under therapy. However, so far, detection of T. whipplei by FISH is available only in specialized centers and is still regarded as a research rather than a routine technique.

PCR

Although PAS staining is still the first-line method for analysis of duodenal biopsy specimens, PCR outcompetes PAS staining with respect to total performance (sensitivity, specificity, time to result, and hands-on time) (43).
T. whipplei of high bacterial loads, such as explanted heart valves in cases, it is only suitable for examination of specimens containing T. whipplei activity than -specific PCR protocols. Therefore, amplification) followed by sequence analysis shows lower sensitivity than panbacterial PCR (16S rRNA gene amplification). Universal bacterial results will not rule out infection (52). Universal bacterial and doxycycline for 1 year followed by a life-long monotherapy. Hydroxychloroquine is thought to neutralize the low pH in acidic vacuoles, in which T. whipplei replicates (23). Relapse of Whipple’s disease following therapy with doxycycline plus hydroxychloroquine has been reported (66).

For isolated organ manifestations, e.g., endocarditis or joint infection, there are no published recommendations for therapy in vitro. The patient was treated with a combination of hydroxychloroquine, sulfamethoxazole, and trimethoprim, resulting in high rates of CNS relapse (63). Current recommendations consist of an initial therapy with a parenteral expanded-spectrum cephalosporin, carbapenem, or high-dose penicillin G to achieve complete clearance of T. whipplei from the CNS, followed by 1 year of oral treatment with co-trimoxazole (Table 2) (64).

**ANTIMICROBIAL SUSCEPTIBILITIES**

T. whipplei was susceptible in vitro to many antibiotics, including penicillin G, macrolides, doxycycline, rifampin, chloramphenicol, and co-trimoxazole (59). Ciprofloxacin was found to be ineffective (60). Ceftriaxone and gentamicin showed high-level activity against extracellular but not intracellular bacteria. Susceptibility to imipenem was variable. T. whipplei is resistant to trimethoprim, as the gene encoding its target (dihydrofolate reductase) is absent from the T. whipplei genome (61). Consequently, sulfamethoxazole is the active compound of co-trimoxazole, but reduced susceptibility and resistance of clinical T. whipplei isolates to sulfonamides have recently been reported also (reference 62 and references therein). If left untreated, systemic Whipple’s disease is fatal. The former commonly used treatment with tetracycline resulted in high rates of CNS relapse (63). Current recommendations consist of an initial therapy with a parenteral expanded-spectrum cephalosporin, carbapenem, or high-dose penicillin G to achieve complete clearance of T. whipplei from the CNS, followed by 1 year of oral treatment with co-trimoxazole (Table 2) (64). Substantial clinical improvement within 7 to 21 days and subsequent complete recovery can be achieved in most patients. However, for trimethoprim-sulfamethoxazole, treatment failures and relapses have been reported (reference 65 and references therein). A highly efficient alternative regimen showing bactericidal activity consists of a combination of hydroxychloroquine and doxycycline for 1 year, followed by a lifelong monotherapy with doxycycline (65) (Table 2). Hydroxychloroquine is thought to neutralize the low pH in acidic vacuoles, in which T. whipplei replicates (23). Relapse of Whipple’s disease following therapy with doxycycline plus hydroxychloroquine has been reported (66).

For isolated organ manifestations, e.g., endocarditis or joint infection, there are no published recommendations for

**FIGURE 3** FISH of a heart valve section in a case of culture-negative endocarditis using a T. whipplei-specific probe (Cy3, orange) (48). The low-magnification image shows extensive areas with bacterial colonization (slightly orange glimmer) along with calcified tissue (bright yellow-green autofluorescence). Host cell nuclei are stained blue with 4',6-diamidino-2-phenylindole (DAPI). Inset shows dense clusters of T. whipplei cells at a higher magnification (orange). doi:10.1128/9781555817381.ch67.f3
FIGURE 4 Hierarchical scheme for the diagnosis of Whipple’s disease (modified from references 3 and 4). 1, positive PCR should be confirmed by 16S rRNA gene sequencing or a second specific PCR detecting a different *T. whipplei* target sequence; 2, IHC and FISH are available only in specialized laboratories. doi:10.1128/9781555817381.ch67.f4

Treatment, but a shorter duration of the standard antibiotic treatment may be feasible. In the case of cerebral involvement, patients may benefit from adjunctive corticosteroid therapy. Corticosteroids have also been suggested in patients with IRIS (67). Immune therapy with gamma interferon was successfully used in a patient with relapsing disease (68).

EVALUATION, INTERPRETATION, AND REPORTING OF RESULTS

Following the first diagnosis of Whipple’s disease in a patient, the attending physicians and the responsible laboratory personnel (pathologist and microbiologist) should jointly review the test results and their correlation with the clinical presentation of the patient and decide on confirmation.

tory diagnostic approaches with a second, independent sample or method. A positive PCR should be confirmed by sequence analysis or by a different PCR test targeting another T. whippelii-specific DNA sequence. In each case, examination of small bowel biopsy specimens and CSF should be considered. For PCR, fresh tissue specimens are always preferable to paraffin-embedded samples, as the sensitivity is considerably higher and the risk of DNA contamination (as it might occur when extracting DNA from paraffin blocks) is much lower. Negative PCR results from blood samples do not rule out infection due to the generally low sensitivity observed with this specimen type. In the case of saliva and stool, positive PCR results do not differentiate between a carrier state and a florid infection.

Once the laboratory detection of T. whippelii is confirmed, a decision on the treatment regimen and follow-up strategy must be made. In the case of any doubts about the diagnosis, therapy, and/or follow-up of a patient or when complications occur (e.g., primary treatment failure or relapse), experts from reference centers or specialized laboratories should be contacted.

Antimicrobial chemotherapy has played a vital role in the treatment of human infectious diseases since the discovery of penicillin in the 1920s. Hundreds of antimicrobial agents have been developed, and multiple agents in a variety of classes are currently available for clinical use. However, the sheer numbers and continuing development of agents make it difficult for clinicians to keep up with progress in the field. Similarly, this variety presents significant challenges for clinical microbiologists, who must decide which agents are appropriate for inclusion in routine and specialized susceptibility testing.

This chapter provides an overview of the antibacterial agents currently marketed in the United States, with major emphasis on their mechanisms of action, spectra of activity, important pharmacologic parameters, and toxicities. Selected antibacterials not available in the United States are briefly mentioned as well. Antibiotics that have fallen into disuse or remained investigational are mentioned only briefly.

**PENICILLINS**

The penicillins (Table 1) are a group of natural and semisynthetic antibiotics containing the chemical nucleus 6-amino-penicillanic acid, which consists of a β-lactam ring fused to a thiazolidine ring (Fig. 1a). The naturally occurring compounds are produced by a number of *Penicillium* spp. The penicillins differ from one another in the substitution at position 6, where changes in the side chain may modify the pharmacokinetic and antibacterial properties of the drug.

**Mechanism of Action**

The major antibacterial action of penicillins is derived from their ability to inhibit multiple bacterial enzymes, namely, penicillin-binding proteins (PBPs), that catalyze the last steps of peptidoglycan synthesis (1). This ability to inhibit bacterial cell wall enzymes, such as the transpeptidases, usually confers bactericidal activity against Gram-positive bacteria. This activity of the penicillins is often related to their ability to trigger membrane-associated autolytic enzymes that destroy the cell wall.

Penicillins also can bind to bacterial endopeptidases, to bacterial carboxypeptidases, and to bifunctional PBPs with both transpeptidase and transglycosylase activities, enzymes involved in bacterial cell division (2).

**Pharmacology**

Levels of oral absorption differ markedly among the penicillins. As a natural congener of benzylpenicillin (penicillin G), phenoxymethyl penicillin (penicillin V) resists gastric acid inactivation and is better absorbed from the gastrointestinal tract than is penicillin G. Amoxicillin is a semisynthetic analog of ampicillin and has greater gastrointestinal absorption than ampicillin (95% versus 40% absorption). The isoxazolyl penicillins, also referred to as antistaphylococcal penicillins, cloxacillin, and dicloxacillin, are acid stable and are also absorbed from the gastrointestinal tract, allowing for oral administration. Nafcillin and oxacillin are administered only intravenously.

Repository forms of penicillin G, available in procaine or benzathine, delay absorption from an intramuscular depot. Procaine penicillin G provides detectable levels for 12 to 24 h, while benzathine penicillin G achieves only very low levels in blood for prolonged periods (3 to 4 weeks) and is useful for the therapy of syphilis and for prophylaxis of streptococcal pharyngitis and rheumatic fever.

Penicillins are well distributed to many body compartments, including lung, liver, kidney, muscle, bone, and placenta. Penetration into the eye, brain, cerebrospinal fluid (CSF), and prostate is poor in the absence of inflammation. These drugs are metabolized to a small degree and are rapidly excreted, essentially unchanged, via the kidney. With average half-lives of 0.5 to 1.5 h, they are usually administered every 4 to 6 h to maintain effective blood levels. The renal tubular excretion of penicillins can be blocked by probenecid; thus, their half-lives in serum are prolonged, though this is rarely done in clinical practice. Recommended dosage reductions for many penicillins begin in patients who demonstrate a creatinine clearance of less than 50 ml/min, with alterations being made to either the dose, the frequency of administration, or both. Dosages of all penicillins except nafcillin, oxacillin, and dicloxacillin are adjusted for hemodialysis. Many penicillins also require significant dosage adjustments for peritoneal dialysis.

**Spectrum of Activity**

The penicillins have antibacterial activity against most Gram-positive and many Gram-negative and anaerobic...

  - Amoxicillin-clavulanate
  - Piperacillin-tazobactam

Organisms. Penicillin G is very effective against penicillin-susceptible Staphylococcus aureus (<10% of isolates), Streptococcus pneumoniae, Streptococcus pyogenes, viridans group streptococci, Streptococcus bovis, Neisseria gonorrhoeae (rarely susceptible to penicillin G), Neisseria meningitidis, Pasteurella multocida, anaerobic cocci, Clostridium spp., Fusobacterium spp., Prevotella spp., and Porphyromonas spp. However, the occurrence of penicillin-resistant pneumococci has increased worldwide (3–5). Penicillin G is the drug of choice for treatment of syphilis and Actinomyces infections. Penicillin V has a spectrum of activity similar to that of penicillin G. Both drugs are drugs of choice for the treatment of streptococcal tonsillitis and for the primary and secondary prevention of rheumatic fever (6). Penicillinase-resistant penicillins, of which oxacillin, nafcillin, and dicloxacillin are the three in clinical use, are effective primarily against penicillinase-producing staphylococci. The agents are at least 25 times more active than other penicillins against penicillinase-positive staphylococci. Although they are also active against fully penicillin-susceptible S. pneumoniae and S. pyogenes, their MICs for these organisms are higher than those of penicillin G. They are not active against enterococci, members of the family Enterobacteriaceae, Pseudomonas spp., or members of the Bacillus fragilis group. Mecillinam and temocillin, two penicillins not currently available in the United States, have increased stability to hydrolysis by β-lactamases, including some extended-spectrum β-lactamases (ESBLs). However, their increased enzymatic stability is balanced with the loss of antibacterial activity against gram-positive bacteria.

Ampicillin and amoxicillin have spectra of activity similar to that of penicillin G, but they are more active against enterococci and Listeria monocytogenes. These are the drugs of choice for prevention of infective endocarditis in patients with high-risk cardiac conditions undergoing invasive dental, respiratory tract, gastrointestinal, and genitourinary procedures (7). Although they are also more active against Haemophilus influenzae and Haemophilus parainfluenzae, at least 25% of H. influenzae isolates are resistant, usually because of β-lactamase production. Salmonella and Shigella spp., including Salmonella enterica serovar Typhi, are susce-
tible to these agents. Ampicillin is more effective against shigellae, whereas amoxicillin is more effective against salmonellae. Both of these agents are degraded by β-lactamase and are inactive against *Pseudomonas* spp. and many *Enterobacteriaceae*.

The carboxypenicillins and ureidopenicillins have increased activity against Gram-negative bacteria that are resistant to ampicillin. Although these drugs are susceptible to staphylococcal penicillinase, they are more stable to hydrolysis by the β-lactamases produced by *Enterobacteriaceae* and *Pseudomonas aeruginosa*. Ticarcillin is the only commercially available carboxypenicillin and is available only in the United States as a product coformulated with clavulanic acid. Ticarcillin is relatively active against streptococci as well as against *Haemophilus* spp., *Neisseria* spp., and a variety of anaerobes. Ticarcillin inhibits many non-β-lactamase-producing *Enterobacteriaceae* but is inactive against *Klebsiella* spp. unless combined with clavulanic acid. Ticarcillin is not active against enterococci.

The ureidopenicillins, of which piperacillin is the only clinically available compound in the United States, have greater in vitro activity against streptococci and enterococci than do the carboxypenicillins, and they inhibit more than 75% of non-ESBL-producing *Klebsiella* spp. (8). When initially introduced, they exhibited excellent activity against many *Enterobacteriaceae* and anaerobic bacteria, including members of the *B. fragilis* group. Today their use has been compromised by plasmid-encoded β-lactamases (9). On a weight basis, piperacillin is considerably more potent than ticarcillin against *P. aeruginosa* (10). These agents may also act synergistically with aminoglycosides against *P. aeruginosa*. Piperacillin is currently available only in the United States as a product coformulated with the β-lactamase inhibitor tazobactam.

**Adverse Effects**

Common reactions to penicillins include allergic skin rashes, diarrhea, and drug fever. Severe anaphylactic reactions, which can be fatal, may occur in previously sensitized patients rechallenged with penicillins, but fortunately, such reactions are quite rare. At high doses (usually >30 × 10^6 U/day), penicillin G can cause myoclonic twitching and seizures due to central nervous system toxicity. All of the penicillins may cause interstitial nephritis on an allergic basis. Hepatitis has been associated with prolonged use of oxacillin. High doses of many of the currently available penicillin formulations are associated with considerable sodium loads that have rarely been linked to hypokalemia. Neutropenia may occur with any of the penicillins, particularly when administered at high doses for longer than several weeks. Thrombocytopenia and Coombs test-positive hemolytic anemia are rare complications of penicillin therapy. Bleeding tendencies due to interference with platelet function can occur with the use of carboxypenicillins and ureido- penicillins (11). Although pseudomembranous colitis has been associated with all the penicillins, it occurs more frequently with ampicillin (12).

**CEPHALOSPORINS**

Cephalosporins are derivatives of the fermentation products of *Cephalosporium acremonium* (also designated *Acremonium chrysogenum*). They contain a 7-aminocephalosporanic acid nucleus, which consists of a β-lactam ring fused to a dihydrothiazine ring (Fig. 1b). Various substitutions at positions 3 and 7 alter their antibacterial activities and pharmacokinetic properties. Addition of a methoxy group at position 7 of the β-lactam ring results in a group of compounds called cephamycins, which are highly resistant to hydrolysis by a variety of class A β-lactamases, including many ESBLs.

**Mechanism of Action**

Like the penicillins, cephalosporins act by binding to PBPs of susceptible organisms, thereby interfering with the synthesis of peptidoglycan of the bacterial cell wall. In addition, these β-lactam agents may produce bactericidal effects by triggering autolytic enzymes in the cell envelope (1). Of note are the unique chemical structure-activity relationships for ceftaroline and cefotibipro, which contain a thiazole moiety and a vinylpyrrolidinone moiety, respectively, at position 3 of the cepham ring. These chemical side chains promote binding of the drugs to the staphylococcal PBP 2a and the pneumococcal PBP 2x, thereby conferring bactericidal activity against methicillin-resistant *S. aureus* (MRSA) and against penicillin- and ceftriaxone-resistant pneumococci (13).

**Pharmacology**

Most cephalosporins require parenteral administration, but many are available in oral formulations (Table 2). Cefuroxime, cefalexin, cefaclor, cefprozil, cefuroxime axetil, cefdinir, cefditoren pivoxil, cefixime, cefpodoxime proxetil, and cefditiben can be dosed orally with good gastrointestinal absorption (60 to 90% of the oral dose). Cefuroxime axetil is an acetoxyethyl ester of cefuroxime, and it is deesterified at the intestinal mucosa and absorbed into the bloodstream as cefuroxime. Cefditoren pivoxil and cefpodoxime proxetil are prodrugs that are absorbed and hydrolyzed by esterases in vivo to release the active drugs cefditoren and cefpodoxime, respectively. Relatively high concentrations of these agents are attained across the placenta and in synovial, pleural, pericardial, and peritoneal fluids. Levels in bile are usually high, especially with the injectable ceftriaxone, which has significant biliary excretion. The parenteral cephalosporins cefotaxime, ceftriaxone, cefazidime, and cepfime penetrate into the CSF and may be useful for the treatment of meningitis. Cefuroxime penetrates inflamed meninges, but levels in CSF are inadequate in providing bactericidal activity against susceptible bacteria.

Cefotaxime is converted to the desacetyl form before excretion. All cephalosporins except ceftriaxone are excreted primarily by the kidney, and for these drugs, dosage adjustments are necessary in patients with renal insufficiency (creatinine clearance of <50 ml/min). Like that of the penicillins, the renal excretion of cephalosporins, except for ceftriaxone, is impaired by probenecid. In general, these agents are removed by hemodialysis but not by peritoneal dialysis. Of the cephalosporins, ceftriaxone has the longest elimination half-life, at 6.8 to 8.7 h, permitting once- or twice-daily drug administration in the treatment of serious infections.

Ceftaroline fosamil and cefotibipro medocaril were developed as water-soluble prodrugs of ceftaroline and cefotibipro, respectively, and they undergo rapid conversion (<1 h) to the respective active drugs after intravenous administration. With a half-life of 2.5 h, infusion of 600 mg of ceftaroline results in a maximum concentration of 27.9 µg/ml in serum (14). Following infusion of cefotibipro medocaril at 500 mg, the maximum concentration achieved in serum is 36 µg/ml (15). With a terminal half-life of 3.4 h, the drug undergoes minimal hepatic metabolism and is primarily eliminated in the urine. Dosage adjustment is necessary for both drugs in patients with renal insufficiency.
CATARHALIS, N. gonorrhoeae, and MCM 11th Edition than cefoxitin against susceptible cefoxitin against Gram-positive cocci, but it is more potent (18, 19). Cefotetan is two to four times less active than the group to the cephamycins is increasingly problematic Haemophilus Enterobacteriaceae useful antimicrobial activity against Pseudomonas Moraxella catarrhalis H. influenzae produced by many strains of Escherichia coli, though penicillinase-producing non-MRSA (methicillin-resistant S. aureus) isolates are susceptible. Some Enterobacteriaceae, including non-β-lactamase-producing strains of Escherichia coli, Klebsiella spp., and Proteus mirabilis, are susceptible. Pseudomonas spp., including P. aeruginosa, many Proteus spp., and Serratia and Enterobacter spp., are resistant. These agents are active against penicillin-susceptible anaerobes except members of the B. fragilis group. They have only modest activity against H. influenzae.

The broad-spectrum (cephalosporin II or second-generation) cephalosporins are stable against some β-lactamases found in Gram-negative bacteria and, as a result, have increased activity against Gram-negative organisms. The agents are more active than narrow-spectrum drugs against E. coli, Klebsiella spp., and Proteus spp. Their activity also extends to cover some Enterobacter and Serratia strains, and they have good activity against Haemophilus spp., Neisseria spp., and many anaerobes. However, they are hydrolyzed by plasmid-encoded ESBLs and carbapenemases now produced by many Enterobacteriaceae. Cefaclor, cefuroxime, and cefprozil are active against ampicillin-resistant H. influenzae and Moraxella catarrhalis (16, 17). None of these agents has useful antimicrobial activity against Pseudomonas spp.

Cefoxitin and cefotetan belong to a unique group of expanded-spectrum cephalosporins (cephamycins) that have marked activity against anaerobes, including members of the B. fragilis group, though resistance within the B. fragilis group to the cephamycins is increasingly problematic (18, 19). Cefotetan is two to four times less active than cefoxitin against Gram-positive cocci, but it is more potent than cefoxitin against susceptible Enterobacteriaceae. The two cephamycins are equally active against H. influenzae, M. catarrhalis, and N. gonorrhoeae, including penicillin-resistant strains. While these drugs are comparable in their activities against the B. fragilis group, cefoxitin is more active than cefotetan against Prevotella spp., Porphyromonas spp., and Gram-positive anaerobic cocci. Cefotetan has the advantage of a more prolonged half-life in serum. Both molecules are also stable against ESBLs produced by a variety of Enterobacteriaceae, though their clinical utility for infections due to these organisms remains uncertain.

Expanded-spectrum (cephalosporin III or third-generation) cephalosporins are generally less active than the narrow-spectrum agents against Gram-positive cocci, but they are much more active against the Enterobacteriaceae. Their expanded spectra of Gram-negative activity is due primarily to their stability to low-level production of chromosomal β-lactamases and to the early plasmid-encoded penicillinases (9). They are also notable for their ability to pass through the outer cell envelopes of Gram-negative bacilli (20, 21). There are two subclasses among these agents: those with potent activity against P. aeruginosa (ceftazidime and cefoperazone) and those without such activity (cefotaxime, ceftriaxone, and the oral agents in this subclass). Cefotaxime and ceftriaxone, however, are far more potent against streptococci than the other expanded-spectrum cephalosporins, while the Gram-positive activity of ceftazidime is clinically marginal. All the expanded-spectrum cephalosporins are hydrolyzed by ESBLs and carbapenemases that are found in Gram-negative pathogens. Ceftriaxone, however, is currently in clinical development with the β-lactamase inhibitor avibactam to counteract the effects of many of these enzymes (see below).

Cefotaxime inhibits more than 90% of strains of non-ESBL- or non-carbapenemase-producing Enterobacteriaceae, including those resistant to aminoglycosides, with MIC90s for E. coli, Proteus spp., and Klebsiella spp. of <0.5 μg/mL. Its activity against strains of Serratia marcescens, Enterobacter cloacae, and Acinetobacter spp. is limited, and it is inactive against P. aeruginosa.

Ceftriaxone and cefotaxime have similar spectra of activity. Both have high potency (MIC90s, ≤0.12 μg/mL) against both penicillinase-positive and -negative strains of N. gonorrhoeae and are usually effective as single-dose therapy for infections caused by these organisms (22). However, N. gonorrhoeae strains with reduced susceptibility to these drugs have emerged (23). Because of its long half-life in serum (>6 h, the longest of the currently available cephalosporins), ceftriaxone is used frequently in outpatient antibiotic therapy of serious infections, including Lyme disease (24).
Cefoperazone is less active than cefotaxime against many Enterobacteriaceae and Gram-positive cocci. However, it has some clinically useful activity against P. aeruginosa, with an MIC$_{50}$ of ≤16 μg/ml. Its activity against anaerobes is similar to that of cefotaxime (25). Ceftazidime has more potent activity than other expanded-spectrum cephalosporins or the ureidopenicillins against P. aeruginosa, with an MIC$_{50}$ of <8 μg/ml (21). This cephalosporin has activity similar to that of cefotaxime against the Enterobacteriaceae but is not as active against Gram-positive cocci. It has little activity against Gram-negative anaerobes.

Cefdinir (26), cefditoren (16, 27, 28), cefixime (29), cefpodoxime (30), and cefditiben (25) are expanded-spectrum oral cephalosporins that are more stable than the narrow- and broad-spectrum oral cephalosporins against Gram-negative bacterial β-lactamases. Compared with the earlier cephalosporins, the newer drugs are equally active against streptococci (MIC$_{90}$ ≤0.06 μg/ml) but less active against methicillin-susceptible staphylococci (MIC$_{90}$, 2 μg/ml). With activities similar to that of cefotaxime against many non-ESBL- or non-carbapenemase-producing Enterobacteriaceae, H. influenzae, M. catarrhalis, and N. gonorrhoeae, they are inactive against Pseudomonas, Enterobacter, Serratia, and Morganella spp. and anaerobes. None of the currently available cephalosporins is clinically useful against enterococci.

Cefepime is an expanded-spectrum (cephalosporin IV or fourth-generation) cephalosporin approved for clinical use in the United States. It tends to have greater potency against Enterobacteriaceae with high levels of AmpC cephalosporinases, due to greater penetrability and increased stability to β-lactamases. Compared with the fourth-generation cephalosporins approved for clinical use against enterococci, and Morganella, M. catarrhalis, Pseudomonas, they are inactive against M. catarrhalis, N. gonorrhoeae, P. aeruginosa, Enterococcus spp., enterococci, and streptococci (38). The Gram-negative activity of ceftriaxone is limited mainly to Gram-negative respiratory tract pathogens, including β-lactamase-producing H. influenzae, M. catarrhalis (MIC$_{90}$ of 0.125 and 0.25 μg/ml, respectively), and N. gonorrhoeae (MIC$_{90}$ of 0.25 μg/ml), as well as Enterobacteriaceae that do not produce ESBLs or carbapenemases. It is weakly active against P. aeruginosa, Acinetobacter spp., and Gram-negative bacilli with inducible AmpC β-lactamases and has no clinical utility for these pathogens. However, its activity against β-lactamase-producing strains is enhanced by the addition of avibactam; the combination is being studied for clinical utility. Cefotiboprole in vitro antibacterial activity similar to that of cefepime against P. aeruginosa and Enterobacteriaceae with derepressed AmpC β-lactamases (MIC$_{90}$ of 8 to 16 μg/ml), but it is inactive against ESBL-producing Enterobacteriaceae and MDR Acinetobacter baumannii isolates (13). Both drugs display varied activities against anaerobes, with good activity against Clostridium spp. (except Clostridium difficile), Fusobacterium, Lactobacillus, Peptostreptococcus, Propionobacterium acnes, and Veillonella, but are inactive against B. fragilis, members of the B. fragilis group, and Prevotella (39). Ceftobiprole remains unavailable in the United States but received European regulatory approval in late 2013 for use in adults with hospital-acquired pneumonia (excluding those with ventilator-associated pneumonia) and community-acquired pneumonia.

### Adverse Effects

Cephalosporins are generally very well tolerated. The most common side effects are diarrhea and hypersensitivity reactions, such as rash, drug fever, and serum sickness. Cross-reactions with these drugs occur in only 3% to 7% of penicillin-allergic patients (40). Other infrequent side effects include pseudomembranous colitis, elevated serum creatinine and transaminase levels, leukopenia, thrombocytopenia, and Coombs test-positive hemolytic anemia. These abnormalities are usually mild and reversible. Prolonged use of ceftriaxone has been associated with the formation of gallbladder sludge, which usually resolves after the drug is discontinued (41), and rarely cholecystitis. Disulfiram-like reactions have been described in patients receiving cefotetan and cefoperazone. This reaction is attributed to the N-methylthiotetrazole side chains of these antibiotics, which are similar to the chemical structure of disulfiram. Hypoprothrombinemia and bleeding tendencies have been observed with these cephalosporins. Causes of the coagulopathy include (i) alteration of the healthy gut biota by the antibiotics, with inhibition of the synthesis of vitamin K and its precursors, and (ii) the N-methylthiotetrazole side chain, which inhibits the vitamin K-dependent carboxylase enzyme responsible for converting clotting factors II, VII, IX, and X to their active forms and also prevents regeneration of active vitamin K from its inactive form (42). Also of note has been the recent recognition of neurotoxicity, which manifests primarily as impaired consciousness in patients receiving high doses of cefepime with impaired renal function (43). In July 2012, the U.S. prescribing information was updated to reflect concerns regarding increased seizure risk with use of cefepime at high doses, again particularly...
in older patients with decreased renal function. Use of cefepime compared to other agents was also linked to an increased risk of mortality, though these reports have been refuted by the FDA (44).

OTHER β-LACTAM ANTIBIOTICS

■ Monobactams

Monobactams are monocyclic β-lactams with various side chains affixed to a monocyclic nucleus (Fig. 1c). Aztreonam is the only monobactam antibiotic currently in clinical use, although several other monocyclic agents are in early stages of clinical development.

Mechanism of Action

Azcronam binds primarily to PBP 3 of Gram-negative aerobes, including P. aeruginosa, thereby disrupting bacterial cell wall synthesis. It is not hydrolyzed by many of the early Bush and Jacoby group 1 and 2 plasmid-encoded and chromosomally encoded β-lactamases (39) but is susceptible to hydrolysis by ESBLs and serine carbapenemases. It has high affinity for the group 1 cephalosporinases but does not induce the production of these enzymes (45). Metallo-β-lactamases are unable to hydrolyze aztreonam, leading to its potential clinical use against carbapenemase-producing Gram-negative pathogens (9). Aztreonam is currently in clinical development in combination with the broad-spectrum β-lactamase inhibitor avibactam (see below).

Pharmacology

Given intravenously, aztreonam is widely distributed to body tissues and fluids. Average drug concentrations in serum exceed the MIC≥8 for most Enterobacteriaceae by four to eight times for 8 h and are inhibitory to P. aeruginosa for 4 h. It crosses inflamed meninges in an amount sufficient to be potentially therapeutic for meningitis caused by susceptible organisms. Its half-life in serum is about 1.7 h, and it is excreted mainly unchanged by the kidney. Dosage modification is necessary for patients with renal failure. The drug is removed by both hemodialysis and peritoneal dialysis.

Spectrum of Activity

The antibacterial activity of aztreonam is limited to aerobic Gram-negative bacilli, inhibiting susceptible Enterobacteriaceae, Neisseria spp., and Haemophilus spp., with MIC₉₀ of ≤0.5 μg/ml (46, 47). However, most Acinetobacter spp., Burkholderia cepacia, and Stenotrophomonas maltophilia are resistant. It can demonstrate in vitro synergism when combined with aminoglycosides against aztreonam-resistant organisms, including P. aeruginosa and some aminoglycoside-resistant Gram-negative bacilli (48). Aztreonam is not active against Gram-positive bacteria or anaerobes.

Adverse Effects

Azcronam is generally a safe agent, with a toxicity profile similar to those of other β-lactam drugs. Nausea, diarrhea, skin rash, eosinophilia, mild elevation of serum transaminase levels, and transiently elevated serum creatinine levels have occurred. It has minimal cross-reactivity with other β-lactams and can be used safely in patients allergic to penicillins or cephalosporins (49).

■ Carbapenems

Carbapenems are a unique class of β-lactam agents with the widest spectrum of antibacterial activity of the currently available antibiotics. Structurally, they differ from other β-lactams in having a hydroxyethyl side chain in the trans configuration at position 6 and possessing a carbon atom in place of a sulfur or oxygen atom in the bicyclic nucleus (Fig. 1d). The unique stereochemistry of the hydroxyethyl side chain confers stability against most β-lactamases. Doripenem, ertapenem, imipenem, and meropenem are the carbapenems currently available for clinical use (50).

Mechanism of Action

Carbapenems bind with high affinity to PBP 2 and then to PBP’s 1a and 1b of Gram-negative bacteria, causing spherical cell formation and lysis (51). They display potent binding to all PBP’s in staphylococci, with the exception of PBP 2a in MRSA, against which they have poor activity (52). They are stable toward most plasmid- or chromosomally mediated β-lactamases except for the more frequently occurring carbapenemases (9). Bacterial resistance arises from production of carbapenem-hydrolyzing enzymes that hydrolyze the carbapenem nucleus: the group 2d carbapenemases (OXA β-lactamases), group 2f serine carbapenemases (KPC, SME, NMC-A, IMI, and GES), and metallo-β-lactamases (plasmid-encoded IMP, VIM, and NDM, as well as chromosomal enzymes in S. maltophilia and B. fragilis). Resistance in Enterobacteriaceae can also occur from hyperproduction of group 1 cephalosporinases combined with outer membrane porin alterations that result in decreased uptake of the drugs. In P. aeruginosa, carbapenem resistance frequently occurs as a combination of decreased uptake (due to inactivation of the OprD porin) and increased AmpC production, although efflux can also be upregulated in this pathogen to give insufficient concentrations of drug for effective antibacterial activity (53).

Pharmacology

After intravenous administration, the carbapenems distribute widely in the body but undergo no significant biliary excretion. Imipenem is metabolized and inactivated in the kidneys by a dehydropeptidase I (DHP-I) enzyme found in the brush borders of proximal renal tubular cells. To achieve adequate concentrations in serum and urine, a DHP inhibitor, cilastatin, is combined with imipenem in a 1:1 dosage ratio for clinical use. Cilastatin has no antibacterial activity, nor does it alter the activity of imipenem. It has a renal protective effect by preventing excessive accumulation of potentially toxic imipenem metabolites in renal tubular cells. Meropenem, ertapenem, and doripenem contain a β-methyl group substitution at position C-1 of the bicyclic carbapenem nucleus, which results in increased stability to inactivation by human renal DHP-I. These agents do not require concurrent administration of a DHP-I inhibitor.

The pharmacokinetics of doripenem, imipenem, and meropenem are very similar, with elimination half-lives in serum of about 1 h. Peak concentrations of the drugs in serum are about 25 to 35 μg/ml and 55 to 70 μg/ml following 0.5-g and 1-g doses, respectively. These drugs penetrate inflamed meninges well, with drug levels of 0.5 to 6 μg/ml in the CSF (50, 54). Ertapenem is highly (>95%) bound to human plasma proteins, with poor penetration into the CSF. Its relatively long plasma half-life of 4 h allows for once-daily dosing frequency. A peak serum concentration of 155 μg/ml is reached following a single intravenous dose of 1 g of ertapenem (55). Dosage adjustment of these carbapenem drugs is necessary for creatinine clearance of ≤50 ml/min. These agents, including cilastatin, are effectively removed by hemodialysis.
Spectrum of Activity

In general, all the carbapenems have similar antibacterial potencies, with minor differences. They have excellent in vitro activity against aerobic Gram-positive species: staphylococci (penicillin-susceptible and -resistant isolates); viridans group streptococci; group A, B, C, and G streptococci; Bacillus spp.; and L. monocytogenes. Doripenem and imipenem are two to four times more active than meropenem and ertapenem against streptococci and methicillin-susceptible staphylococci (MIC₉₀ of ≤0.5 μg/ml), but methicillin-resistant staphylococci are resistant to all clinically approved carbapenems. Although the MICs of carbapenems for penicillin-resistant pneumococci are elevated (MIC₉₀ of 0.25 to 2 μg/ml), most strains remain susceptible to these drugs, with doripenem and imipenem being most potent (56–58). Ertapenem has poor activity against Enterococcus faecalis, but these isolates are inhibited by other carbapenems at ≤4 μg/ml. However, Enterococcus faecium is usually resistant to all carbapenems.

More than 90% of Enterobacteriaceae, including those resistant to other β-lactams and aminoglycosides, are susceptible to carbapenems, with the following decreasing order of activity: doripenem, ertapenem, meropenem > biapenem > imipenem (59, 60). These agents are highly active against clinical isolates of ESBL-producing K. pneumoniae and E. coli, with MIC₉₀ of 0.015 to 0.125 μg/ml (59, 61). Most Enterobacter spp., Citrobacter spp., and Serratia spp. are inhibited by carbapenem concentrations of ≤1 μg/ml. Ertapenem is inactive against Acinetobacter and Pseudomonas. Most strains of P. aeruginosa are inhibited by other carbapenems at 2 to 4 μg/ml, with meropenem and doripenem being the most potent agents, including against many imipenem-resistant strains (53, 59). While they inhibit B. cepacia and Pseudomonas putida, carbapenems are inactive against S. maltophilia due to its production of the chromosomal metallo-β-lactamase (62). Emergence of resistant Pseudomonas spp. has been observed during therapy with carbapenems.

Carbapenems are the most potent β-lactams against anaerobes, with activities comparable to that of metronidazole. The MIC₉₀ for anaerobic Gram-positive cocci, Clostridium, members of the B. fragilis group, Fusobacterium, Porphyromonas, and Prevotella are ≤4 μg/ml (63–65). This class of drugs is also active in vitro against Actinomyces, Nocardia, and atypical mycobacteria, with imipenem being substantially more active than the other carbapenems against these organisms (66, 67).

Adverse Effects

The side effects of carbapenems are similar to those of other β-lactam antibiotics. Nausea, vomiting, and diarrhea occur in up to 5% of patients, usually associated with parenteral administration of ertapenem and imipenem. Pseudomembranous colitis can occur with carbapenems. Allergic reactions, such as drug fever, skin rashes, and urticaria, are seen in about 3% of patients. Cross-reactivity with other β-lactam agents is possible but has not been fully studied. Seizures of unclear etiology have occurred in up to 5% of patients receiving imipenem, particularly in the elderly age group and in patients with renal insufficiency or underlying neurologic disorders, while other carbapenems have low seizure-inducing potential (<1%) (57). Reversible elevation of serum transaminases, leukopenia, and thrombocytopenia have been described for carbapenems, but coagulopathy has not been reported.

β-LACTAMASE INHIBITORS

Clavulanic Acid

Clavulanic acid is a naturally occurring weak antimicrobial agent found initially in cultures of Streptomyces clavuligerus (68). It inhibits penicillinases from staphylococci and many group 2 β-lactamases from Gram-negative bacteria. This agent acts primarily as a “suicide inhibitor” by forming an irreversible acyl enzyme complex with the β-lactamase, leading to loss of activity of the enzyme.

Clavulanic acid acts synergistically with various penicillins and cephalosporins against β-lactamase-producing staphylococci, klebsiellae, H. influenzae, M. catarrhalis, N. gonorrhoeae, E. coli, Proteus spp., members of the B. fragilis group, Prevotella spp., and Porphyromonas spp. (69, 70). Many plasmid-mediated TEM, SHV, and CTX-M β-lactamases, including ESBLs, present in cephalosporin-resistant strains of K. pneumoniae and E. coli can be inactivated by this drug (71). However, the role of clavulanic acid-containing products in the management of these infections remains unclear. Inducible and plasmid-encoded AmpC β-lactamases (chromosomal group I cephalosporinases) of Enterobacter, Citrobacter, Proteus, Acinetobacter, Stenotrophomonas, and Pseudomonas spp. are not inhibited by clavulanic acid (9). With the currently common occurrence of multiple β-lactamases appearing in Gram-negative pathogens, clavulanic acid combinations may not provide sufficient concentrations of the inhibitor to be effective for serious infections.

In the United States, clavulanic acid is available for clinical use in combination with oral amoxicillin at dosage ratios of 1:2, 1:4, 1:7, and 1:16 and in a 1:15 or 1:30 parenteral combination with ticarcillin. Intravenous combinations of clavulanic acid and amoxicillin at ratios of 1:5 and 1:10 are also used outside North America. The pharmacologic parameters of amoxicillin and ticarcillin are not significantly altered when either drug is combined with clavulanic acid. Amoxicillin-clavulanate is moderately well absorbed from the gastrointestinal tract, with a half-life in serum of about 1 h for each component. One-third of a dose is metabolized, while the remainder is excreted unchanged in the urine. The drug is widely distributed to various body tissues and fluids, but it penetrates uninflamed meninges very poorly. Adverse reactions, with the exception of diarrhea, are similar to those reported for amoxicillin or ticarcillin used alone. Nausea, vomiting, abdominal cramps, and diarrhea occur in 5 to 10% of patients taking amoxicillin-clavulanate. The incidence of allergic skin reactions is similar to that of amoxicillin alone.

Sublactam

Sublactam is a semisynthetic 6-desaminopenicillanic sulfone with weak antibacterial activity (72). It inhibits certain plasmid- and chromosomally mediated β-lactamases of S. aureus, many Enterobacteriaceae, H. influenzae, M. catarrhalis, Neisseria spp., Legionella spp., members of the B. fragilis group, Prevotella spp., Porphyromonas spp., and Mycobacterium spp. (73). The efficiency of sublactam inhibition is less than for clavulanic acid (74). Sublactam alone is active against N. gonorrhoeae, N. meningitidis, some Acinetobacter spp., and B. cepacia (73, 75). It acts synergistically with penicillins and cephalosporins against organisms that are otherwise resistant to the β-lactam drugs because of the production of β-lactamases. A combination of sublactam (8 μg/ml) and ampicillin (16 μg/ml) inhibits most strains of staphylococci and many strains of Klebsiella spp., E. coli, H. influenzae, M. catarrhalis, Neisseria spp., the B. fragilis group, Prevotella spp., and Porphyromonas spp. that are
ampicillin resistant (76, 77). Like clavulanic acid, sulbactam does not inhibit the cephalosporinases of Enterobacter, Citrobacter, Providencia, indole-positive Proteus, Pseudomonas spp., or S. maltophilia.

For clinical use, sulbactam is combined with ampicillin as a parenteral preparation in a 1:2 ratio. The pharmacologic properties of the drugs are not affected by each other in this combination. Ampicillin-sulbactam penetrates well into body tissues and fluids, including peritoneal and blister fluids. It enters the CSF in the presence of inflamed meninges. Like ampicillin, sulbactam has a half-life in serum of 1 h, and 85% of the drug is excreted unchanged via the kidneys. Since clearances of both sulbactam and ampicillin are affected similarly in patients with impaired renal function, dosage adjustments are similar for the two drugs.

The most common side effects of the ampicillin-sulbactam combination have been nausea, diarrhea, and skin rash. Transient eosinophilia and transaminasemia have been reported. Adverse reactions attributed to ampicillin may also occur with the use of ampicillin-sulbactam.

Tazobactam

Tazobactam is a penicillanic acid sulfone derivative structurally related to sulbactam. Like clavulanic acid and sulbactam, tazobactam acts as a suicide β-lactamase inhibitor. Tazobactam actively inhibits the β-lactamases found in staphylococci, H. influenzae, N. gonorrhoeae, the B. fragilis group, Prevotella spp., and Porphyromonas spp. (74, 78, 79). It also has some activity against the group 1 β-lactamases of Acinetobacter, Citrobacter, Proteus, Providencia, and Morganella spp. (73, 74, 80). Like clavulanic acid, tazobactam displays inhibition of many ESBL-producing Enterobacteriaceae, especially E. coli, Klebsiella spp., and P. mirabilis (74). Of the penicillin-β-lactamase inhibitor combinations, piperacillin-tazobactam is the most active (2- to 8-fold-lower MICs) against β-lactamase-producing aerobic and anaerobic Gram-negative bacteria (74, 81).

Available as a 1:8 ratio dosage combination with piperacillin, tazobactam is administered parenterally. The two drugs do not affect each other's metabolism or pharmacokinetics. High concentrations of both agents are achieved in the intestinal mucosa, lung, and skin, with relatively poor distribution to muscle, fat, prostate, and CSF (in the absence of inflamed meninges). With a half-life in serum of about 1 h, elimination of tazobactam is mainly via the renal route and is not affected by hepatic failure (82). Major adverse effects of the piperacillin-tazobactam combination are similar to those of piperacillin alone, such as diarrhea, skin rash, and allergic reactions. Mild elevation in serum transaminase levels may be encountered in about 10% of patients.

Tazobactam is currently under development as a 1:2 combination with ceftolozane. This combination has recently completed phase 3 trials for the treatment of complicated intra-abdominal infections and complicated urinary tract infections. The addition of tazobactam to ceftolozane improves the activity of ceftolozane against many organisms producing specific group 2 broad-spectrum β-lactamases, including the important CTX-M-14 and CTX-M-15 ESBLs commonly found in E. coli. Compared to the doses of tazobactam utilized in piperacillin-tazobactam, the higher dose of tazobactam utilized in combination with ceftolozane improves the activity of the combination against many AmpC-producing organisms, including Enterobacter spp. However, the combination still appears less active than cefepime against ceftazidime-resistant Enterobacter spp. (83).

Avibactam

Avibactam, formerly NXL104, is a novel diazabicyclooctane non-β-lactam inhibitor of class A and C β-lactamases as well as some class D enzymes (84). Avibactam inhibits these enzymes through the formation of reversible covalent carbamoyl linkages (85, 86). It is currently undergoing clinical studies in combination with ceftazidime, cefaroline, and aztreonam for the treatment of nosocomial Gram-negative infections. When tested at a concentration of 4 μg/ml in combination with ceftazidime against Enterobacteriaceae, this drug potentiated the activities of the cephalosporins 4- to 8,000-fold, with MICs of ≤1.0 μg/ml for all organisms, including those producing AmpC β-lactamases, ESBLs of TEM, SHV, or CTX-M types, and KPC carbapenemases (84). Although it effectively restores the activity of imipenem against isolates producing class A carbapenemases, avibactam does not inhibit metallo-β-lactamases, such as NDM, IMP, and VIM (84).

MK7655

MK7655 is a novel β-lactamase inhibitor that is being developed in combination with imipenem. Like avibactam, it possesses a diazabicyclooctane structure (87). The addition of MK7655 to imipenem results in the protection of imipenem from hydrolysis by both class A carbapenemases, such as KPC, and hyperproduced AmpC cephalosporinases, resulting in the restoration of antibacterial activity against many multiresistant pathogens (88). MK7655 does not inhibit the class B metallo-β-lactamases in the NDM, IMP, or VIM families; its activity against OXA-type class D β-lactamases appears variable.

QUINOLONES

Quinolones belong to a group of potent antibiotics biochemically related to nalidixic acid, which was developed initially as a urinary antiseptic. Newer quinolones have been synthesized by modifying the original bicyclic 4-quinolone (or naphthyridone) nucleus with different side chain substituents (89). Each of these newer agents, also known as fluoroquinolones, contains a fluorine atom attached to the nucleus at position 6. Quinolones that are currently available for clinical use in the United States are listed in Table 3. Grepafloxacin, temafloxacin, and trovafloxacin were with-
drawn from clinical use due to toxicities, while sparfloxacin, lomefloxacin, and gatifloxacin are no longer available for systemic use in the United States. However, gatifloxacin and besifloxacin are approved for ophthalmic use. Delafloxacin, finafloxacin, and nemonoxacin are currently entering or are in phase 3 clinical trials in the United States (90). Ozenoxacin is a topical nonfluorinated quinolone that has completed a phase 3 trial for impetigo (90).

**Mechanism of Action**
The primary bacterial target of the quinolones is DNA gyrase, a type II DNA topoisomerase enzyme essential for DNA replication, recombination, and repair (91). Newer fluoroquinolones also inhibit DNA topoisomerase IV. The DNA gyrase A subunit is the main target of quinolones in Gram-negative bacteria, whereas topoisomerase IV is the primary target in Gram-positive bacteria. Inhibition of these bacterial enzyme targets causes relaxation or decatenation of the supercoiled DNA, leading to termination of chromosomal replication and interference with cell division and gene expression. By inhibiting bacterial DNA synthesis, these agents are bactericidal. However, the antibacterial activities of quinolones are reduced in the presence of low pH, urine, and divalent cations (Mg$^{2+}$ and Ca$^{2+}$).

Bacterial resistance to quinolones may occur by several mechanisms: (i) single-step chromosomal mutations in the structural genes (gyrA, gyrB, parC, and parE) encoding the DNA gyrase and topoisomerase IV, (ii) mutations in the regulatory genes governing bacterial outer membrane permeability to the drug, (iii) expression or overexpression of energy-dependent multidrug efflux pump AcrAB, (iv) acquisition of plasmid-mediated resistance genes (qnrA, qnrB, and qnrS) encoding proteins that prevent the binding of quinolones to bacterial DNA gyrase and topoisomerase IV, and (v) acquisition of a plasmid containing the resistance gene qacE(Δ1)-Ib-cr, which encodes a variant aminoglycoside acetyltransferase capable of acetylating the amino nitrogen on the piperazinyl substituent of quinolones, such as ciprofloxacin and norfloxacin but not levofloxacin, and reducing their activity. The last two mechanisms confer low-level resistance to quinolones (92, 93).

**Pharmacology**
Fluoroquinolones are generally well absorbed from the gastrointestinal tract, with the exception of norfloxacin. The oral bioavailability varies from 60% to 95% for the various fluoroquinolones (94). After oral administration, serum concentrations peak in 1 to 2 h. The presence of food does not significantly alter the absorption of these drugs. However, coadministration with iron- or zinc-containing multivitamins or with antacids containing aluminum, magnesium, or calcium substantially reduces the gastrointestinal absorption and subsequent peak concentrations of quinolones in serum. The degree of serum protein binding is generally low, ranging from 8% for ofloxacin to 54% for moxifloxacin. The prolonged elimination half-lives of fluoroquinolones allow for twice- or once-daily dosing (95, 96). Ciprofloxacin, levofloxacin, and moxifloxacin are also available for intravenous use, while besifloxacin, ciprofloxacin, gatifloxacin, levofloxacin, moxifloxacin, and ofloxacin are available commercially as ophthalmic preparations.

Quinolones have good penetration into lung, kidney, muscle, bone, intestinal wall, and extracellular body fluids. Concentrations in prostate are about two times those in serum, and concentrations of 25 to 100 times above peak serum concentrations are achieved in urine. Moxifloxacin is eliminated to a significantly lesser extent in the urine than levofloxacin or ciprofloxacin, leading to recommendations that it not be used for urinary tract infections. In the presence of meningeal inflammation, only ofloxacin, levofloxacin, gatifloxacin, and moxifloxacin achieve concentrations of >1 μg/ml in the CSF, though ciprofloxacin at high doses (i.e., 400 mg intravenously every 8 h) has been successfully used in the treatment of Gram-negative meningitis (97, 98). Quinolones penetrate well into phagocytes, such that concentrations within neutrophils and macrophages are as high as 14 times concentrations in sera (99). This feature accounts for their excellent in vivo activity against such intracellular pathogens as Brucella, Listeria, Salmonella, and Mycobacterium spp.

Ofloxacin and levofloxacin exhibit little or no in vivo metabolism and are excreted mainly (90%) via the kidneys. The other quinolones are cleared by both hepatic and renal routes in various proportions, with elimination primarily via the kidneys. This renal elimination is blocked by probenecid. Small amounts of these drugs are also excreted in the bile.

The clearance of other fluoroquinolones is significantly diminished in the presence of renal failure. All of these drugs are only partially removed by hemodialysis (<15%) and are minimally affected by peritoneal dialysis because of their marked extravascular penetration, as reflected in their very large volumes of distribution.

**Spectrum of Activity**
Quinolones may be categorized into groups with similar spectra of antibacterial activity (Table 3), with the fluoroquinolones exhibiting a broad spectrum of activity (89). The narrow-spectrum quinolones, represented primarily by nalidixic acid, are inactive against Gram-positive cocci, and their clinical utility is limited by widespread prevalence and the rapid emergence of bacterial resistance. Broad-spectrum fluoroquinolones are active against both Gram-positive and Gram-negative bacteria (100). Increased activity against Gram-positive cocci and favorable pharmacodynamic properties (high ratios of the area under the curve from 0 to 24 h to the MIC) are major features of the newer fluoroquinolones, such as gemifloxacin, with potency 2- to 8-fold greater than those of earlier agents (100, 101). When quinolones are more susceptible, quinolones' MICs for the staphylococci are in the range of 0.03 to 1 μg/ml; however, many methicillin-resistant staphylococci are resistant to these agents (102). Although gemifloxacin and moxifloxacin are less potent against enterococci than against the staphylococci, they are 4- to 8-fold (MIC$_{90}$ of 0.03 to 0.25 μg/ml) more active than levofloxacin against MDR S. pneumoniae.

Several fluoroquinolones are in late stages of clinical development. These agents include delafloxacin, which is active against many MRSA isolates (MIC$_{90}$ = 0.12 μg/ml) and is currently undergoing phase 3 clinical trials for complicated skin and skin structure infections. Its activity against enteric Gram-negative organisms appears similar to that of ciprofloxacin, though it may be slightly more potent against P. aeruginosa (103). Delafloxacin is also being studied in phase 3 trials for the treatment of gonorrhea as a single-dose oral formulation (http://clinicaltrials.gov/ct2/show/NCT02015637). Nemonoxacin is active against some MRSA isolates for which the MIC$_{90}$ is 1 μg/ml, and it has a Gram-negative spectrum similar to that of levofloxacin (104). Finafloxacin activity is impacted by pH in that it has improved activity in acidic environments, leading to its development for the treatment of infections caused by *Helicobacter pylori* (105). Finafloxacin was equivalent to levofloxacin against ciprofloxacin-resistant MRSA and was
comparable to ciprofloxacin against many Gram-negative organisms, depending on the pH tested (105). Ozenoxacin is active against many quinolone-resistant MRSA isolates as well as other Gram-positive organisms likely to cause skin infections (106).

Of the quinolones currently available for systemic use, only moxifloxacin possesses reliable activity against anaerobes, including members of the B. fragilis group as well as Prevotella, Porphyromonas, Fusobacterium, Clostridium, and anaerobic Gram-positive cocci at concentrations of 0.06 to 2 μg/ml. However, there are increasing reports of resistance to moxifloxacin among many Gram-negative anaerobes (107–109).

The fluoroquinolones possess excellent activity in vivo against susceptible Enterobacteriaceae, P. aeruginosa, Citrobacter, Serratia, and Acinetobacter spp., H. influenzae, and Gram-negative cocci, such as N. gonorrhoeae, N. meningitidis, and M. catarrhalis (100). However, the emergence of resistance in many of these organisms over the past decade has markedly compromised the utility of these agents for severe infections. The emergence of resistance to the fluoroquinolones in E. coli has become a particularly significant challenge due to the emergence of ST131 E. coli, a MDR strain which is very often fluoroquinolone resistant (110, 111). Many U.S. medical centers now report rates of ciprofloxacin resistance in their E. coli isolates of >25%. Enteropathogenic Gram-negative bacilli, such as Salmonella, Shigella, Yersinia enterocolitica, Vibrio spp., Aeromonas spp., Plesiomonas spp., Campylobacter jejuni, and enteroinvasive and enterotoxigenic E. coli, are typically susceptible to the quinolones (102). Clinical studies have shown these drugs to be effective in the prophylaxis and treatment of infectious diarrheas. However, reduced susceptibility and resistance to quinolones have emerged in clinical isolates of Salmonella, Shigella, and Campylobacter spp. (112). Legionella spp. are susceptible to these agents, with the MICs of most fluoroquinolones being 0.12 to 1.0 μg/ml for these organisms (100). Ciprofloxacin and levofloxacin are the only oral antibiotics with MICs of 0.1 to 1 μg/ml; however, resistance rates are substantial in many areas. Bacteroides fragilis spp. and S. maltophilia are variably resistant to quinolones, though S. maltophilia is often inhibited by moxifloxacin (113).

The fluoroquinolones, especially levofloxacin, gatifloxacin, and moxifloxacin, are active in vitro against the Mycobacterium species M. tuberculosis, M. fortuitum group, M. chelonae, M. kansasi, and M. xenopi (114–116). Moxifloxacin, in combination with other antituberculosis drugs, is currently being studied in late-stage clinical trials for the short-term treatment of drug-susceptible tuberculosis (http://www.thalliance.org/portfolio/node/53). Moxifloxacin is reliably the most active fluoroquinolone against members of the Mycobacterium avium complex, while other members of the class have fair to poor activity (117). They also exhibit activity against Chlamydia trachomatis, Chlamydia pneumoniae, and Mycoplasma hominis, with MIC90 of 0.1 to 1 μg/ml but are less potent against Ureaplasma urealyticum (102, 118). Fluoroquinolones reliably inhibit Rickettsia conori, Rickettsia rickettsii, and Coxiella burnetii (119–121) as well as Bartonella spp. (122) and Brucella melitensis (123).

Although quinolones possess in vitro activity against Plasmodium falciparum at achievable serum concentrations, they are relatively ineffective when used clinically for the treatment of malaria. Nocardia spp. is relatively resistant to the quinolones, though moxifloxacin and gatifloxacin appear to have markedly improved activities compared to those of older agents (124, 125).

No significant inoculum effect has been observed among the bacteria susceptible to quinolones. Combinations of quinolones with β-lactam drugs or aminoglycosides are usually indifferent or additive in their effects against Gram-negative and Gram-positive bacteria and mycobacteria (126). However, bactericidal activities of quinolones can be antagonized by rifampin or chloramphenicol.

Adverse Effects
Gastrointestinal symptoms, occurring in up to 10% of patients as nausea, vomiting, abdominal discomfort, and diarrhea, are the most common side effects (127–129). C. difficile colitis has increasingly been associated with the use of the fluoroquinolones, particularly some of the newer agents (130). Headaches, fatigue, insomnia, dizziness, agitation, and, rarely, seizures, can occur. These adverse neurologic effects are usually associated with high dosages in elderly patients or concurrent use of nonsteroidal anti-inflammatory drugs.

Allergic reactions are uncommon and often manifest as rash, urticaria, and generalized pruritus. Photosensitivity is rare but may be observed with the fluoroquinolones currently available for systemic use. Rare laboratory abnormalities occurring during fluoroquinolone therapy include elevations in serum transaminases, eosinophilia, leukopenia, and thrombocytopenia. Gatifloxacin for systemic use was removed from the U.S. market due to the sequelae hypoglycemia and hyperglycemia.

Ciprofloxacin can increase the levels of theophylline and caffeine in serum as a result of decreased hepatic clearance (127, 131). Other reported drug interactions include augmentation of the anticoagulant effects of warfarin and an increase in serum cyclosporine levels with ciprofloxacin (131).

Although irreversible cartilage erosions and skeletal abnormalities were observed in studies of quinolone toxicity in animals (127), such effects have not yet been documented unequivocally in humans. The use of quinolones is generally considered to be contraindicated in children and in pregnant or nursing mothers; however, several recent trials of fluoroquinolones for otitis media in children have been completed, and adverse events were no different than those of the comparator agent (132, 133). All of the systemic fluoroquinolones now carry a black box warning in their prescribing information for increased risk of tendonitis and tendon rupture in all ages of patients. It appears that the risk increases with age and with coadministration of corticosteroids. In addition, fluoroquinolones carry a black box warning for exacerbating muscle weakness in patients with myasthenia gravis (134). All of the fluoroquinolones available for systemic use in the United States carry a warning for QT interval prolongation and torsades de pointes. These cases are uncommon and occur mostly in patients with a history of cardiac dysrhythmias, abnormal serum electrolytes, and impaired renal function.

AMINOGLYCOSIDES AND AMINOCYCLOTOLS
Since the first aminoglycoside (aminoglycosidic aminocyclitol), streptomycin, was introduced in 1944, this class of antibiotic has played a vital role in the treatment of serious Gram-negative infections. Among the unique features of the aminoglycosides are their bactericidal activities against aerobic Gram-negative bacilli (including Pseudomonas spp.)
and *M. tuberculosis*; there is also a relatively low incidence of bacterial resistance to them. The currently available aminoglycosides are derived from *Micromonospora* spp. (gentamicin) or from *Streptomyces* spp. (kanamycin, neomycin, streptomycin, and tobramycin). Streptomycin, neomycin, kanamycin, tobramycin, and gentamicin are naturally occurring aminoglycosides, whereas amikacin is a semisynthetic derivative of kanamycin. Structurally, each of these aminoglycosides contains two or more amino sugars linked by glycosidic bonds to an aminocyclitol ring nucleus.

**Mechanism of Action**

Aminoglycosides are bactericidal agents that inhibit bacterial protein synthesis by binding irreversibly to the bacterial 30S ribosomal subunit. The aminoglycoside-bound bacterial ribosomes then become unavailable for translation of mRNA during protein synthesis, thereby leading to cell death (135). The aminoglycosides also cause misreading of the genetic code, with resultant production of nonsense proteins. To reach the intracellular ribosomal binding targets, an aerobic energy-dependent process is necessary to enable successful penetration of the bacterial inner cell membrane by the aminoglycosides. The requirement of an aerobic environment for this step accounts for the aminoglycosides’ lack of activity against anaerobic bacteria. Bacterial uptake of these agents is facilitated by inhibitors of bacterial cell wall synthesis, such as β-lactams and vancomycin. This interaction forms the basis of antibacterial synergism between aminoglycosides and β-lactam antibiotics. There are three known mechanisms of bacterial resistance to aminoglycosides: (i) decreased intracellular accumulation of the antibiotic by alteration of the outer membrane’s permeability, decreasing inner membrane transport, or active efflux; (ii) modification of the target site by mutation of the ribosomal proteins or 16S RNA or posttranscriptional methylation of 16S RNA (136); and (iii) enzymatic modification of the drug (the most common resistance mechanism) (137).

**Pharmacology**

All aminoglycosides have similar pharmacologic properties. Gastrointestinal absorption of these agents is unpredictable and always low. Because of its severe toxicity with systemic administration, neomycin is available only for oral and topical use. After intravenous administration, aminoglycosides are freely distributed in the extracellular space but penetrate poorly into the CSF, vitreous fluid of the eye, biliary tract, prostate, and tracheobronchial secretions, even in the presence of inflammation.

In adults with normal renal function, the aminoglycosides have half-lives in serum of about 2 to 3 h. They are excreted, essentially unchanged, primarily via the kidneys. There is considerable variation in the means of elimination of aminoglycosides among individuals, especially in patients with impaired renal function. Monitoring of serum aminoglycoside levels in these patients is essential for providing adequate therapy and reducing toxicity. With their features of concentration-dependent killing and prolonged postantibiotic effect, aminoglycosides may be administered once daily to achieve maximum bactericidal activity at high concentrations in serum without increased risk of toxicities (138). In renal failure, the drugs accumulate and dosage reductions or lengthening of the dosing interval is necessary. Aminoglycosides are substantially removed by hemodialysis and to a lesser extent by peritoneal dialysis.

**Spectrum of Activity**

Aminoglycoside antibiotics are active primarily against aerobic Gram-negative bacilli and *S. aureus*. As a group, they are particularly potent against the *Enterobacteriaceae*, *P. aeruginosa*, and *Acinetobacter* spp. Certain differences in antimicrobial spectra among the various aminoglycosides do exist. Widespread resistance among *Enterobacteriaceae* has limited the usefulness of streptomycin. It is now most commonly used as part of a multidrug regimen in the treatment of *M. tuberculosis* (it is the most active of the aminoglycosides against this organism) or of high-level gentamicin-resistant but high-level streptomycin-susceptible enterococcal infections (139). As a single agent, streptomycin can be used in the therapy of infections due to *Francisella tularensis* (tularemia) and *Yersinia pestis* (plague) (140). It has historically been used in conjunction with doxycycline for the treatment of brucellosis but has largely been replaced by gentamicin in this role due to the difficulty in obtaining serum-level monitoring of streptomycin.

Although gentamicin and tobramycin have very similar antibacterial activity profiles, gentamicin is more active in vitro against *Serrata* spp., whereas tobramycin is more active against *P. aeruginosa* (141). However, these minor differences have not been correlated with greater efficacy of one agent over the other. For the most part, gentamicin and tobramycin are susceptible to inactivation by the same modifying enzymes produced by resistant bacteria, except that, in contrast to gentamicin, tobramycin can be inactivated by 6-aminoglycoside-modifying enzymes and therefore is active against most *Enterobacteriaceae* that are resistant to gentamicin and tobramycin (142). Amikacin is resistant to many of these aminoglycoside-modifying enzymes and therefore is active against most *Enterobacteriaceae* that are resistant to gentamicin and tobramycin (142). Amikacin is often used as the aminoglycoside of choice when gentamicin and tobramycin resistances are prevalent. In addition, amikacin is active against many drug-susceptible *Mycoplasma* spp. (143). Aminoglycosides are only moderately active against *Haemophilus* and *Neisseria* spp. Of the agents active against *Bartonella* spp., aminoglycosides are the only drugs consistently bactericidal toward this group of organisms (140).

Although active against staphylococci, aminoglycosides are not recommended as single agents for the treatment of staphylococcal infections. Gentamicin is often combined with a penicillin or vancomycin for synergy in the treatment of serious infections due to staphylococci, enterococci, or viridans group streptococci (139, 144). However, this practice has fallen out of favor for native valve endocarditis due to *S. aureus* and is increasingly being questioned in enterococcal native valve endocarditis due to the toxicity associated with even short-term aminoglycoside use (145, 146). The aminoglycosides are not active against anaerobes.

Spectinomycin is not currently available for clinical use in the United States. It has historically been used primarily for uncomplicated anogenital infections due to *N. gonorrhoeae* in patients with penicillin or cephalosporin allergy and contraindications to fluorquinolone therapy (22). However, spectinomycin is ineffective for pharyngeal gonococcal infections, syphilis, or chlamydial infections.

**Adverse Effects**

Considerable intrinsic toxicity, mainly in the form of nephrotoxicity and auditory or vestibular toxicity, is characteristic of all of the aminoglycosides. The nephrotoxic potential varies among the aminoglycosides, with neomycin being the most toxic and streptomycin the least. This effect is usually reversible when the drug is discontinued. Hypotension, prolonged duration of therapy, preexisting renal insufficiency, and possibly excessive trough serum aminoglycoside
concentrations increase the risk of nephrotoxicity with these agents.

All aminoglycosides are capable of causing damage to the eighth cranial nerve in humans. Vestibular toxicity is more frequently associated with streptomycin, gentamicin, and tobramycin, whereas auditory toxicity is more typical of kanamycin and amikacin. This frequently irreversible side effect may occur even after discontinuation of the drug and is cumulative with repeated courses of the agent. The otoxicity is a result of selective destruction of the hair cells in the cochlea. Clinically detectable auditory and vestibular dysfunction has been reported to occur in 3 to 5% of patients receiving gentamicin, tobramycin, or amikacin who underwent audiometric testing (147).

Neuromuscular paralysis, which is usually reversible, can occur after rapid intravenous infusion of aminoglycosides. This phenomenon occurs particularly in the setting of myasthenia gravis or concurrent use of succinylcholine during anesthesia. Other minor adverse reactions include local pain and allergic skin rashes. Serious adverse reactions have not been reported for spectinomycin.

MACROLIDES

Macrolides have been in use since the early 1950s, with erythromycin being the prototypical antibiotic of this class for over 30 years (148). Their chemical structures consist of a macrocyclic lactone ring attached to two sugar moieties, desosamine and cladinose. They differ from each other in the sizes (14 to 16 atoms) and substitution patterns of their lactone rings. Erythromycin is a naturally occurring 14-membered macrolide derived from Streptomyces erythreus, and other natural analogs include oleandomycin, spiramycin, and josamycin. Clarithromycin is a semisynthetic 14-membered-ring macrolide, while azithromycin is a 15-membered-ring derivative, also known as an azalide, with a nitrogen atom incorporated in its lactone ring. These newer macrolides offer significant advantages over erythromycin because of expanded antimicrobial spectra, improved pharmacokinetic parameters, and less frequent adverse effects and drug interactions.

Mechanism of Action

Macrolides are generally bacteriostatic agents that inhibit bacterial RNA-dependent protein synthesis. They may be bactericidal at high drug concentrations and against a low inoculum of bacteria. They bind reversibly to the 23S rRNA of the 50S ribosomal subunits of susceptible organisms, thereby blocking the translocation reaction of polypeptide chain elongation (149). The presence of erm(B) gene-encoded rRNA methyltransferases that modify the bacterial 23S rRNA target-binding site is the primary mechanism of macrolide resistance and confers macrolide-lincosamide-streptogramin B (MLSβ) co-resistance (150, 151). Expression of erm may be constitutive or inducible. If inducible, the bacterial strains appear to be resistant to erythromycin (an inducer) but susceptible to clindamycin. However, treatment with clindamycin may lead to selection of resistant mutants and therapeutic failure (150). Other uncommon mechanisms of resistance to macrolides include production of macrolide-inactivating enzymes (esterases, phosphorylases, and glycosidases), mef- and msr-encoded active efflux of drug, mtrR promoter gene mutation-induced overproduction of an mtrCDE-encoded efflux pump, and mutations in 23S rRNA (151, 152).

Pharmacology

Erythromycin is available in various topical, parenteral (lactobionate), and oral (base stearate, ethylsuccinate, and estolate) preparations. While clarithromycin is available only in oral forms, azithromycin is formulated for oral and intravenous administration. When administered orally, the erythromycin base is rapidly inactivated by gastric acid, whereas the newer macrolides are stable against acid degradation. Intestinal absorption of erythromycin (except for the estolate form) and azithromycin is reduced to 50% in the presence of food. Peak levels in serum of 2 to 3, 1 to 2, and 0.4 μg/ml are reached at 3 h after oral doses of erythromycin (500 mg), clarithromycin (250 mg), and azithromycin (500 mg), respectively. Much higher concentrations of erythromycin and azithromycin are achieved with intravenous infusion. Tissue distributions of macrolides are excellent, with concentrations in various tissues 10- to 100-fold higher than those in serum (153). The high concentrations reached rapidly within neutrophils and macrophages account for their potent activity against intracellular pathogens (154). They penetrate poorly into the brain and CSF, but they do cross the placenta and are excreted in breast milk.

Erythromycin and clarithromycin are metabolized by the liver and excreted primarily in the bile. Azithromycin is excreted largely unchanged in the bile. Clarithromycin exhibits first-pass metabolism, producing a microbiologically active 14-hydroxy derivative that is two to four times more potent than the parent drug against some organisms. Erythromycin, clarithromycin, 14-hydroxy clarithromycin, and azithromycin have terminal half-lives in serum of 1.5, 5.0, 5.5, and 41 h, respectively. Because of its exceptionally high tissue penetration, azithromycin has a half-life in tissue of 2 to 4 days (154). Dosage adjustment of clarithromycin is necessary with moderate to severe renal failure (creatinine clearance of <30 ml/min). Except for clarithromycin, macrolides are removed minimally by hemodialysis or peritoneal dialysis.

Spectrum of Activity

Macrolides are relatively broad-spectrum antibiotics, with activity against Gram-positive and some Gram-negative bacteria, mycoplasmas, chlamydiae, treponemes, and rickettsiae (153, 154). Erythromycin shows good activity against staphylococci and streptococci, including S. pneumoniae, but the emergence of resistance among these isolates is increasingly common (3–5, 155). Clarithromycin is 2- to 4-fold more potent than the other macrolides, and azithromycin is less active than erythromycin against most staphylococci and streptococci (156). These drugs may be bactericidal against susceptible strains of streptococci but are generally thought to be bacteriostatic agents against most other organisms. Erythromycin-resistant strains display cross-resistance to clarithromycin and azithromycin. The vast majority of methicillin-resistant staphylococci and many enterococci are resistant to all macrolides. These drugs are also active against Corynebacterium spp., L. monocytogenes, and Actinomyces israelii (156). The antibacterial activities of macrolides against Gram-negative bacilli are influenced by pH, with increasing potency (lower MICs) as the pH rises to 8.5. H. influenzae and M. catarrhalis are more susceptible to azithromycin (MIC90 of 0.5 μg/ml) than to other macrolides (8- to 16-fold higher MIC90s) (157, 158). However, additive (and possibly synergistic) activity between clarithromycin and its 14-hydroxy metabolite reduces the MIC of clarithromycin for H. influenzae 2- to 4-fold
against (159). Clarithromycin is the most active drug in this class against C. pneumoniae (MIC\textsubscript{90} of 0.25 \(\mu\)g/ml) and Legionella isolates (MIC\textsubscript{90} of 0.25 \(\mu\)g/ml) (156). All three macrolides are equally potent against Bordetella pertussis and M. pneumoniae; erythromycin has long been established as the drug of choice for the therapy of infections due to these pathogens and Legionella spp., though the newer macrolides are increasingly used clinically due to their superior tolerability, pharmacokinetics, and drug interaction profile. However, fluoroquinolones may be superior to macrolides for infections due to Legionella spp. (160). Macrolides are active against Campylobacter spp., H. pylori, P. multocida, N. meningitidis, and Borrelia burgdorferi (156, 158). Unlike other macrolides, azithromycin is also active in vitro against some strains of E. coli, Shigella spp., Salmonella spp., and Y. enterocolitica, although resistant strains are commonly encountered today (157, 159, 161).

Macrolide antibiotics are effective in vitro against many pathogens that cause sexually transmitted diseases. N. gonorrhoeae, Haeckophilus ducreyi, C. trachomatis, and U. urealyticum are all susceptible, but only azithromycin is active against M. hominis (156, 157). Azithromycin (2 g as a single dose) may be used for the treatment of gonorrhea in patients unable to receive ceftriaxone due to severe allergy (162). Azithromycin as a 2-g dose is suggested as a possible third-line therapy in early-syphils patients who cannot tolerate penicillin G or doxycline; however, resistance to azithromycin has been reported (22). Azithromycin is effective as an alternative to tetracyclines for the treatment of genital chlamydial infections (163). As a group, macrolides are among the most potent agents inhibitory toward Bartonella spp. (122). The macrolides have good activity against some anaerobic bacteria, such as Actinomyces spp., Clostridium perfringens, Peptostreptococcus spp., Propionibacterium spp., Prevotella spp., Porphyromonas spp., and some anaerobic Gram-positive cocci, with MIC\textsubscript{90}s of 1 to 4 \(\mu\)g/ml (164). They are much less active against the Bacteroides spp., with MIC\textsubscript{90}s in excess of 32 \(\mu\)g/ml. They also have poor activity against Fusobacterium nucleatum, Clostridium innocuum, and Lactobacillus spp., for which the macrolides exhibit MIC\textsubscript{90}s in excess of 32 \(\mu\)g/ml.

Atypical mycobacteria are more susceptible than M. tuberculosis to macrolide antibiotics. Clarithromycin is widely considered the gold standard agent against these organisms (143, 157). The MIC\textsubscript{90}s of clarithromycin and azithromycin for M. avium complex are in the range of 2 to 4 \(\mu\)g/ml, allowing additive or synergistic killing activity against these organisms within infected macrophages when these drugs are combined with other antitubercular drugs (156). Clarithromycin is used to treat infections due to Mycobacterium chelonae and many other nontuberculous mycobacteria (143).

Clarithromycin and azithromycin offer comparable in vitro activities against Toxoplasma gondii and are alternative therapies for this organism (165).

**Adverse Effects**

The incidence of serious side effects related to the use of the macrolides is relatively low. Gastrointestinal irritation, such as abdominal cramps, nausea, vomiting, and diarrhea, is common with oral administration of erythromycin and can occur when the drug is given intravenously. These side effects occur less frequently with clarithromycin and azithromycin. Thrombophlebitis is associated with intravenous erythromycin infusion and is one of the reasons that intravenous azithromycin has largely replaced intravenous erythromycin in most clinical settings. Hypersensitivity reactions may include skin rash, fever, and eosinophilia. Cholestatic hepatitis occurring in adults has frequently been associated with erythromycin estolate but has also been reported with other forms of erythromycin (160) and azithromycin (167). For this reason, erythromycin estolate is no longer recommended for use in adults.

Reversible hearing loss may occur with the use of large doses and very high serum concentrations of erythromycin (>4 g/day), usually in elderly patients with renal insufficiency (168). Ototoxicity has also been reported with high doses of clarithromycin and azithromycin used to treat M. avium complex infections. Pseudomembranous colitis and superinfection of the gastrointestinal tract or vagina with Candida spp. or Gram-negative bacilli occur rarely. Erythromycin is a potent inhibitor of cytochrome P450 enzymes, leading to multiple drug-drug interactions with this agent (169). While significantly less so than erythromycin, clarithromycin remains a clinically important inhibitor of cytochrome P450 and also possesses a number of clinically significant drug interactions. Azithromycin minimally inhibits these hepatic enzymes and is much less likely to be associated with clinically significant drug interactions. In March of 2013, the FDA issued a drug safety communication regarding azithromycin and increased risk of sudden cardiac death due to cardiac dysrhythmias. The agency warned that azithromycin use may lead to potentially fatal irregular heart rhythms and stated that the risk was highest in patients with a history of cardiac dysrhythmias, electrolyte abnormalities, or concurrent use of cardiac antiarrhythmic medications.

**Fidaxomicin**

Fidaxomicin is a nonabsorbable macrocyclic 18-ring macrolide antibiotic that is FDA approved for the treatment of diarrhea due to Clostridium difficile. Fidaxomicin acts by inhibiting RNA polymerase, leading to impaired RNA chain synthesis and transcription (170). The drug is available only for clinical use as a tablet and is administered at a dose of 200 mg every 12 h, which results in high concentrations in the intestinal tract but concentrations in serum of less than 10 ng/ml. Its major metabolite, OP-1118, is also active against Clostridium difficile and also achieves serum concentrations. The MIC\textsubscript{90} of fidaxomicin against C. difficile is 0.5 \(\mu\)g/ml, while stool concentrations of fidaxomicin are well in excess of 500 \(\mu\)g/ml. The activity of fidaxomicin against B. fragilis, as well as other nonclostridial intestinal anaerobes, is significantly less, with MICs for B. fragilis, Prevotella spp., eubacteria, facultative Gram-negative rods, Clostridium ramosum, and other intestinal anaerobes typically in the 256- to 1,024-\(\mu\)g/ml range (171). The emergence of C. difficile with alterations in the rpoB and/or rpoC gene through serial passage, for which MICs of fidaxomicin are elevated, as well as in a clinical case has been reported, but its clinical significance remains uncertain due to MICs remaining 100 times less than fidaxomicin concentrations in the stool (172).

In clinical trials versus vancomycin administered at a dose of 125 mg every 6 h, fidaxomicin at 200 mg every 12 h was found to be noninferior to vancomycin for the treatment of C. difficile disease. Relapse rates were approximately 10% to 15% better in patients receiving fidaxomicin. The suggested mechanism for this advantage in relapse rates is fidaxomicin’s relative sparing of the normal intestinal microbiota compared to what occurs with vancomycin (173). Though the drug appears to offer a therapeutic advantage over vancomycin with respect to relapse rates, clinical use of the compound has been slowed by the high cost of the medication.
KETOLIDES

Ketolides are semisynthetic derivatives of erythromycin A, having a ketone group instead of an l-cladinose moiety at the 3 position on the erythronolide A ring. This modification of the chemical structure results in increased stability in acid media, noninducibility of MLSB resistance, and enhanced activity against Gram-positive cocci. The ketolides currently under clinical development also have a substituted carbamate link between carbon atoms 11 and 12 in the macrolide nucleus. This modification enables them to retain activity against bacteria whose ribosomes have been methylated at position A2058 as a result of acquired methylase genes (174). Telithromycin is the first and only ketolide currently approved for clinical use in the United States. However, its clinical use is severely limited due to cases of fulminant hepatic failure, which has resulted in a warning in its prescribing information for hepatotoxicity. In addition, telithromycin possesses a black box warning for respiratory failure in patients with myasthenia gravis. Another ketolide with similar antibacterial properties, cethromycin, completed phase 3 studies, but an FDA advisory committee voted that, while the drug appeared to be safe, the studies did not demonstrate sufficient efficacy in mild to moderate community-acquired pneumonia (CAP). The FDA refused to approve the agent and issued a complete response letter in August 2009, resulting in apparent discontinuation of clinical development. Solithromycin (CEM-101) is a fluoroketolide currently undergoing phase 3 clinical studies for community-acquired bacterial pneumonia (CABP). It has an antibacterial spectrum similar to telithromycin’s, with MICs generally within 2-fold of that of the seminal ketolide, but is expected to demonstrate a more robust safety profile based on preclinical studies (175).

Mechanism of Action

Like the macrolide antibiotics, ketolides inhibit bacterial protein synthesis in susceptible organisms by binding to the bacterial 23S rRNA at domains II and V of the peptidyltransferase site in 50S ribosomal subunit 47 (176). These drugs may also inhibit the formation of the 30S ribosomal unit. Although ketolides do not induce MLSB resistance, staphylococci with constitutively expressed MLSB resistance excluder genes are resistant to telithromycin. Although these drugs do not appear to be affected by efflux, mutations in the 23S rRNA and ribosomal proteins L4 and L22 (177) or ermB gene mutation-induced rRNA methylation (178) can lead to in vitro resistance to ketolides. This class of drugs has a low potential to select for resistance or induce cross-resistance among other MLSB antimicrobials.

Pharmacology

Telithromycin is administered orally as a once-daily dose of 800 mg, with rapid gastrointestinal absorption, yielding a mean peak concentration in plasma of 2 μg/ml in 1 to 2 h and steady state in 2 days. A mean trough concentration in plasma of 0.07 μg/ml is attained at 24 h after dosing (179). The oral bioavailability of 57% is unaffected by food ingestion. With about 70% of the drug being protein bound, telithromycin exhibits biphasic elimination from plasma, with initial and terminal half-lives of 2 to 3 h and 9 to 10 h, respectively. The drug penetrates well into bronchopulmonary, tonsillar, and sinus tissues and into middle ear fluid, and it is accumulated by polymorphonuclear neutrophils with an intracellular concentration-to-plasma concentration ratio of >500 at 24 h. Hepatic metabolism with elimination via feces (~80%) is the main route of excretion, and <15% of the administered dose is eliminated in urine. Dosage adjustments are not necessary in patients with renal or hepatic impairment.

Spectrum of Activity

Ketolides possess potent activity against respiratory pathogens as well as intracellular bacteria, and all that have been developed have been designed specifically for the treatment of community-acquired respiratory tract infections. Telithromycin is more potent than macrolides against S. pneumoniae isolates, irrespective of penicillin susceptibility, with an MIC<sub>90</sub> of ≤1 μg/ml; 90% of penicillin-resistant strains are inhibited at 0.25 μg/ml (180–183). Almost all macrolide-resistant strains of pneumococci are inhibited by the ketolides at ≤0.5 μg/ml, regardless of the underlying mechanism of macrolide resistance (3–5). Telithromycin is more active than erythromycin and clarithromycin and as potent as azithromycin against H. influenzae (MIC<sub>90</sub> of 2 to 4 μg/ml) and M. catarrhalis (MIC<sub>90</sub> of 0.06 to 0.125 μg/ml). The activity of telithromycin is unaffected by β-lactamase production in these strains, but the MICs are increased 2-fold in the presence of 5% CO₂. Significant postantibiotic effects may be observed for up to 9 h with this drug against the major respiratory pathogens (184).

Telithromycin is also active against staphylococci, with MIC<sub>90</sub> of 0.125 to 0.25 μg/ml for S. aureus and coagulase-negative staphylococci, regardless of the organism’s susceptibility to oxacillin. However, isolates harboring the constitutive MLSB mechanism of resistance are resistant to ketolides. Enterococci without underlying resistance to macrolides and clindamycin are susceptible to telithromycin, with MIC<sub>90</sub> of 0.125 μg/ml for E. faecalis and E. faecium. Higher MIC<sub>90</sub> (4 to 8 μg/ml) are observed with erythromycin- or clindamycin-resistant enterococci (185). Telithromycin displays good in vitro activity against beta-hemolytic streptococci and viridans group streptococci, regardless of their susceptibility to benzylpenicillin, with all isolates inhibited at ≤0.5 μg/ml. While streptococcal isolates with the mefA (gene-mediated) drug efflux mechanism of resistance to erythromycin remain susceptible to telithromycin, ketolide MICs for them are higher (2 to 16 μg/ml) among the strains with inducible or constitutive erm (gene-mediated) resistance to erythromycin. Other Gram-positive cocci, such as Peptococcus, Leuconostoc, Stomatococcus, and Rhodococcus equi, are susceptible to telithromycin, with MIC<sub>90</sub> for them of 0.03 to 0.25 μg/ml.

Ketolides are also very active against Gram-positive bacilli, inhibiting Corynebacterium (including C. diphtheriae and C. jeikeium), Listeria, Lactobacillus, Actinomyces, and Erysipelothrix at concentrations of ≤0.125 μg/ml (185). Telithromycin is inhibitory (MIC<sub>90</sub> of 0.125 to 0.5 μg/ml) to Peptostreptococcus spp., Prevotella spp., Porphyromonas spp., Bifidobacteria spp., and Clostridium perfringens, but it is not active against other Clostridium spp., Fusobacterium, and members of the B. fragilis group (186). This drug has poor activity against other Gram-negative bacilli, including the Entero bacteriaceae, Acinetobacter spp., P. aeruginosa, and Borrelia burgdorferi (187).

Intracellular pathogens, such as Legionella, Mycoplasma, and Chlamydia, are highly susceptible to telithromycin, for which MIC<sub>90</sub> are 0.004 to 0.25 μg/ml (181).Ricketsia spp., Bartonella spp., C. burnetti, and F. tularensis are also susceptible to this agent. Telithromycin is comparable to the macrolides in its activity against M. chelonae and M. avium, with an MIC<sub>90</sub> of 4 μg/ml. It is not active against M. tuberculosis, M. bovis, and other atypical mycobacteria (188).
Adverse Effects
Telithromycin’s clinical utility has been severely hampered by the warnings for hepatotoxicity and respiratory failure in myasthenia gravis that have been added to the prescribing information. However, during registration trials, telithromycin was well tolerated by all patient populations, with gastrointestinal adverse effects, such as diarrhea (15%), nausea (9%), vomiting, and dizziness, as the most frequent adverse effects (189). Occurrence of C. difficile-associated diarrhea has not been reported in clinical trial studies. While elevation of serum transaminase levels is found in <10% of patients, rare cases of severe hepatotoxicity can occur (190). Since ketolides are substrates and inhibitors of the hepatic cytochrome P450 CYP3A4 isoenzyme pathway, their potential to lengthen the QT interval is augmented by concomitant administration of other CYP3A4 inhibitors, such as the triazole antifungal agents (191).

LINCOSAMIDES
The lincosamide antibiotics include lincomycin, which was initially isolated from Streptomyces lincolnensis, and clindamycin, which is a chemical modification of lincomycin. The chemical structure of each drug consists of an amino acid linked to an amino sugar. Compared with lincomycin, clindamycin has increased antibacterial activity and improved absorption after oral administration (192). Both drugs are available for parenteral and oral use, but lincomycin is very rarely used in the United States and will not be discussed further.

Mechanism of Action
Lincosamides bind to the 50S ribosomal subunits of susceptible bacteria and prevent elongation of peptide chains by interfering with peptidyl transfer, thereby suppressing protein synthesis. The ribosomal binding sites are the same as, or closely related to, those that bind macrolides, streptogramins, and chloramphenicol (193). Clindamycin can be bactericidal or bacteriostatic, depending on the drug concentration, bacterial species, and inoculum of bacteria.

Pharmacology
About 90% of an oral clindamycin dose is absorbed from the gastrointestinal tract, with no interference from the ingestion of food. A single oral dose of 150 mg yields a peak concentration in serum of 2 to 3 μg/ml in 1 h. Peak levels in serum of 10 to 12 μg/ml are obtained at 1 h after a 600-mg intravenous dose. Therapeutic serum drug levels are maintained for 6 to 9 h after these doses (194).

Clindamycin distributes well into bone, lungs, pleural fluid, and bile, but it penetrates poorly into CSF, even in patients with meningitis. It readily crosses the placenta and enters fetal tissues. Clindamycin is actively concentrated in neutrophils and macrophages.

The normal half-life of clindamycin is 2.4 h. Most of the drug is metabolized by the liver and excreted in an inactive form in the urine. Its half-life is prolonged by severe liver dysfunction, necessitating dosage reduction in patients with severe liver disease. Although the serum drug levels are increased in patients with severe renal failure, dose modification is not essential. The drug is not removed significantly by hemodialysis or peritoneal dialysis.

Spectrum of Activity
Clindamycin has a broad spectrum of activity against the aerobic Gram-positive cocci and against anaerobes, which include methicillin-susceptible Staphylococcus spp., S. pneumoniae, and group A and viridans group streptococci (192, 194). The MIC90s are in the range of 0.01 to 0.1 μg/ml for susceptible strains of these organisms. However, resistance to clindamycin has emerged in clinical isolates of some bacteria that are also resistant to erythromycin (3–5, 155). The prevalence of clindamycin-resistant S. aureus strains is 20% or higher in some institutions, with up to 85% coresistance in USA100 MRSA strains. USA300 community-associated MRSA strains often retain susceptibility to clindamycin. Resistance in beta-hemolytic streptococci, pneumococci, and viridans group streptococci is considerable as well. Enterococci and all Enterobacteriaceae are uniformly resistant to the lincosamides.

Clindamycin is one of the most active antibiotics available against anaerobes, including members of the B. fragilis group and C. perfringens, with MIC90s of ≤2 μg/ml (194, 195). However, clindamycin resistance is increasing. In a recent study, more than 30% of Bacteroides spp. were resistant to clindamycin; MIC90s for them were >128 μg/ml (196, 197). Thirty percent of all anaerobic clinical isolates in a more recent European series were resistant to clindamycin, with resistance highest in Bacteroides and Parabacteroides spp., excluding B. fragilis strains (54% resistant), Prevotella spp., and other Gram-negative anaerobes (31% resistant) (198). Ten to 20% of clostridial species, 10% of peptococci, and most Fusobacterium varium strains have also been found to be resistant to clindamycin (199, 199). Clindamycin has been used successfully as a single-agent therapy for actinomycosis (200), babesiosis (165, 201), and malaria (202). It is also effective in combination with pyrimethamine for toxoplasma encephalitis (203) and in combination with primaqune for Pneumocystis jirovecii pneumonia (204). Clindamycin phosphate and benzoyl peroxide (1.2%/2.5%) as a gel is also used for the topical treatment of acne vulgaris.

Adverse Effects
Clindamycin-associated diarrhea occurs in up to 20% of patients, and use of this drug has been commonly associated with pseudomembranous colitis caused by toxin-producing C. difficile (12). This complication is not dose related and may occur after oral or parenteral therapy. Prompt cessation of the antibiotic in conjunction with oral vancomycin or metronidazole is effective in reversing this complication. Other uncommon side effects include skin rashes, fever, and reversible elevation of serum transaminases. Clindamycin can block neuromuscular transmission and may potentiate the action of neuromuscular blocking agents during anesthesia.

TETRACYCLINES AND GLYCICYLCYCLINES
Tetracyclines are broad-spectrum bacteriostatic antibiotics with the hydronaphthacene nucleus, which contains four fused rings. The congeners form three groups based on their durations of action. Tetracycline is a short-acting drug, demeclocycline is an intermediate-acting drug, and doxycycline and minocycline are long-acting drugs. Demeclocycline is used mostly for the syndrome of inappropriate antidiuretic hormone secretion and is not routinely used for its antibacterial properties. Glycylcyclines are a group of semisynthetic tetracycline derivatives containing a glyclamido substitution at position 9. Tigecycline (a 9-(R)-butylglycylamido derivative of minocycline) is the first in this class of drugs available for clinical use (205). Omadacycline is an aminomethylcycline closely related to tigecycline.
that is entering phase 3 studies in the United States. Eravacycline, a C-7, C-9-disubstitution fluorocycline, is currently in phase 3 clinical trials for treatment of complicated intra-abdominal infections (CIADI).

**Mechanism of Action**

Tetracyclines and glycylcyclines act against susceptible microorganisms by inhibiting protein synthesis. They enter bacteria by an energy-dependent process and bind reversibly to the 30S ribosomal subunits, preventing the attachment of aminocaidyl-tRNA to the ribosomal acceptor A site in the RNA-ribosome complex (206, 207). Resistance to tetracyclines occurs among clinical isolates as a result of active efflux of the drug from the cell, an altered ribosomal target site that prevents binding of the drug (ribosomal protection) or production of modifying enzymes that inactivate the drug. With stearic hindrance from the bulky side group at position 9, glycylcyclines are unaffected by bacterial ribosomal protection proteins and evade most efflux pumps present in tetracycline-resistant strains. These drugs also have higher binding affinities for the bacterial ribosomes than tetracyclines (207). Reduced susceptibility to tigecycline has been found in clinical strains of Enterobacteriaceae (particularly problematic for Proteus spp., Morganella spp., and Providencia spp.), A. baumannii, P. aeruginosa, and S. aureus strains possessing chromosomally encoded multicomponent efflux pumps (208–211) and in some Bacteroides spp. with the tet(X) gene-mediated monoxygenase enzyme that degrades tetracyclines (212).

**Pharmacology**

Tetracyclines are incompletely absorbed from the gastrointestinal tract, but their absorption is improved in the fasting state. Ingestion of food, especially dairy products, and other substances, such as divalent- and trivalent-cation-containing antacids and iron preparations, impairs the absorption of these drugs. Less interference with absorption by foods occurs with doxycycline and minocycline. Minocycline and doxycycline are readily absorbed, and therefore lower doses are required. Peak concentrations in serum of 3 to 5 μg/ml are reached in 2 h after standard oral dosages. Intravenous preparations are available, and peak concentrations in serum of 3 to 9 μg/ml are reached in 1 h after intravenous administration, depending on the tetracycline infused and the dose (213). Tetracyclines are usually bacteriostatic at these clinically achievable concentrations in serum.

Tissue penetration of these drugs is excellent, but levels in CSF are low even in the presence of meningeal inflammation. Tetracyclines cross the placenta and are incorporated into fetal bone and teeth. They are excreted in high concentrations in human milk. Therefore, tetracyclines are not advised for pregnant or lactating women. Minocycline, the most lipophilic tetracycline at physiologic pH, reaches relatively high concentrations in saliva and tears (214).

Many tetracyclines are metabolized by the liver and concentrated in the bile. Biliary concentrations of tetracyclines are three to five times higher than concurrent levels in plasma, with significant drug accumulation in the blood of patients with hepatic insufficiency or biliary obstruction. Doxycycline is eliminated unchanged in the urine, and 35 to 60% of the dose is recovered in the urine. Minocycline is eliminated primarily through nonrenal routes, with only approximately 5 to 12% of the dose recovered in the urine. Renal failure prolongs the half-lives of the tetracyclines except doxycycline and minocycline (213). Therefore, doxycycline or minocycline should be considered the tetracycline of choice for extrarenal infections in the presence of renal failure.

Tigecycline is administered as an intravenous formulation because of limited oral bioavailability. After multiple doses of 50 mg infused every 12 h, the peak serum concentration is approximately 0.8 μg/ml (215, 216). Despite having plasma protein binding of 80%, the drug has a rapid and wide distribution into tissues, including bone, resulting in 3- to 5-fold-higher drug exposures in skin and soft tissue than in the blood. Penetration into CSF in patients with or without meningitis is marginal, with a drug level of 0.025 μg/ml in the CSF at 12 h after infusion of a single 100-mg dose (217). It is eliminated primarily by the liver via glucuronidation and biliary excretion of unchanged drug, and the mean elimination half-life is 36 h. With <30% of the drug excreted unchanged in the urine, dosage adjustment is not required for renal insufficiency, hemodialysis, or mild to moderate hepatic dysfunction.

Omadacycline and eravacycline are being developed in both oral and intravenous formulations (218). The half-life of omadacycline is approximately 17 h, with a 100-mg intravenous administration resulting in a time to maximum concentration of the drug in serum (Cmax) of approximately 1.8 μg/ml (219). Like tigecycline, omadacycline and eravacycline evade the ribosomal protection resistance mechanism and most efflux pumps that are associated with tetracycline resistance. However, similarly to tigecycline, omadacycline is a substrate for the AcrAB multidrug efflux pump commonly found in Proteus spp. and Klebsiella spp. as well as the MexXY efflux system found in P. aeruginosa.

**Spectrum of Activity**

All tetracyclines have similar antimicrobial spectra, with activities against many Gram-positive and Gram-negative bacteria, mycoplasmas, chlamydias, rickettsiae, and some protozoa. Many Gram-positive aerobic cocci, including S. aureus, S. pyogenes, and S. pneumoniae, are susceptible at concentrations achievable in the serum. However, tetracycline-resistant strains of S. pneumoniae are common (3–5). A substantial percentage of E. coli isolates are now doxycycline and minocycline resistant. Neither of these agents is recommended in the 2010 IDSA guidelines for cystitis and pylonephritis (220, 221). Pseudomonads and many Enterobacteriaceae are also resistant. Most strains of Shigella and Salmonella spp. are resistant to these agents. With activity against Burkholderia pseudomallei, Brucella spp., Vibrio spp., and Mycobacterium marinum (222), they have been used successfully in the treatment of infections due to these bacteria. Their efficacy in the therapy of choler are diminishing owing to the emergence of resistant Vibrio cholerae isolates (223). Minocycline is active against Nocardia spp. (224). There is also renewed interest in minocycline for the treatment of MDR Acinetobacter spp. and S. maltophilia. Minocycline is the most active tetracycline against these 2 problematic pathogens, and a large percentage of isolates remain susceptible despite resistance to a variety of other antibiotics (225, 226). Some anaerobic bacteria are susceptible to tetracyclines, though resistance is increasingly common (227). However, tigecycline retains activity against most anaerobes, as demonstrated in a recent study (228).

These drugs are useful in the treatment of urethritis and acute pelvic inflammatory diseases caused by C. trachomatis, U. urealyticum, and M. hominis. Resistance to tetracyclines is prevalent among N. gonorrhoeae strains (229). The drugs are effective for the treatment of other chlamydial infections (psittacosis, lymphogranuloma venereum, and trachoma)
The antibacterial spectrum of omadacycline appears comparable to that of tigecycline, but it is less potent than tigecycline against many Gram-negative pathogens. Reduced susceptibility is seen in K. pneumoniae isolates that express the AcrAB efflux pump (237).

**Adverse Effects**
Tetracyclines have irritative effects on the upper gastrointestinal tract, producing esophageal ulcerations, nausea, vomiting, and epigastric distress. Alterations in the enteric biota occur with the use of tetracyclines, often resulting in diarrhea, and pseudomembranous colitis can develop with prolonged use. Hypersensitivity reactions are unusual, generally manifesting themselves as urticaria, fixed drug eruptions, morbilliform rashes, and anaphylaxis. Cross-reactivity among tetracyclines is the rule. Photosensitivity reactions consist of an erythematous rash on areas exposed to sunlight and can occur with all analogs, especially demeclocycline (238).

Minocycline has been known to cause vertigo, and benign intracranial hypertension (pseudotumor cerebri) has been described with many of the analogs (239). Tetracycline can aggravate preexisting renal failure by inhibiting protein synthesis, increasing the azotemia from amino acid metabolism. Tetracyclines cause depression of bone growth, permanent discoloration of the teeth, and enamel hypoplasia when given during tooth and skeletal development (240). Therefore, these drugs are usually avoided in childhood (<8 years of age) and during pregnancy. Tigecycline is reasonably well tolerated; a notable exception is that the rates of both nausea and vomiting were significantly higher in the tigecycline arms of the registration studies than those of the comparator. However, only mild nausea was reported in clinical studies with omadacycline and eravacycline (218). Headache and diarrhea are the most commonly reported other side effects. Due to adverse effects similar to those of the tetracyclines on bone and tooth development, use of this drug is contraindicated during pregnancy, for nursing mothers, and for those <18 years of age. It may also show cross-hypersensitivity to tetracyclines (241).

### GLYCOPEPETIDES AND LIPOPEPTIDES
Vancomycin, a bactericidal antibiotic obtained from *Streptomyces orientalis*, is the only nonlipoglycopeptide marketed for clinical use in the United States. Initially introduced for its efficacy against penicillin-resistant staphylococci, it has become most useful against methicillin-resistant staphylococci and in patients allergic to penicillins or cephalosporins. Teicoplanin (formerly teichomycin A), a complex glycopeptide chemically related to vancomycin (242), is currently available for clinical use in most countries of the world except the United States. Dalbavancin, oritavancin, and telavancin are semisynthetic lipoglycopeptides (glycopeptide derivatives with hydrophobic substituents); the last was approved for clinical use in the United States (243–246). Both dalbavancin and oritavancin have completed phase 3 studies for skin and skin structure infections. Both dalbavancin and oritavancin were approved by the FDA in mid-2014. Daptomycin is a unique, naturally occurring cyclic lipopeptide antibiotic found among the fermentation by-products of *Streptomyces roseosporus* and has more potent activity against Gram-positive bacteria than vancomycin.

### Mechanism of Action
Glycopeptides inhibit peptidoglycan synthesis in the bacterial cell wall by complexing with the D-alanyl-D-alanine

---

(22). Other infections responsive to tetracyclines include granuloma inguinale, chancroid, relapsing fever, and tularemia. Tetracyclines are the drugs of choice for treating rickettsial infections (Rocky Mountain spotted fever, endemic and Verruga erythema, and Q fever). Many pathogenic spirochetes, including *Treponema pallidum* and *B. burgdorferi*, are susceptible (22, 230). Protozoans, such as *Plasmodium falciparum* and *Entamoeba histolytica*, are also inhibited by these drugs (165, 230).

Tigecycline is indicated for the treatment of complicated skin and skin structure infections, clAI, and CABP by the FDA. However, in October 2013, the prescribing information was updated with a black box warning to reflect increased mortality in patients who received tigecycline versus comparator agents. Although the cause of the increase in mortality is not clear, the FDA now recommends that tigecycline be used only when alternative treatments are not suitable. It is possible that this increased mortality may be related to the low concentrations in serum (i.e., <1.0 μg/ml) that are achieved with the dosing regimen of 50 mg every 12 h as stated in the package label (205, 231). Most staphylococci, including methicillin-resistant and vancomycin-intermediate strains, are inhibited by tigecycline at ≤1 μg/ml. The MIC90 for vancomycin-susceptible and -resistant enterococci are typically 0.25 to 0.5 μg/ml, and *E. faecium* and *E. faecalis* are inhibited equally well by this drug. However, tigecycline exhibits no bactericidal activity against staphylococci and enterococci in time-kill studies. *P. aeruginosa* is uniformly resistant to tigecycline.

Vibriod group streptococci, beta-hemolytic streptococci, and MDR pneumococci are highly susceptible to tigecycline; MIC90 for them range from ≤0.25 to 0.5 μg/ml. The drug is also active against most *Enterobacteriaceae* and nonfermentative Gram-negative bacilli, including strains producing ESBLs, with MIC90 of ≤2 μg/ml. It inhibits MDR *A. baumannii* and *S. maltophilia* at MIC of 2 μg/ml (232, 233). For the fastidious respiratory tract pathogens *H. influenzae* and *M. catarrhalis*, MIC90 are 0.5 μg/ml and 1 μg/ml, respectively. *Proteus, Morganella, Providencia*, and *P. aeruginosa* are generally resistant (MIC90 for them are >16 μg/ml). Tigecycline also exhibits some activity against most *B. fragilis* group isolates (MIC90 of 8 μg/ml), peptostreptococci (MIC90 of 4 μg/ml), *Clostridium sp.* (MIC90 of 0.5 μg/ml), *Prevotella sp.*, *Propionibacterium*, and *Fusobacterium* (64, 234).

Tigecycline exhibits a more potent activity against *M. pneumoniae*, *M. hominis*, *C. pneumoniae*, and *C. trachomatis* than tetracyclines, with MIC90 in the range of 0.125 to 0.5 μg/ml. It is less active toward *U. urealyticum* and *Legionella spp.*, with MIC90 of 8 μg/ml. Rapidly growing mycobacteria, including *M. abscessus*, *M. chelonae*, and members of the *M. fortuitum* group, are 4- to 11-fold more susceptible (MIC90 for them are ≤0.25 μg/ml) to this drug than to tetracyclines (235). However, slowly growing nontuberculous mycobacteria, such as *M. kansasi*, *M. marinum*, and *M. xenopi*, are less susceptible to tigecycline than to minocycline.

Susceptibility testing with tigecycline should be done using freshly prepared media or media containing a biocatalytic oxygen-reducing reagent (e.g., Oxysure), because the drug is prone to oxidative degradation. Testing using aged broth media (prepared >12 h prior to inoculation) yielded MIC results that were generally 1 to 2 dilutions higher than those obtained using fresh media (236). Commercial media high in Mn2+ (>2.5 ppm) have been reported to increase MICs of tigecycline during susceptibility testing (146).

---

68. Antibacterial Agents  ▪  1187
portion of the cell wall precursor. Resistance to vancomycin and teicoplanin can occur by one of two mechanisms: (i) a complex series of bacterial cytoplasmic enzymes present in vancomycin-resistant enterococci synthesize abnormal peptidoglycan precursors terminating in \( \beta-D\)-alanyl-\(\beta-D\)-lactate or \(\beta-D\)-alanyl-\(\beta-D\)-alanine residues, instead of the usual \(\beta-D\)-alanyl-\(\beta-D\)-alanine residues, thereby markedly lowering the drug’s binding affinity with the glycopeptides, or (ii) the accumulation of peptidoglycan precursors (murine monomers) increases, resulting in a thickened cell wall with “trapping” of drug molecules, which prevents further diffusion of the drug into the inner part of cell wall layers of VISA (247).

Daptomycin binds irreversibly to the cytoplasmic membrane of susceptible bacteria via a calcium ion-dependent insertion of the hydrophobic tail of the molecule and causes generalized disruption of membrane permeability (248). The end effect is cell death without cell lysis, providing this drug with potent bactericidal activity. It is unable to penetrate the outer membrane of Gram-negative bacteria. Reduced susceptibility and resistance to daptomycin have occurred in enterococci (249, 250) and S. aureus (251, 252), possibly due to the physical barrier of a thickened \(\beta-D\)-alanyl-\(\beta-D\)-alanine cell wall similar to those found in VISA, alteration of the charge of the outer cell envelope (253), or cumulative point mutations in genes encoding various bacterial enzymes (254).

Oritavancin and telavancin have a dual mechanism of action: (i) inhibition of the transglycosylation process of peptidoglycan cell wall synthesis by formation of a complex with the \(\beta-D\)-alanyl-\(\beta-D\)-alanine residues and (ii) depolarization of the bacterial cell membrane. The depolarization effect on membrane potential depends both on the presence of lipid II and on an interaction between telavancin and \(\beta-D\)-alanyl-\(\beta-D\)-alanine residues, affecting diverse S. aureus strains, including those with decreased susceptibility to vancomycin and daptomycin (255, 256).

Pharmacology
Vancomycin can be administered orally or parenterally. After oral administration, the drug is poorly absorbed, and high concentrations in stools are achieved, accounting for its efficacy in treating pseudomembranous colitis (257). Dependent bactericidal activity on membrane potential depends both on the presence of lipid II and on an interaction between telavancin and \(\beta-D\)-alanyl-\(\beta-D\)-alanine residues, affecting diverse S. aureus strains, including those with decreased susceptibility to vancomycin and daptomycin (255, 256).

Vancomycin has a half-life in serum of 6 h in patients with healthy renal function and is eliminated from the body almost exclusively by glomerular filtration. In severe renal insufficiency, its excretion is prolonged to about 9 days, and it may be removed by hemodialysis, depending on the type of membrane and dialyzer used. The true extent of removal by peritoneal dialysis remains controversial, though historically it was thought that glycopeptidase were not removed.

Intravenous infusion of daptomycin at a dosage of 6 mg/kg of body weight results in peak and trough concentrations of 82 and 6 \(\mu\)g/ml, respectively, in serum. About 90% of the drug is bound to plasma proteins, with limited metabolism. The volume of distribution is low at 0.1 liter/kg, suggesting that penetration into some sites of infection may be an issue. Daptomycin shows poor penetration into the CSF and alveolar space, where it is bound by surfactant, precluding its use for the treatment of meningitis and pneumonia (261). Its elimination half-life is 9 h, and 80% of the drug is excreted via the kidney, with two-thirds as intact drug (261). The dosing interval is increased to every 48 h when creatinine clearance is \(\leq 50\) ml/min (262). Daptomycin is approximately 95% protein bound in human plasma, with good penetration into tissues and a prolonged half-life of 7 to 9 h. It exhibits concentration-dependent bactericidal activity in vitro (262). The drug is eliminated from the body via urinary excretion, with 75% of the drug unchanged. Hemodialysis removes \(~6\)% of telavancin, and dosage reduction is necessary in cases of renal insufficiency, with a creatinine clearance of \(<50\) ml/min (263).

Dalbavancin is approximately 93% bound to human plasma proteins, with a volume of distribution of approximately 0.15 liter/kg (264). The compound also possesses a very long terminal half-life of 240 h, with good tissue penetration in both animal and human studies (265). In contrast to vancomycin and teicoplanin, dalbavancin appears to have both renal and nonrenal clearance mechanisms, with only about 30% of an administered dose recovered in the urine (265).

Telavancin, oritavancin is highly bound to plasma proteins, with a free fraction of approximately 15% (266). Oritavancin undergoes a more complex 3-phase elimination than the other two agents and has the longest terminal half-life of any of the three lipoglycopeptides, at approximately 340 h. The drug is not metabolized, and only 1% and 5% of the drug is recovered in the feces and urine, respectively, 7 days after administration of a dose. Oritavancin also distributes widely and penetrates a variety of tissues.

Spectrum of Activity
Glycopeptides and lipopeptides are active mainly against aerobic and anaerobic Gram-positive organisms, including methicillin-susceptible and -resistant staphylococci, streptococci, enterococci, Corynebacterium spp., Bacillus spp., L. monocytogenes, Clostridium spp., and Actinomyces spp. The MICs of vancomycin against S. aureus, Staphylococcus epidermidis, streptococci, and enterococci are typically in the range of 0.25 to 2 \(\mu\)g/ml (267). Daptomycin (268, 269) is 2- to 4-fold more active than vancomycin against these Gram-positive cocci, with MICs usually at least 2-fold lower for telavancin, dalbavancin, and oritavancin than for daptomycin (270, 271). Resistance to vancomycin has emerged among clinical isolates of enterococci (272) and staphylococci, although vancomycin-intermediate staphylococcal strains are more prevalent than fully resistant strains (273). The cross-resistance of vancomycin with daptomycin and the lipoglycopeptides is varied in these strains.

Vancomycin is useful in the prevention and treatment of endocarditis due to Gram-positive bacteria in patients who are allergic to penicillin (139). It is the drug of choice for treating Corynebacterium jeikeium infections (274) and is useful for antibiotic-associated C. difficile colitis (130).

The glycopeptides and lipopeptides are not active against Gram-negative organisms or mycobacteria. They show no cross-resistance with other unrelated antibiotics. They act synergistically with aminoglycosides or rifampin against staphylococci and streptococci. Vancomycin can be used against these Gram-positive cocci, although vancomycin-resistant enterococci (VISA), pneumococci, and streptococci are usually \(\leq 1\) \(\mu\)g/ml (278, 279). Vancomycin-susceptible and -resistant
enterococci are inhibited equally at MICs of ≤ 4 μg/ml. Daptomycin is active (MICs of ≤2 μg/ml) against Listeria, Corynebacterium spp., Propionibacterium, C. difficile, C. perfringens, and peptostreptococci (280, 281). While Leuconostoc, Pediococcus, and Lactobacillus spp. are susceptible, other Clostridium spp., Actinomyces spp., and Eubacterium spp. showed MICs of 4 to 16 μg/ml. Since the optimal in vitro activity of daptomycin depends on the calcium ion concentration in the growth medium, media used for susceptibility testing with this drug should contain the recommended calcium concentration of 50 μg/ml. Disk diffusion methods were found to be unreliable in testing daptomycin susceptibility and are no longer recommended. The agar dilution method has not been validated for testing this drug.

With antimicrobial spectra of activity similar to those of glycopeptides, lipoglycopeptides are more potent than vancomycin and teicoplanin against a broad range of Gram-positive bacteria (244, 282–285). MICs of daptomycin for MSSA, MRSA, and coagulase-negative staphylococci range from 0.06 μg/ml for dalbavancin to 1 μg/ml for oritavancin. Although lipoglycopeptide MICs are higher than those for glycopeptide-susceptible strains, VISA, hVISA, and VRSA isolates are more susceptible to these drugs, with the MICs for them ranging from 0.5 to 4 μg/ml (286, 287). Lipoglycopeptides retain activity against staphylococci that exhibit reduced susceptibility to daptomycin and linezolid. Vancomycin-resistant enterococci are inhibited by dalbavancin, oritavancin, and telavancin in the range of 0.06 to 1 μg/ml; MICs for E. faecalis are 2-fold higher than for E. faecium. Vancomycin-resistant enterococci of the VanA and VanB phenotypes are usually resistant; MICs of dalbavancin and telavancin but not oritavancin are 4 to >64 μg/ml (282, 288). These drugs are most active against streptococci, including MDR pneumococci, with MICs ranging from 0.015 to 0.125 μg/ml (289). Telavancin also exhibits potent activity against Actinomyces spp., C. difficile, C. perfringens, Corynebacterium spp. (including C. jeikeium), Lactobacillus spp., and P. acnes, with MICs ranging from 0.06 to 1 μg/ml (290). Susceptibility testing for oritavancin has resulted in disparate MIC values over the drug’s lengthy development history, which dates from the late 1990s. The propensity of the compound to stick to plastic was not initially recognized, resulting in artificially high MIC values. With the addition of surfactant to the testing media to prevent adsorption, oritavancin MICs for many organisms, particularly staphylococci, are now reported as lower values (266).

**Adverse Effects**

The most frequent side effects of vancomycin are fever, chills, and phlebitis at the site of infusion. Rapid or bolus infusion of vancomycin causes tingling and flushing of the face, neck, and thorax, known as the “red man syndrome,” as a result of histamine release by basophils and mast cells (291). This phenomenon is not due to allergic hypersensitivity, and it may also occur with telavancin. Allergic maculopapular or diffuse erythematous rashes can occur in up to 5% of patients. Reversible leukopenia or eosinophilia can rarely develop with glycopeptide therapy. High-frequency hearing loss due to ototoxicity has been reported in patients receiving high daily doses of vancomycin, especially among those who were >50 years of age (292). Vancomycin-induced nephrotoxicity is rare, but this risk increases with use of large doses of the drug at >4 g per day (293) and during combination therapy with vancomycin and aminoglycosides. The necessity to monitor vancomycin blood levels to reduce the risk for nephrotoxicity has diminished with the increased purity of this fermentation product that has been attained since its introduction.

Common adverse reactions of daptomycin include diarrhea, rash, dizziness, and dyspnea. Elevated serum creatinine phosphokinase levels (an effect that delayed the development of the drug), myalgia, and myopathy can occur but are reversible (294, 295) and are significantly reduced with lower dosages and once-daily dosing frequency. Nephrotoxicity has been consistently associated with telavancin use during its clinical development. The current U.S. prescribing information, updated in June 2013, contains warnings about nephrotoxicity and increased mortality in patients with MRSA pneumonia who have creatinine clearances of less than 50 ml/min. The warning states that telavancin should be used for MRSA pneumonia only when other options are not acceptable. Taste disturbance, nausea, vomiting, and foamy urine were the most common adverse reactions (<10%) to telavancin during clinical development (263). Telavancin is labeled as a category C agent with regard to use in pregnant women; teratogenic effects were seen in three animal species at clinically relevant doses. Telavancin should be used in pregnant women only when no other options are available.

**STREPTOGRAMINS**

Streptogramins are natural cyclic peptides produced by Streptomyces spp. They are a unique class of antibiotics in which each member is a combination of at least two structurally unrelated components, group A and B streptogramins, acting synergistically against susceptible bacteria (296). Group A streptogramins are polyunsaturated macrolactones consisting of lactam and lactone linkages with an oxazole ring, and the main compounds in this group are pristinamycin IA and pristinamycin IB. Group B streptogramins are cyclic hexadepsipeptides, with pristinamycin IA and pristinamycin IC as the principal compounds. Quinupristin-dalfopristin is the first injectable streptogramin antibacterial combination developed for clinical use in the United States. It is a 30:70 mixture of the semisynthetic streptogramins quinupristin and dalfopristin, which are water-soluble derivatives of pristinamycin IA and pristinamycin IB, respectively.

**Mechanism of Action**

The streptogramins exert a synergistic bactericidal effect on susceptible organisms by inhibiting bacterial protein synthesis. They enter bacterial cells via passive diffusion and then bind specifically and irreversibly to the 50S subunits of the 70S bacterial ribosomes. Binding of group A streptogramins to the ribosome induces a conformational change in the ribosome that increases its affinity for group B compounds. Group A streptogramins prevent peptidyl bond formation during the chain elongation step, while group B components cause release of the incomplete peptide chains from the 50S ribosomal subunit (149).

Acquired bacterial resistance to the streptogramins, which may be chromosomal or plasmid mediated, is due mainly to modification of the drug target by methylation of the bacterial 23S rRNA, resulting in resistance to all macrolides, lincosamides, and group B streptogramins (MLSb resistance phenotype) but not to group A streptogramins. Mutations in the L22 ribosomal protein gene (rjIV), active efflux of group A and B streptogramins, and drug inactivation by streptogramin A acetylase and streptogramin B hydrolase have been described.
Pharmacokinetics
Quinupristin-dalfopristin is administered intravenously, with distribution into most tissues. Both components are highly protein bound (70 to 90%) and rapidly cleared from plasma via biliary excretion by hepatic conjugation processes (297). Less than 20% of the administered drug combination is excreted in the urine. Following intravenous doses of 7.5 mg/kg of body weight, peak concentrations in serum of quinupristin and dalfopristin reach 2.7 and 7.2 μg/ml, respectively, with elimination half-lives of 1 and 0.75 h. The two components penetrate and accumulate in macrophages, and the ratio of peak in vivo cellular-to-extracellular concentrations is 50:35. The drug combination does not cross a noninflamed blood-brain barrier or placenta to any significant degree. Dosage adjustment is needed for patients with renal insufficiency (creatinine clearance, <30 ml/min), and the drug combination is removed in modest amounts by dialysis.

Spectrum of Activity
Streptogramins are active mainly against Gram-positive bacteria, with modest activities against selected Gram-negative and anaerobic pathogens. Quinupristin-dalfopristin has potent bactericidal activity against MSSA, MRSA, coagulase-negative staphylococci, and streptococci, with MIC90s of ≤1 μg/ml and minimum bactericidal concentrations (MBCs) within 2- to 4-fold of the MICs (298, 299). Staphylococci and streptococci, including S. pneumoniae, that are resistant to β-lactam drugs, macrolides, and fluoroquinolones usually remain susceptible to quinupristin-dalfopristin, but staphylococci with MLSB resistance due to methylation of the 23S rRNA-binding site are inhibited but not killed by quinupristin-dalfopristin (298). While most E. faecium strains are susceptible (MIC90 of ≤4 μg/ml), E. faecalis is intrinsically resistant (MIC90 of ≥32 μg/ml) to the drug combination because of active efflux of dalfopristin. Although it is not bactericidal against enterococci, quinupristin-dalfopristin inhibits vancomycin-resistant E. faecium (VanA or VanB phenotype), including MDR strains, at MIC90s of ≤2 μg/ml (297). This drug combination offers a therapeutic option for serious MDR Gram-positive bacterial infections (296, 300–302). N. meningitidis, N. gonorrhoeae, M. pneumoniae, C. pneumoniae, and Legionella pneumophila are all highly susceptible to the drug (MIC90 of ≤2 μg/ml). Quinupristin-dalfopristin is also active against M. catarrhalis and H. influenzae, with MIC90s of ≤4 μg/ml. Enterobacteriaceae and other nonfermenting Gram-negative bacilli are resistant. Among the anaerobes, C. perfringens and C. difficile are the most susceptible (MIC90s of 0.25 μg/ml). Quinupristin-dalfopristin is active against the B. fragilis group (MIC90 of 4 μg/ml) as well as other anaerobic bacteria, including Prevotella, Porphyromonas, Fusobacterium, P. acnes, Lactobacillus, and peptostreptococci, with MIC90s of 2 to 4 μg/ml.

Adverse Effects
Phlebitis at the site of intravenous infusion is the major local adverse reaction; the incidence and severity are dose and concentration related, which has led to the recommendation that the drug be administered only through a central line (297, 303). The most common systemic side effects, up to 47% of patients in one series, that may lead to discontinuation of therapy are arthralgias and myalgia, both of which are reversible upon discontinuation of the combination (87, 304). Elevated levels of serum transaminases and cutaneous reactions, such as itching, burning, and erythema of the face, neck, or upper body, have also been reported.

OXAZOLIDINONES
Oxazolidinones are chemically unique synthetic antimicrobials originally discovered in the 1970s (305). Linezolid is currently the only oxazolidinone available for clinical use (306), although a new-drug application (NDA) has been submitted for tedizolid for the treatment of acute bacterial skin and skin structure infections (ABSSSI). Other analogs are in preclinical or clinical development, including the oxazolidinones that are being investigated for the management of tuberculosis (307–309).

Mechanism of Action
Oxazolidinones inhibit bacterial protein synthesis by preventing the formation of a functional initiation complex consisting of tRNA<sup>Met</sup>, mRNA, initiation factors, and the ribosome (310).

Linezolid binds to the domain V region of 23S rRNA in the 50S ribosomal subunit, thereby disturbing the binding site for tRNA<sup>Met</sup> and inhibiting the formation of a functional 70S initiation complex, thus preventing initiation of mRNA translation. In this regard, this class of antimicrobials is unique, lacking cross-resistance to other antibiotics that also inhibit ribosomal protein synthesis; Resistance to linezolid has occurred in clinical isolates of MRSA, vancomycin-resistant enterococci, and pneumococci as a result of point mutations in domain V of the 23S rRNA gene (311, 312), mutations in the L3L4 ribosomal protein, and the methyltransferase coded by the cfr gene (313). The last mechanism is perhaps the most worrisome since it is found on mobile genetic elements. Oxazolidinones are generally inactive against Gram-negative bacteria because of endogenous efflux pumps present in these organisms (310).

Pharmacology
Linezolid is available in oral and parenteral forms. Rapid and extensive absorption occurs after oral administration (>95% bioavailability), reaching maximum serum concentrations of 15 to 20 μg/ml within 2 h after an oral dose of 600 mg (314). The drug is metabolized primarily in the liver, and the elimination half-life is about 5 h. With 30% of the drug being protein bound, it is well distributed in all body tissues, including the CSF (315). The drug is eliminated via the kidneys, with 30% being excreted unchanged in the urine. No dose adjustment is necessary in patients with renal insufficiency or mild to moderate hepatic impairment, while 20% of a dose is removed by hemodialysis (316).

Spectrum of Activity
As a group, oxazolidinones have varied activities against most Gram-positive bacteria and mycobacteria. Linezolid has excellent activity against staphylococci (including meticillin-resistant strains), streptococci, and MDR enterococci, with MIC90s ranging from 1 to 4 μg/ml (317–319). The MIC90s are in the range of 0.5 to 2 μg/ml for pneumococci.

Although the antibacterial effect of linezolid is generally bacteriostatic, the drug is bactericidal against most strains of pneumococci. Other bacteria that are inhibited by linezolid include Actinomyces spp., Bacillus cereus, Corynebacterium spp., Leuconostoc, Pediococcus, R. equi, L. monocytogenes, Clostridium spp., and Gram-positive anaerobic cocci (300). The MIC90s range from 1 to 4 μg/ml across these organisms. Linezolid is an important therapeutic option for skin and soft tissue infections (322), respiratory
tract infections (323), and infections due to methicillin-resistant staphylococci (324, 325) and vancomycin-resistant enterococci (326–328).

**Adverse Effects**

The most common drug-related adverse events (≤5% incidence) are diarrhea, headache, and nausea (329, 330). Prolonged use of linezolid (usually of >28 days' duration) has led to rare optic neuropathy (331), peripheral neuropathy (332), and myelosuppression, including anemia, leukopenia, thrombocytopenia, and pancytopenia, which are reversible upon discontinuation of therapy (333, 334). All of these adverse events, as well as lactic acidosis, are thought to be related to the propensity of linezolid to interfere with mitochondrial RNA (335). As a mild nonselective inhibitor of monoamine oxidase, linezolid can interact with adrenergic or serotonergic drugs, and rare cases of serotonin syndrome have occurred with concomitant use of selective serotonin reuptake inhibitor drugs and other serotonergically active medications (336).

**SULFONAMIDES AND TRIMETHOPRIM**

Sulfonamides were the first effective systemic antimicrobial agents used in the United States during the 1930s. They are derived from sulfanilamide, which shares chemical similarities with para-aminobenzoic acid, a factor essential for bacterial folic acid synthesis. Various substitutions at the sulfonyl radical attached to the benzene ring nucleus enhance the antibacterial activity and also determine the pharmacologic properties of the drug.

Trimethoprim (TMP) is a pyrimidine analog that inhibits the enzyme dihydrofolate reductase, interfering with folic acid metabolism, subsequent pyrimidine synthesis, and one-carbon fragment metabolism in bacteria. Since TMP and sulfonamides block the bacterial folic acid metabolic pathway at different sites, they potentiate the antibacterial activity of one another and act synergistically against a wide variety of organisms. Such a combination, TMP-sulfamethoxazole (TMP-SMX), also called co-trimoxazole, was introduced clinically in 1968 and has proven to be very effective in the treatment of many infections (337).

**Mechanism of Action**

Sulfonamides competitively inhibit bacterial modification of para-aminobenzoic acid into dihydrofolic acid, whereas TMP inhibits bacterial dihydrofolate reductase. This sequential inhibition of folate metabolism ultimately prevents the synthesis of bacterial DNA (338). Since mammalian cells do not synthesize folic acid, human purine synthesis is not affected significantly by sulfonamides or TMP. The antibacterial effects of these agents may be reduced in patients receiving high doses of folic acid.

**Pharmacology**

Sulfonamides are usually administered in oral and topical forms. The only intravenous formulation currently available in the United States is TMP-SMX. Mafenide acetate (Sulfamylon cream) and silver sulfadiazine are applied topically in burn patients and have significant percutaneous absorption. Sulfacetamide is available as an ophthalmic preparation.

The orally administered sulfonamides are absorbed rapidly and completely from the gastrointestinal tract. They are metabolized in the liver by acetylation and glucuronidation and are excreted by the kidney as free drug and inactive metabolites. Sulfonamides compete for bilirubin-binding sites on plasma albumin and increase levels of unconjugated bilirubin in blood. For this reason, they should not be given to neonates, in whom increased serum bilirubin levels may cause kernicterus.

Sulfonamides are well distributed throughout the body, with levels in the cerebrospinal, synovial, pleural, and peritoneal fluids being about 80% of the concentrations in serum. They readily cross the placenta and enter the fetal circulation. Sulfonamides may be used in renal failure, but the drugs may accumulate during prolonged therapy as a result of reduced renal excretion.

TMP is available only for oral use and is absorbed almost completely from the gastrointestinal tract. After the usual 100-mg dose, peak levels in serum reach 1 μg/ml in 1 to 4 h. This drug distributes widely in body tissues, including the kidney, lung, and prostate, and in body fluids (339). Concentrations in CSF are about 40% of levels in serum. Its half-life in serum is about 10 h in healthy subjects and is prolonged in those with renal insufficiency. Up to 80% of a dose is excreted unchanged in the urine by tubular secretion; the remaining fraction is excreted as inactive metabolites by the kidney or in the bile.

A fixed combination of TMP-SMX at a dose ratio of 1:5 is available for oral and intravenous use. An intravenous dose of 160 mg of TMP with 800 mg of SMX produces average peak levels in serum of 3.4 and 47.3 μg/ml, respectively, in 1 h. Similar peak levels are reached at 2 to 4 h after the same dose is taken orally. Widely distributed in the body, both drugs reach therapeutic levels in the CSF (40% of levels in serum). Excretion is primarily by the kidney; dosage reduction is necessary in patients with creatinine clearances of <30 ml/min. Both TMP and SMX are removed by hemodialysis and partially by peritoneal dialysis.

**Spectrum of Activity**

Sulfonamides are inhibitory to a variety of Gram-positive and Gram-negative bacteria, actinomycetes, chlamydiae, toxoplasmas, and plasmodia. Their **in vitro** antimicrobial activities are irregular, being strongly influenced by inoculum size and composition of the test media. Susceptibility testing end points are often difficult to determine because of the presence of hazy growth within zones of inhibition in disk diffusion tests and because of the phenomenon of "trailing" in dilution tests.

Sulfadiazine in combination with pyrimethamine has been used successfully to treat toxoplasmosis (165). Sulfonamides are active against *Nocardia asteroides* (224), and they show moderate activity against *M. kansasi*, members of the *M. fortuitum* group, *M. marinum*, and *Mycobacterium scrofulaceum* (340). Other uses of sulfonamides include therapy of melioidosis, dermatitis herpetiformis, lymphogranuloma venereum, and chancroid.

Among the Gram-negative bacilli, *E. coli* strains were initially susceptible to the sulfonamides, especially at levels achievable in urine. However, increasing bacterial resistance has limited their efficacy in recent years. *S. marcescens*, *P. aeruginosa*, enterococci, and anaerobes are usually resistant to the sulfonamides.

TMP is active **in vitro** against many Gram-positive cocci and most Gram-negative bacilli. *P. aeruginosa*, most anaerobes, *M. pneumoniae*, and mycobacteria are resistant. The MICs vary considerably depending on the test medium used. Like the sulfonamides, TMP was used primarily in the therapy of uncomplicated and recurrent urinary tract infections due to susceptible organisms (341). However, resistance to TMP is now prevalent among Enterobacteriaceae.
Combinations of TMP with other agents, such as rifampin, polymyxins, and aminoglycosides, have demonstrated in vitro synergistic antibacterial activity against various Gram-negative bacilli. TMP combined with dapson is effective in the treatment of *P. jirovecii* pneumonia in immunocompromised patients.

Many Gram-positive cocci, including staphylococci and streptococci (except group A), and most Gram-negative bacilli except *P. aeruginosa* are susceptible to TMP-SMX (342). Staphylococci have surprisingly retained susceptibility to TMP-SMX, with recent surveillance data demonstrating >99% and 92% susceptibilities for methicillin-susceptible and methicillin-resistant *S. aureus* (343). However, 10% to 50% of strains of *S. pneumoniae* are resistant in many parts of the world. The drug combination has variable bactericidal effects on enterococci in vitro, depending on the test medium used for susceptibility testing (344). Unlike many bacteria that can utilize only thymidine for growth, enterococci can use thymidine, thymine, exogenous folinic acid, dihydrofolate, and tetrahydrofolate, resulting in higher MICs (25- to 50-fold increase) on media containing these compounds (345). This finding also explains the ineffectiveness of TMP-SMX against enterococci in vitro.

TMP-SMX is often active against *M. catarrhalis* and *H. influenzae*, including β-lactamase-producing strains; however, it is no longer recommended as empirical therapy for acute otitis media, sinusitis, acute bronchitis, and pneumonia due to the increasing resistance in *S. pneumoniae*. It has shown excellent results in the prophylaxis and therapy of acute and chronic urinary tract infections; however, these results have been compromised by resistance rates in *E. coli* that now exceed 20% in most centers (111, 341, 346). The drug combination is also useful in treating susceptible infections due to salmonellae, shigellae, enteropathogenic *E. coli*, and *Y. enterocolitica* (347). It has been used successfully for prophylaxis and treatment of traveler’s diarrhea (348), but resistance to TMP-SMX in *Shigella* spp. and *E. coli* now severely limits its usefulness in many parts of the world.

Other microorganisms susceptible to TMP-SMX include *Brucella* spp., *B. pseudomallei*, *B.cepacia*, *S. maltophilia*, *M. kansasi*, *M. marinum*, and *M. scrofulaceum*. *M. tuberculosis* and *M. chelonae* are generally resistant. It is a valuable antibiotic for the treatment of *Nocardia* species infections (349), *B. cepacia* and *S. maltophilia* bacteremia, *L. monocytogenes* meningitis, gastroenteritis due to *Isospora belli* and *Cyclospora* spp. (165), and Whipple’s disease. In immunocompromised hosts (e.g., those with leukemia or AIDS or organ transplant recipients), TMP-SMX is the drug of choice for the prophylaxis and treatment of *P. jirovecii* pneumonia (350).

**Adverse Effects**

Sulfonamides are known to cause nausea, vomiting, headache, and fever. Hypersensitivity reactions can occur as rashes, vasculitis, erythema nodosum, erythema multiforme, and Stevens-Johnson syndrome (351). Very high doses of less-water-soluble sulfonamides may result in crystalluria, with renal tubular deposits of sulfonamide crystals. Bone marrow toxicity with anemia, leukopenia, or thrombocytopenia can occur. Sulfonamides should be avoided in patients with glucose-6-phosphate dehydrogenase deficiency because of associated hemolytic anemia. Sulfonamides also potentiate the effects of warfarin, phenytoin, and oral hypoglycemic agents.

In general, TMP is well tolerated. With prolonged use, megaloblastic anemia, neutropenia, and thrombocytopenia can develop, especially in folate-deficient patients. Adverse reactions to TMP-SMX due to either the TMP or, more commonly, the SMX component can occur. Mild gastrointestinal symptoms and allergic skin rashes occur in about 3% of patients (352). Megaloblastic bone marrow changes may develop with leukopenia, thrombocytopenia, or granulocytopenia, usually in patients with preexisting folate deficiency. Nephrotoxicity usually occurs in patients with underlying renal dysfunction. Trimethoprim blocks apical membrane sodium channels in the kidney in a fashion similar to that of the potassium-sparing diuretic amiloride, resulting in hyperkalemia particularly when used at higher doses (353). Patients with AIDS have a much higher frequency (as much as 70%) of adverse reactions (354).

**POLYMYXINS**

Polyoxymyxins are cationic cyclic polypeptides originally derived from *Bacillus polymyxa*. They consist of five different compounds (polyoxymyxins A to E) and have limited spectra of antimicrobial activity and significant toxicity (355). Only polyoxymyxins B and E (colistin) are used clinically in humans.

**Mechanism of Action**

Acting like detergents or surfactants, members of this group of antibiotics interact with the phospholipids of the bacterial cell membrane, thereby increasing cell permeability and disrupting osmotic integrity. This process results in leakage of intracellular constituents, leading to cell death. The bactericidal action is reduced in the presence of calcium, which interferes with the attachment of drugs to the cell membrane. With almost complete cross-resistance existing between polyoxymyxin B and colistin, Gram-negative bacteria can become resistant by alterations of the outer cell membrane from reduced levels of lipopolysaccharides, reduced levels of specific outer membrane proteins, reduced cell envelope Mg2+ and Ca2+ contents, and lipid alterations. In addition, the presence of a polyoxymyxin B efflux pump system and colistinase, which inactivates colistin, has been reported (356).

**Pharmacology**

Polyoxymyxins are usually administered parenterally, orally, or topically. They are not significantly absorbed when given orally or topically, and intramuscular injections can be painful. Peak concentrations in serum of 5 μg/ml are obtained with a total daily dose of intravenous polyoxymyxin B at 2.5 mg (or 25,000 U/kg) (357). Polyoxymyxin E is available commercially as colistin sulfate and colistimethate sodium, an inactive sulfomethyl produg of colistin, with the former given orally for local antibacterial effect in the gut and the latter used for intravenous or intramuscular injections. The half-life of polyoxymyxin B in serum is about 6 to 7 h, and that of colistin is 2 to 4 h. They do not penetrate well into pleural fluid, synovial fluid, or CSF even in the presence of inflammation (358). Excretion of colistimethate sodium is mostly via the kidneys by glomerular filtration; the mechanism of free colistin clearance after colistimethate sodium administration is less clear (359). Polyoxymyxin B is only minimally excreted by the kidneys and undergoes extensive tubular reabsorption. Only 4% of the dose of polyoxymyxin B is eliminated renally (360). These drugs are not removed by hemodialysis, but small amounts can be removed by peritoneal dialysis.

Polyoxymyxin is often used topically as 0.1% polyoxymyxin in combination with bacitracin or neomycin for treatment of skin, mucous membrane, eye, and ear infections. It is poorly
absorbed from these surfaces. When the drug is used for irrigation of serous or wound cavities, systemic absorption can be significant enough to produce toxicity.

**Spectrum of Activity**

Polymyxins are active only against select Gram-negative bacilli, especially *Pseudomonas* spp. and *Acinetobacter* spp. The MIC<sub>50</sub> for *Pseudomonas* spp., including *P. aeruginosa*, and *Acinetobacter baumannii* are <8 μg/ml. Proteus, *Providence*, *Serratia*, and *Neisseria* isolates are usually resistant (355). Emergence of resistance during therapy has been reported frequently, with only 93% and 97% susceptibility reported in *P. aeruginosa* and *A. baumannii*, respectively (343). No cross-resistance is seen with other classes of antibiotics. Polymyxins B and E have identical antimicrobial spectra and show complete cross-resistance to one another.

The combination of polymyxins with TMP-SMX may be synergistic in the treatment of serious infection due to multiply resistant *Serratia* spp., *P. aeruginosa*, *B. cepacia*, and *S. maltophilia* (62, 361). The polymyxins are usually reserved for serious, life-threatening *Pseudomonas* or Gram-negative bacillary infections caused by organisms resistant to all other antibiotics, such as carbapenemase-producing Enterobacteriaceae (356). Aerosolized polymyxins have been used successfully to treat respiratory tract colonization and nosocomial pneumonia due to MDR Gram-negative bacilli or *P. aeruginosa* in patients with or without cystic fibrosis or bronchiectasis (357, 362).

**Adverse Effects**

Neurotoxicity and nephrotoxicity are the two major side effects of polymyxins (357). Paresthesia with flushing, dizziness, vertigo, ataxia, slurred speech, drowsiness, or mental confusion occurs when levels in serum exceed 1 to 2 μg/ml (356). Polymyxins also have a curare-like effect that can block neuromuscular transmission. Dose-related renal dysfunction occurs in about 20% of patients receiving appropriate therapeutic dosages. Allergic reactions, such as fever and skin rashes, are rare, but urticaria and shock after rapid intravenous infusion have occurred.

**CHLORAMPHENICOL**

Chloramphenicol is a nitrobenzene cyclic antibiotic originally derived from *Streptomyces venezuelae*. It is a highly effective broad-spectrum antimicrobial agent with specific indications for use in seriously ill patients but is rarely used clinically in the United States due to its well-known toxicities.

**Mechanism of Action**

The drug is a bacteriostatic agent that inhibits protein synthesis by binding reversibly to the peptidyltransferase component of the 50S ribosomal subunit and preventing the transpeptidation process of peptide chain elongation. At therapeutic concentrations achievable in the serum, it can be bactericidal against common meningial pathogens, such as *S. pneumoniae*, *N. meningitidis*, and *H. influenzae* (363, 364). Bacterial resistance occurs due to the plasmid-mediated production of *cat*, the gene encoding chloramphenicol acetyltransferase, an enzyme, which inactivates the drug (365).

**Pharmacology**

Chloramphenicol is available for topical, oral, or parenteral use. It is not absorbed in any significant amount when applied topically, but it is rapidly and completely absorbed from the gastrointestinal tract. After an oral or intravenous dose of 1 g, peak concentrations in serum at 2 h can reach 10 to 15 μg/ml. It diffuses well into many tissues and body fluids, including CSF, where levels are generally 30 to 50% of concentrations in serum even without meningeal inflammation (366). The antibiotic readily crosses the placental barrier and is present in human milk.

Chloramphenicol is metabolized and inactivated by glucuronidation in the liver, with a half-life of 4 h in adults. The active drug (5 to 10%) and its inactive metabolites are excreted by the kidneys. Careful monitoring of serum chloramphenicol levels, maintaining peak concentrations in serum in the therapeutic range of 10 to 20 μg/ml, is useful for ensuring therapeutic efficacy and reduced toxicity. Patients with hepatic failure have high levels of active drug in serum owing to the drug’s prolonged half-life. Dosage modification is not necessary in the presence of renal insufficiency, since the metabolites are not as toxic as the active drug. Levels in serum are not affected by hemodialysis or peritoneal dialysis.

**Spectrum of Activity**

Chloramphenicol is active against many Gram-positive and Gram-negative bacteria, chlamydiae, mycoplasmas, and rickettsiae. MIC<sub>50</sub> for most Gram-positive aerobic and anaerobic cocci are ≤12.5 μg/ml (364). However, the drug is usually inactive against MRSA and methicillin-resistant *S. epidermidis* and is variably active against enterococci. *N. meningitidis*, *H. influenzae* (ampicillin-resistant and -susceptible strains), and most *Enterobacteriaceae* are susceptible. Its activities against *Serratia* and *Enterobacter* isolates are varied, and strains of *Pseudomonas* spp. are usually resistant. Salmonellae, including *Salmonella enterica* serovar Typhi, are also susceptible, but resistant isolates are being encountered with increasing frequency (367).

Chloramphenicol is also active against anaerobic bacteria, including members of the *B. fragilis* group. Almost all of these isolates are inhibited at concentrations of ≤10 μg/ml (199, 109). It is also active against *Rickettsia* spp. and *Coxella burnetti*.

**Adverse Effects**

Bone marrow toxicity is the major complication of chloramphenicol use. This side effect may occur as either dose-related bone marrow suppression or idiosyncratic aplastic anemia. Reversible bone marrow depression with anemia, leukopenia, and thrombocytopenia occurs as a result of a direct pharmacologic effect of the drug on hematopoiesis. High doses (>4 g/day), prolonged therapy, and excessively high levels in serum (>20 μg/ml) predispose patients to develop this type of complication. The second form of bone marrow toxicity is a rare but usually fatal complication that manifests as aplastic anemia. This response is not dose related, and the precise mechanism is unknown. It can occur weeks to months after the use of chloramphenicol, and it can develop after the use of oral, intravenous, or topical preparations.

Gray baby syndrome, characterized by vomiting, abdominal distention, cyanosis, hypothermia, and circulatory collapse, may occur in premature infants and neonates treated with chloramphenicol. This toxicity results from the immature hepatic function of neonates, which impairs hepatic inactivation of the drug. In patients receiving prolonged chloramphenicol therapy, reversible optic neuritis causing decreased visual acuity can occur. Chloramphenicol can occasionally cause hypersensitivity reactions, including skin rashes, drugfevers, and anaphylaxis. It potentiates the actions
of warfarin, phenytoin, and oral hypoglycemic agents by competitive inhibition of hepatic microsomal enzymes.

**METRONIDAZOLE**

Metronidazole is a 5-nitroimidazole derivative that was first introduced in 1959 for the treatment of *Trichomonas vaginalis* infections. It now has an important therapeutic role in the treatment of infections due to anaerobic bacteria and certain protozoan parasites. Tinidazole, a second-generation 5-nitroimidazole compound, is approved in the United States for treatment of trichomoniasis, giardiasis, and amebiasis.

**Mechanism of Action**

Metronidazole owes its bactericidal activity to the nitro group of its chemical structure. After the drug gains entry into the cells of susceptible organisms, the nitro group is reduced by a nitroreductase enzyme in the cytoplasm, generating certain short-lived, highly cytotoxic intermediate compounds or free radicals that disrupt host DNA (368). Resistance to nitroimidazoles may be due to decreased uptake of the drug or inducible production of 5-nitroimidazole reductase, which can scavenge the free-radical intermediates (369).

**Pharmacology**

Metronidazole can be administered via the topical, oral, or intravenous route. It is absorbed rapidly and almost completely when given orally. Peak levels in serum of 6 μg/ml are obtained 1 h after an oral dose of 250 mg. Intravenous doses of 7.5 mg/kg result in peak concentrations in serum of 20 to 25 μg/ml. The drug has a half-life in serum of 8 h. Therapeutic levels are achieved in all body tissues and fluids, including abscess cavities and CSF, even without meningeal inflammation. The drug crosses the placenta and is secreted in breast milk. It is metabolized mainly in the liver, and 60 to 80% is excreted in the kidney. With impaired hepatic function, plasma clearance of metronidazole is delayed and dosage adjustments are necessary. The pharmacokinetics is minimally affected by renal insufficiency. Metronidazole and its metabolites are removed completely by dialysis.

**Spectrum of Activity**

Metronidazole exhibits potent activity against almost all anaerobic bacteria, including members of the B. fragilis group, *Fusobacterium*, and *Clostridium* (195). It is the only antimicrobial agent with consistent bactericidal activity against members of the B. fragilis group. However, the susceptibilities of Gram-positive anaerobic cocci are somewhat varied; MIC_{90} values for these organisms are 16 μg/mL. Most strains of the genera *Actinomyces*, *Arachnia*, and *Propionibacterium* are resistant. Frequencies of metronidazole-resistant *B. fragilis* group isolates (MICs of >16 μg/mL) in the range of 2% to 5% have been reported from various institutions (199, 109). Tinidazole is somewhat more potent than metronidazole in its antianaerobic activities (370). Nitroimidazoles have no activity against aerobic bacteria, including the Enterobacteriaceae.

Metronidazole is effective in the treatment of antibiotic-associated colitis caused by *C. difficile* (12) and is equivalent to oral vancomycin in mild to moderate disease; however, recent data have shown it to be inferior to vancomycin in more severe disease (371). It is also useful for treating polymicrobial soft tissue infections and mixed aerobic-anaerobic intra-abdominal and pelvic infections.

Metronidazole and tinidazole are active against the protozoa *Trichomonas vaginalis*, *Giardia lamblia*, and *Entamoeba histolytica*. It is the drug of choice for the treatment of trichomoniasis, giardiasis, and intestinal and invasive amebiasis, including amebic liver abscesses (165, 372).

**Adverse Effects**

Metronidazole is generally well tolerated, and adverse side effects are uncommon. It can cause mild gastrointestinal symptoms, such as nausea, abdominal cramps, and diarrhea. An unpleasant, metallic taste is often experienced with oral therapy. Metronidazole can potentiate the effect of warfarin and prolong the prothrombin time as well as cause a disulfiram-like reaction when patients receiving metronidazole therapy consume alcohol.

Although metronidazole is carcinogenic in mice and rats, there is no evidence for carcinogenicity in humans. However, use of this agent during pregnancy, especially during the first trimester, and in nursing mothers should be avoided.

**RIFAMYCINS**

Rifamycins are macrocyclic compounds produced by the mold *Streptomyces mediterranei*. Rifampin, also known as rifampicin, a semisynthetic antibiotic derived from rifamycin B, was the first of this class introduced for clinical use in 1968 as an effective antituberculous drug. A closely related compound, rifabutin, a derivative of rifamycin S, is another potent antmycobacterial agent, especially against *M. avium* complex (373). Rifapentine possesses a much longer half-life than rifampin and has been shown to be effective in shortening regimens for the treatment of latent *M. tuberculosis* infection (374). Rifaximin, a derivative of rifampin, possesses an additional pyridomimidazole ring and is a nonabsorbed oral drug that can be used for therapy of uncomplicated traveler’s diarrhea but is most commonly prescribed in the United States for the management of hepatic encephalopathy.

**Mechanism of Action**

Rifaximin exert their bactericidal effects by forming a stable complex with bacterial-DNA-dependent RNA polymerase, preventing the chain initiation process of DNA transcription (375). Mammalian RNA synthesis is not affected, because the mammalian enzyme is much less sensitive to the drug. Rifampin-resistant isolates possess an altered RNA polymerase enzyme that arises easily from single-step mutations during monotherapy with rifampin.

**Pharmacology**

Rifampin is well absorbed after oral administration, reaching peak concentrations in serum of 5 to 10 μg/mL in 2 to 4 h following a 600-mg dose. A parenteral preparation is also available. Rifampin is deacetylated in the liver to an active metabolite and excreted in the bile, and it undergoes enterohepatic circulation. The normal half-life in serum varies from 1.5 to 5 h. The drug distributes well to almost all body tissues and fluids, reaching concentrations equal to or exceeding that in the serum. Levels in the CSF are highest in the presence of inflamed meninges. Rifampin is able to enter phagocytes and kill living intracellular organisms (376), and it crosses the placenta. About 30 to 40% of the drug is excreted in the urine, and it does not accumulate in patients with impaired renal function. Hemodialysis and peritoneal dialysis do not eliminate the drug. Dosage adjustments are necessary for patients with severe hepatic dysfunction.

Because it has an additional pyridomimidazole ring in its chemical structure, rifaximin is largely unabsorbed after oral
administration, with >99% of the drug present in the stool, and <1% of an oral dose is detectable in the plasma of both healthy volunteers and persons with damaged intestinal mucosa (377). Average fecal concentrations of the drug reach 8,000 μg/g on the third day of therapy at an oral dose of 400 mg twice daily (378).

**Spectrum of Activity**

In addition to having well-known antimycobacterial effects (379), rifampin has a wide spectrum of antimicrobial activity. It is bactericidal against susceptible Gram-positive cocci, such as staphylococci (including methicillin-resistant strains), streptococci, and anaerobic cocci, with MICs in the range of 0.01 to 0.5 μg/ml. It remains an important adjunct in the combination therapy of serious and chronic staphylococcal infections (380–382). However, it is bacteriostatic against enterococci, with usual MICs of <16 μg/ml (275).

*N. gonorrhoeae, N. meningitidis, and H. influenzae, including β-lactamase-producing strains, are susceptible to rifampin, which is used frequently in the prophylaxis of meningococcal and *H. influenzae* type b meningitis (383). MICs for *Enterobacteriaceae* are ≤12 μg/ml, while MICs for *S. marcescens* and *P. aeruginosa* are higher (275). Besides fluoroquinolones, rifampin is one of the most active agents against *L. pneumophila* and other *Legionella* spp., with MICs of ≤0.03 μg/ml. Because of its ability to enter phagocytes, rifampin inhibits the intracellular growth of *Brucella* spp. and *C. burnetii* (120), and it is used frequently in the combination therapy of infections due to these organisms. Although strains of *Chlamydia* spp. are susceptible to rifampin in vitro, resistance emerges rapidly when rifampin is used alone, as is seen in many bacterial species.

Rifaximin has broad-spectrum inhibitory activity against enteric bacterial pathogens, including enterotoxigenic and enteraggregative strains of *E. coli, Aeromonas, Shigella,* and *Salmonella,* with MIC90s ranging from 4 to 16 μg/ml (377, 384). Although it is less active against *C. jejuni* (MIC90 of 512 μg/ml), *Y. enterocolitica* (MIC90 of 128 μg/ml), *C. difficile* (MIC90 of 128 μg/ml), and *H. pylori* (MIC90 of 4 μg/ml), concentrations of rifaximin achieved in the intestinal lumen are >10-fold higher than the MICs of the drug for these pathogens. This drug has been used successfully to treat and prevent uncomplicated traveler's diarrhea (385). Rifaximin offered no benefit over a comparator when studied against *C. difficile* infections. Rapid emergence of resistance in *C. difficile* to this agent has been documented, and its role in therapy for *C. difficile* infections remains unclear (371).

**Adverse Effects**

Rifaximin has many side effects, including gastrointestinal discomfort and hypersensitivity reactions, such as drug fever, skin rashes, and eosinophilia. It produces a harmless, orange-red coloration of saliva, tears, urine, and sweat. In up to 20% of patients, an influenza-like syndrome with fever, chills, arthralgias, and myalgias may develop after several months of intermittent therapy (386). This immunologic reaction may be associated with hemolytic anemia, thrombocytopenia, and renal failure. Rifampin-induced hepatitis occurs in <1% of patients and is more frequent during concurrent isoniazid therapy for tuberculosis. Rifampin is a potent inducer of cytochrome P450 enzymes; other rifamycins also possess this property but to a slightly lesser extent. This induction results in an impressive array of clinically significant drug-drug interactions that markedly complicate the therapeutic use of the rifamycins.

Headache, nausea, abdominal pain, and fatigue are the most frequent side effects reported for rifaximin. Rare hypersensitivity reactions, including allergic dermatitis, rash, angioneurotic edema, urticaria, and pruritus, can occur with rifaximin, which is contraindicated in those who are allergic to rifampin (377). However, unlike rifampin, rifaximin does not cause clinically relevant interactions with drugs because of the lack of systemic absorption of this drug.

**NITROFURANTOIN**

Nitrofurantoin belongs to a class of compounds consisting of a primary nitro group joined to a heterocyclic ring. Its role in human therapeutics is limited to treatment of urinary tract infections (341).

**Mechanism of Action**

Nitrofurantoin exerts its antibacterial effects via multiple mechanisms. At high concentrations, nitrofurantoin is converted by bacterial nitroreductases to highly reactive electrophilic intermediates that bind nonspecifically to bacterial ribosomal proteins and rRNA, causing complete cessation of synthesis of bacterial DNA, RNA, and proteins (387). It inhibits the inducible synthesis of essential bacterial enzymes (β-galactosidase and galactokinase) at concentrations near the MICs for susceptible organisms and disrupts bacterial metabolism in the absence of reductive activation of the drug (387).

**Pharmacology**

The drug is available in microcrystalline and macrocrystalline forms. It is administered orally and is well absorbed from the gastrointestinal tract. Very low levels of the drug are achieved in serum and most body tissues after the usual oral doses. With a half-life in serum of about 20 min, two-thirds of the drug is rapidly metabolized and inactivated in various tissues. The remaining one-third is excreted unchanged into the urine. An average dose of nitrofurantoin yields a concentration in urine of 30 to 250 μg/ml in patients with healthy renal function. In alkaline urine, more of the drug is dissociated into the ionized form, resulting in lowered antibacterial activity. Nitrofurantoin accumulates in the sera of patients with creatinine clearances of ≤60 ml/min. The drug is removed by hemodialysis. The risk of systemic toxicity increases in the presence of severe uremia. It is contraindicated in patients with significant renal impairment and hepatic failure.

**Spectrum of Activity**

Nitrofurantoin has a broad spectrum of antibacterial activity against Gram-positive and Gram-negative bacteria, particularly the common urinary tract pathogens. It is active against Gram-positive cocci, such as *S. aureus, S. epidermidis, Staphylococcus saprophyticus,* and *E. faecalis,* with MICs in the range of ≤0.5 to 64 μg/ml (234, 343). *S. pneumoniae, S. pyogenes,* and *Corynebacterium* spp. are also susceptible, but they rarely cause urinary tract infections. Approximately 90% of *E. coli* strains and many coliform bacteria are susceptible to nitrofurantoin at MICs of ≤32 μg/ml. However, only one-third to one-half of *Enterobacter* spp. and *Klebsiella* isolates are susceptible. *Pseudomonas* spp. and most *Proteus* spp. are resistant. Susceptible organisms rarely become resistant to this drug during therapy. Nitrofurantoin is a first-line recommendation for cystitis in the recently updated IDSA guidelines (220).
Adverse Effects
Gastrointestinal irritation with anorexia, nausea, and vomiting is the most common side effect. Diarrhea and abdominal cramps may occur. Hypersensitivity reactions, such as drug fever, chills, arthralgia, skin rashes, and a lupus-like syndrome, have been observed (388). Pulmonary reactions are the most common serious side effects associated with nitrofurantoin use. Acute pneumonitis with fever, cough, dyspnea, eosinophilia, and pulmonary infiltrates present on chest radiographs can occur after a few days of therapy (388). This immunologically mediated reaction is more common in elderly patients and is rapidly reversible after cessation of therapy. Chronic pulmonary reactions with interstitial pneumonitis leading to irreversible pulmonary fibrosis can occur in patients on continuous therapy for 6 months or more (389).

Peripheral polyneuropathy is a serious side effect that occurs more often in patients with renal failure than in other patients. Hemolytic anemia, megaloblastic anemia, and bone marrow suppression with leukopenia can occur. Rare hepatotoxic reactions, such as cholestatic jaundice and chronic active hepatitis, have been reported (390).

FOSFOMYCIN
Fosfomycin, first isolated from cultures of Streptomyces spp. in 1969, is a phosphonic acid derivative originally named phosphonomycin (391). In the United States, it is used as single-dose therapy for uncomplicated urinary tract infections due to susceptible organisms, though it is increasingly being investigated and utilized in the therapy of MDR urinary tract infections (341, 392).

Mechanism of Action
Fosfomycin is bactericidal because it inhibits UDP-N-acetylglucosamine enolpyruvyl transferase (MurA), a bacterial cytoplasmic enzyme that catalyzes the formation of uridine diphosphate-N-acetylmuramic acid during the initial step of peptidoglycan synthesis (391). There is little cross-resistance between fosfomycin and other antibacterial agents, most likely because it differs from other agents in its chemical structure and site of action. Resistance to fosfomycin can occur by three mechanisms: (i) mutations of the structural or regulatory genes for the bacterial proteins (GlpT and UhpT) that transport the drug into the cell, (ii) plasmid-mediated production of a drug-inactivating enzyme (FosA), and (iii) overproduction of the target enzyme MurA (394, 395).

Pharmacology
Originally formulated as sodium and calcium salts for oral and intravenous use, fosfomycin is available in the United States as an oral, water-soluble tromethamine salt. Following oral administration, it is rapidly absorbed and converted to the free acid fosfomycin. With markedly improved oral bioavailability over earlier formulations (35 to 40%), fosfomycin has a mean elimination half-life of 5.5 h, and it is primarily excreted unchanged in the urine (396). Following a single oral dose of 3 g, peak serum concentrations (range, 22 to 32 μg/ml) are achieved in 2 h after administration, with peak urinary concentrations (1,000 to 4,400 μg/ml) occurring within 4 h and remaining high (>128 μg/ml) for 24 to 48 h, sufficient to inhibit most urinary tract pathogens. Peak urinary concentrations are reached later and lowered when the drug is administered with food or antiperistaltic agents. In patients with renal impairment (creatinine clearance, <30 ml/min), peak serum concentra-

tions of fosfomycin are increased, with decreased urinary elimination and reduced urinary concentrations of the drug. While not bound to plasma protein, it is widely distributed in various body fluids and tissues, including kidneys, prostate, and seminal vesicles, from which it is cleared slowly. Although it crosses the placental barrier, the drug can be used safely during pregnancy if clearly needed.

Spectrum of Activity
Fosfomycin has a broad spectrum of antibacterial activity against most Gram-positive and Gram-negative bacteria isolated from patients with lower urinary tract infections. E. coli, Serratia, Klebsiella, Citrobacter, Enterobacter spp., S. aureus, and enterococci are generally inhibited by fosfomycin at concentrations of <64 μg/ml (396, 397). MDR urinary tract isolates, including ESBL-producing E. coli isolates, are often susceptible to this agent (398). Fosfomycin is bactericidal at concentrations that are similar to the MIC values, with ≤2-fold differences. It is more active than TMP and nalidixic acid, while being similar to norfloxacin and co-trimoxazole, in its activity against these organisms (397). At a breakpoint concentration of ≤128 μg/ml, 60%, 20%, and 40% of isolates of Pseudomonas spp., Morganella morganii, and S. saprophyticus, respectively, are susceptible to fosfomycin (399). In multiple-dose use, bacterial resistance to fosfomycin emerges rapidly as the result of chromosomal mutations or, more rarely, by acquisition of mobile elements. However, cross-resistance with other antimicrobials has been uncommon (400). Resistance appears to be increasing in some parts of the world where the drug has been widely used for the treatment of urinary tract infections caused by ESBL-producing E. coli (401). The in vitro activity of fosfomycin is affected by test medium and conditions (396, 399). Fosfomycin has greater in vitro activity and closer correlation with in vivo activity when the test medium is supplemented with glucose-6-phosphate at 25 μg/ml, as recommended for susceptibility testing by the agar and broth dilution methods. The disk diffusion testing method utilizes disks containing 200 μg of fosfomycin tromethamine and 50 or 100 μg of glucose-6-phosphate.

Adverse Effects
Mild, self-limiting gastrointestinal disturbances, mainly diarrhea, are the most frequent side effects (3% to 5%). Other minor adverse events include headaches, dizziness, rash, and vaginitis.

BACITRACIN
Originally isolated from Bacillus licheniformis (formerly B. subtilis), bacitracin is a cyclic polypeptide antibiotic. Although it was introduced initially for the systemic treatment of severe staphylococcal infections, it is now restricted to topical use because of its systemic toxicity. Bacitracin inhibits dephosphorylation of a lipid pyrophosphate, a step essential for bacterial cell wall synthesis. It also disrupts the bacterial cytoplasmic membrane. Bacitracin is often used in various topical preparations, such as creams, ointments, antibiotic sprays and powders, and solutions for wound irrigation or bladder instillation. When used as a topical antibiotic, no significant amount of bacitracin is absorbed systemically. Large doses used to irrigate serous cavities may be associated with systemic toxicity. This drug is active mainly against Gram-positive bacteria, especially staphylococci and group A beta-hemolytic streptococci. However, group C and G streptococci are less susceptible, while group B streptococci are resistant (402).
Strains of Neisseria spp. are also susceptible, but Gram-negative bacilli are resistant. Bacitracin is often combined with neomycin, polymyxin B, or both in topical preparations to provide broad-spectrum antibacterial coverage.

Systemic administration of bacitracin results in significant nephrotoxicity. Side effects are rare when the drug is given orally or applied topically. The drug is nonirritating to skin or mucous membranes. Allergic skin sensitization is rare.

**Mupirocin**

Mupirocin, formerly pseudomonic acid A, is a topical antibacterial agent derived from the fermentation products of *Pseudomonas fluorescens* (403). It contains a unique 9-hydroxynonanoic acid moiety in its chemical structure, and it inhibits isoleucyl-tRNA synthetase, resulting in cessation of bacterial protein synthesis (404). Low-level resistance (MICs of 4 to 256 μg/ml) results from an altered synthetase enzyme due to mutations in the bacterial chromosomal ileS gene, whereas high-level, transferable resistance (MIC of ≥512 μg/ml) is mediated by the plasmid-borne mupA and mupB genes, which encode an additional isoleucyl-tRNA synthetase (405).

Originally developed for the topical treatment of superficial soft tissue infections, particularly those due to staphylococci, mupirocin is available as a 2% ointment or cream in the United States. After topical application, <1% of the drug is absorbed systemically, with no detectable levels in the urine or feces. Penetration into deeper dermal layers of the skin is increased with traumatized skin or use of occlusive dressings. The drug is highly protein bound (95%), and its activity is lowered in the presence of serum. It is most active at moderately acid pH, with no inoculum effect (406). Mupirocin is slowly metabolized in the skin to the inactive monic acid.

*In vitro* activity is directed primarily against the Gram-positive cocci. *S. aureus*, including MRSA, and coagulase-negative staphylococci are uniformly susceptible, with MICs of <0.5 μg/ml (407). Emergence of resistant strains of staphylococci can occur with widespread use of mupirocin (408–410). Most streptococci (including *S. pneumoniae*, beta-hemolytic streptococci of groups A, B, C, and G, and viridans group streptococci) are inhibited by mupirocin concentrations of ≤1 μg/ml. Resistant bacteria include enterococci, *Corynebacterium* spp., *Erysipelothrix* spp., *P. acnes*, Gram-positive anaerobes, and most Gram-negative bacilli. However, *H. influenzae*, *N. gonorrhoeae*, *N. meningitidis*, *M. catarrhalis*, *B. pertussis*, and *P. multocida* are susceptible; MICs for them are in the range of 0.02 to 0.25 μg/ml. There is no cross-resistance between mupirocin and other major groups of antibiotics. Clinically, mupirocin is efficacious in the therapy of superficial skin infections, such as impetigo, folliculitis, and burn wound infections that are caused by staphylococci or streptococci (411). Although this drug has been used successfully to eradicate nasal carriage of *S. aureus*, including methicillin-resistant strains (412), it may not prevent nosocomial *S. aureus* infections (413). No systemic toxic effects have been reported with mupirocin. Local irritation, such as burning, stinging, itch, and rash, which may be due to the polyethylene glycol base in the vehicle ointment, may occur.

**Retapamulin**

Retapamulin belongs to a new class of antibiotics called pleuromutilins, which are derived from a fermentation product of *Plenotus mutius* (an edible mushroom). This class of agents selectively inhibits the elongation phase of bacterial protein synthesis by preventing normal formation of active 50S ribosomal subunits and interfering with peptide bond formation (414). Low-level resistance to retapamulin has been induced in vitro with stepwise mutations in the rplC gene, which encodes the bacterial ribosomal protein L3 (415), but the frequency of such resistance is very low, and high-level mutational resistance is unlikely to occur. However, a recently described plasmid-mediated gene (*cfr*) encodes an enzyme that methylates the ribosomal binding site for pleuromutilins and leads to cross-resistance to lincosamides, oxazolidinones, chloramphenicol, and streptogramin B (313).

Retapamulin is active against *S. aureus*, *S. pyogenes*, *Streptococcus agalactiae*, and viridans group streptococci at very low concentrations (MICs of 0.03 to 0.5 μg/ml), including MRSA and isolates resistant to β-lactams, macrolides, quinolones, and mupirocin, without target-specific cross-resistance to other antibacterial agents (416, 417). More than 50% of mupirocin- and fusidic acid-resistant strains of MRSA and *S. aureus* remain susceptible to this drug (418). It is also active against *S. pneumoniae*, *H. influenzae*, *M. catarrhalis*, and most anaerobes, including *P. acnes*. Retapamulin is licensed in the United States as a 1% ointment for the topical treatment of impetigo caused by MSSA and *S. pyogenes*. No systemic toxic effects have occurred with the topical use of retapamulin. Irritation, itching, pain, rash, and contact dermatitis at the application site were reported in <2% of patients in clinical studies of this drug.

**APPENDIX**

**Approximate Concentrations of Antibacterial Agents in Serum**

The concentrations of antimicrobial agents listed in the table below are approximations taken from various reports and publications. Several factors can influence the level of antimicrobial agent in individual patients, including inherent differences in the patients themselves, their physical condition, the dosages, and the routes of administration. The values can also be influenced by the assay methods used to obtain them. Therefore, these concentrations should be used only as approximate values, and clinicians should use their knowledge of the patient and the drugs, the recommendations from U.S. Food and Drug Administration-approved package inserts, or other reputable sources in planning their therapeutic regimens.

Mechanisms of Resistance to Antibacterial Agents*

JEAN B. PATEL AND SANDRA S. RICHTER

GENERAL CONCEPTS, INOCULUM EFFECTS, AND TOLERANCE

When the growing problem of antimicrobial resistance in bacteria is considered, it is worth remembering that resistance is not a new phenomenon, nor is it unexpected in an environment in which potent antimicrobial agents are used. The diversity of the microbial world and the relatively specific activities of our antimicrobial agents virtually ensure widespread resistance among bacteria. In many cases, this resistance is recognized when an antibiotic is first tested for development. For example, it is not considered a problem or threat that *Escherichia coli* is resistant to vancomycin. We simply understand that *E. coli* is not among vancomycin’s spectrum of activity, and we avoid using vancomycin when *E. coli* infection is known or highly suspected (i.e., it has natural or intrinsic resistance to vancomycin). Conversely, the increasing resistance of *E. coli* to ciprofloxacin represents an important problem, since we frequently use the fluoroquinolone class of antimicrobial agents to treat infections in which *E. coli* is likely to be involved. So when we speak of the problem of resistance, we must recognize that most problems result from expression of resistance by bacteria that are intrinsically susceptible to the antibiotic in question (i.e., they have acquired resistance).

It is also important to recognize that resistance as a clinical entity is essentially a relative phenomenon, in many ways a problem only indirectly related to the microbiological techniques often used to detect it. For example, it is possible to incorporate enough ticarcillin into an agar plate to inhibit an ampicillin-resistant *Enterococcus faecium* (in many cases this requires about 10,000 μg/ml). So in one sense, ampicillin-resistant *E. faecium* is susceptible to high concentrations of ticarcillin. However, such concentrations cannot be achieved at the site of infection, so ampicillin-resistant *E. faecium* is not considered susceptible to ticarcillin. In the treatment of meningitis, relatively minor increases in the MIC can foil treatment, but in the treatment of simple urinary tract infections, in many cases, increases in the MIC are less relevant, given the tendency of many antibiotics to concentrate in the urine. It is the responsibility of the Clinical and Laboratory Standards Institute (CLSI; formerly the National Committee for Clinical Laboratory Standards), the Food and Drug Administration, and other standard-setting bodies in different countries to establish breakpoints for antimicrobial agents that are based on in vitro susceptibility, pharmacokinetic/pharmacodynamic modeling, and clinical-outcome data. The dependence of cure on MIC and antimicrobial concentration at the site of infection is why the CLSI *Streptococcus pneumoniae* susceptible breakpoint for the treatment of meningitis with penicillin is lower than the breakpoint for parenteral therapy of pneumonia.

The relativity of resistance is no better exemplified than by considerations of susceptibility in bacterial strains that exhibit significant inoculum effects, such as those resistant by virtue of producing β-lactamase. β-Lactamase-mediated resistance results from a chemical interaction in which the β-lactamase molecule binds to the β-lactam antibiotic in a manner that ultimately results in the hydrolysis of the critical β-lactam ring structure (Fig. 1). The rapidity and efficiency with which binding and hydrolysis proceed are dependent upon the affinity with which the β-lactamase molecule binds the antibiotic and the efficiency of the subsequent hydrolysis. High-affinity and rapid hydrolysis mean that the cell wall synthesis machinery (penicillin-binding proteins [PBPs]) can be defended with relatively few β-lactam molecules compared to the number of β-lactam molecules likely to be present in the vicinity of the PBPs. Low affinity and slow hydrolysis mean that more β-lactam molecules are necessary for effective resistance but also that resistance can be more easily overcome by adding more antibiotic molecules. Increasing the inoculum of organisms in a solution with a fixed concentration of β-lactam antibiotic has the effect of increasing the number of β-lactam molecules and can in some instances result in clinically important levels of resistance. A *Klebsiella pneumoniae* strain that produces the extended-spectrum β-lactamase (ESBL) TEM-26, for example, may exhibit a standard inoculum (ca. 10⁵ CFU/ml) MIC for cefotaxime of 1 μg/ml. However, when the inoculum is increased to 10⁷ CFU/ml, the MIC increases to >256 μg/ml (1).

A second, more amorphous and difficult-to-evaluate concept in considering antimicrobial resistance is that of tolerance, or resistance to killing, at antimicrobial concentrations sufficient to inhibit further growth. Tolerance is an unimportant concept for the treatment of most infections, since for therapeutic success it is usually sufficient to inhibit further growth of bacteria (bacteriostatic activity), allowing the patient’s immune defenses to kill the growth-inhibited organisms and clean up the debris. In some instances, however, antimicrobial killing...
Mechanisms of Resistance to Antibacterial Agents

FIGURE 1 Serine β-lactamases and their reactions with β-lactam carbonyl donors. Modified from reference 344. doi:10.1128/9781555817381.ch69.f1

of the bacteria (bactericidal activity) is required to yield a high percentage of treatment success. Instances where bactericidal activity is preferred include endocarditis, meningitis, and osteomyelitis, in which the immune system has limited access to the infection site. They also include circumstances in which the immune system is severely compromised, such as in patients undergoing high-dose chemotherapy for hematologic malignancies. In these instances, antibiotics that are primarily bacteriostatic, such as the tetracyclines or the macrolides, are considered poor choices for therapy, whereas β-lactam antibiotics, which are primarily bactericidal, are preferred. Some bacteria are naturally tolerant to β-lactam antibiotics. Bactericidal activity against enterococci, for example, requires two agents, one active against cell wall synthesis and an aminoglycoside (2). Recognition of this bactericidal synergism raised cure rates for enterococcal endocarditis from about 40 to 70% or greater (3). Unfortunately, expression of aminoglycoside-modifying enzymes (AMEs) negates the synergism and appears to decrease the cure rates for enterococcal endocarditis. Although some level of tolerance to β-lactam antibiotics can be demonstrated for several different bacterial species, the impact on the treatment of clinical infections appears to be less dramatic than with enterococci.

Emergence and Spread of Antibiotic Resistance

The emergence of antimicrobial resistance phenotypes is inevitably linked to the clinical (or other) use of the antimicrobial agent against which resistance is directed. One reason for this association is trivial—we do not generally test for resistance to antibiotics that are not in clinical use. The second reason is that nature abhors a vacuum, so when an effective antibiotic eliminates a susceptible biota, resistant varieties soon fill the niche. Once a resistance phenotype has emerged within a previously susceptible species, the rapidity and efficiency with which it spreads are affected by a host of different factors, including the degree of resistance expressed, the ability of the organism to tolerate the resistance mechanism, linkage to other genes, site of primary colonization, and others. The rapidity and completeness of resistance gene spread are often unpredictable. For example, the staphylococcal β-lactamase gene (conferring resistance to penicillin) was first described shortly after the introduction of penicillin into clinical use and is now almost universally present within staphylococci in hospitals.
and communities. It was not until the early 1980s that this gene was described to occur in Enterococcus, and it has never spread widely in this genus. The reverse appears to be true with the vancomycin resistance genes, which are found widely in E. faecium but remain exceedingly rare in Staphylococcus aureus.

An important cause of the spread of antimicrobial resistance is the failure to adhere to appropriate infection control techniques, both within and outside hospitals. It is well established that strains of methicillin-resistant S. aureus (MRSA) within individual hospitals, and even within entire cities, are often clonally related, as determined by genetic techniques such as pulsed-field gel electrophoresis, multilocus sequence typing, and staphylococcal protein A typing (4). The spread of these problematic pathogens has been attributed to transmission from patient to patient, presumably not only transiently or persistently colonized health care workers (5). The primary site of S. aureus colonization is the anterior nares. Colonization of the nares facilitates aerosol transmission of the resistant bacteria, particularly during periods of viral upper respiratory tract infection in colonized workers. It also facilitates direct transmission, given the frequent contact between hands and nose of many people and the frequently poor hand-washing practices of health care workers. The clinical consequences of patient colonization can be significant. Studies have shown a correlation between patient colonization with MRSA and subsequent infection during periods of high risk, such as the postoperative period (6).

Although antibiotic resistance is predominantly a nosocomial problem, resistant bacteria are also spread in the community setting. Sites in which resistant bacteria have been known to spread include day care centers and nursing homes (7, 8). Transmission probably reaches its peak in the winter months, when viral upper respiratory tract infections are prevalent. The prevalence of viral upper respiratory tract infections works in two ways to increase transmission: (i) it probably increases the inoculum of resistant organisms being spread by those already colonized and (ii) it makes those who are not colonized more likely to become colonized because of the increased likelihood that they will receive antimicrobial therapy. Nursing homes are predisposed to resistance for a variety of reasons, including the debilitated state of much of their population, frequent movement back and forth to tertiary care hospitals, and frequent use of antimicrobial agents in an effort to ward off infections that necessitate hospital admissions.

A final important source of the emergence and spread of antibiotic-resistant bacteria is nonhuman niches in which antibiotics are used. It is now well established that antimicrobial use in food animals is associated with both resistance in bacterial species that contaminate food and infect humans, primarily Salmonella and Campylobacter, and the transfer of resistance determinants to their human counterparts, such as Enterococcus (9). Compelling evidence that high rates of ciprofloxacin resistance in E. coli can be associated with the use of fluoroquinolones in poultry also exists (10). Finally, the European outbreak of vancomycin-resistant enterococci with the vanA determinant in the 1990s was almost certainly fueled by the use of avoparcin (a glycopeptide antibiotic) as a growth promoter in food animals (11). The Alliance for the Prudent Use of Antibiotics and other groups support a ban on the nontherapeutic use of antimicrobial agents in animals to address rising levels of resistant bacteria present in food and the environment (12).

Genetic Basis of Resistance

Acquired antimicrobial resistance results from biochemical processes that are encoded by bacterial genes. A general list of mechanisms of resistance is presented in Table 1. In order to understand the biochemical processes, it is useful to first discuss the genetic underpinnings of resistance and its evolution. Antimicrobial resistance arises by (i) mutation of cellular genes, (ii) acquisition of exogenous resistance genes, or (iii) mutation of acquired genes.

Mutation of Cellular Genes

All antibiotics have targets, which are often (but not always) proteins with important functional responsibilities for cell growth or maintenance. Cellular genes encode these proteins. Interactions between antibiotics and target proteins are often quite specific, and changing a single amino acid, frequently as a result of a single base change in the gene, can sometimes alter these interactions. Perhaps the most familiar example of this mechanism is resistance to rifampin. Rifampin targets the cellular RNA polymerase (encoded by rpoB), and a single point mutation in this gene may confer complete resistance. These mutations occur in most bacterial species at a relatively high frequency (ca. 10^{-6}/CFU). Incubating enough cells with inhibitory concentrations of rifampin eliminates susceptible cells and allows the resistant mutants to proliferate. The rifampin in the medium does not actually cause resistance but, rather, selects mutants that occur naturally but which have no selective advantage for survival in the absence of rifampin in the environment. Other examples of mutational resistance include resistance to streptomycin by ribosomal mutation (13), resistance to fluoroquinolones through mutations of cellular topoisomerases (14), and resistance to linezolid by mutations in the rRNA (15), among others.

Resistance mutations may also be found in genes that regulate cellular processes. Perhaps the most completely studied example of regulatory mutation resulting in resistance is the derepression of the chromosomal β-lactamase of Enterobacter spp. (16). Mutations in a cellular amidase gene (designated ampD) result in buildup of a cell wall breakdown product that has the effect of dramatically increasing expression of a chromosomal β-lactamase gene (ampC). Other examples of regulatory changes include the downregulation of expression of the porin OMP2 in Pseudomonas aeruginosa associated with resistance to imipenem (17) or the insertion of an insertion sequence (IS) element upstream of a chromosomal carbapenemase conferring imipenem resistance on Bacteroides fragilis (18).

Whether mutational resistance is likely to persist depends in some measure on whether the resistance mutation is tolerable to the cell. For example, although decreased expression of OMP2 appears to be readily achievable for P. aeruginosa, the fact that these resistant strains have not spread widely in the nearly 20 years of carbapenem use probably reflects the fact that this porin has functions that are beneficial to the bacterium, favoring reexpression of the porin once the imipenem threat has been dissipated. Similarly, intermediate levels of susceptibility to vancomycin in S. aureus have thus far been attributed to marked changes in the composition of the cell wall (19). These changes are unlikely to be favored in an environment free of vancomycin, since S. aureus likely ‘‘decided’’ a long time ago the optimal size and composition of its cell wall. The deleterious effects of acquiring resistance are often referred to as fitness cost.

Disadvantageous resistance mutations do not always disappear. Although initial point mutations in the rpoB gene...

(Continued on next page)
that confer rifampin resistance on Salmonella enterica serotype Typhimurium appear to decrease the fitness of the organism for survival in vivo, persistence in a live host is frequently associated with compensatory mutations that at least partially restore fitness to the strain while retaining the resistance (rather than mutating back to susceptibility) (20). Similarly, transfer of mutated pbp5 into E. faecalis strains is often associated with decreases in the expression of ampicillin resistance, but growth on increased concentrations of ampicillin easily yields colonies that grow well at higher concentrations (21). Similar findings have been reported for S. aureus strains transformed with the meca gene, encoding methicillin resistance (22). In summary, while mutational resistance often confers a fitness cost, subsequent adaptations may make expression of resistance less costly.

**Acquisition of Resistance Genes**

If resistance is not achievable through mutation, resistance determinants can be acquired. Most antimicrobial agents are natural products or derivatives of natural products. Therefore, resistance genes for most antibiotics must exist in the microbial world, either in the species that produce the antibiotic or within species that live in the same ecological niche as the antibiotic producers (23). The challenge for susceptible human pathogens is to find and acquire these resistance determinants. To assist in this acquisition, bacteria have evolved a range of mechanisms that promote gene exchange. Perhaps the simplest of these techniques is natural transformation, referring to the ability of some bacterial species to absorb naked DNA molecules from the environment under the appropriate circumstances (24). Once taken up by the susceptible bacterium, these foreign pieces of DNA enter the bacterial chromosome by recombining across regions of sufficient homology. In some cases, functional genes result from this recombination. If the acquired gene encodes a protein that is less susceptible to inhibition than the native protein, a reduction in susceptibility may result. Perhaps the best-studied example of the formation of these “mosaic” genes is confer resistance is penicillin and cephalosporin resistance in Streptococcus pneumoniae (24). A variety of mosaic pbp genes have been described to occur in resistant strains, with the level and degree of resistance determined by the number and nature of gene recombinations. Mosaic topoisomerase genes have also been described to occur in fluoroquinolone-resistant transformable bacteria (25).

Most bacteria are incapable of natural transformation and so have developed other mechanisms for acquiring useful genetic determinants. A commonly employed mechanism for genetic exchange is the transfer of conjugative plasmids. These extrachromosomal replicative DNA forms may bear a variety of important genes. Some plasmids are relatively narrow in their host range, while others transfer into and replicate within several different species. Transfer frequencies can be very high, as in the F factor of E. coli (virtual complete transfer in 1 h) or the phenolamine-responsive plasmids found in E. faecalis (ca. $10^3$ transconjugant/recipiec CFU in 24 h), or can be more modest, as observed with the broad-host-range replicative plasmids, such as pAMβ1 ($10^2$ to $10^6$ transconjugant/recipiec CFU in 24 h) (26). Having entered into a new genus on broad-host-range plasmids, resistance determinants can readily transfer onto more frequently transferable plasmids to increase their movement through the new genus. In the first case of true vancomycin-resistant S. aureus described in the literature, it appears that vancomycin resistance transposon Tn546 entered into S. aureus from Enterococcus faecalis on a broad-host-range plasmid and then transposed to a conjugative plasmid native to the staphylococcus (27, 28). Plasmids may also integrate into the chromosome of the recipient strains, potentially increasing the stability of the genetic information that they carry.

Bacteria also take advantage of bacterial viruses (bacteriophages) for genetic exchange. These discrete packages deliver to uninfected cells a quantity of DNA approximating the size of their genome (in most cases roughly 40 kb). Designed to incorporate their own genome into the manufactured phage head, they sometimes incorporate bits of chromosomal DNA adjacent to the phage integration site (specialized transduction) and other times incorporate an appropriate-size plasmid or chromosomal DNA segment unrelated to the integrated phage genome (generalized transduction). Since the staphylococcal β-lactamase gene is frequently identified on nonconjugative plasmids of approximately 35 to 40 kb, and since bacteriophages have been well described for staphylococci for decades, it has been speculated that the high prevalence of β-lactamase production in staphylococci has resulted from bacteriophage-mediated transfer of these plasmids. Bacteriophages have also been implicated in the transfer of virulence determinants (29).
Nonreplicative mobile elements known as transposons have also been implicated in the transfer of resistance genes (30). Transposons encode their own ability to transfer between replicons (autonomously replicating DNA segments). In some cases, the transposons themselves encode conjugation functions which allow them to transfer from bacterial chromosome to bacterial chromosome. The best characterized of these conjugative transposons is Tn916, an 18-kb element originally described for E. faecalis but which has a very broad host range (31). Tn916 encodes resistance to tetracycline and minocycline through the tet(M) resistance gene. Many different Tn916-like transposons have now been described for enterococci and other organisms, and some of them, such as Tn1545 from S. pneumoniae, possess additional resistance genes (conferring resistance to erythromycin and kanamycin) (31). Some investigators have suggested that the conjugation events associated with Tn916-like transposons are akin to cell fusion events, in which portions of the genome distinct from that adjacent to the inserted transposon can exchange via homologous recombination (32). Transposons with structural similarity to Tn916 have been implicated in the transfer of vancomycin resistance between E. faecium strains (33).

Transposons lacking conjugative functions may also transfer between strains. The most common mechanism by which this transfer is presumed to occur is either transient or more permanent integration into transferable plasmids. Among the more common classes of nonconjugative transposons are the Tn3 family elements (including Tn917, conferring erythromycin resistance, and Tn1546, conferring VanA-type vancomycin resistance) (34, 35) and the composite elements formed by mobile IS elements flanking resistance genes (including Tn4001, conferring high-level gentamicin resistance on many Gram-positive species) (36).

In recent years, the importance of "common regions" has increasingly been recognized (37). These regions, which are often conserved near the 3′ conserved regions of integrons, have been implicated in the movement of a range of different antimicrobial resistance determinants. These regions represent an atypical type of IS element (IS911-like). They lack typical inverted repeats and transpose by a rolling-circle mechanism that allows them to transpose adjacent DNA without a flanking second copy of the element.

The precise origin of resistance genes is often difficult to discern, but in some cases it is at least possible to determine that acquired resistance determinants originated in other genera. The VanB-type vancomycin resistance gene in enterococci, for example, has a G+C content of nearly 50% (38). The enterococcal genome, in contrast, has a G+C content of approximately 35 to 38%. These differences virtually confirm the origin of the vanB resistance gene. Many investigators have suggested that the VanB-type vancomycin resistance gene acquired resistance determinants originated in a genus other than Enterococcus. The likely origin appears to be streptococci, probably species that manufacture glycopeptide antibiotics, with entry into the enterococci facilitated by the incorporation of these resistance operons into transposons.

It is worth noting at this point that any concept of the bacterial genome as a fixed entity is untenable. Comparisons of E. coli genomes reveal striking differences between enteropathogenic and uropathogenic strains with the different regions constituting pathogenicity islands that confer specific virulence traits that give the strains their clinical profiles (39, 40). Data emanating from a comparative study of 36 S. aureus genomes indicate that 22% of the genome is dispensable, with many of these variable regions constituting presumed pathogenicity islands and regions of antimicrobial resistance (41). Finally, it is estimated that 25% of the genome of E. faecalis strain V583 was acquired from outside the genus (42).

Mutation of Acquired Genes

As bacteria have responded to the challenge of antimicrobial agents, so have we responded to the challenge of antibiotic resistance. One typical response to the appearance of antimicrobial resistance has been a concerted effort to develop novel antimicrobial agents that are active against resistant strains. The emergence of β-lactamase-mediated resistance to antibiotics is an instructive example of this interplay. Ampicillin was developed as the first penicillin with clinically significant activity against Gram-negative rods, primarily E. coli. Within a few years of the clinical introduction of ampicillin, strains of E. coli that were resistant to this antibiotic by virtue of production of a plasmid-mediated β-lactamase designated TEM (named after the patient from whom the resistant strain was isolated) were described. S. aureus expressed a similar β-lactamase, prompting a concerted effort on the part of the pharmaceutical industry to develop β-lactam antibiotics resistant to hydrolysis. Among the more successful compounds that were developed were methicillin (with activity against penicillinase-producing S. aureus), the cephalosporins and carbapenems (with widespread activities against many β-lactamase-producing species), and the β-lactamase inhibitors, which restored the activities of β-lactams susceptible to hydrolysis.

The most successful and widely developed class of β-lactamase-resistant β-lactam antibiotics is the cephalosporins. So many of these agents have been developed for clinical use that they are frequently lumped into "generations" to facilitate remembering their spectra of activity. The third-generation, or extended-spectrum, cephalosporins, such as cefotaxime, ceftriaxone, and ceftaxime, are particularly potent antibiotics that are resistant to hydrolysis by the original TEM enzyme. Unfortunately, increasing clinical use of these agents, particularly ceftriaxime, was associated with the emergence of resistant Gram-negative rods, particularly K. pneumoniae (43). Molecular analysis of these resistant strains revealed that the resistance was mediated by β-lactamase, and that many of these β-lactamases were derived from the native TEM enzyme through one or more point mutations in the blaTEM gene.

Biochemical Mechanisms of Resistance

Modification of the Antibiotic

Many antibiotic-modifying enzymes, including the β-lactamases, the AMEs, and chloramphenicol acetyltransferases (CATs), have been described. Although these enzymes are in many cases acquired, some are intrinsic to certain genera. For example, chromosomal β-lactamases are intrinsic to almost all Gram-negative rods. Expression of these enzymes is often only at a very low level, conferring resistance to only very susceptible β-lactams, as with K. pneumoniae resistance to ampicillin through expression of the chromosomal SHV-1 enzyme (44), or to no β-lactams at all, as with wild-type E. coli strains. In some bacterial genera (notably Enterobacter and Pseudomonas), chromosomal β-lactamases are under regulatory control, with derangements in these regulatory mechanisms resulting in high-level, broad-spectrum β-lactam resistance (45). In some instances, AMEs are intrinsic to bacterial species as well, as with the chromosomal acetyltransferases of Providencia stuartii and Serratia marcescens (46, 47).

Modifying enzymes in general confer high levels of resistance to the antibiotics against which they have activity.
Expression of the TEM-1 β-lactamase by E. coli, for example, can increase the ampicillin MIC from 8 μg/ml to >10,000 μg/ml. Similarly, expression of the bifunctional aminoglycoside resistance enzyme in E. faecalis raises the gentamicin MIC from 32 to 64 μg/ml to >2,000 μg/ml. As effective as these mechanisms are, however, some antibiotics appear to be immune to inactivating enzymes. Vancomycin has been in clinical use since 1958, yet there are still no examples of vancomycin-modifying enzymes in bacteria.

Modification of the Target Molecule
Since antibiotic interaction with target molecules is generally quite specific, minor alterations of the target molecule can have important effects on antibiotic binding. There are numerous examples of antibiotic target modification as a mechanism of resistance, including the many erythromycin ribosomal methylases that confer resistance to the macrolide-lincosamide-streptogramin B (MLSB) class of antibiotics (48). Modifications of PBPs can affect the affinities of these molecules for β-lactam antibiotics, as noted above for S. pneumoniae and especially for ampicillin-resistant E. faecalis, through mutations in PBP 5 (21, 24). Modifications of PBPs seem to be a favored mechanism of resistance in Gram-positive bacteria, whereas β-lactam production is favored in Gram-negative rods. Although the reason for this difference is unknown, it is interesting that β-lactamases produced by Gram-positive bacteria diffuse into the external medium once produced, whereas those produced by Gram-negative rods are kept within the periplasmic space by the outer membrane. The ability to concentrate β-lactamases enhances their efficacy and may help explain the preference for this mechanism among Gram-negative rods.

Other important examples of target modification include the altered cell wall precursors that confer resistance to glycopeptide antibiotics, mutated DNA gyrase and topoisomerase IV conferring resistance to quinolone antimicrobial agents, ribosomal protection mechanisms conferring resistance to tetracyclines, and RNA polymerase mutations conferring resistance to rifampin. The degree of resistance conferred by target modifications is variable and may be dependent upon the ability of the mutated target to perform its normal function. Mutations in PBPs of S. pneumoniae, for example, confer a relatively low level of resistance (although one that is significant in the treatment of meningitis) (24), whereas VanA-type vancomycin resistance confers a very high level of resistance to vancomycin in enterococci (49).

Restricted Access to the Target
It is axiomatic that an antibiotic must reach its target in order to be effective. Therefore, for targets for which barriers must be crossed by the antibiotic, strengthening these barriers can be a highly effective mechanism of resistance. All Gram-negative bacteria have an outer membrane that must be traversed before the cytoplasmic membrane can be reached. Reductions in the quantities of known or presumed porins (channels for movement of materials across the outer membrane) have been documented as important contributors to resistance to imipenem in P. aeruginosa, cefepime in Enterobacter cloacae, and cefoxitin or ceftazidime in K. pneumoniae (17, 50, 51). In most instances, this restricted entry must be in combination with the production of an at least moderately active β-lactamase to confer high-level resistance. Barriers to entry can also exist in the cytoplasmic membrane. Movement of aminoglycosides across the cytoplasmic membrane is an oxygen-dependent process, so these antibiotics are inactive in anaerobic environments (and hence against strictly anaerobic species) (52).

Efflux Pumps
Among the most active areas of research in antimicrobial resistance is the identification and characterization of pumps that extrude one or more antimicrobial classes from bacterial cells. Several classes of pumps have been described for Gram-positive and/or Gram-negative bacteria. They may be quite selective, or they may have a broad substrate specificity. The majority of these pumps are located in the cytoplasmic membrane and use proton motive force to drive drug efflux. The major families of efflux transporters are (i) the major facilitator superfamily (MFS), which includes QacA and NorA/Bmr of Gram-positive bacteria and EmR of E. coli; (ii) the small multidrug resistance family, including Smr of S. aureus and EmRE of E. coli; and (iii) the resistance-nodulation-cell division (RND) family, including AcrAB-ToIC of E. coli and MexAB-OprM of P. aeruginosa. The structure of the AcrAB-ToIC RND-type efflux pump is shown in Fig. 2. Deciphering the crystal structure of this pump was a major achievement (53). Among other things, it revealed that there was a periplasmic opening in the pump that could allow passage of molecules, explaining the previously confusing observation that RND pumps included β-lactam antibiotics (which do not enter the cytoplasm) among their substrates. In some instances, combinations of different types of pumps can result in higher levels of resistance than are achieved by the activity of a single pump alone (54).

Attribution of resistance to a specific mechanism may be difficult when more than one mechanism is involved. For example, resistance to imipenem in P. aeruginosa is contributed to by reduced access (through downregulation of OprD2) and production of AmpC β-lactamase (17). Neither mechanism alone is sufficient to yield clinically significant levels of resistance, yet both are required for high levels of resistance to result.

RESISTANCE MECHANISMS FOR DIFFERENT ANTIMICROBIAL CLASSES

Aminoglycoside Resistance
In explaining resistance to aminoglycosides (amikacin, gentamicin, kanamycin, neomycin, netilmicin, paromomycin, streptomycin, and tobramycin), we first explain how aminoglycosides reach their target in bacterial cells and then review their mechanisms of action. The clinical indications for aminoglycoside therapy are also summarized.

The aminoglycosides contain an aminocyclitol ring (streptidine or 2-deoxystreptamine) and two or more amino sugars linked by glycosidic bonds. They are hydrophilic antimicrobial agents whose antimicrobial activity is concentration dependent. They are particularly active against aerobic, Gram-negative rods. As a class, these agents have other highly desirable qualities: they are rapidly bactericidal, demonstrate a postantibiotic effect, and exhibit predictable pharmacodynamics.

Mechanisms of Action of Aminoglycosides
Aminoglycosides have unique effects on protein translation in prokaryotes. These effects may explain why aminoglycosides are bactericidal, whereas most other antibiotics that target the ribosome (chloramphenicol, macrolides, and tetracyclines) are bacteriostatic.

First, aminoglycosides penetrate bacteria by three main steps. The positively charged aminoglycoside binds to the
Resistance to aminoglycosides can occur by four mechanisms: (i) loss of cell permeability (decreased uptake), (ii) alterations in the ribosome that prevent binding, (iii) expulsion by efflux pumps, and (iv) enzymatic inactivation by AMEs.

Resistance due to Decreased Uptake and Altered Electrical Potential, Divalent Cations, and Efflux

It is well known that bacterial respiration generates an electrical potential across the membrane. Hence, anaerobes and facultative anaerobes (e.g., enterococci or certain small-colony variants of staphylococci) do not allow movement of aminoglycosides across their cell membranes. This intrinsic resistance confers low-level cross-resistance to all aminoglycosides.

Studies of *P. aeruginosa* and *E. coli* indicate that movement across the outer membrane may be due to a self-promoted uptake mechanism. The cationic aminoglycosides displace divalent cations (e.g., Mg\(^{2+}\)) that cross-bridge adjacent lipopolysaccharide (LPS) molecules, thereby permeabilizing the outer membrane and allowing entry of aminoglycosides (57). Consistently with this model, divalent cations have long been known to antagonize the activities of aminoglycosides against Gram-negative bacteria (58).

Recent data indicate that *P. aeruginosa* possesses an inducible RND-type pump (MexXY-OprM) that extrudes ami-
noglycosides (59, 60). In *E. coli*, aminoglycosides are captured from both periplasm and cytoplasm by the AcrD multidrug efflux transporter (61). Evaluating a multidrug-resistant (MDR) strain of *Acinetobacter baumannii*, BM4454, that was resistant to aminoglycosides, Manges et al. found an RND-type efflux pump in *A. baumannii* (62) and showed that it was under stringent control by a two-component regulatory and sensor system, adeRS (63).

**Modification of the Ribosome**

Bacterial cells have multiple copies of the rRNA genes. Mutations that affect aminoglycoside binding to the ribosome include alterations in ribosomal proteins and 16S rRNA and enzymatic methylation of the rRNA. Ribosomal mutations have been demonstrated to confer resistance to spectinomycin and streptomycin (64) and to other aminoglycosides as well (65). An emerging resistance problem is the 16S rRNA methylases found in Gram-negative rods. The first enzyme was found in *K. pneumoniae* BM4536 and designated *rmA* (aminoglycoside resistance methylase A) (66, 67). Subsequently, the enzymes named Rmt for rRNA methyltransferase were described. These currently include RmtA, RmtB, RmtC, RmtD, RmtE, and RmtF (68–70). These enzymes confer broad-spectrum resistance to the aminoglycosides, including new drugs like plazomicin, and they are increasingly identified on plasmids with broad-spectrum β-lactamases like CTX-M, NDM, and KPC (71, 72).

**AMEs**

As in the case with β-lactamases (see below), aminoglycoside inactivation by AMEs is the most important mechanism in terms of frequency and level of resistance (73). AMEs are believed to originate from actinomycetes that synthesize these antibiotics (*Streptomyces* and *Micromonospora* spp.). It is also possible that AMEs originated from enzymes involved in normal cellular respiration (housekeeping functions) (74). These enzymes are aminoglycoside phosphotransferases (APHs), nucleotidyltransferases or adenyltransferases (ANTs), and acetyltransferases (AACs). AMEs covalently modify specific amino or hydroxyl groups, resulting in aminoglycosides that bind poorly (with higher Kₘ and less affinity) to the ribosome. AMEs can be passed from one bacterium to another by mobile genetic elements. These resistance determinants are frequently carried on specialized transposable genetic elements called integrons (75, 76).

Sites of AME modification of aminoglycosides are delineated by a standard numbering system. The streptidine or 2-deoxystreptamine nucleus forms the center for the numbering scheme (from 2-deoxystreptamine derive all amino-sugars except streptomycin and spectinomycin). The first sugar moiety at the 4 position has positions numbered with a single prime (1′ to 6′); the second sugar moiety at the 6 position gets positions numbered with a double prime (1″ to 6″). Hence, AAC(6)″ acylates an amino group at the 6″ position (via an acetyltransferase) on the amino sugar attached to position 4 (Fig. 3). Each AME class consists of numerous enzymes that can modify different OH or NH₂ groups. These are divided into subclasses. In each subclass, there are different enzyme types that are designated by a roman numeral, e.g., AAC(3)-I. Isoenzymes are also described and are designated by a lowercase letter, a or b, etc. These isoenzymes are functionally identical and confer identical resistance phenotypes.

Currently, there are seven major phosphotransferases [APH(3′), APH(2′), APH(3″), APH(6), APH(9), APH(4), and APH(7″)], four nucleotidyltransferases [ANT(6), ANT(3″), ANT(4″), and ANT(2″)], and four acetyltransferases [AAC(2″), AAC(6), AAC(1), and AAC(3)]. A bifunctional AME able to acylate and phosphorylate [AAC(6)-APH(2″)] also exists. This enzyme is found in *Staphylococcus*, *Streptococcus*, and *Enterococcus* and is responsible for high-level resistance to aminoglycosides (77). The gene *aac(6′)-aph(2″)*, which encodes the synthesis of this enzyme, is present in Tn4001-like transposons which are inserted in both plasmids and the chromosomes of aminoglycoside-resistant isolates. Most aminoglycoside-resistant health care-associated MRSA strains express this enzyme.

**β-Lactam Resistance**

**PBP-Mediated Resistance**

β-Lactam antibiotics (penicillins, cephalosporins, monobactams, and carbapenems) are the safest and mostly widely used class of antibiotics ever developed. They act by inhibiting the PBPs, the transpeptidases that manufacture peptidoglycan. The specific functions of different PBPs have been identified for some bacteria, but the precise ways in which they interact with each other and with cell wall precursors remain largely a mystery. Some are clearly essential for cell viability (generally the high-molecular-weight transpeptidases and their partner transglycosylases), while others appear to be dispensable, with no apparent deleterious effects on cellular structure or function resulting from their absence.

---

**FIGURE 3** Sites of modification on kanamycin B by various AMEs. The arrows point to the sites of modification by the specific enzymes, namely, acetyltransferases, phosphotransferases, and nucleotidyltransferases. Reprinted with permission from reference 345.

doi:10.1128/9781555817381.ch69.f3
(most commonly the low-molecular-weight carboxypeptidases). It has long been suspected that some PBPs are redundant and can perform the functions of others. For example, E. faecium strains in which all of the PBPs except low-affinity PBP 5 are saturated grow normally, implying that PBP 5 can perform all of the penicillin-inhibitable functions required for cell wall synthesis (78). On the other hand, E. faecium strains in which pbp5 has been deleted grow normally as well, implying that the other PBPs can provide all of these functions (21).

PBPs are all members of a larger family of serine peptidases that includes most of the β-lactamases. PBPs and β-lactamases interact with β-lactam molecules (themselves structural analogues of the peptidyl-D-ala-D-ala termini of peptidoglycan precursors) by catalytically disrupting the β-lactam bond, resulting in a serine ester-activated acyl enzyme derivative (Fig. 1). In the case of β-lactamases, a water molecule then hydrolyzes the ester linkage of the acyl enzyme intermediate, releasing the irreversibly damaged penicillloyl (or cephalosporyl) moiety and regenerating the active enzyme. PBP–β-lactam acyl enzyme derivatives are in general less accommodating to nucleophilic attack by water molecules, resulting in a persistence of the covalent bond and inactivation of the PBP. The stability of this interaction allows identification of these proteins by binding to radiolabeled penicillin and is the genesis of their designation as PBPs. Because β-lactamases have no definable function in the cell other than to interact with β-lactam molecules, their affinity for the β-lactam and the rapidity with which the reaction proceeds determine their effectiveness and hence the level of resistance. Conversely, since PBPs have a very important alternative function (manufacture of the cell wall), the affinity of the interaction between PBPs and the β-lactam is a measure of distraction from their primary functions and thereby often defines the level of susceptibility of the strain.

Inhibition of PBPs interrupts cell wall synthesis, which by itself should inhibit cell growth rather than kill the cell. However, the interaction of β-lactam molecules with PBPs triggers the activity of cell wall-degrading molecules known as autolysins, which rupture the cell, leading to cell death (79). The extent to which these autolytic enzymes are activated correlates in most cases with the killing activity of a β-lactam against a particular bacterial strain.

Some bacterial species are intrinsically resistant to some β-lactam antibiotics by virtue of decreased PBP affinity. For example, enterococci are resistant to clinically achievable levels of cephalosporin antibiotics because of the presence of low-affinity PBP 5. Similar low affinity is demonstrated for the semisynthetic antistaphylococcal penicillins nafcillin and oxacillin, as well as for the antipseudomonal penicillins carbencillin and ticarcillin. Enterococcal PBP 5 is bound with a diminished affinity by ampicillin and the ureidopenicillins mecloxicillin and piperacillin, resulting in MICs that are higher than for streptococci but within the concentration range achievable in human serum.

PBP-mediated resistance for normally susceptible bacteria takes several forms, including (i) overproduction of a PBP, (ii) acquisition of a foreign PBP with low affinity, (iii) recombination of a susceptible PBP with more resistant varieties, and (iv) point mutations within PBPs that lower affinity for the β-lactam antibiotic. PBP-mediated resistance is predominantly found in Gram-positive bacteria. However, there are examples of Gram-negative bacteria with PBP-mediated resistance, and we point these out as they come up.

### PBP Overexpression

Increased expression of a PBP as a mechanism of conferring resistance is relatively uncommon. Clear examples of settings in which increased quantities of a PBP are associated with resistance include the increased levels of methicillin resistance found in S. aureus strains overexpressing PBP 4 (80) and increased levels of penicillin resistance in Enterococcus hirae and E. faecium strains that overexpress PBP 5 (21, 81). The existence of this mechanism serves as a reminder that, as with β-lactamases, susceptibility or resistance depends on the number of β-lactam molecules relative to the number of targets. Increasing the number of target molecules can, under the correct circumstances, result in resistance. Conversely, imipenem’s effectiveness against E. coli has been partially attributed to the fact that its primary target is PBP 2, which is present in roughly 200 copies, in contrast to PBP 3, estimated at 2,000 copies. In any case, overproduction of PBPs is a rare mechanism of resistance to β-lactam antibiotics.

### Acquisition of Foreign PBPs

Acquisition of a foreign PBP as a mechanism of resistance is best exemplified by the expression of methicillin resistance in S. aureus strains by virtue of the expression of PBP 2a, a low-affinity PBP not native to S. aureus and encoded by mecA (82). Isolates with the mecA gene are resistant to all β-lactams except for the new cephalosporins (e.g., cefaroline and cefobiprole) that can bind to PBP 2a (83). PBP 2a is classified as a class B PBP, meaning that it has a functional C-terminal transpeptidase domain but an N-terminal domain whose function has yet to be determined. This contrasts with class A PBPs, which have N termini with glycosyltransferase activities and C termini with transpeptidase activities. As a result, the transglycosylase domain of S. aureus PBP 2 is required for expression of β-lactam resistance by PBP 2a (84). The cooperation of specific class A PBPs with low-affinity class B PBPs has also been shown for E. faecalis and, more recently, for E. faecium (85, 86).

The origin of the mecA gene is unknown. A mecA homologue has been identified in Staphylococcus sciuri, a primitive staphylococcal species associated with rodents and primitive mammals (87). The deduced amino acid sequences of the two enzymes exhibited 88% similarity across the entire protein and 91% identity within the transpeptidase domain. S. sciuri strains are not methicillin resistant, however, which may be due to the lack of an effective promoter upstream of the gene. S. sciuri mecA homologues in which the promoter has spontaneously mutated express higher levels of methicillin resistance both in S. sciuri and when cloned on a high-copy-number vector in S. aureus (88). Expression of methicillin resistance in S. aureus is commonly under regulatory control, either by the product of the upstream mecl gene or in trans by the homologous blaZ gene, which regulates the expression of β-lactamase (the promoter regions of mecA and the blaZ β-lactamase genes are similar) (89). The mecl/blaZ repressors are, in turn, controlled by the mecR1/blaR1 sensors/transducers, although the precise mechanism of this interaction is incompletely understood. The efficiency of induction varies with the mechanism (blaR1-β-lactam-mediated induction is faster), leading to complications in detecting the methicillin resistance phenotype. In fact, only a small minority of a resistant population may express high levels of resistance. Several techniques are used in the laboratory to “bring out” the resistance (prolonged incubation, increased salt in the media, and cefoxitin susceptibility testing), and more recently, techniques have been
developed to bypass phenotypic expression in favor of directly identifying the mecA gene or directly detecting PBP 2a.

Expression of PBP 2a-mediated resistance to β-lactams in S. aureus is also influenced by the expression of other genetic loci called the fem (factors essential for methicillin resistance) or aux (auxiliary) genes (92). The fem and aux genes were first identified by transposon mutagenesis of MRSA strains to search for insertions that would reduce the expression of resistance. Many fem and aux factors have now been identified, and all are involved in the formation of the staphylococcal cell wall (82). These data indicate that minor perturbations of the normal processes prevent PBP 2a from functioning, suggesting that it is a very particular enzyme. However, when cloned into a heterologous (E. faecalis) background, PBP 2a was found to be capable of synthesizing peptidoglycan polymers using precursors distinctly different from those found in S. aureus (90).

The mecA gene is located within a larger (ca. 21- to 67-kb) region of the chromosome known as the staphylococcal chromosomal cassette (SCCmec) region (91). SCCmec is a mobile element, with mobility conferred by the presence of the ccrR/scrR or ccrA gene. The basic elements of SCCmec are the mecR1/medlpbb2a region and ccrA. In recent community-acquired S. aureus isolates, little else is included in the SCCmec complexes (types IV to VII) (92). Hence, the SCCmec region in these isolates is relatively small (20 to 30 kb), and the isolates themselves tend to be resistant only to methicillin. As of this writing, 11 different mec regions (SCCmec I to XI) have been described (92–94). Nosocomial isolates have larger SCCmec regions, owing to the accumulation over time of integrated plasmids or transposons that contribute to the multiresistance of these isolates (91). Although the SCCmec element has never been shown to be transferable in vitro, compelling data that the type IV SCCmec element has been recently acquired have emerged from the study of clinical isolates (95). Transfer of the mec region between staphylococcal strains has never been conclusively documented. The spread of MRSA within institutions is therefore largely due to the transmission of resistant organisms from patient to patient, probably on the hands of transiently colonized health care workers (5).

Single strains have spread through entire hospitals and even cities, mecA stability differs among different S. aureus clones (96), suggesting one potential explanation for the limited lineages within which the resistance determinant has been found. In 2011, human and animal MRSA isolates from Europe with a divergent mecA homologue termed mecC were first reported (97). Isolates harboring mecC were detected by susceptibility testing but not by commercial assays targeting mecA or PBP 2a.

**Resistance Mutations by Recombination with Foreign DNA**

Resistance through recombination between native, susceptible PBPs and those of less susceptible species is largely restricted to species that are capable of natural transformation or of taking up naked DNA from the environment. Prominent among these species are S. pneumoniae, viridans group streptococci, Neisseria gonorrhoeae, and Neisseria meningitidis (24). S. pneumoniae contains six PBPs (1a, 1b, 2a, 2b, 2x, and 3), all of which are subject to recombination, with foreign PBPs taken up by transformation. In most cases, resistant pBP genes demonstrate mosaic patterns (individual segments of foreign pBP genes integrated with the native pBP gene) with the foreign DNA in the less penicillin-susceptible viridans group streptococci (24). In fact, genetic exchange appears common between these closely related species, with mosaic patterns demonstrable even in PBPs from susceptible Streptococcus mitis strains (98). Penicillin resistance in S. pneumoniae can be established by alterations in PBPs 2x, 2b, and 1a, whereas only alterations in PBPs 2x and 1a are required for cephalosporin resistance (98). Penicillin resistance has been described to occur in S. pneumoniae for some time, with cephalosporin resistance emerging more recently, most commonly in strains already resistant to penicillin. However, strains resistant to cephalosporins but susceptible to penicillin have also been reported (99). High-level resistance (≥2 µg/ml) usually implies modification of more than one PBP, sometimes with several mosaic regions in each one (98).

As with PBP 2a-mediated resistance to methicillin in S. aureus, expression of penicillin and cephalosporin resistance in S. pneumoniae is dependent on the proper functioning of auxiliary genes. The fib locus of S. pneumoniae (fibA and fibB) is analogous to femA and femB in S. aureus. It is involved in the formation of interpeptide bridges, and inactivation of the fib locus is associated with reduction of cross-linked muropeptides and loss of penicillin resistance even in the presence of low-affinity mosaic PBPs (100). The marR-mur operon encodes enzymes involved in the biosynthesis of branched structured cell wall muropeptides commonly found in penicillin-resistant pneumococci (101). Inactivation of marR-mur results in loss of branched-chain muropeptides as well as loss of penicillin resistance.

Among Gram-negative species, Neisseria organisms are well known to be naturally transformable. It is therefore not entirely surprising that strains of both Neisseria gonorrhoeae and Neisseria meningitidis in which mosaic PBP genes are associated with decreased susceptibility to penicillin have been described (24). Similarly to the S. pneumoniae picture, the resistant portions of the PBP genes have been acquired from closely related commensals Neisseria meningitidis is a polymicrobial species. Resistance in N. meningitidis, however, is extremely rare, both β-lactamase-mediated resistance and PBP-mediated resistance to β-lactams in N. gonorrhoeae are quite common.

**Point Mutations**

The final mechanism of PBP-mediated β-lactam resistance results from point mutations within the pBP genes that result in lower affinity for the β-lactam in question. This form of mutational resistance is seen most commonly in PBP 5 of E. faecium strains, raising penicillin MICs from 4 to 16 µg/ml to as high as >1,000 µg/ml. High-level penicillin-resistant strains now represent the majority of clinical E. faecium isolates in the United States (103). These mutations further reduce the affinity for cephalosporins and other β-lactams, with lower affinity for the nonmutated version, leading to an increase in resistance that may have implications for the likelihood that antibiotic use will promote colonization with MRD E. faecium (104). Most of the mutations occur in the vicinity of one or more of several conserved boxes important for β-lactam binding (105). A systematic study of several common mutations of PBP 5 has revealed that resistance increases with increasing number of mutations, with some loci conferring higher levels of resistance than others (106).

Reduced penicillin susceptibility in group B streptococci (GBS) is uncommon and usually associated with point mutations in PBP 2x (107, 108). Mutations in PBP 1a and PBP 2a have also been detected in a non-penicillin-susceptible GBS isolate (109). In rare instances, point mutations of the S. aureus pBP2 gene have been associated with methi-
β-Lactamase-Mediated Resistance

Classification of β-Lactamases

Two major schemes are currently used to classify β-lactamases: the Ambler (AMB) classification system and the Bush-Jacoby classification system (113). The Ambler classification separates β-lactamases into four distinct classes (A to D) based on similarities in amino acid sequence. Classes A, C, and D are serine β-lactamases, whereas class B enzymes are metallo-β-lactamases that require one or two zinc atoms for activity (see above). The Bush-Jacoby classification system (formerly referred to as the Bush-Medeiros-Jacoby scheme [114–116]) classifies β-lactamases according to functional similarities (substrate and inhibitor profiles). There are four categories (groups) and multiple subgroups in the updated Bush-Jacoby system (groups 1, 2 [2a, 2b, 2br, 2d, 2bc, 2c, and 2f], etc.) (115). A comparison of the two classification systems is summarized in Table 2. Both classification systems are referred to in this chapter. More than 1,000 β-lactamases have been reported (http://www.lahey.org/studies). The most recent increases are mostly the result of diversification within well-established β-lactamases. The largest increases in numbers occurred in the class A and class D families. To illustrate, there are currently more than 217 TEM β-lactamases, 183 SHV β-lactamases, more than 400 OXA enzymes, 152 CTX-M ESBIs, and 120 CMY β-lactamases. Most worrisome is the increase in the number of carbapenemases. Numbers of IMP, VIM, and NDM metallo-β-lactamases have increased to 48, 41, and 10, respectively. There are now 18 variants of KPC. A complete listing can be found at http://www.lahey.org/studies.

β-Lactamase Mechanism

β-Lactamases are members of a superfamly of active-site serine proteases or D,D-peptidases (117). The mechanism of hydrolysis of β-lactams by β-lactamases is best studied for TEM-1. TEM-1 β-lactamase disrupts the amide bond of a β-lactam in a two-step reaction. First, the negatively charged carboxylate group of the β-lactam antibiotic is attracted to the active site by the enzyme’s positively charged residues. The β-lactam is properly positioned, making key hydrogen bonding interactions with the enzyme (118). The residues in the active site that facilitate this attraction in the serine β-lactamases are often called the oxyanion hole or electrophilic center. Next, the β-lactam is acylated (Fig. 1). A conserved serine, Ser70, in the active site of TEM-1 serves as the reactive nucleophile in this acylation reaction. Recent ultrahigh-resolution X-ray crystallography studies of TEM-1 (0.85 Å) indicate that Glu166, acting through the catalytic water, activates Ser70 for nucleophilic attack of the β-lactam ring. Then, a strategically positioned water molecule is activated by a general base (e.g., again Glu166 and the same water molecule). This water molecule deacylates the β-lactam and regenerates the active β-lactamase. This symmetric mechanism is also supported by the ultrahigh-resolution structure (0.90 Å) of another common class A β-lactamase, SHV-2, found in K. pneumoniae (119). There is general consensus on the mechanics of deacylation by the class A TEM-1 β-lactamase (attention to Glu166), but the details of acylation still remain contentious. Debate centers on which residue is the active site (Lys73 or Glu166) deprotonates the reactive Ser70 or whether both pathways are in competition with the other (120).
Genetic Environment of β-Lactamases

β-Lactamases can be chromosomal, plasmid-, or transposon-encoded enzymes that are produced in a constitutive or inducible manner. An increasing number of β-lactamases that are encoded on integrons have been found. Integrons are genetic elements of variable length that contain a 5′ conserved integrase gene (int), mobile antibiotic resistance genes (called cassettes), and an integration site for the gene cassette, attI (att, attachment). To date, five distinct integron classes have been found to be associated with cassettes that contain antibiotic resistance genes. Three main classes of integrons (classes 1 to 3) have been described for Gram-negative bacteria. Integrons capture antibiotic resistance gene cassettes by using a site-specific recombination mechanism. In the class 1 integrons, the 3′ conserved segment includes three open reading frames, qacE/A, a deletion derivative of the antiseptic resistance gene qacE, and sulf, a sulfonamide resistance gene. As integrons carry multiple resistance determinants and can be readily mobilized, their impact on antibiotic resistance is significant. In the words of Hall and Collis, “integrons thus act both as natural cloning systems and as expression vectors” (121). The capture and spread of antibiotic resistance determinants by integrons underlie the rapid evolution of multiple-antibiotic resistance antibiotic resistance integrons within diverse Gram-negative clinical isolates (122). As reviewed by Stokes and Hall (123), integrons were originally found on mobile elements from pathogenic bacteria and were found to be a major reservoir of antibiotic resistance genes. Analysis of their gene content suggests that integrons are phylogenetically diverse and have been with bacteria for a long time. Interestingly, integrons have been found in approximately 9% of sequenced bacterial genomes. It is maintained that the integron/gene cassette system has a function in evolution beyond just conferring resistance to antibiotics. Consequently, integrons may be the agents of change that drive bacterial evolution and adaptation. It should be noted that gene cassettes are mobile and can also exist in free circular form. However, these cassettes do not include all functions required for their mobility. Cassettes are formally part of the integron only when they are integrated at the integrase receptor site. The genes within the cassette do not have promoters.

Integrons are an important source for the spread of bla genes. Integrons containing β-lactamases have been found in A. baumannii, P. aeruginosa, and other species of Gram-negative bacteria encompassing Ambler class A, B, and D β-lactamases (124). The β-lactamase enzymes/families found on integrons are VEB-1, VEB-2, GES-1, GES-2, IBI-1, IBI-1, CXT-M-2, CXT-M-9, PSE-1, and numerous OXA β-lactamases (125–127). OXA and metallo-β-lactamases that confer resistance to carbapenems (IMP-1 to IMP-4, IMP-6 to IMP-8, IMP-12, VIM-1, VIM-2, and GIM-1) are also included in integron-encoded β-lactamases (124, 128).

Class A β-Lactamases (Bush Group 2b Penicillinases)

Class A β-lactamases possess four important structural motifs that create a complex hydrogen-bonding network to fix the β-lactam in the substrate-binding pocket. Residues Ser70-Xaa-Xaa-Lys73 (where Xaa designates 100% random amino acid substitutions), Ser130-Asp131-Asn132 (SDN loop), and Lys/Arg234-Thr/Ser235-Gly236 define the conserved residues critical for β-lactam binding and hydrolysis (117). The Ω loop (amino acids Arg164 to Asn179) is unique in class A β-lactamases. A highly conserved Gln166 that functions as a general base (electron donor) in the catalytic process is located in the Ω loop (see above). The salt bridge formed between Arg164 and Asn179 defines the limits, or “neck,” of the Ω loop.

The two commonly encountered class A β-lactamases found in Enterobacteriaceae are designated TEM-1 and SHV-1. TEM-1 and SHV-1 β-lactamases are primarily penicillinases with diminished activity against cephalosporin substrates. These two families of β-lactamases have received considerable attention over the past 3 decades since they are the progenitors of the ESBLs and IRT β-lactamases, now common in many hospitals.

Bush Group 2be ESBLs are generally class A β-lactamases that have “expanded” or changed their substrate profile as a result of amino acid substitutions. Normally, extended-spectrum cephalosporins are very poor substrates for hydrolysis by Bush group 2be enzymes (high β-lactamases). Among the extended-spectrum cephalosporins are extremely potent β-lactams. Mutations at critical amino acids expand the spectra of these enzymes and allow the hydrolysis of extended-spectrum cephalosporins (128). In most cases, ESBL mutations render the enzymes more susceptible to inhibition by mechanism-based inactivators (clavulanic acid, sulbactam, and tazobactam). An explanation for this increased susceptibility can be found by studying reactions of β-lactamases with β-lactamase inhibitors using Raman spectroscopy and stopped-flow kinetics. Increased amounts of certain key intermediates of SHV-2 and SHV-5 are formed (i.e., the enamine intermediate). As a result, the Kᵣ values of the mechanism-based inhibitors are reduced (increased susceptibility to inhibitors) up to 50-fold in SHV-2 and SHV-5 enzymes. The impact of enteric Gram-negative rods possessing ESBLs on the choice of empirical and definitive antimicrobial therapy has been substantial (129–133).

Among the TEM family enzymes, five amino acid residues appear to be most important for conferring the ESBL phenotype: Gly238 and Ala237 (located on the β3 β-sheet), Arg164 and Asp179 (located on the neck of the Ω loop), and Asp104 (located directly across from G238 and A237 at the opening of the active-site cavity) (118, 134). Of note, the replacement of Gly with Ser, Ala, or Asp at ABL position 238 is a common mutation in both TEM and SHV ESBLs (http://www.lahey.org/studies/).

CTX-M ESBLs

CTX-M β-lactamases were first reported in the 1980s, but isolates with these enzymes were less common than isolates with TEM or SHV enzymes (135). However, CTX-M ESBLs have demonstrated a global dissemination, and now these are the most common ESBLs. These enzymes can be divided into distinct clusters (see http://www.lahey.org/studies/). Unlike most (but not all) TEM- and SHV-derived ESBLs, CTX-M β-lactamases hydrolyze extended-spectrum cephalosporins better than they do ceftazidime. CTX-M enzymes are readily inhibited by tazobactam and clavulanic acid. They are also inhibited by the new β-lactamase inhibitor avibactam (136).

CTX-M β-lactamases are commonly found in K. pneumoniae and E. coli but can also be found in several other species of Enterobacteriaceae, including typhoidal and nontyphoidal Salmonella, Shigella spp., Citrobacter freundii, Enterobacter spp., and Serratia marcescens (137–139). A comprehensive review delineates the lineage of many CTX-M enzymes resulting from Klytéra spp. (135). Of note, different genetic elements are involved in the mobilization of blaCTX-M genes. In addition, CTX-M enzymes have spread via some successful E. coli lineages, such as ST131.
Many clinically important ESBLs other than TEM, SHV, and CTX-M (K1, GES, PER, VEB, BES, IBI, and OXA-type) have been described (140–142).

Structural Biology of ESBLs
Important insights have emerged from the study of a number of atomic structures of class A ESBLs. The common theme that emerges is that the active site is selectively remodeled and expanded to accommodate the bulky R1 side chain of extended-spectrum cephalosporins. Although the details of this modification are different for many of the ESBLs, the remodeling comes at a price. Many of these ESBLs are not as catalytically efficient (e.g., reduced $k_{cat}/K_{m}$) as the wild-type progenitors against certain substrates. With the expanded substrate spectrum, one uniformly observes decreases in penicillin MICs and in $k_{cat}/K_{m}$ ratios. In addition, these enzymes are less stable to proteolysis and heat. The structures of Toho-1, TEM-52, TEM-64, the Gly238Ala ESBL in TEM, SHV-2, and K1 β-lactamases all reveal insights into why expanded-spectrum cephalosporins fit in the active site (119, 143–149).

Serine Carbapenemases of Bush Group 2f or Class A type
In the past, β-lactamases able to hydrolyze carbapenems were rare. It is regrettable that this is no longer the case. Representatives of these carbapenemases are SME, NMC, IMI, GES, and KPC (125, 148, 150). $bla_{NMC-A}$ and $bla_{NMC}$ are chromosomally located genes in Enterobacter cloacae and are induced by cefoxitin and imipenem (151, 152). $bla_{NMC-A}$ is regulated by a LysR-type regulatory protein (153). It is felt that $bla_{NMC}$ is also regulated in the same manner (152). $bla_{NMC}$ is a chromosomally located gene encoding serine carbapenemase of class A in E. cloacae and Serratia marcescens.

A notable increase in bacteria expressing class A carbapenemases, specifically KPC, has occurred in the United States. First found in K. pneumoniae, these β-lactamases have been detected in nearly all species of Enterobacteriaceae and in non-Enterobacteriaceae, such as Acinetobacter spp. and Pseudomonas aeruginosa (154), among others. The gene encoding KPC is found on plasmids, some of which are conjugative. In addition, the gene has disseminated by transmission of successful bacterial lineages, such as K. pneumoniae ST258 (155). Bacteria bearing KPC enzymes are now found in nearly all parts of the world, including North and South America, the Caribbean, Europe, Israel, and Asia. These isolates are highly resistant to penicillins, cephalosporins, and commercially available β-lactam-β-lactamase inhibitor combinations and carbapenems. The new β-lactamase inhibitory avibactam is active against KPCs, suggesting that β-lactam drugs combined with avibactam may be therapeutic options for treating infections caused by KPC-producing bacteria (136).

Detection of KPC β-lactamases has been a problem for clinical laboratories, but by using the revised CLSI carbapenem breakpoints for Enterobacteriaceae (i.e., the breakpoints recommended in 2010 and after) and by implementing newly available tests for carbapenemase production, the detection of this important resistance mechanism is becoming easier. Using the imipenem, meropenem, and doripenem susceptibility breakpoint of $\leq 1$ μg/mL and ertapenem breakpoint of $\leq 0.5$ μg/mL, the vast majority of carbapenemase-producing isolates will test nonsusceptible to the carbapenems (154). Both the CLSI and the European breakpoint-setting organization, EUCAST, recommend that susceptibility data alone be used for making breakpoint decisions and that tests for resistance mechanisms, like carbapenemases, be used for infection control and epidemiological purposes (http://www.eucast.org/fileadmin/src/media/PDFs/EUCAST_files/Breakpoint_tables/Breakpoint_table_v.4.0.pdf) (137).

Tests for carbapenemase production are improving. Initially, tests with β-lactamase inhibitors, such as clavulanic acid or boronic acid, were used, but these tests can result in inaccurate results if other enzymes are present (156). The CLSI recommended the modified Hodge test (MHT). In this test, a lawn of susceptible E. coli cells (e.g., strain ATCC 25922), a carbapenem disk (ertapenem or meropenem), and a streak of the suspected KPC producer are placed upon an agar plate and incubated overnight. Growth up to the disk is checked the next day and, if present, suggests carbapenemase production. This test suffers from false-positive results and false-negative results for carbapenemases other than KPC, specifically NDM (157). More recently, the Carba NP test was described (158). This is a colorimetric, rapid test for carbapenemase production which can be employed in multiple laboratory settings, but it can fail to detect OXA-48 carbapenemases (see chapter 73). Several molecular assays have been developed to detect multiple carbapenemase-resistant determinants (see chapter 77 for more information).

The crystal structure of only KPC has been determined. KPC has an overall structure similar to that of other class A enzymes, and interestingly, this β-lactamase has only 50% protein sequence conservation compared to CTX-M-1, 39% compared to SHV-1, and 35% compared to TEM-1 (159).

The KPC β-lactamase possesses a large and shallow active site, allowing it to accommodate “bulkier” β-lactams. As a result of these structural changes, KPC is regarded as a versatile β-lactamase (160).

Among these serine carbapenemases exists a notable curiosity, $bla_{GES-2}$ is a plasmid-borne β-lactamase gene found in P. aeruginosa (161). $bla_{GES-2}$ is a point mutation mutant of $bla_{GES-1}$, which encodes a clavulanic acid-inhibited ESBL (a non-TEM, non-SHV ESBL). It is curious that GES-1 is an ESBL and that a single point mutation (Gly→Asp at position 170 in the β loop) can add an imipenemase activity to GES-2 (162). The OXA carbapenemases are discussed below.

Inhibitor-Resistant Class A β-Lactamase: Bush Group 2br
Amino acid mutations within TEM and SHV that confer resistance to inhibition by β-lactamase inhibitors have also been characterized at the following amino acid positions: Ser69, Ser130, Arg244, Arg275, and Asn276 (163). The OXA carbapenemases are discussed below.

Mutants of TEM β-lactamases that maintain the ESBL phenotype but also demonstrate inhibitor resistance are being recovered. These are referred to as CMTs. There are several reports of CMTs (174–177). It is still unknown how these enzymes will affect empirical treatment. At this time,
clinical microbiology laboratories do not have the resources to detect these complex phenotypes.

Class B β-Lactamas (Bush Group 3 Enzymes)
In contrast to the serine-dependent β-lactamas (classes A, C, and D), class B β-lactamas are metalloenzymes. These enzymes contain an αββ motif with a central β sandwich and two α helices on each side. Consequently, class B β-lactamas require zinc or another heavy metal for catalysis, and their activities are inhibited by chelating agents (EDTA). This zinc atom is held in place by three histidines and a water molecule. Some metallo-β-lactamas contain a secondary Zn binding site. These two sites function separately, with the primary Zn binding site assisted by the bridging water molecule (179). The important structural elements described for class A β-lactamas show very little primary-structure sequence identity (17 to 37%), the three-dimensional structures of the known metallo-β-lactamas appear to be similar (180–183).

Because of the metal ion, the catalytic pathway of metallo-β-lactamas does not involve an acyl enzyme intermediate as it does in classes A and C. The catalytic pathway in class B also incorporates a hydrolytic water molecule (the “bridging” water molecule) that possesses enhanced nucleophilicity due to the proximity to the metal ion. The zinc ions coordinate two water molecules. The addition of the hydroxide to the carbonyl carbon of the β-lactam leads to the formation of a transient, noncovalent reaction intermediate. The mechanistic details of this pathway have been summarized by Crowder et al. (184) and are beyond the scope of this chapter.

The majority of metallo-β-lactamas are chromosomally encoded, and their expression may be constitutive or inducible. The metallo-β-lactamas of B. cereus, Stenotrophomonas maltophilia, Aeromonas hydrophila, and Aeromonas jandaei are inducible. In A. jandaei, regulation of the metallo-β-lactase appears to involve two-component signal transduction systems (185).

The metallo-β-lactamas of the VIM and IMP types are now established as important threats to our antimicrobial armamentarium. These metallo-β-lactamas are broad-spectrum enzymes and are active against most β-lactams, including carbapenems, and have been found in various Gram-negative clinical isolates mostly in the Far East and the Mediterranean regions. blaVIM is an integron-borne metallo-β-lactamase that is usually found in P. aeruginosa isolates. Unfortunately, the VIM metallo-β-lactamate has spread to species of Enterobacteriaceae and also Acinetobacter spp. (186). blaVIM has now spread to more than 20 countries (187). The majority of metallo-β-lactamas are mobilized on integrons, transposons, and mobile common regions (178). Similarly, IMP metallo-β-lactamas are very wide-spread. IMP metallo-β-lactamas have been found as part of integrons in the following bacteria: P. aeruginosa, Pseudomonas putida, Serratia marcescens, Pseudomonas stutzeri, Acinetobacter baumannii, Pseudomonas fluorescens, K. pneumoniae, Klebsiella oxytoca, Enterobacter aerogenes, Achromobacter xylosoxidans, and Escherichia coli (178).

A novel class B carbapenemase has raised significant concern because of its widespread dissemination in a relatively short period of time (188). NDM (New Delhi metallo-β-lactamate) is a class B β-lactamate encoded by a very mobile genetic element, and the pattern of spread is proving to be more complex and apparently more unpredictable than that of the gene encoding KPC. Moreover, the number of patients possessing bacteria containing blaNDM is growing. The gene has moved from India and Pakistan to the United Kingdom, the United States, Kenya, Japan, Canada, Belgium, The Netherlands, Taiwan, Oman, and Australia. blaNDM has been found on plasmids of different sizes and has been located near a pathogenicity island. The resistance determinants flanking this bla gene seem to be numerous, including chromosomal β-lactamas (blaKPC and blaSHV) and chloramphenicol and aminoglycoside resistance genes. The global impact of this gene and its spread must be carefully monitored.

As stated above, the atomic structures of a number of class B β-lactamas have been solved (179–181, 189). The structures are being used to design novel inhibitors of class B β-lactamas.

Class C β-Lactamas
Ambler class C (Bush-Jacoby-Medeiros group 1) chromosomal β-lactamas are produced to a greater or lesser degree by almost all Gram-negative bacteria (Salmonella, Klebsiella, Proteus mirabilis, Proteus vulgaris, and Stenotrophomonas maltophilia being the major exceptions) (190). Chromosomally encoded (and inducible) enzymes are particularly important in clinical isolates of C. freundii, E. aerogenes, E. cloacae, Morganella morganii, P. aeruginosa, and S. marcescens. Although class C β-lactamas hydrolyze cephalosporins (including extended-spectrum cephalosporins) more effectively than they do penicillins, it should be kept in mind that these enzymes have a great efficiency for hydrolysis of penicillins (the Kcat is very low). Most class C enzymes are resistant to inhibition by clavulanate, sulbactam, and tazobactam (in the case of tazobactam, the resistance to inhibition is generally less), but avibactam, a new inhibitor, demonstrates activity for class C enzymes (136).

Class C β-lactamas have larger active-site cavities than do class A enzymes, which may allow them to bind the bulky extended-spectrum cephalosporins (oxymino-β-lactams) (191, 192). It is claimed that this conformational expansion and flexibility facilitate hydrolysis of oxymino-β-lactams by making the acyl enzyme intermediate more open to attack by water (191–193).

The important structural elements described for class A enzymes are also present in class C β-lactamas. The active-site serine (Ser64) is located near the N terminus of a long helix and is followed on the next helix turn by a lysine (Ser64-Xaa-Xaa-Lys67). The second element contains a Tyr-Xaa-Xaa-Xaa (Tyr150) or Ser-Xaa-Xaa pattern corresponding to the Ser130-Asp131-Asn132 loop of class A β-lactamas. The opposite side of the active site is marked by Lys315/Arg/His-Thr/Ser-Gly, corresponding to the KTG motif of class A enzymes.

Class C cephalosporinases acylate β-lactams in the same manner as class A enzymes do. In many ways, the reaction mechanism of class C β-lactamas remains enigmatic (194,
First, the catalytic Ser64 attacks the β-lactam carbonyl carbon and the acyl enzyme forms. The approaches of the activated water molecule are different between AmpC and class A enzymes (class C from the β-face). This implies that the deacylation mechanism is distinct. Unlike with class A enzymes, the ring amine of the acyl enzyme of class C facilitates deacylation. This “substrate-assisted catalysis” generally distinguishes class C from class A (although there are reports of substrate-assisted catalysis occurring in class A TEM enzymes as well) (196). In an examination of the catalytic mechanism, a “Glu166 equivalent” in class C β-lactamases is not readily apparent; this role may be filled by the tyrosine (Tyr150) in the Tyr-Xaa-Asn motif. The current thinking is that the conserved residue, Tyr150, acts as the general base in the acylation mechanism by increasing the nucleophilicity of Ser64. However, Tyr150 may stay protonated during the reaction and is thus not able to serve as an anionic base during hydrolysis. The proton on Tyr150 helps stabilize the water’s developing negative charge. However, mutagenesis studies do not rule out a role for Lys67 in the coordinate base mechanism as well (197).

The first class C β-lactamase structure determined was for the AmpC cephalosporinase of *C. freundii*, determined by Oefner et al. (198). The structures of the P99 β-lactamase of *E. cloacae*, AmpC β-lactamase from *E. coli*, and *E. cloacae* GCl1 and *E. cloacae* 908R β-lactamases have ensued (199, 200) (http://www.rcsb.org). The GCl1 β-lactamase of *E. cloacae* has improved hydrolytic activity for oxyimino-β-lactam antibiotics because of a tripeptide insertion in the Ω loop (a tandem repeat, Ala211-Val212-Arg213). In a strict sense, this is a class C ESBL. As a result of this addition, the width of the opening of the active-site binding cavity is larger and the substrate spectrum has expanded (191). As stated in the paragraph above, a number of other structures of the *E. coli* class C β-lactamases have been solved in an attempt to decipher the mechanism of catalysis. In the clinically important class C enzyme-producing Gram-negative rods, β-lactamase production is normally repressed. The details of the repression have been mostly elucidated for *Enterobacter* spp. (16). Repression and activation are closely linked to the processes of cell wall synthesis and breakdown. The molecule that serves as both the repressor and the activator of ampC transcription is AmpR, a transcriptional regulator of the *lysR* family. AmpR is present as a repressor by virtue of its interaction with UDP-MurNAc pentapeptide, a peptidoglycan precursor molecule. In this form, AmpR is incapable of activating AmpC and in fact serves as a repressor of ampC expression. In the setting of high concentrations of the cell wall breakdown product anhydro-MurNAc tripeptide (or anhydro-MurNAc penta- peptide), however, UDP-MurNAc pentapeptide is displaced from its site in AmpR, resulting in the conversion of AmpR to an activator of ampC transcription.

Increases in ampC expression may result from the actions of β-lactam antibiotics, certain of which cause the release of significant quantities of anhydro-MurNAc tripeptide and/or pentapeptide from the peptidoglycan. This anhydro-UDP-MurNAc tripeptide enters the cell through a channel (AmpG) and overwhelms the recycling ability of the cystolic amidase (AmpD) specific for recycling of muramylpeptide. Under these circumstances (induction), β-lactamase is produced only as long as the antibiotic is present in the medium.

Constitutive high-level production of AmpC β-lactama- se most commonly results from a mutation in the *ampD* gene, reducing the quantity of (or eliminating) AmpD from the cytoplasm. Under these circumstances, a constant high level of anhydro-MurNAc tripeptide is present in the cyto-
OXA carbapenemases hydrolyze imipenem inefficiently, their presence in an organism with an active efflux pump or a porin mutation may confer clinically significant levels of resistance (208). It is notable that A. baumannii isolates possess a chromosomally encoded oxacillinase, OXA-69, that confers very low level imipenem resistance. This gene is ubiquitous in A. baumannii and is referred to as a housekeeping gene (209).

Our understanding of the hydrolytic mechanism of class D β-lactamases is based on the careful study of OXA-10, -13, and -1. OXA β-lactamases are unique because of the direct role of carboxylation of the active-site Lys70. The carboxylic acid on Lys70 can ionize to yield a carbamate that hydrogen bonds with the nucleophilic Ser67 residue. In this manner, the carboxylated Lys70 residue may serve as the general base by activating both Ser67 for acylation and the hydroxyl group for deacylation.

More relevant to the issue of carbapenem resistance are the crystal structures of OXA-24/40 and OXA-48. OXA-24/40 is one of the most widespread carbapenemases found in A. baumannii (210). This enzyme was originally part of a clinical epidemic in Spain that involved a 10-month-long outbreak affecting 29 patients, 23 of them hospitalized in five intensive care units. The work by Santillana et al. (211) showed that OXA-24/40 has a hydrophobic barrier formed by Tyr112 and Met223 side chains, which define a tunnel-like entrance to the active site (211). Docquier et al. (212) found that OXA-48 is similar to OXA-10 in structure and not like OXA-24/40. Molecular-dynamics simulation showed that the monomer may position itself between Leu65, Leu158, and Thr213, with the C6 ethoxy group approaching Val110. In this manner, H2O gets near Lys73 and can attack C=O at the amide bond.

OXA-48 was initially isolated from K. pneumoniae in Turkey, but now it has been identified in a number of different species of Enterobacteriaceae and in patients all over the world. This enzyme weakly hydrolyzes carbapenem, but when it is combined with permeability defects, isolates can demonstrate high-level carbapenem resistance. OXA-48 is an unusual carbapenemase because it does not hydrolyze cephalosporins, so isolates with this enzyme can test carbapenem resistant but cephalosporin susceptible. However, bacteria harboring OXA-48 often carry another β-lactamase as well, like an ESBL, so that the isolate tests resistant to both cephalosporins and carbapenems (213).

**Chloramphenicol Resistance**

Acetyltransferases

Acetyltransferases is a broad-spectrum antimicrobial agent whose use has waned in recent years due to its well-characterized hematologic toxicity and a wealth of less toxic therapeautic options. The most common mechanism of resistance to chloramphenicol is the elaboration of CATs. A large number of CAT genes have been reported, and these determinants generally confer extremely high levels of resistance on the organisms expressing them. Substantial structural similarities exist among the different CAT variants, although their nucleotide sequences may be very divergent (214). Relationships among the different CATs have been described in detail in a review by Schwarz and colleagues (215). Chloramphenicol contains two hydroxyl groups that are acetylated in a reaction catalyzed by CAT in which acetyl coenzyme A serves as the acyl donor. Initial acetylation occurs at the C-3 hydroxyl group to yield 3-acetoxy-chloramphenicol (216). Following nonenzymatic rearrangement to 1-acetoxy-chloramphenicol and reacetylation, the 1,3-diaceetoxy-chloramphenicol product is formed. Neither the mono- nor the di-acetoxy derivatives are able to bind to the 50S ribosomal subunit and inhibit prokaryotic peptidyltransferase (216).

CATs are generally divided into two types: type A (classical) CATs and type B (xenobiotic) CATs (215). For S. aureus, five structurally similar type A CATs (A, B, C, D, and that encoded by the prototypic plasmid pC194) have been described (217). The cat genes encoding these enzymes are commonly located on small, multicopy plasmids, and expression is inducible by a translational attenuation mechanism (215). E. faecalis and S. pneumoniae also express inducible CAT genes that are similar to the type D gene of S. aureus. Two cat genes encoding constitutive CAT expression have been described to occur in Clostridium perfringens, catP is generally found within transposon Tn4451, whereas catQ (nearly identical to catD of Clostridium difficile) is chromosomal (215). Three types of type A CATs (I, II, and III) have been identified in Gram-negative bacteria. The widely prevalent type I enzymes are distinguished by their ability to bind and inhibit (without acetylation) the activity of luscinic acid. These enzymes are frequently found to be associated with transposon Tn9 or related elements. Type II CATs are notable for their sensitivity to inhibition by thiol-reactive agents and by their association with H. influenzae (218). Most knowledge of the structural features of the type A CAT enzymes comes from the study of the type III enzyme, for which the tertiary structure is known at high resolution (214). The structural determinants of binding for each substrate are also known for this enzyme.

Type B (xenobiotic) acetyltransferases (214) are structurally unrelated to classic CATs, and those that have been demonstrated to acetylate chloramphenicol confer only low levels of chloramphenicol resistance even when present in high copy numbers. Their natural substrate is likely something other than chloramphenicol, explaining their limited ability to acetylate this antibiotic. First described to occur in Agrobacterium tumefaciens, they have now been identified in a wide range of species (216). Included among this class of agents are the virginiamicin acetyltransferases found in S. aureus and E. faecium (see Quinupristin-Dalfopristin Resistance below). In fact, although they are members of this class, the use of chloramphenicol does not confer resistance to chloramphenicol, nor have they been demonstrated to be able to acetylate chloramphenicol in vitro (217). They are, however, quite adept at acetylating streptogramins. The crystal structures of two trimeric type B CATs have been determined (219, 220).

Decreased Accumulation of Chloramphenicol

It is now well recognized that chloramphenicol serves as a substrate for many of the MDR efflux pumps that exist in Gram-positive and Gram-negative bacteria, including those found in E. coli, P. aeruginosa, Bacillus subtilis, and S. aureus (221). In addition, there are efflux systems that are specific for chloramphenicol. The first chloramphenicol-specific efflux gene that was described was cmlA within the In4 integron of Tn1696 (222). cmlA encodes an efflux mechanism that uses chloramphenicol but not florfenicol (a chloramphenicol derivative licensed for use in animals in 1996 in the United States for the treatment of bovine respiratory pathogens) as a substrate. Gram-negative bacteria also express efflux genes specific for both chloramphenicol and florfenicol (fopP and fopS). These resistance genes are being reported with increasing frequency for animal-derived E. coli and Salmonella isolates (223, 224). In fact, the chloram-
phenicol resistance expressed by MDR Salmonella enterica serovar Typhimurium DT104 is most commonly encoded by floR (223), emphasizing again the potential negative impact of using similar antimicrobial agents in humans and animals. Very recently, chloramphenicol resistance in Actinobacter baumannii has been attributed to the activity of an MFS-type pump designated CmrA (225).

**Daptomycin Resistance**

Daptomycin is a cyclic lipopeptide antibiotic with activity exclusively against Gram-positive bacteria. It has bactericidal activity against most strains and acts by a cooperative interaction in the presence of physiological concentrations of calcium that result in the formation of pores in the cytoplasmic membranes of target bacterial cells. The result is leakage of ions from the cell and cell death. Resistance to daptomycin is rare but has been found in both enterococci and staphylococci.

The setting where *S. aureus* strains with reduced susceptibility to daptomycin usually occur is during prolonged treatment of deep-seated infections (226). The mechanisms of daptomycin resistance involve complex changes in the cell membrane, including phospholipid content, fluidity, and surface charge, that have not been completely defined (227).

Whole-genome sequencing of non-daptomycin-susceptible *S. aureus* strains revealed deletions in *mprF*, *pgsA*, or *clx2* genes, which encode phospholipid synthesis and may reduce the cell membrane negative charge, causing electrorepulsion of daptomycin (228). The vanSR (vancomycin resistance-associated sensor/regulator) signaling pathway (229) plays a role in the expression of daptomycin resistance in *S. aureus* isolates with *mprF* mutations (230). A thickened cell wall has been noted in many non-daptomycin-susceptible *S. aureus* strains (228, 231) as well as isolates with intermediate-level resistance to vancomycin (232), but the mechanisms may differ since nonsusceptibility to only one of these agents may occur (230, 233).

In *E. faecalis*, daptomycin resistance has been associated with deletions in phospholipid metabolism genes (*gbdD* and *cd*) as well as a gene (*liaF*) thought to be part of the LiaFSR system, which regulates a stress-sensing response to antimicrobial therapy (234). Whole-genome sequencing of a daptomycin-resistant *E. faecium* strain demonstrated changes in the YycFG regulator system (similar to the LiaFSR system) and mutations of genes involved in phospholipid metabolism (235).

**Glycopeptide Resistance**

Glycopeptide antibiotics (vancomycin and teicoplanin) inhibit cell wall synthesis by binding to the peptidoglycan precursor molecule as it exits the cytoplasmic membrane. This binding prevents the cross-linking (transpeptidation) of peptidoglycan precursors necessary for the formation of normal, stable cell walls. The large size of the glycopeptide molecules also appears to inhibit the other peptidoglycan precursor molecule as it exits the cytoplasmic membranes of Gram-negative bacteria, so vancomycin cannot access the target in these species. Hence, vancomycin is active only against bacteria lacking outer membranes, which are predominantly Gram positive.

Acquired resistance to vancomycin in Gram-positive bacteria comes in three varieties largely defined by the species within which they have been described: (i) altered pentapeptide precursors terminating in D-lactate or D-serine rather than the D-alanine in enterococci, (ii) mutational cell wall changes in staphylococci, and (iii) tolerance in pneumococci. The importance of the first type of resistance is characterized by both its prevalence and the importance of the species as a cause of infection, whereas the other two are defined more by the importance of the species than by their prevalence.

To date, nine varieties of enterococcal glycopeptide resistance that alter the vancomycin-binding target have been described. Four operons (*VanA, VanB, VanD, VanM*) encode terminal D-lactate precursors, and five operons (*VanC, VanE, VanG, VanL, VanN*) produce precursors ending in D-serine (236–238). Of these, the most clinically important are *VanA* and *VanB* (50). *VanA* and *VanB* are encoded by similar operons in which three genes (*vanH*, *vanA*, and *vanX* or *vanFB*, *vanB*, and *vanXB*) are required for expression of resistance (30). Two other genes (*vanY* and *vanZ* or *vanYB* and *vanW*) serve to amplify resistance but are not required for its expression (239, 240), and two more genes (*vanS* and *vanR* or *vanSB* and *vanRB*) regulate the transcription of the three essential genes (240, 241). The ultimate purpose of these genes is to alter the structure of the pentapeptide precursor from terminating in D-alanine–D-alanine to D-alanine–D-lactate, in so doing reducing the binding affinity of vancomycin to its target roughly 1,000-fold. The sequence of reactions resulting in this structure is outlined in reference 242. Since the terminal amino acid is cleaved from the pentapeptide in the transpeptidation reaction, the final composition of the cell wall is indistinguishable from that of strains lacking the resistance determinant. Apparently, the enterococcal PBP’s, which facilitate transpeptidation, have no trouble processing the altered precursors.

*VanA* enterococci are phenotypically resistant to vancomycin and teicoplanin, whereas *VanB* strains are resistant to vancomycin but appear to be susceptible to teicoplanin. This susceptibility results from the fact that teicoplanin does not induce expression of resistance (241). Once the *VanB* operon is expressed, however, resistance to teicoplanin results. Consequently, teicoplanin has been disappointing as a therapy for infections caused by *VanB* enterococci, since mutations in the *VanB* regulatory apparatus resulting in either inducibility by teicoplanin or constitutive expression occur readily during therapy (243–245).

Both *VanA* and *VanB* operons are carried by transposons. *VanA* is found exclusively within transposon Tn1546, a 10.4-kb Tn3 family element that is presumed to disseminate among enterococci by integrating into conjugative plasmids (240). The genes of the *VanA* operon are found to be highly conserved in their sequence when different strains are compared, but the restriction maps of the operons and of Tn1546 often differ markedly among clinical strains (246). These differences result from insertions of a variety of IS elements with or without subsequent deletions of parts of the mobile element and have been used by some investigators to establish lineages of strains within defined clinical settings. The *VanB* operon is most commonly encoded on highly similar transposons designated Tn5382 or Tn1549 (33, 247). These transposons exhibit significant homology to prototype enterococcal conjugative transposon Tn916. In contrast to the *vanA* gene, three allelic variants of *vanB* (*vanB1*, *vanB2*, and *vanB3*) have been described. The *vanB2* gene is associated with Tn5382 (248).

The overwhelming majority of clinical vancomycin-resistant enterococcal strains are *E. faecium*, a predilection that remains unexplained (103). The vast majority of vancomycin-resistant *E. faecium* strains that cause clinical infec-
tion are also resistant to ampicillin, owing to the expansion of a group of hospital-adapted clones (referred to as clonal complex 17) that have emerged around the world. Clonal complex 17 strains are found worldwide and are characterized by their resistance to ampicillin and by the fact that they frequently harbor putative virulence determinants, such as esp and etp of *E. faecium* (249, 250).

Despite in vitro transfer of the VanA determinant to *S. aureus* (251) and at least 14 case reports of patient cultures with VanA-expressing *S. aureus* (252–254), vancomycin-resistant *S. aureus* (VRSA) remains exceedingly rare. In all cases, resistance has been conferred by the VanA operon, and in one well-characterized case transfer appears to have been facilitated by the presence of Tn5546 on a broad-host-range plasmid in *E. faecalis*, with transposition of Tn5546 to a staphylococcal plasmid once entry into the staphylococcus occurred (27, 28).

The VanC operon is intrinsic to the cell wall synthesis machinery of the minor enterococcal species *Enterococcus casseliflavus* (including the biotype formerly classified as *Enterococcus faecalis*) and *Enterococcus gallinarum* (255, 256). The peptidoglycan precursor in VanC strains terminates in d-alanine–d-serine, reducing vancomycin affinity about 7-fold and resulting in low levels of resistance, with vancomycin MICs of 2 to 32 μg/mL. The cell wall precursors encoded by VanE, VanG, VanL, and VanN also terminate in d-alanine–d-serine and facilitate low-level glycopeptide resistance (257). In 2011 and 2012, epidemiologically unrelated *Streptococcus agalactiae* isolates with VanC elements for which nonsusceptible vancomycin MICs were 4 μg/mL were recovered from 2 patients in the United States (New York and New Mexico) (258). Both strains were positive by a PCR assay targeting the VanG sequence of *Enterococcus faecalis* (259), but the VanG sequences of only the New York strain shared complete sequence homology (253). A *Streptococcus* genomic isolate for which the vancomycin MIC was 4 μg/mL and with VanG elements nearly identical to those of the non-vancomycin-susceptible *S. agalactiae* New York strain was recovered from the urine of a Minnesota patient in 2012 (B. Beall, personal communication).

The modified pentapeptide precursor of *F. succinogenes* VanD terminates in d-alanine–d-lactate, and these strains have moderate levels of glycopeptide resistance (vancomycin MIC of 2–8 μg/mL). The failure to observe dissemination of VanD may be explained in part by the fact that the VanX-equivalent enzyme in *F. succinogenes* BM4339 appears to be ineffective in an enterococcal background. Resistance was expressed in BM4339 because that strain lacked a functional cell wall peptidoglycan (260). In S. aureus, intermediate-level resistance to glycopeptides (vancomycin-intermediate and glycopeptide-intermediate *S. aureus* [VISA/GISA]) occurs more frequently than full resistance. Human VISA (hVISA) (heterogeneous VISA) strains are susceptible to vancomycin at MICs of ≤2 μg/mL by the CLSI broth microdilution method (260). However, within these cultures are smaller populations of cells that express intermediate levels of resistance requiring special techniques (population analysis profile [PAP-AUC] analysis) for accurate detection. The hVISA and VISA phenotypes are characterized by thickened cell walls, which may decrease glycopeptide susceptibility by providing an excess of false targets for glycopeptide binding (228). In many, but not all, cases, conversion to the hVISA or VISA phenotype is associated with the vraSR two-component regulatory circuit, which responds to cell wall damage in *S. aureus* and regulates more than 40 genes, some of which are associated with the biosynthesis of peptidoglycan (260–262). Interestingly, recent work suggests that the hVISA phenotype can be selected by exposure to β-lactam antibiotics as well as by exposure to glycopeptides (263). Animal studies suggest that the level of resistance expressed by hVISA strains reduces the effectiveness of vancomycin therapy (264).

Glycopeptide resistance has also been reported for coagulase-negative species of staphylococci. Unlike in *S. aureus*, resistance in *Staphylococcus haemolyticus* has been associated with changes in the composition of the cross-links of the peptidoglycan (265). The mechanism by which this may lead to vancomycin resistance is incompletely understood.

Vancomycin is, in general, a less bactericidal antibiotic than are the β-lactams. Evidence for the importance of this observation can be found in several species. The bacteremia associated with *S. aureus* endocarditis, for example, takes roughly twice as much time to clear with vancomycin treatment as in treatment by the β-lactam oxacillin (266).

Recent clinical data also suggest that vancomycin treatment is associated with higher rates of failure and relapse than is nafcillin treatment for bacteremia due to methicillin-susceptible *S. aureus* (267). Vancomycin efficacy appears to be particularly poor against some strains of MRSA. In a recent clinical trial, vancomycin successfully treated left-side endocarditis in only 2 of 9 cases, a success rate that was similar to that of daptomycin (2 of 10 cases) (212). Reports of vancomycin tolerance in *Streptococcus pneumoniae* first appeared in 1993 (268). *S. pneumoniae* is the most common cause of bacterial meningitis in most patient populations, and bactericidal therapy is optimal for treatment of this condition. At least one case of presumed recrudescence of meningitis after treatment of a case of vancomycin-tolerant pneumococcal meningitis has been reported (269). Tolerance appears to involve mutations within an operon (vpx125) encoding an ABC transporter, but the mechanism by which this occurs remains undefined (270). Further work will be required before we understand the true importance of pneumococcal tolerance for the treatment of clinical infections.

**Linezolid Resistance**

The oxazolidinone antibiotic linezolid inhibits bacterial protein synthesis by interaction with the N-formylmethionyl-tRNA–ribosome–mRNA ternary complex commonly referred to as the initiation complex (271). Linezolid exerts excellent bacteriostatic activity against a wide range of Gram-positive pathogens, including methicillin-resistant staphylococci and MDR enterococci. Clinical use of this agent has been associated with the emergence of resistant strains, most commonly after prolonged therapy of difficult-to-eradicate bacteria. Resistance has now been described for both enterococci and staphylococci, but overall rates several years after clinical introduction of this agent remain very low (272). Resistance is most often associated with a G2576U (*Escherichia coli* numbering scheme) point mutation in the 23S rRNA, although mutations at other positions may also contribute to resistance (273). Resistance to linezolid, macrolides, and chloramphenicol has been attributed to a 6-bp deletion in the gene encoding ribosomal protein L4 in *S. pneumoniae* (274). Since the 23S subunit genes exist in multiple copies in different bacteria (four in *E. faecalis* and *S. pneumoniae*, six in *F. succinogenes*, and five or six in *S. aureus*), more than one copy of the genes must be mutated to confer resistance, with strains having a higher percentage of mutated 23S genes expressing greater levels of resistance (275). Gene conversion, or recombination between mutated genes
and wild-type genes, can rapidly increase the levels of resistance once the first gene mutation has occurred (276). In this fashion, persistent selective pressure exerted by linezolid can lead to rapid development of high-level (MIC > 128 μg/ml) resistance.

Plasmid-mediated resistance to linezolid through the expression of the cfr tRNA methylase gene has been reported for staphylococci (276), but the prevalence of this type of linezolid resistance remains very low (272).

**Macrolide Resistance**

Erythromycin (the first macrolide) was initially isolated from Streptomyces erythraeus, a soil organism found in the Philippines. There are currently four macrolides in common use: erythromycin, clarithromycin, azithromycin, and roxithromycin. Macrolides inhibit protein synthesis in susceptible organisms by binding reversibly to the peptidyl-tRNA binding region of the 50S ribosomal subunit, inhibiting translocation of a newly synthesized peptidyl-tRNA molecule from the acceptor site on the ribosome to the peptidyl (or donor site). Erythromycin does not bind to mammalian ribosomes. Most Gram-negative organisms are resistant to erythromycin because entry of erythromycin into the cell is restricted.

Resistance to macrolides occurs by several mechanisms. Among the more important of these mechanisms is methylation of the ribosome, preventing erythromycin binding (277). This methylation is most commonly accomplished by different erm (erythromycin ribosomal methylase) genes. Methylation of ribosomes confer resistance to macrolides, the related lincosamides (clindamycin and lincomycin), and streptogramins B (MLSB resistance). Many erm genes have been described—erm(A) and the related erm(TR), plus erm(B) and the related erm(AM)—and resistance is frequently inducible by macrolides but not by clindamycin (iMLSB). In some strains, erm-type resistance is expressed constitutively (cMLSB), resulting in resistance to clindamycin as well.

The second major mechanism of resistance to macrolides is expression of efflux pumps encoded by mef genes (Mef in Gram-positive bacteria and Acr-AB-ToIC in H. influenzae and E. coli) (278). The efflux pumps confer resistance to the macrolides but not to clindamycin, hence the phenotypic description of this resistance as the "M" type. mef genes have been studied most extensively for Streptococcus pneumoniae [mef(E)] and Streptococcus pyogenes [mef(A)], but similar genes have been described for a variety of Gram-positive genera. The prevalences of mef-mediated resistance versus that mediated by MLSB-type mechanisms in S. pneumoniae vary in different parts of the world. Minor mechanisms of resistance to macrolides include esterases that hydrolyze the antibiotics and point mutations within the 50S tRNA gene.

**Ketolide Resistance**

Ketolides belong to a new class of semisynthetic 14-membered-ring macrolides, which differ from erythromycin by having a 3-keto group instead of the neutral sugar L-cladinose. Ketolides bind to an additional site on the bacterial ribosome, increasing their binding affinity relative to that of other macrolides (279). Telithromycin, a ketolide, is uniformly and highly active against pneumococci (regardless of their susceptibility or resistance to erythromycin and/or penicillin), erythromycin-susceptible S. pyogenes, and erythromycin-resistant S. pyogenes strains of the M phenotype or iMLSB or cMLSB phenotype [in which resistance is mediated by a methylase encoded by the erm(TR) gene] (280). Ketolides are less active against erythromycin-resistant S. pyogenes strains with the cMLSB phenotype or the iMLSA subtype (in which resistance is mediated by a methylase encoded by the ermB gene); these strains range in phenotype from the upper limits of susceptibility to resistant. Methicillin-resistant staphylococci, which commonly express a cMLSB phenotype, are not susceptible to telithromycin (281).

**Quinupristin-Dalfopristin Resistance**

Quinupristin-dalfopristin is a mixture of semisynthetic streptogramins A and B licensed in Europe and the United States. A related streptogramin A and B combination, virginiamycin, has been used for years as a growth promoter in animal feed. Resistance to these mixtures can result from resistance to streptogramin A alone and was first described for staphylococci conferred by genes encoding streptogramin A acetyltransferases [vat(A), vat(B), and vat(C)] or ATP-binding efflux genes [ugal(A) and ugal(B)]. Quinupristin-dalfopristin’s excellent activities against E. faecium and MRSA make it an alternative for the treatment of MDR E. faecium and health care-associated MRSA infections, especially since the combination retains in vitro activity against streptogramin B-resistant strains. Two acetyltransferase-encoding resistance genes that confer resistance to quinupristin-dalfopristin in E. faecium, vat(D) [previously sat(A)] and vat(E) [previously sat(G)], have now been described. In most cases, these resistance genes are found along with an erm gene (281), suggesting that resistance to both streptogramins A and B may be necessary to confer clinically significant levels of resistance to quinupristin-dalfopristin in E. faecium. These resistance genes are frequently present on transferable plasmids. Although quinupristin-dalfopristin remains active against the majority of human E. faecium strains, the use of virginiamycin in animal feeds has been associated with high percentages of resistance in isolates derived from animals (282). In many cases, the known mechanisms of resistance to quinupristin-dalfopristin are not present in these isolates (282), indicating that there is still much to be learned about resistance to quinupristin-dalfopristin in E. faecium.

**Metronidazole Resistance**

Metronidazole is a member of the nitroimidazole family of bactericidal antimicrobials. The 5-nitroimidazole molecule is a prodrug whose activation depends upon reduction of the nitro group in the absence of oxygen. An exception to this rule occurs in Helicobacter pylori, in which the RdxA protein reduces metronidazole in a microaerophilic environment (283). The nitro group of metronidazole accepts a single electron from electron transport proteins (ferredoxins) in bacteria, yielding a toxic radical anion. Metronidazole’s activity appears to result in DNA damage and cell death (284). Resistance to metronidazole is rare. Decreased uptake and/or a reduced rate of reduction is believed to be responsible for metronidazole resistance in some cases (285). Five Bacteroides genes, nimA to nimE, have been implicated in resistance to 5-nitroimidazole antibiotics. Analysis of the NimA-susceptible and -resistant Bacteroides strains and recent crystal structure analysis suggest that the enzyme utilizes pyruvate for a two-electron reaction resulting in an amine that prevents the formation of the toxic anion radical (286, 287). Expression of nim genes varies depending on the positioning of a variety of IS elements that supply active promoters (288). Recent data indicate that the enzyme thioredoxin reductase is responsible for the reduction of metronidazole in Trichomonas vaginalis (289).
Nitrofurantoin Resistance

The antibiotics nitrofurazone and nitrofurantoin are used in the treatment of genitourinary infections and as topical antibacterial agents. Nitrofurazone is used primarily as a topical antiseptic (290). Nitrofurantoin (1-[[3-nitrofuranyl-1-dene]aminojahydrantoin] is a synthetic antibacterial agent used primarily in the treatment of urinary tract infections. The mechanism of action of nitrofurazone and nitrofuranto is not fully elucidated. Investigators have reported that the ability of nitrofurantoin to kill bacteria correlates with the presence of bacterial nitroreductases which convert nitrofurantoin to highly reactive electrophilic intermediates (291). These intermediates are believed to attack bacterial ribosomal proteins nonspecifically, causing complete inhibition of protein synthesis. In E. coli, nitroreductases are type 1 oxygen-insensitive enzymes encoded by the nfrA (nfsA) and nfrB (nfsB) genes. Strains of bacteria that are resistant to nitrofurantoin have been shown to possess diminished nitroreductase activity (292), which may seriously compromise their fitness (293). Resistance to nitrofurantoin from reduced nitroreductase activity seems to be present in other genera as well.

Polymyxin B and Polymyxin E (Colistin) Resistance

Clinical and scientific interest in the cationic polypeptides is increasing. Although they were first used in the early 1960s, colistin (polymyxin E) and polymyxin B are now often used as first-line therapy of infections caused by MDR Gram-negative bacteria. The polymyxins are polycationic peptide antibiotics isolated from Bacillus polymyxa (294). They exert their bactericidal activity by binding to the cell membrane of Gram-negative bacteria and disrupting its permeability, resulting in leakage of intracellular components. They also disrupt bacterial biofilm formation. In mechanistic terms, polymyxin binds to phosphorylated head groups of lipid A. Hence, by disrupting cell membranes, these agents become rapidly bactericidal against certain Gram-negative bacteria (295, 296).

Not all Gram-negative bacteria are susceptible to polymyxins. Organisms that are resistant to polymyxins have cell walls that prevent access of the drug to the cell membrane. In general, polymyxins are bactericidal against P. aeruginosa, Acinetobacter spp., some Proteus mirabilis strains, and some strains of Serratia marcescens. Proteus spp., Providencia spp., Neisseria spp., and Gram-positive bacteria are resistant to polymyxins (294).

Polymyxin-resistant mutants and bacteria exhibit a modified lipopolysaccharide (LPS) or loss of LPS production. Modification of the phosphate groups of lipid A with positively charged groups, such as 4-amino-4-deoxy-t-arabinose, is the most common resistance mechanism in E. coli, Salmonella serovar Typhimurium, K. pneumoniae, P. aeruginosa, Acinetobacter spp., and many other pathogenic Gram-negative bacteria (297). This modification of lipid A is mediated by two-component regulatory systems, such as PhoP-PhoQ and the downstream regulatory system PmrA-PmrB. Several mutations that affect these regulatory systems have been described in polymyxin-resistant isolates. LPS modifications include alteration of the fatty acid content of lipid A, and complete loss of LPS production was identified in a resistant strain of Acinetobacter spp. (298). There are non-LPS mechanisms of resistance, including changes in outer membrane protein expression and the overexpression of efflux pumps (299).

Quinolone Resistance

The fluoroquinolones are among the most widely used antimicrobial agents in both hospital and community settings. Quinolone antibiotics act by directly inhibiting DNA synthesis. Their targets include two type 2 topoisomerases: DNA gyrase and topoisomerase IV. These two enzymes are structurally related in that both exist as tetramers composed of two different subunits (GyrA and GyrB of DNA gyrase and ParC and ParE of topoisomerase IV). DNA gyrase acts to maintain negative supercoiling of DNA, whereas topoisomerase IV separates interlocked daughter DNA strands formed during replication, facilitating segregation into daughter cells. Fluoroquinolones bind to the topoisomerase-DNA complexes and disrupt various cellular processes involving DNA (replication fork, transcription of RNA, and DNA helicase) (299–301). The result is cellular death by unclear mechanisms.

The affinities of fluoroquinolones for the two targets vary, explaining to some degree the differing potencies of the various agents against different bacterial species. The enzyme for which a particular fluoroquinolone exerts the greatest affinity is referred to as the primary target (302–304). In general, the primary target of fluoroquinolones in Gram-negative bacteria is DNA gyrase, whereas in Gram-positive bacteria it is topoisomerase IV.

Alterations in Target Enzymes

The most common mechanism of clinically significant levels of fluoroquinolone resistance is through alterations of the topoisomerase enzymes. These alterations are created by spontaneous mutations that occur within the respective genes. In GyrA and ParC, resistance-associated mutations are often localized to a region in the amino terminus of the enzyme containing the active-site tyrosine that is covalently linked to the broken DNA strand. This 130-bp region of gyrA has been referred to as the quinolone resistance-determining region. X-ray crystallographic studies of a fragment of the GyrA enzyme suggest that these mutations are clustered in three dimensions, lending support to the hypothesis that the region constitutes a part of the quinolone binding site (305). Particularly frequent sites for resistance-associated mutations are serine 83 and aspartate 87 of GyrA and serine 79 and aspartate 83 of ParC (306).

Experimental data suggest that point mutations occur singly in roughly 1 in 10^9 to 10^10 cells. The level of resistance conferred by a single point mutation in the primary target enzyme depends upon the reduction of enzyme affinity created by the mutation, as well as the affinity of the fluoroquinolone for the secondary target. In this scenario, it is expected that fluoroquinolones exhibiting strong affinity for both target enzymes are less likely to be associated with the emergence of resistant strains, since the retained activity against the secondary target would be enough to inhibit the bacterium even in the presence of a primary target mutation. Fluoroquinolone-species combinations for which single mutations result in significantly higher MICs (such as ciprofloxacin and S. aureus or P. aeruginosa) are expected to be readily selected in clinical settings (307).

Most highly resistant strains exhibit more than one mutation in both the GyrA and ParC enzymes, a phenomenon that can be reproduced in the laboratory by serial passage of strains on progressively higher concentrations of fluoroquinolones. It is noteworthy in this context that fluoroquinolone resistance conferred by enzyme mutations is essentially class resistance. In other words, the activities of all fluoroquinolones are affected by mutations that result in resistance. Therefore, while single point mutations that confer resistance to one fluoroquinolone may not result in MICs conferring clinical resistance to another, the MICs of the second fluoroquinolone will inevitably be increased. In the
setting of such preexisting mutations, the second fluoroquinolone could then select for an additional mutation that would result in clinically significant levels of resistance. This reasoning has led to the recommendation that the most potent and broadly active fluoroquinolone always be used first to prevent the emergence of resistance. The wisdom of this recommendation remains to be tested.

Mutations in GyrB and ParE are far less common than in their companion subunits and tend to cluster in the midportion of the subunit (308). A clear understanding of the impact that these mutations have on enzyme structure or function awaits detailed crystallographic studies of enzyme-fluoroquinolone complexes.

Resistance due to Decreased Intracellular Accumulation
Fluoroquinolones penetrate the outer membrane of Gram-negative bacteria through porins, so the absence of specific porins can affect the level of susceptibility. However, their ability to diffuse through outer and cytoplasmic membranes is sufficient to retain activity against strains solely lacking porins (309). More important in reducing intracellular accumulation of fluoroquinolones is the expression of MDR pumps (306). The intrinsic efflux pump complexes in Gram-negative bacteria extend from the cytoplasmic membrane through the outer membrane, whereas Gram-positive pumps need only traverse the cytoplasmic membrane. These pumps move compounds across the bacterial membranes by proton motive force and are presumed to represent systems by which bacteria rid themselves of toxic materials. Resistance results when expression of pumps is increased due to mutations within their regulatory genes (310). By themselves, pumps generally confer only a low level of resistance to fluoroquinolones. However, their expression may amplify the level of resistance conferred by point mutations within the topoisomerase genes. By so doing, they may increase the risk that use of a given fluoroquinolone will select for resistant mutants through single point mutations. In recent years, a plasmid-mediated efflux pump (QepA) has been recognized among strains of Enterobacteriaceae (311). This pump extrudes the hydrophilic fluoroquinolones (ciprofloxacin, enrofloxacin, and norfloxacin).

The major type of plasmid-mediated fluoroquinolone resistance present in Gram-negative bacteria is conferred by the Qnr proteins (312, 313), which protect DNA from quinolone binding (314, 315). In general, only low levels of resistance are conferred by this mechanism, but as with other accessory mechanisms, the presence of Qnr can facilitate the clinical emergence of strains resistant by virtue of point mutations in the topoisomerase genes. Five variants of Qnr have now been described (A, B, C, D, and S). There are several alleles within the A, B, and S variants (http://www.lahey.org/qnrStudies/). The prevalence of this mechanism is increasing, which may be partly explained by the frequent presence of qnr within complex sulfate integrons (313) often associated with insertion elements (37).

Plasmid-mediated fluoroquinolone resistance can also be conferred by the AAC(6′)-Ib-cr protein, which is a mutant of the AAC(6′)-Ib AME (311). This confers low levels of resistance to ciprofloxacin and norfloxacin.

Rifampin Resistance
Rifampin is particularly active against Gram-positive bacteria and mycobacteria. It acts by inhibiting bacterial-DNA-dependent RNA polymerase. Point mutations in the chromosomal rpoB gene confer resistance to rifampin (316). The frequency with which these point mutations occur precludes using rifampin as a single agent for the treatment of bacterial infections.

Tetracycline Resistance
The tetracyclines are a group of bacteriostatic antibiotics that act by inhibiting attachment of aminoacyl-tRNA to the ribosome acceptor site, thereby preventing elongation of the peptide chains of nascent proteins (317). In order to gain access to the bacterial ribosome, tetracyclines need to enter the cell. In E. coli and presumably other Gram-negative bacteria, they enter the periplasmic space through outer membrane porins OmpC and OmpF, probably chelated to magnesium ions (318). Once in the periplasmic space, the weakly lipophilic tetracycline molecule dissociates from the magnesium ion and crosses into the cell by diffusing through the lipid bilayer in an energy-dependent process. Once inside the cell, tetracycline-ion complexes bind to the ribosome at a single, high-affinity binding site on the 30S subunit, blocking access of the aminoacyl-tRNA to the ribosome acceptor site. Although of high affinity, binding of tetracycline to the ribosome is reversible (319).

Tetracyclines are broad-spectrum and effective antimicrobial agents. Unfortunately, widespread use of tetracyclines to treat clinical infections and for promotion of growth in livestock has been associated with the emergence and dissemination of a variety of resistance determinants. As a consequence, the number of infections for which tetracyclines are recommended as first-line therapy has been limited for many years (319). The vast majority of tetracycline resistance determinants fall into one of two classes: (i) efflux or (ii) ribosomal protection. The designations of the different resistance determinants and their classes can be found in detail in an excellent review of tetracyclines by Chopra and Roberts (318). Initial designations of tetracycline resistance determinants used the prefix tet or orf, with letters (A, for example) designating the different determinants. Since the number of resistance determinants now exceeds the number of letters in the alphabet, a system using numbers has been devised (320).

Tetracycline efflux proteins are all membrane associated and members of the MFS proteins. They expel tetracycline from the cell by exchanging a proton for a tetracycline-ion complex. In general, the efflux proteins confer resistance to tetracyclines but tend to spare minocycline (318). The single exception to this rule is the Tet(B) protein of Gram-negative organisms, which confers resistance to both tetracycline and minocycline. The efflux proteins have been divided into six groups based on amino acid identity. Group 1 consists of Tet efflux proteins that are found primarily in Gram-negative species [with the exception of Tet(Z)], whereas group 2 (consisting only of Tet(K) and Tet(L)) is found primarily in Gram-positive species. Groups 3 through 6 are small groups consisting of one or two efflux proteins each.

Ribosome protection proteins comprise the other major mechanism of tetracycline resistance. These proteins exhibit homology to elongation factors EF-Tu and EF-G and exhibit ribosome-dependent GTPase activity (321). They act by binding to the ribosome, thereby changing its conformation and inhibiting binding of tetracycline. Tet(M) and Tet(O) are the best characterized of these proteins. Ribosome protection genes are widespread in bacteria, in many cases as a result of their incorporation into broad-host-range conjugative transposons.

Both efflux proteins and ribosomal protection proteins are regulated in ways that allow their expression to be in-
creased in the presence of tetracyclines. The efflux proteins of Gram-negative organisms are regulated by repressors that are divergently transcribed relative to the efflux proteins (322). Binding of the repressors to tetracycline changes the conformation of the repressor so that it can no longer bind to the operator region, resulting in increased transcription of both the efflux protein and the repressor genes. The Gram-positive efflux genes are not associated with specific protein repressors; sequence analysis suggests that these determinants may be regulated by mechanisms similar to translational attenuation, but study of this area has been limited (323). Transcription of ribosomal protection genes is augmented by growth in the presence of tetracycline.

Intrinsic mechanisms of tetracycline resistance exist in many, if not all, Gram-negative bacteria. Among the best characterized of these systems is the mar (multiple antibiotic resistance) operon (324). This locus consists of a repressor (MarR) that represses transcription of marA, which encodes a transcriptional activator of a variety of genes. Overexpression of MarA results in decreased expression of OmpF, a porin through which tetracycline enters the periplasmic space, and increased expression of multidrug efflux pump AcrAB, a member of the RND family of efflux proteins, which includes tetracyclines among its substrates. Several similar pump systems have been described for P. aeruginosa and other Gram-negative bacteria (325). As our knowledge of the genomes of different bacterial species becomes more complete, we will no doubt discover several other pump systems that affect levels of susceptibility to tetracyclines and other antibiotics.

The remarkable diversity of species within which tetracycline resistance determinants are found owes much to the inclusion of these resistance genes within broad-host-range transferable genetic elements. These include transferable plasmids in Gram-negative species, where tet genes may be found included within integrons, and conjugative transposons. Among the best studied of the conjugative transposons is the Tn916 family, originally described for E. faecalis (31). The complete sequence of Tn916 has been determined and is remarkable for its dearth of restriction enzyme digestion sites (except in the region of the tet(M) gene, which appears to be a late arrival to the element) (326). This lack of restriction sites facilitates its entry into a variety of different bacterial species. Transfer of Tn916-like elements from enterococci into many other species has been demonstrated in vitro and in animal models, and the remnants of Tn916-like sequences in N. gonorrhoeae are impressive testimony to its ability to travel widely (31). Transfer of Tn916-like elements, which is increased after exposure to tetracycline, has also been suggested to facilitate transfer of unlinked genes, further amplifying the risks of overexposure to tetracycline in the environment.

Tetracycline Resistance
The FDA approval of the glycycline tigecycline in 2005 provided a broad-spectrum antimicrobial alternative for treating infections due to resistant pathogens, including MRSA and carbapenem-resistant Enterobacteriaceae. Tigecycline’s broad spectrum of antimicrobial activity is due to its resistance to the common efflux or ribosomal protection mechanisms that confer resistance to older tetracyclines. Some bacterial species, notably P. aeruginosa and Proteus spp., are intrinsically resistant to tigecycline because they express RND-type efflux pumps that effectively extrude the antibiotic (327). Resistance to tigecycline in other Gram-negative species has also been reported, generally resulting from activation of normally repressed AcrAB-type RND efflux pumps (328). Mutations in the S10 ribosomal protein previously demonstrated in tetracycline-resistant N. gonorrhoeae and RamR mutations associated with increased expression of the AcrAB efflux system have been associated with tigecycline resistance in K. pneumoniae (329).

Trimethoprim-Sulfamethoxazole Resistance
Bioavailability of several amino acids and purines depends upon the availability of tetrahydrofolate. With few exceptions, bacteria are unable to absorb preformed folic acid and hence rely upon their ability to synthesize it. Sulfamethoxazole and trimethoprim are inhibitors of two enzymes (dihydropteroic acid synthase [DHPS] and dihydrofolate reductase [DHFR]) that act sequentially in the manufacture of tetrahydrofolate. It is thought that the two inhibitors act synergistically to inhibit folate synthesis, although the mechanism for possible synergism (since sequential blockade of a fully inhibited pathway should not augment resistance) is not clear.

Intrinsic Resistance
Trimethoprim-sulfamethoxazole is a remarkably broad-spectrum antimicrobial agent. Intrinsic resistance is relatively rare and may occur by decreased access to the target enzymes (P. aeruginosa) (330) or low-affinity DHFR enzymes (Neisseria spp., Clostridium spp., Brucella spp., Bacteroides spp., Moraxella catarrhalis, and Nocardioida spp.) (331) or by the ability to absorb exogenous folate (Enterococcus spp. and Lactococcus spp.) (332) or thymine (Enterococcus spp.) (333). The decreased access to the target enzyme in P. aeruginosa appears to be due to both a permeability barrier and active efflux from the cell (334, 335). The percentage contribution of each of these mechanisms to resistance remains unclear.

Acquired Resistance to Trimethoprim
Mutational resistance to trimethoprim has been described for several species and involves promoter mutations leading to overproduction of DHFR (in E. coli), point mutations within the dhfr gene leading to resistance (in S. aureus and S. pneumoniae), or both mechanisms (in H. influenzae) (336). More common is the acquisition of low-affinity dhfr genes, of which approximately 20 have been described (337). Expression of the dhfrI gene and variants of the dhfrII gene, which are most commonly found on plasmids in Gram-negative bacteria, increases resistance to levels greatly exceeding clinically achievable concentrations.

Acquired Resistance to Sulfonamides
Point mutations or small insertions of DNA segments within chromosomal dhps genes conferring resistance to sulfonamides have been reported for many different species (337, 338). More-extensive changes within dhps genes resulting in resistance have been reported for N. meningitidis and S. pyogenes. In these instances, the extensive changes have suggested acquisition of at least some parts of the dhps genes from other species via transformation and recombination (339). Plasmid-mediated, transferable resistance to sulfonamides has been reported for Gram-negative bacteria (338). Unlike with the diversity in dhfr genes, only two acquired low-affinity dhps genes (sulI and sulII) have been described. Genes conferring resistance to sulfonamides are frequently incorporated into MDR integrons, which are themselves frequently integrated into transferable plasmids. The transferability of these resistance plasmids and the frequent association with other resistance genes explain in part the widespread nature and persistence of resistance to
this antimicrobial combination. One trimethoprim-sulfamethoxazole-resistant *E. coli* strain was reported to have spread widely in the United States, causing urinary tract infections in young women in at least two states (340), although more-recent data suggest that this widespread prevalence may owe more to parallel emergence of related strains than to direct spread of an outbreak isolate (341).

**Mupirocin Resistance**

Mupirocin is a topical antimicrobial agent that can be used to treat skin and soft tissue infections, such as impetigo, or secondary wound infections caused by *Streptococcus pyogenes* or *S. aureus*. This drug is also used with increasing frequency to decolonize nasal passages of MRSA patients in an effort to reduce health care-associated MRSA infections or outbreaks of community-associated MRSA (342). The drug exerts antimicrobial activity by inhibiting the bacterium's isoleucyl tRNA synthetase and thereby inhibiting RNA and protein synthesis. Both low-level and high-level mupirocin resistance has been described for staphylococci. Low-level-resistance strains (MICs ≥8 μg/ml and ≤64 μg/ml) have acquired mutations in the native gene encoding isoleucyl tRNA synthetase. High-level-resistance strains (MICs ≥512 μg/ml) have acquired a gene encoding a novel isoleucyl tRNA synthetase, such as mupA. The clinical significance of low-level resistance is not well understood, but failure to decolonize or achieve sustained decolonization have been associated with mupA-mediated resistance. The mupA gene is commonly found on a conjugative plasmid, and rates of high-level mupirocin resistance tend to increase with increasing use of the topical agent. A new resistance determinant conferring high-level mupirocin resistance was identified in *S. aureus*. The gene, mupB, has low identity to mupA but encodes a protein with structural motifs common to isoleucyl tRNA synthetase. So far, only a single mupB-positive strain has been identified (343).

69. Mechanisms of Resistance to Antibacterial Agents

MCM 11th Edition

Mechanisms of Resistance to Antibacterial Agents

Determination of the antimicrobial susceptibilities of significant bacterial isolates is one of the principal functions of clinical microbiology laboratories. From the physician’s pragmatic point of view, the results of susceptibility tests are often considered important or more important than the identification of the pathogen involved. This is particularly true in an era of increasing antimicrobial resistance in which treatment options are at times limited to newer, more costly antibacterial agents. As a result, the laboratory must give high priority not only to producing technically accurate data but also to reporting those data to physicians in an easily interpretable manner.

The main objective of susceptibility testing is to predict the outcome of treatment with the antimicrobial agents tested. Results are generally reported as categories of susceptibility. The implication of the result category “susceptible” is that there is a high probability that the patient will respond to treatment with the appropriate dosage regimen for that antimicrobial agent. The result “resistant” implies that treatment with the antimicrobial agent is likely to fail. One group has coined the term “90-60 rule”; that is, for many infections, we can expect treatment success about 90% of the time when the organism tests as “susceptible” to that treatment, and success may still occur in around 60% of cases when the organism tests as “resistant” to the agent used (1). The 60% apparent response rate to ineffective antimicrobials is said to reflect the natural response to many bacterial infections in immunologically healthy hosts (2).

Most test methods also include an “intermediate” category of susceptibility, which can have several meanings. With agents that can be safely administered at higher doses (e.g., penicillins, cephalosporins), this category may imply that higher doses may be required to ensure efficacy or that the agent may prove efficacious if it is normally concentrated in an infected body fluid, e.g., urine. Conversely, for body compartments where drug penetration is restricted even in the presence of inflammation (e.g., cerebrospinal fluid), it suggests that extreme caution should be taken in the use of the agent. It may also represent a buffer zone that prevents truly resistant strains from being incorrectly categorized as susceptible and vice versa. Recently, one of the standard-setting bodies (the Clinical and Laboratory Standards Institute [CLSI]) added an additional interpretive category: “susceptible dose dependent.” This is designed to replace the “intermediate” interpretation where the agent is likely to be efficacious if approved dosing regimens resulting in higher exposures can be safely used (as, e.g., with many β-lactams).

A further aim of susceptibility testing is to guide the clinician in the selection of the most appropriate agent for a particular clinical problem. In most clinical settings, susceptibility test results are usually obtained 24 to 48 h or more after the patient has been given empirical treatment. The test results may confirm the susceptibility of the organism to the drug initially prescribed or may indicate resistance, in which case alternative therapy will likely be required. Where possible, the report describing the susceptibility testing results should provide the clinician with alternative agents to which the organism is susceptible. These alternatives also may be useful if the patient subsequently develops an adverse reaction to the initial antimicrobial agent. There is a growing emphasis from the professional societies, managed care organizations, and institutional stewardship programs on the use of susceptibility test results to direct therapy toward the most-narrow-spectrum, least-expensive agent to which the pathogen should respond. This is particularly true for hospitalized patients, in whom the rate of antimicrobial resistance tends to be higher, and it is easier to make therapeutic changes for inpatients than for outpatients. This makes the accuracy of susceptibility testing even more critical for effective patient care.

Clinical microbiology laboratories should perform susceptibility testing only with pathogens for which well-standardized methods are available and whose resistance is known or suspected of being a clinical problem; susceptibility testing should not be performed on normal microbiota or colonizing organisms. Currently, routine susceptibility testing methods are best standardized for common aerobic and facultative bacteria and systemic antibacterial agents. For some uncommon or highly fastidious bacteria and for most topical antibacterial agents, simple routine test methods have not been standardized. Taking into account this limitation, the CLSI has released recommendations on how some uncommon and fastidious bacteria may be tested and the results interpreted (3). With some pathogens (e.g., Mycobacterium tuberculosis and invasive fungi other than Candida spp.), routine testing is important for patient management, but testing is best performed by specialized laboratories in which test volumes are sufficient to maintain technical proficiency and where unusual or inaccurate results are likely to be recognized. Susceptibility testing methods for certain other pathogens (e.g., mycoplasmas, chlamydiae, legionellae, spirochetes, viruses, protozoa, and helminths)
may not be well established at present and/or are limited to a few specialty laboratories. A number of choices exist in antibacterial susceptibility testing with respect to methodology and selection of agents for routine testing.

SELECTING AN ANTIMICROBIAL SUSCEPTIBILITY TESTING METHOD

Clinical microbiology laboratories can choose from among several conventional or novel methods for performance of routine antibacterial susceptibility testing. These include the broth microdilution, disk diffusion, antimicrobial gradient, and automated instrument methods. In recent years, there has been a trend toward the use of commercial broth microdilution and automated instrument methods instead of the disk diffusion procedure. However, there remains ongoing interest in the disk diffusion test because of its inherent flexibility in drug selection, its ability to respond quickly to the introduction of new agents or changes in interpretive breakpoints, and its low cost. The availability of numerous antibacterial agents and the diversity of antimicrobial agent formulae of different institutions have made it difficult for manufacturers of commercial test systems to provide standard test panels that fit everyone’s needs. Thus, the inherent flexibility in drug selection that is provided by the disk diffusion test is an undeniable asset of the method. The test is also one of the most established and best proven of all susceptibility tests and continues to be updated and refined through frequent (usually annual) CLSI (4, 5) and European Committee on Antimicrobial Susceptibility Testing (EUCAST) (6, 7) publications. Instrumentation is now available for reading and interpreting zone diameters, as well as for storing this information, and may reduce interobserver reading errors (8–11).

Advantages of the microdilution and agar gradient diffusion methods include the generation of a quantitative result (i.e., an MIC) rather than a category result, the ability to test accurately some anaerobic or fastidious species that may not be tested by the disk diffusion method (3, 12–15), and the ancillary benefits of computer systems that accompany many of the microdilution and automated systems (14). Indeed, computerized management systems are very important in laboratories that may have limited or inflexible laboratory information systems. However, an MIC method should not be chosen on the basis that MICs are routinely more useful to physicians. There is no clear evidence that MICs are more relevant than susceptibility category results to the selection of appropriate antibacterial therapy for most infections (16, 17), although the integration of MIC results into a more detailed and patient-focused report has been suggested (18).

A laboratory may choose to perform rapid, automated antibacterial susceptibility testing in order to generate results faster than manual methods can generate them. The provision of susceptibility results 1 day sooner than that provided by conventional methods seems a logical advance in patient care, especially in cases of bacteremia (19–23). The impetus for more-rapid susceptibility tests has been boosted by the introduction of very rapid (same-day) mass-spectroscopic identification of bacterial pathogens into routine laboratories (24). Also emerging are rapid commercial PCR technologies capable of detecting critical resistances with same-day impact on antimicrobial treatment (25, 26). Several studies have demonstrated both the clinical and economic benefits derived from the use of rapid susceptibility testing and reporting (27–30), while a further study has not shown such a benefit (31). However, rapid susceptibility testing results may not have substantial impact unless the laboratory uses more-aggressive means of communication and makes physicians aware of the results (32). A previously cited shortcoming of rapid susceptibility testing methods was the failure to detect some inducible or subtle resistance mechanisms (33–36). However, the instruments most notorious for such problems are no longer marketed, and the manufacturers of the remaining instruments have made substantial efforts to correct earlier problems (37–40) or to extend testing to include fastidious organisms (41). It is important to emphasize that accuracy should not be sacrificed in an effort to generate a rapid susceptibility testing result.

SELECTING ANTIBACTERIAL AGENTS FOR ROUTINE TESTING

Laboratories have the responsibility of testing and reporting the antimicrobial agents that are most appropriate for the organism isolated, the site of infection, and the clinical practice setting in which the laboratory functions. The battery of antimicrobial agents routinely tested and reported on by the laboratory will depend on the characteristics of the patients under care in the institution and the likelihood of encountering highly resistant organisms (14). A laboratory serving a tertiary-care medical center that specializes in the care of immunosuppressed patients may need to test routinely agents that are broader in spectrum than those tested by a laboratory that supports a primary-care outpatient practice in which antibacterial-resistant organisms are less commonly encountered.

When a laboratory’s routine susceptibility testing batteries are determined, several principles should be followed. First, the antimicrobial agents that are included in the institution’s formulary and that physicians prescribe on a daily basis should be tested. Second, the species tested strongly influences the choice of antimicrobial agents for testing. The CLSI publishes tables that list the antimicrobial agents appropriate for testing various groups of aerobic and fastidious bacteria (5). The guidelines indicate the drugs that are most appropriate for testing against each organism group based on treatment success, resistance patterns, and in vitro activities of the agents (e.g., cerebrospinal fluid, blood, urine). The lists also provide a few agents that may be tested as surrogates for other agents because of the greater ability of a particular agent to detect resistance to closely related drugs (e.g., the use of the cefoxitin disk test to predict overall β-lactam resistance in staphylococci) (5). This initial list of agents must be tailored to an individual institution’s specific needs through discussions with infectious disease physicians, pharmacists, and committee members concerned with infection control and the institutional formulary (14).

A third important step in defining routine testing batteries is ascertaining the availability of specific antimicrobial agents for testing by a laboratory’s routine testing methodology. Certain methods (e.g., the disk diffusion, gradient diffusion, and in-house-prepared-broth and -agar dilution methods) allow the greatest flexibility in the selection of test batteries. In contrast, some commercial systems may have less flexibility or may experience delays in adding the latest antimicrobial agents approved for clinical use. However, practicality limits the maximum number of drugs that can be tested simultaneously with an isolate by any susceptibility testing method. For example, a maximum of 12 disks can be placed on a 150-mm-diameter Mueller-Hinton agar plate, and a similar number can ordinarily be accommodated in a microdilution panel if full concentration ranges of each
agent are to be included for routine determination of MICs. Most commercial test panels attempt to resolve this problem by testing a larger array of antimicrobial agents, although in a very limited concentration range (perhaps 2 to 4 dilutions for each agent).

**ESTABLISHING SUSCEPTIBILITY BREAKPOINTS**

There is general agreement that the MIC is the most basic laboratory measurement of the activity of an antimicrobial agent against an organism. It is defined as the lowest concentration that will inhibit the growth of a test organism over a defined interval related to the organism’s growth rate, most commonly 18 to 24 h. The MIC is the fundamental measurement that forms the basis of most susceptibility testing methods and against which the levels of drug achieved in human body fluids may be compared to determine breakpoints for defining susceptibility.

The conventional technique for measuring the MIC involves exposing the test organism to a series of 2-fold dilutions of the antimicrobial agent in a suitable culture system, e.g., broth or agar for bacteria. The 2-fold-dilution scheme was originally used because of the convenience of preparing dilutions from a single starting concentration in broth or agar dilution methods. Subsequently, this system proved to be meaningful because an antimicrobial’s MICs for a single bacterial species in the absence of resistance mechanisms have a statistically normal distribution when plotted on a logarithmic scale. This provides investigators with the opportunity to examine the distributions of MICs for bacterial populations and distinguish strains for which the MICs fall outside the normal distribution. How-ever, distributions of MICs have limited direct application since they vary between species, and for some strains for which the MICs are above the normal range, the MICs may be below clinically derived breakpoints. Recent evidence suggests that such strains are still likely to respond to treatment, a position agreed to by both the CLSI and EUCAST, although this position is still controversial for some resistance mechanisms (45).

**Pharmacokinetics and Pharmacodynamics**

Pharmacokinetics examines the absorption, distribution, accumulation, and elimination (metabolism and excretion) of a drug in the body over time. These parameters are usually determined using healthy volunteers. A drug’s MICs can be compared with the concentration of the drug achievable in blood or other body fluids (e.g., cerebrospinal fluid). In the past, breakpoints were chosen generally such that the MICs for susceptible pathogens would be exceeded by the drug level for most or all of the dosing interval. Newer data now considered when establishing breakpoints include pharmacodynamic calculations. Pharmacodynamics is the study of the time course of drug action against the microorganism. For antimicrobial agents, the desired action is pathogen eradication. In vitro pharmacodynamic studies have revealed that agents fall into three classes: those with principally time-dependent antimicrobial action and no or short postantibiotic effects, those with time-dependent action and long postantibiotic effects, and those with prominent concentration-dependent action (16). For drugs with time-dependent action and no or short postantibiotic effects, the critical determinant of bacterial killing in vivo is the percentage of time in a dosing interval that the drug concentration is above the MIC. For the other two classes, the important determinant is the ratio of the area under the concentration-time curve to the MIC and/or the ratio of the peak concentration to the MIC. For β-lactams, short-acting macrolides, and clindamycin, the relevant measure is the percentage of time that the drug concentration is above the MIC, and for aminoglycosides, long-acting macrolides, tetracyclines, glycopeptides, and fluoroquinolones, the ratio of the area under the concentration-time curve or of the peak concentration to the MIC is the relevant parameter (46, 47). These values can be used to calculate the maximum MICs or breakpoints that would allow the achievement of optimum efficacy with standard drug-dosing schedules.

**Clinical and Bacteriological Response Rates**

During clinical trials, the clinical and/or bacteriologic eradication response rates of organisms for which the MICs of new antimicrobial agents have been determined give an indication of the relevance of breakpoints selected by using the MIC distributions and the pharmacokinetic/pharmacodynamic properties of the drug. Response rates of at least 80% may be expected for organisms classified as susceptible, although the rates can be lower depending on the site and type of infection. While in some countries breakpoints are determined primarily from clinical and bacteriologic response rates, the CLSI and EUCAST evaluate clinical and bacteriological response rates in conjunction with population distributions, pharmacokinetics, and pharmacodynamics in establishing the breakpoints in an attempt to provide the best correlation between in vitro test results and clinical outcome (48, 49).
Inhibition Zone Diameter Distributions for Disk Diffusion Methods

Once the MIC breakpoints are selected, disk diffusion breakpoints can be chosen by plotting the inhibition zone diameters against the MICs derived from the testing of a large number of strains of various species. A statistical approach that uses the linear-regression formula has been used in the past to calculate the appropriate zone diameter intercepts for the predetermined MIC breakpoints, but this is no longer recommended. The usual, pragmatic approach to deriving disk diffusion breakpoints is the use of the error rate-bounded method, in which the zone diameter criteria are selected on the basis of the minimization of the disk interpretative errors, especially the very major errors (50, 51) (Fig. 1). Newer statistical techniques are being studied to improve the correlation with MICs (52). The newest CLSI approach focuses on the rate of interpretive errors near the proposed breakpoint versus those with MICs more than a single log₂ dilution from the MIC breakpoints (48). The concept is that errors that occur with isolates for which MICs are very close to the MIC breakpoints are less of a concern than errors with more highly resistant or susceptible strains.

Breakpoints derived by professional groups or regulatory bodies in various countries are often quite similar. For instance, there is a small number of breakpoint discrepancies between the CLSI and the U.S. Food and Drug Administration, and these are under review by both groups. However, there can be notable differences in the breakpoints used in different countries or regions for the same agents. The reasons for the differences may be that certain countries use different dosages or administration intervals for some drugs. In addition, some countries are more conservative in assessing the susceptibility to antimicrobial agents and place greater emphasis on the detection of emerging resistance, noted primarily by examination of microorganism population distributions. Technical factors, such as the inoculum density, atmosphere of incubation, and test medium, can also affect MICs and zone diameters, thereby justifying different interpretive criteria in some countries. These technical differences are summarized in chapter 71 of this Manual. Two non-U.S. methods minimize or avoid the use of an intermediate category of susceptibility, based on the rationale that such results are of little value to clinicians (53, 54). The lack of a buffer between susceptible and resistant categories can result in higher rates of incorrect categorization. It may be safer for a laboratory to employ a method that uses an intermediate category or, if not, to report intermediate results as resistant.

Information on a range of international susceptibility testing methods that are known to conform to the International Organization for Standards reference method and their associated breakpoint documents can be downloaded or purchased from the following websites: the CLSI website at http://www.clsi.org and the EUCAST website at http://www.eucast.org (EUCAST now sets or harmonizes breakpoints for all its member countries).

MOLECULAR DETECTION OF RESISTANCE

As highlighted in chapter 77, there is now a range of molecular techniques for the detection of many resistance genes. While none are currently recommended for routine testing, some have found a place in larger laboratories, where detection of certain important resistance genes can be implemented in a cost-effective manner. Examples include the detection of mecA in Staphylococcus species, especially Staphylococcus aureus, and the detection of vanA and vanB genes in Enterococcus species. In addition, molecular techniques are now available for the rapid detection of methicillin-resistant S. aureus and coagulase-negative staphylococci, vancomycin resistance genes in enterococci, and certain resistance genes in Gram-negative bacteria from positive

![FIGURE 1](Comparison of zone diameters with MICs of a hypothetical antimicrobial agent. doi:10.1128/9781555817381.ch70.f1)
SELECTED USE OF CONFIRMATORY AND SUPPLEMENTARY TESTS

While performing routine testing, a laboratory will encounter isolates or tests results (i) that are unexpected, (ii) for which there is no testing guidance available, or (iii) which are considered to be of major epidemiological importance. The CLSI and EUCAST provide some guidance on what resistances might be considered unexpected (either uncommon or never reported (5,61). Recommendations on how to proceed vary, but if results are not attributable to simple laboratory errors and are reproducible, then testing by an alternative method and, if necessary, referral to a reference laboratory are warranted. For some key resistances, e.g., carbapenem resistance in Enterobacteriaceae, the most effective confirmatory method is resistance gene detection, as described in chapter 77. In other circumstances, one of the special phenotypic tests described in chapter 73 will suffice.

Inducible resistance is considered to be clinically important for a small number of antimicrobial-bacterial combinations. At present, only methods for detecting inducible resistance to clindamycin in Staphylococcus and Streptococcus species have been sufficiently evaluated and standardized to be recommended for routine laboratory use (5).

For some clinical conditions, e.g., bacterial meningitis caused by Streptococcus pneumoniae, susceptibility test interpretation and clinician guidance can be enhanced by performing MIC measurements if these data were not generated by the laboratory’s routine method. Customized or locally prepared microtiter trays may be used or, alternatively, tested by a commercial gradient diffusion method (62).

REPORTING OF RESULTS

The reporting of results is the crucial final step in susceptibility testing. There are no universally agreed upon practices for generating reports, but the following elements should be considered. Categorical reporting, that is, reporting the test results as susceptible (S), intermediate (I), or resistant (R), is standard practice and widely understood by clinicians. When available, MIC data may be reported but should appear only along with a categorical interpretation. Susceptibility test reports should be formatted in such a way that the results are unambiguous in either a printed or an electronic form, especially if reporting more than one organism. Most importantly, so-called cascade reporting is recommended to reduce the chance of the clinician choosing a broader-spectrum antimicrobial agent inappropriately (18, 63). Cascade reporting involves the withholding of results for broader-spectrum antimicrobials from the report when the isolate tested is susceptible to narrower-spectrum agents, e.g., withholding a vancomycin result when an isolate of Staphylococcus aureus tests as susceptible to oxacillin or cefoxitin. Such reporting is considered to be an essential part of hospital antimicrobial stewardship programs (64, 65), as is the production of annual reports that summarize overall susceptibility and resistance patterns (antibiograms) (66).

FUTURE DIRECTIONS AND NEEDS IN ANTIMICROBIAL SUSCEPTIBILITY TESTING

Antimicrobial resistance is becoming widespread among a variety of clinically significant bacterial species (67). Therefore, microbiology laboratories play a key role in the patient management process by providing accurate data on which physicians can base therapy decisions. Susceptibility testing results, however, are also used by investigators in surveillance studies and by infection control practitioners to detect and control the spread of antibiotic-resistant organisms (66, 68). Surveillance can be performed at the laboratory, local, regional, national, and international levels through direct interchange of data from laboratory information systems to centralized databases (68). Thus, the accuracy of stored results becomes almost as important as the accuracy of test performance and interpretation.

To meet these challenges and responsibilities, clinical microbiologists must continuously assess and update their susceptibility testing strategies. The first priority is to use accurate and reliable methods, whether they are conventional or perhaps newer molecular methods. Then, careful monitoring of test performance with well-characterized control strains that challenge the capability of the testing methods becomes essential. Today, laboratories must use a variety of testing methods, each tailored specifically to a particular species or group of organisms. It is not likely that a single method, whether conventional or commercial, will be optimal for all antimicrobial agents, organisms, and resistance mechanisms. This will require increased education and training for clinical microbiologists in the future. Some assistance may be sought from the computer-based “expert” systems that allow a rapid and accurate view of antimicrobial susceptibility profiles and recognition of potentially aberrant results or novel resistance mechanisms (61). Rapid progress is also being made on molecular methods that are starting to have practical application in routine clinical laboratories (chapter 77).

More-effective means of conveying critical antimicrobial susceptibility testing information to clinicians in a time frame that allows efficient and effective management of patients and in a format that is unambiguous to clinicians in various practice specialties are still needed. Clinical microbiologists should become more proactive in the reporting of antimicrobial susceptibility results and in cross-linking that information to other databases (e.g., those for pharmacy prescriptions) to ensure that patients receive the most efficacious cost-effective therapy.

I thank James Jorgensen and Mary Jane Ferraro for valuable contributions to past versions of this chapter.

Susceptibility Test Methods: Dilution and Disk Diffusion Methods*

James H. Jorgensen and John D. Turnidge

There are a number of methods for antimicrobial susceptibility testing of bacteria, which can be categorized into (i) dilution methods that generate MIC results and (ii) disk diffusion methods that generate a zone diameter result. Susceptibility testing methods can also be categorized as generic reference methods, which are described by standards-setting organizations (e.g., The Clinical and Laboratory Standards Institute [CLSI], The European Committee on Antimicrobial Susceptibility Testing [EUCAST], The British Society for Antimicrobial Chemotherapy [BSAC], and the International Organization for Standardization [ISO, Geneva, Switzerland]), and commercial methods, which are mostly mechanized or automated (e.g., MicroScan [Siemens Healthcare Diagnostics, Deerfield, IL], Vitek 2 [bioMérieux, Durham, NC], Phoenix [BD, Sparks, MD], and Sensititre ARIS [Thermo Fisher Scientific, Cleveland, OH]) or gradient diffusion methods (e.g., Etest [bioMérieux, Durham, NC], or M.I.C.Evaluators [Oxoid, Basingstoke, United Kingdom]). Generic reference methods are those in which the reagents for testing can be obtained from multiple sources and prepared in a laboratory without the need for sophisticated manufacturing processes. The CLSI reference methods are broth macrodilution, broth microdilution, agar dilution, and disk diffusion (1, 2). EUCAST advocates both broth microdilution and disk diffusion methods (http://www.EUCAST.org), and the global standard reference method described by ISO is broth microdilution (3).

The choice of methods to be used in individual laboratories is based on factors such as relative ease of performance, cost, flexibility in selection of drugs for testing, availability of automated or semiautomated devices to facilitate testing, and the perceived accuracy of the methodology (4). Reference dilution methods are typically used by pharmaceutical companies to establish MIC data for new antimicrobial agents, by research laboratories and device manufacturers as a standard by which new susceptibility testing methods are evaluated, and by reference laboratories for confirming unusual susceptibility test results. Although it has become increasingly uncommon, some clinical microbiology laboratories use reference dilution methods for routine diagnostic testing, including preparing their own broth microdilution panels or agar dilution plates. More frequently, clinical microbiology laboratories use automated systems or a combination of MIC and disk diffusion methods for routine susceptibility testing.

Interpretive categories for antimicrobial agent test results (i.e., susceptible, intermediate, susceptible-dose dependent, resistant, and nonsusceptible) are established for MIC values and then disk diffusion methods based on MIC data so that interpretive errors between methods are minimized (5). Briefly, interpretive categories, or breakpoints, are first established for MIC results generated by either the broth or agar reference method. These breakpoints are based upon the normal MIC distributions for a wild-type bacterial species, MIC distributions for strains with known resistance mechanisms affecting the drug class, pharmacokinetic/pharmacodynamic (PK/PD) data from animal models of infection and modeling of human PK/PD data, and data from clinical outcome studies. Subsequently, disk diffusion breakpoints are set by comparing disk diffusion zone diameters on a large collection of strains to MIC data and choosing breakpoints so that interpretive errors between methods are within acceptable limits (a more detailed description is provided later in this chapter). Interpretive categories for MIC methods and disk diffusion are established after both intralaboratory and interlaboratory reproducibility are verified for these methods. Since interpretive criteria of disk diffusion data are set so that there is optimal correlation with MIC results, in most cases, one method of susceptibility testing is not superior to the other. However, there are specific examples of when one method may be preferred. Daptomycin, polymyxin B, and colistin are antimicrobial agents that do not diffuse well in agar, so in most cases, disk diffusion is not an accurate method for these agents and MIC methods are recommended (6, 7). MIC tests are also recommended for susceptibility testing of staphylococci to vancomycin because vancomycin susceptibility testing by disk diffusion is not an accurate method for distinguishing vancomycin-intermediate from vancomycin-susceptible staphylococci (8). Also, MIC testing is necessary for accurate category assignment of Streptococcus pneumoniae isolates to penicillin, several cephalosporins, and carbapenems (9). For some bacteria, there are limited or no disk diffusion data available from well-controlled studies; thus, establishing interpretive criteria for most drugs of interest is not feasible (e.g., Stenotrophomonas maltophilia, Bacillus spp.,

*This chapter contains information presented by Jean B. Patel, Fred C. Tenover, John D. Turnidge, and James H. Jorgensen in chapter 68 of the 10th edition of this Manual.
**Corynebacterium** spp., **Lactobacillus** spp., **Leuconostoc** spp.). An example of a disk diffusion test being preferred to MIC testing is the cefoxitin disk test to predict **mecA**-mediated **β**-lactam resistance in coagulase-negative *Staphylococcus* (10). The disk test is more accurate than cefoxitin or oxacillin MIC testing for detecting **mecA**-mediated resistance in those species.

When MIC testing is performed, CLSI recommends reporting the MIC value along with the interpretive category, but for disk diffusion testing, only the interpretive category should be reported. In most instances, the actual MIC value does not significantly impact patient management, except for cases of endocarditis and meningitis when MIC values direct the appropriate choice of therapy and dosage (11). However, most clinicians typically use only the interpretive category to make their treatment decisions. MIC results also can be informative for epidemiological purposes for multiply resistant isolates. For epidemiological purposes, emerging resistance mechanisms may be identified among those isolates where the antimicrobial agent MIC is above the normal MIC distribution for isolates of the same species (sometimes called epidemiologic cutoff values) but may be within the clinically susceptible or intermediate category for that agent. A valuable source of normal MIC distributions for various bacterial/antimicrobial agent combinations is the EUCAST website (http://www.escmid.org/research_projects/eu_cast/) that describes epidemiologic cutoff values separating wild-type MIC distributions from those of strains that contain a known resistance mechanism.

There are several instances where elevated, but susceptible, MIC information is useful. For example, isolates of *Enterobacteriaceae* that show elevated fluoroquinolone MICs but that are still in the susceptible category may possess a first-step fluoroquinolone mutation (of *gyrA*) or possibly a plasmid-mediated fluoroquinolone resistance mechanism that may either reduce the effectiveness of the drug, as with *Salmonella enterica* serovar Typhi or *Salmonella enterica* serovar Paratyphi infections (12), or allow the organism to survive long enough to develop high-level resistance (13). Similarly, an elevated, but susceptible-range, cephalosporin MIC in an isolate of the *Enterobacteriaceae* using the older breakpoints (pre-2010) may indicate production of an extended-spectrum **β**-lactamase (ESBL). When using the revised CLSI cephalosporin breakpoints for the *Enterobacteriaceae*, tests for ESBL detection are no longer required for the care of individual patients, but ESBL production is useful information for epidemiological and infection control purposes. When treating an infection caused by a multi-drug-resistant isolate, which may be susceptible only to a single antimicrobial agent, clinicians may consider using only agents that give intermediate or even resistant results at an alternative dose, a different route of administration to optimize drug concentrations at the site of infection, or combinations of agents to try and effect a cure (14). An MIC result combined with agent-specific PK/PD data may help to guide this decision.

The selection of antibacterial agents for testing is complicated by the large number of agents available today and the diversity of institutional formularies. A few of these compounds, however, exhibit similar if not identical activities in vitro, so that in some cases, one compound can be tested as a surrogate to represent one or more closely related compounds. The number of such extrapolations has diminished over time as resistance mechanisms have complicated the predictive value of testing surrogate markers. Use of drug surrogates can reduce the number of agents required for testing and, in some cases, provide necessary flexibility in adapting commercial test systems for routine use in a different institution. For instance, the susceptibility of *Staphylococcus* spp. to oxacillin (or cefoxitin) is extrapolated to apply to all currently available penicillinase-stable penicillins, most cephalosporins (with the exception of the anti-MRSA [meticillin-resistant *Staphylococcus aureus*] cephalosporins, e.g., cefaroline and cefotibiprole), penicillin-**β**-lactamase inhibitor combinations, and all current carbapenems. Thus, it is unnecessary to test any of the agents in these chemical classes other than penicillin, oxacillin, cefoxitin, and ceftaroline (1).

It is important that microbiologists work with members of the institution's pharmacy and therapeutics committee to ensure that the antibacterial agents being tested in the laboratory reflect those in the institution’s current formulary (15). Doing so can contribute to the hospital’s efforts to improve antimicrobial stewardship (16). Guidelines for the selection of antibacterial agents to be tested routinely are published annually by the CLSI (10) and are summarized in Table 1. While this listing is sometimes regarded rigidly as the standard for selecting the agents that must be tested, it is a list of agents that should be considered for routine testing only; many variables go into the final decision as to which agents should be tested in any particular setting (17). The CLSI also cautions that the decision about testing and reporting of some agents selectively should be made by the clinical microbiologist in conjunction with the infectious disease practitioners, the pharmacy, and/or the infection control committees (1, 10).

### Dilution Methods

**Broth and agar diffusion** susceptibility testing methods are used to determine the minimal concentration, usually in micrograms per milliliter, of an antimicrobial agent required to inhibit or kill a microorganism. Antimicrobial agents are usually tested at log₂ (2-fold) serial dilutions, and the lowest concentration that inhibits visible growth of an organism is designated the MIC. The concentration range used may vary with the drug, the organism being tested, and the site of infection (e.g., cerebrospinal fluid in meningitis). Ranges should encompass the concentrations defining the interpretative categories (i.e., susceptible, intermediate, susceptible-dose dependent, and resistant) and also the ranges that include the expected MICs for quality control reference strains. Other dilution methods include those that test a single concentration or a selected few concentrations of antimicrobial agents (i.e., breakpoint susceptibility tests and single-drug concentration screens) (see below).

Dilution methods offer flexibility in the sense that the standard medium used to test frequently encountered organisms (e.g., *Staphylococci*, enterococci, members of the family *Enterobacteriaceae*, and *Pseudomonas aeruginosa*) may be supplemented or even replaced with another medium to allow accurate testing of certain fastidious bacterial species that may not be reliably tested by disk diffusion (see chapters 74 and 75). Broth dilution methods form the basis of testing performed by the current automated commercial test systems (see chapter 72).

### Dilution Testing: Agar Method

**Dilution Testing: Agar Method**

**Dilution of Antimicrobial Agents**

The solvents and diluents needed to prepare stock solutions of most commonly used antimicrobial agents are listed in the CLSI document on dilution testing (1).

<sup>a</sup>Modified from the CLSI M100 document (10) with permission. Current standards and supplements to them may be obtained from the CLSI, 950 West Valley Rd., Suite 2500, Wayne, PA 19087-1898. [www.clsi.org](http://www.clsi.org)

<sup>b</sup>Group A comprises primary drugs to be tested and reported, group B comprises those to be tested as primary drugs but reported selectively, group C comprises supplemental drugs to be reported selectively, and group U comprises drugs to be tested with urinary isolates only.

<sup>c</sup>Non-<em>Enterobacteriaceae</em> include <em>Pseudomonas</em> spp. and other nonfastidious, non-glucose-fermenting Gram-negative bacilli but exclude <em>P. aeruginosa</em>, <em>Acinetobacter</em> spp., <em>Burkholderia cepacia</em>, <em>B. mallei</em>, <em>B. pseudomallei</em>, and <em>Stenotrophomonas maltophilia</em>, since there are separate listings of suggested drugs to test and report for them.

<sup>d</sup>Those agents marked with an asterisk (*) should be tested only by using an MIC method and not by using disk diffusion.

<sup>e</sup>Results of tests with penicillin apply to other penicillins (e.g., ampicillin, amoxicillin, carbapenicillins, and ureidopenicillins) against β-lactamase-negative enterococci.

<sup>f</sup>Combination therapy consisting of penicillin, ampicillin, or vancomycin and an aminoglycoside is recommended.

<sup>g</sup>Staphylococci resistant to the penicillinase-resistant penicillins should also be considered resistant to penicillins, β-lactam-β-lactamase inhibitor combinations, cephalosporins (except cephalosporins with anti-MRSA activity, e.g., ceftaroline and ceftobiprole), and carbapenems.

<sup>h</sup>Cefoxitin is used as a surrogate for oxacillin for staphylococci.

<sup>i</sup>For use of aminoglycosides to screen enterococci for synergy resistance, see the sections “Breakpoint Susceptibility Tests” and “Resistance Screens.”

<sup>j</sup>Doxycycline or minocycline may be tested on a supplemental basis because of their greater activities against some nonfermentative Gram-negative bacilli and staphylococci.
**Preparation, Supplementation, and Storage of Media**

Mueller-Hinton agar is the recommended medium for testing most commonly encountered aerobic and facultatively anaerobic bacteria (1). The dehydrated agar base is commercially available and should be prepared as described by the manufacturer. Before sterilization, the molten agar is usually distributed into screw-cap tubes in exact aliquots sufficient to dilute the desired antimicrobial concentrations 10-fold. Tubes of agar, one for each drug concentration to be tested, are sterilized by autoclaving at 121°C for 15 min, and the agar is allowed to equilibrate to 48 to 50°C in a preheated water bath. Once the molten agar has equilibrated, the appropriate volume of antimicrobial agent is added, the tube contents are mixed by gentle inversion and poured into 100-mm-diameter round or square sterile plastic petri plates set on a level surface, and the agar is allowed to solidify. For growth controls, agar plates without antimicrobial agents are also prepared. All plates should be filled to a depth of 3 to 4 mm (20 to 25 ml of agar per round plate and 30 ml per square plate), and the pH of each batch should be checked to confirm the acceptable pH range of 7.2 to 7.4 (1).

After sterilization and temperature equilibration of the molten agar, any necessary supplements are aseptically added to the Mueller-Hinton agar at the time of addition of the drug solutions. For testing of streptococci, supplementation with 5% defibrinated sheep or horse blood is recommended (1). However, sheep blood supplementation may antagonize the activities of sulfonamides and trimethoprim with some organisms (18). The presence of blood also affects results with novobiocin and nafcillin as well as the in vitro activities of cephalosporins against enterococci (19, 20); therefore, blood supplementation should not be used unless necessary for bacterial growth (see chapter 74 for acceptable methods for testing of fastidious bacterial species). Performance standards and the ionic composition of Mueller-Hinton agar have been defined and do not require calcium or magnesium supplementation to achieve expected results (21). The agar should be supplemented with 2% NaCl if testing of oxacillin against staphylococci is being performed (22).

Once prepared, plates should be sealed in plastic bags and stored at 4 to 8°C. In general, they should be used within 5 days of preparation or as long as the MICs for control strains that are tested concomitantly are within the acceptable ranges. However, certain agents are sufficiently labile that plates may not be stored prior to use, e.g., carbenems, cefaclor, and clavulanic acid. Before inoculation, plates that have been stored under refrigeration should be allowed to equilibrate to room temperature, and the agar surface should be dry prior to inoculation.

**Inoculation Procedures**

Variations in inoculum size may substantially affect MICs; therefore, careful inoculum standardization is required to obtain accurate results. The recommended final inoculum for agar dilution is 10⁶ CFU per spot (1). This may be achieved in either of two ways. Four or five colonies are picked from overnight growth cultures on agar-based media and inoculated into 4 to 5 ml of suitable broth that will support good growth (usually tryptic soy broth). Broths are incubated at 35°C until visibly turbid, and then the suspension is diluted until it matches the turbidity of a 0.5 McFarland, barium sulfate (BaSO₄), or latex particle turbidity standard (ca. 10⁸ CFU/ml). The 0.5 McFarland standard may be purchased or the barium sulfate standard may be prepared as described in the CLSI document (1).

The accuracy of the standard should be verified by using a spectrophotometer with a 1-cm light path; for the 0.5 McFarland standard, the absorbance at 625 nm should be 0.08 to 0.13 (1). An alternative inoculum standardization method, one that is preferred by many microbiologists, utilizes direct suspension of colonies from overnight growth cultures on a nonselective agar medium in saline or broth to a turbidity that matches the 0.5 McFarland standard. This approach eliminates the time needed for growing the inoculum in broth (1). In either case, normal saline or sterile broth is used to make a 1:10 dilution of the suspension to give an adjusted concentration of 10⁷ CFU/ml (1).

Once the adjusted bacterial inoculum suspension is prepared, inoculation of the antimicrobial agent plates should be accomplished within 15 min, since longer delays may lead to changes in inoculum size. By using a pipette, a calibrated loop, or more commonly, an inoculum-replicating device, 0.001 to 0.002 ml (1 to 2 μl) of the 10⁷-CFU/ml suspension is delivered to the agar surface, resulting in the final desired inoculum of approximately 10⁵ CFU per spot. For convenience, use of a replicator is preferred, because consistent inoculum volumes for up to 36 different isolates are delivered simultaneously (1, 23). To use this device, an aliquot of the adjusted inoculum for each isolate is pipetted into the appropriate well of an inoculum seed plate and a multipronged inoculator is used to pick up and gently transfer 1 to 2 μl from the wells to the agar surfaces. Replicators are also available that deliver only 0.1 to 0.2 μl per spot and that do not require the 0.5 McFarland standard suspension to be diluted prior to delivery to the agar surface (1). The surfaces of the agar plates must be dry before inoculation, which should begin with a growth control plate that does not contain drug. Then inoculation continues from plates with the lowest drug concentration to plates with the highest drug concentration. Finally, a second growth control plate that does not contain drug is inoculated to check for contamination or significant carryover of the antimicrobial agent. All plates should be clearly marked so that the locations of the different isolates being tested on each plate are known.

**Incubation**

Inoculated plates are allowed to stand for several minutes until the inoculum drops have been completely absorbed by the medium; then they are inverted and incubated in air at 35°C for 16 to 20 h before results are read. To facilitate detection of vancomycin-resistant enterococci and methicillin-resistant or vancomycin-resistant or -intermediate staphylococci, plates containing vancomycin or oxacillin should be incubated for a full 24 h before results are read (1). Incubation should not be carried out in the presence of an increased CO₂ concentration unless a fastidious organism is being tested (see chapter 74).

**Interpretation and Reporting of Results**

Before reading and recording the results obtained with clinical isolates, those obtained with applicable quality control strains tested at the same time should be checked to ensure that their values are within the acceptable ranges (see “Quality Control” below) and the drug-free control plates should be examined for isolate viability and purity. Endpoints for each antimicrobial agent are best determined by placing plates on a dark background and examining them for the lowest concentration that inhibits visible growth, which is recorded as the MIC. A single colony or a faint haze left by the initial inoculum should not be regarded as growth. If two or more colonies persist at antimicrobial
concentrations beyond an otherwise obvious endpoint or if there is no growth at lower concentrations but there is growth at higher concentrations, the isolate should be sub-cultured to confirm purity and the test should be repeated. Substances that may antagonize the antibacterial activities of sulphonamides and trimethoprim may be carried over with the inoculum and cause "trailing," or less definite endpoints (18, 19). Therefore, the MICs of these antimicrobial agents should be interpreted as the endpoints at which 80% or more diminution of growth occurs. Although much less pronounced, trailing endpoints may also occur for some organisms with bacteriostatic drugs such as chloramphenicol, the tetracyclines, linezolid, and quinupristin-dalfopristin (1).

The MIC of each antimicrobial agent is usually recorded in micrograms per milliliter, although in Europe and in the international (ISO) standard reference method, the values are expressed as milligrams per liter (4, 24, 25). These quantitative results should be reported with the appropriate corresponding interpretive category (susceptible, intermediate, or resistant), or the interpretive category may be reported alone. The MIC interpretive standards for these susceptibility categories, as currently recommended by the CLSI (1), are provided in Table 2. For detailed instructions concerning the use of these criteria and categories, the latest CLSI standards for dilution testing methods should be consulted (10).

The five interpretive categories are defined as follows. Susceptible indicates that an infection caused by the tested microorganism may be appropriately treated with the usually recommended regimen of the antimicrobial agent (i.e., the appropriate dose for the recommended period of time). Intermediate indicates that the isolate may be inhibited by attainable concentrations of certain drugs (e.g., the β-lactams) if higher dosages or prolonged infusions can be used safely or if the infection involves a body site where the drug is physiologically concentrated (e.g., the urinary tract). The intermediate category also serves as a buffer zone that prevent slight technical artifacts from causing major interpretive discrepancies. Susceptible-dose dependent focuses specifically on those agents that can be safely administered in higher dosages than those used to set the susceptible breakpoints or by prolonged infusions to increase exposure times at the site of infection. Resistant isolates are not inhibited by the concentration of antimicrobial agent normally achievable with the recommended dose and/or yield results that fall within a range indicating that specific resistance mechanisms are likely to be present (1). The term "nonsusceptible" is used when no resistance breakpoint has been defined for an organism-drug combination because of the absence or rare occurrence of resistant strains (e.g., daptomycin and staphylococci).

Advantages and Disadvantages

Dilution testing by the agar method is a well-standardized, reliable susceptibility testing technique that may be used as a reference method for evaluating other testing methods. In addition, the simultaneous testing of a large number of isolates with a few drugs is efficient (such as when new agents are evaluated in the pharmaceutical industry). Microbial contamination or population heterogeneity is more readily detected by the agar method than by broth methods. The agar dilution method has been considered the reference test method in some areas of Europe (26), while broth microdilution has been much more widely used for research and clinical testing in North America (17) and is now considered the international reference method for determining MICs (3). The major disadvantages of the agar method are associated with the time-consuming and labor-intensive tasks of preparing the plates, especially if the number of different antimicrobial agents to be tested for each isolate is high or if only a few isolates are to be tested. Also, agar dilution is not always evaluated as a susceptibility testing method for newer antimicrobial agents. For example, agar dilution has not been validated for susceptibility testing of ceftaroline, daptomycin, and doripenem (10).

DILUTION TESTING: BROTH METHODS

The general approaches for broth methods include broth macrodilution, in which the broth volume for each antimicrobial concentration is ≥1.0 ml (usually 2 ml) contained in test tubes, and broth microdilution, in which antimicrobial dilutions are most often in 0.1-ml volumes in wells of 96-well microdilution trays.

Broth Macrodilution Methods

Dilution of Antimicrobial Agents

Stock solutions are prepared as discussed in the CLSI document on dilution testing (1) and are the same as those used for agar dilution tests. As in the agar method, the actual volumes used for the dilutions would be proportionally increased according to the number of tests being prepared, with a minimum of 1.0 ml needed for each drug concentration. Because addition of the inoculum results in a 1:2 dilution of each concentration, all final drug concentrations must be prepared at twice the actual desired testing concentration (see "Inoculation Procedures" below).

Preparation, Supplementation, and Storage of Media

Cation-adjusted Mueller-Hinton broth (CAMHB) is recommended for routine testing of commonly encountered nonfastidious organisms (1). Adjustment of the cations Ca²⁺ (20 to 25 mg/liter) and Mg²⁺ (10 to 12.5 mg/liter) is required to ensure acceptable results when Pseudomonas aeruginosa isolates are tested with aminoglycosides and when tetracycline is tested with other bacteria (27). However, for convenience and consistency, cation adjustment of Mueller-Hinton broth is now recommended for testing of all species and antimicrobial agents (1). Some manufacturers provide Mueller-Hinton broth that already has appropriate concentrations of divalent cations, so that the cation content of commercial dehydrated media must be ascertained and care must be taken to supplement only those commercial broths that have not already been adjusted. If adjustment is necessary, it can be accomplished by the addition of suitable volumes of filter-sterilized, chilled CaCl₂ stock (3.68 g of CaCl₂ · 2H₂O dissolved in 100 ml of deionized water for a concentration of 10 mg of Ca²⁺ per ml) and MgCl₂ stock (8.36 g of MgCl₂ · 6H₂O in 100 ml of deionized water for a concentration of 10 mg of Mg²⁺ per ml) to the cooled broth (1). Insufficient cation concentrations result in increased aminoglycoside activity (28), and excess cation content results in decreased aminoglycoside activity against P. aeruginosa (28, 29). While the effects of inappropriate calcium and magnesium ion contents are well recognized, other ions, including zinc and manganese, may adversely affect the activities of some drugs, e.g., carbapenem (30). Other supplements to CAMHB may be required for accurate susceptibility results of specific agents. For example, accurate daptomycin testing requires a calcium supplement so that the final concentration is 50 mg/liter (1, 31) and detection of staphylococcal resistance to oxacillin requires that the CAMHB be supplemented with 2% NaCl (1, 32). (Continued on next page)
susceptibility testing of tigecycline requires that the CAMHB be prepared fresh on the day of testing or frozen within 12 h of preparation (10).

To minimize evaporation and deterioration of antimicrobial agents, tubes should be tightly capped and stored at 4 to 8°C until needed. With most agents, the dilutions should be used within 5 days of preparation or as long as quality control ranges are maintained (see "Quality Control" below). As in agar dilution testing, certain β-lactam agents are too labile for prolonged storage at final test concentrations.

### Inoculation Procedures

The recommended final inoculum for broth dilution testing is $5 \times 10^4$ CFU/mL. Isolates are inoculated into a broth that will support good growth (such as tryptic soy broth) and incubated until turbid. The turbidity is adjusted to match that of a 0.5 McFarland standard (approximately $10^5$ CFU/mL). Alternatively, four or five colonies from overnight growth cultures on a nonselective agar plate may be directly suspended in broth to match the turbidity of the 0.5 McFarland standard (1). A portion of the standardized suspension is diluted independently 1:100 (to $10^6$ CFU/mL) with broth or saline. When 1 ml of this dilution is added to each tube containing 1 ml of CAMHB containing the 2x concentrated drug dilutions, a final inoculum of $5 \times 10^5$ CFU/ml is achieved. Broth not containing an antimicrobial agent is inoculated as a control for organism viability (growth control). All tubes should be inoculated within 30 min of inoculum preparation, and an aliquot of the inoculum should be plated to check for purity.

### Incubation

Tubes are incubated in ambient air at 35°C for 16 to 24 h before MICs are determined. Incubation should be extended to a full 24 h for the detection of vancomycin-resistant enterococci and oxacillin-resistant or vancomycin-resistant or -intermediate staphylococci (1). An atmosphere with increased CO$_2$ should not be used.

### Interpretation and Reporting of Results

Before MICs for the test strains are read and recorded, the growth controls should be examined for viability, inoculum subcultures should be checked for contamination, and appropriateMICs for the quality control strains should be confirmed (see "Quality Control" below). Growth or lack thereof in the antimicrobial agent-containing tubes is best determined by comparison with the growth control. Generally, growth is indicated by turbidity, a single sedimented button of $>2$ mm in diameter, or several buttons with smaller diameters. As with the agar method, trailing endpoints may be seen when trimethoprim or sulfonamides are tested, and the concentration at which 80% or greater diminution of growth is observed is recorded as the MIC (1). Other interpretation problems include the "skipped tube" phenomenon, in which growth is not observed at one concentration but is observed at lower and higher drug concentrations. Most authorities suggest that when this occurs, the skipped tube should be ignored and the concentration that finally inhibits growth at serially higher concentrations should be recorded as the MIC. If more than one skipped tube occurs or if there is growth at higher antimicrobial concentrations but not at lower ones, the results should not be reported and the test for that drug should be repeated.

71. Dilution and Disk Diffusion Methods ■ 1261
The lowest concentration that completely inhibits visible growth of the organism as detected by the unaided eye is recorded as the MIC. The CLSI MIC interpretive standards in effect as of the date of this writing (10) for the susceptibility categories are provided in Table 2. The definitions of and comments concerning these categories that were given for the agar method also pertain to the broth macrodilution method.

Advantages and Disadvantages
The broth macrodilution method is a well-standardized and reliable method that may be useful for research purposes or for testing of one drug with a bacterial isolate. However, because of the laborious nature of the procedure and the availability of more-convenient dilution systems (e.g., microdilution), this procedure is generally not useful for routine susceptibility testing in most clinical microbiology laboratories.

Broth Microdilution Method
The convenience afforded by the availability of dilution susceptibility testing in microdilution trays has led to the widespread use of broth microdilution methods. In fact, the broth microdilution method is now considered the international reference susceptibility testing method (3). The disposable plastic trays, containing a panel of several antimicrobial agents to be tested simultaneously, may be prepared in-house or obtained commercially either frozen or freeze-dried. When commercial systems are used, the manufacturer’s recommendations concerning storage, inoculation, incubation, and interpretation should be followed. The primary focus of this section will be the in-house preparation and use of broth microdilution panels. However, most of the principles and practices discussed here are pertinent to the broth microdilution method regardless of the source of the antibiotic panels.

Dilution of Antimicrobial Agents
Antimicrobial stock solutions are prepared as outlined in the CLSI document on dilution testing (1). The dilution scheme for preparing broth microdilution panels is the same as that described for agar and broth macrodilution methods. Automated dispensing systems for preparation of microdilution panels use tubes that contain from 10 to 200 ml or more of broth containing each antimicrobial concentration. From the master tube dilutions, aliquots of 0.05 or more of broth containing each antimicrobial concentration panels use tubes that contain from 10 to 200 ml or more of broth containing each antimicrobial concentration. The CLSI document on dilution testing (1) provides the antimicrobial dilution scheme are not needed. As a general rule, the inoculum volume is less than 10% of the broth volume in the well, dilution of the antimicrobial concentration by the inoculum does not have to be taken into account (1).

Preparation, Supplementation, and Storage of Media
CAMHB is the recommended medium for broth microdilution testing of nonfastidious organisms and should be prepared as discussed above for the broth macrodilution method. Also, supplementation of the broth with 2% NaCl is required if oxacillin is to be tested on staphylococci (if testing oxacillin rather than cefoxitin) and daptomycin testing oxacillin rather than cefoxitin) and daptomycin test-
16 to 20 h before results are read and should not be incubated in stacks of more than four trays for uniform temperature distribution. The incubator should be kept sufficiently humid to avoid evaporation but not so humid that condensation results in contamination problems. A full 24 h of incubation is recommended for the detection of vancomycin-resistant enterococci and oxacillin-resistant or vancomycin-resistant or -intermediate staphylococci (1). Incubation in an atmosphere with increased CO₂ should not be used with nonfastidious organisms.

Interpretation and Reporting of Results
Before MICs for the clinical isolates are read and recorded, the growth control wells should be examined for organism viability and the inoculum purity should be checked. The appropriateness of the MICs obtained for the quality control strains should be confirmed if tests of these strains were set up simultaneously with those of clinical isolates (see "Quality Control" below). Various viewing devices are available and should be used to facilitate examination of the broth microdilution wells for growth. The simplest and most reliable method is the use of a parabolic magnifying mirror and tray stand that allows clear visual inspection of the undersides of the microdilution trays. Growth is best determined by comparison with that in the growth control well and generally is indicated by turbidity throughout the well or by buttons, single or multiple, in the well bottom. The occurrence of trailing endpoints with trimethoprim or sulfonamides should be ignored, and the MIC endpoint should be based on ≥80% growth inhibition. Results for drugs with more than one skipped well should not be reported, as with the broth macrodilution test.

The CLSI MIC interpretive criteria (10) for susceptibility categories are given in Table 2. It should be noted that these values are published each year and only the most recent tables should be used for interpretation of results. The definitions of the interpretive categories and the comments concerning the use of these standards for agar and broth macrodilution methods are also applicable to broth microdilution methods.

Advantages and Disadvantages
Broth microdilution is a well-standardized reference method for antimicrobial susceptibility testing. Inoculation and reading procedures allow convenient simultaneous testing of multiple antimicrobial agents with individual isolates. Because few laboratories have the facilities required for preparation of broth microdilution trays, several sources of commercially prepared antimicrobial agent panels are available. Such products provide either frozen or freeze-dried trays with wells containing prepared antimicrobial dilutions. Frozen trays must be stored at least at −20°C in the laboratory, whereas dried panels can be stored at room temperature. Most of these products are accompanied by multipoint inoculating devices; however, the trays may be inoculated with multichannel pipettors. Results of testing may be determined by visual examination or by use of semiautomated or automated instrumentation.

Breakpoint Susceptibility Tests
While no longer very popular due to difficulties in performing adequate quality control, breakpoint susceptibility methods conserve reagents and space. Breakpoint testing refers to methods by which antimicrobial agents are tested only at the specific concentrations necessary for differentiating between the interpretive categories of susceptible, intermediate, and resistant rather than in a range of five or more doubling-dilution concentrations used to determine MICs. When two drug concentrations are selected adjacent to the breakpoints defining the intermediate and resistant categories, any one of the interpretive categories may be determined. Growth at both concentrations indicates resistance, growth at only the lower concentration signifies an intermediate result, and no growth at either concentration indicates susceptibility.

Like full-range dilution testing, breakpoint methods require the use of appropriately adjusted and supplemented Mueller-Hinton broth or agar. In addition, the standard inoculation, incubation, and interpretation procedures recommended for the full-range dilution methods should be followed.

Considering the limited range of drug concentrations tested, a greater number and variety of antimicrobial agents can be incorporated into a broth microdilution panel for breakpoint testing than into panels designed for full-range dilution testing (34). However, quality control procedures to ensure that appropriate concentrations of each antimicrobial agent are present are lacking for breakpoint panels.

Resistance Screens
In some circumstances, testing a single drug concentration may be a convenient method for detecting antimicrobial resistance. The most clinically useful resistance screens are those for high-level resistance to gentamicin and streptomycin in enterococci, resistance to vancomycin in Enterococcus spp. and S. aureus (MIC > 8 μg/ml), and resistance to oxacillin in S. aureus (1). These practical and reliable methods are described in chapter 73 of this Manual.

Gradient Diffusion Method
The Etest (bioMérieux) and the M.I.C.Evaluator (Oxoid) are commercial methods for quantitative antimicrobial susceptibility testing that incorporate a preformed antimicrobial gradient applied to one side of a plastic strip to provide drug diffusion into an agar medium. The test is performed in a manner similar to disk diffusion testing, in that a 0.5 McFarland standard suspension of a test isolate is generally swabbed onto the agar surface for inoculation. Following incubation, the MIC is read directly from a scale on the top of the strip at the point where the ellipse of organism growth inhibition intercepts the strip (4). Several strips, each containing a different antimicrobial agent, can be placed on the surface of a large round Mueller-Hinton agar plate, or they can be placed in opposing directions on large rectangular plates. MICs determined by this method generally agree well with MICs generated by standard broth or agar dilution methods (35, 36, 37). The Etests and M.I.C.Evaluators combine the simplicity and flexibility of the disk diffusion test with the ability to determine MICs of up to five antimicrobial agents on a single 150-mm-diameter round agar plate. However, both agar gradient diffusion strips are more expensive than the paper disks used for diffusion testing. Strengths of these methods include the simplicity of the procedure itself and the ability to determine an MIC of an infrequently tested drug and to test fastidious or anaerobic bacteria by applying the strips onto specialized enriched media (see chapters 74 and 75).

QUALITY CONTROL
Quality control recommendations are designed for evaluation of the precision and accuracy of test procedures, moni-
toring of reagent performance, and evaluation of the performance of the individuals who are conducting the tests.

Reference Strains
A critical element of quality control is the selection and use of reference bacterial strains that are genetically stable and for which MICs are in the midrange of MIC concentrations of each antimicrobial agent tested (1). That is, the dilutions in a series should ideally encompass at least two concentration increments above and below the previously established MIC for the reference strain. If there are four or fewer dilutions in a series or if nonconsecutive dilutions are tested (e.g., in breakpoint susceptibility testing), quality control for the correct interpretive category only rather than actual MIC ranges can be accomplished. Escherichia coli ATCC 25922, P. aeruginosa ATCC 27853, Enterococcus faecalis ATCC 29212, and S. aureus ATCC 29213 are the recommended reference strains for both agar and broth dilution MIC methods (1). The β-lactamase-producing strain E. coli ATCC 35218 is recommended only for penicillin–β-lactamase inhibitor combinations (1). These organisms may be obtained from the American Type Culture Collection or other reliable commercial sources. For proper storage and subculture procedures, the recommendations of either the CLSI (1) or the commercial provider should be followed.

MIC Ranges
The acceptable quality control MIC ranges for the various reference strains are given in the annual CLSI M100 supplements (10) and should be readily available in each clinical laboratory. An out-of-control result is defined as an MIC not within the acceptable range of values. Certain out-of-control results can be directly related to the medium used for testing. High MICs of gentamicin for P. aeruginosa ATCC 27853 suggest an inappropriately high divalent cation content or excessively low pH of the Mueller-Hinton medium, and low MICs indicate an insufficient divalent cation concentration or elevated pH. Although trimethoprim-sulfamethoxazole is not recommended for therapy of Enterococcus faecalis infections, results obtained with the ATCC 29212 strain can be useful for detecting excessive amounts of substances such as thymidine in the testing medium that interfere with the in vitro activity of antifolate drugs. Trimethoprim-sulfamethoxazole MICs of >0.5/9.5 μg/ml indicate the presence of such interfering substances (1). Extensive quality control (QC) troubleshooting guidance is available in the annual CLSI supplement (10).

Batch and Lot Quality Control
Representative plates, panels, or trays from each new reagent batch, if prepared in-house, or from each new lot, if obtained from a commercial source, should be subjected to quality control and sterility testing. Antimicrobial agent MICs obtained by testing reference quality control strains should be within acceptable CLSI ranges (10). If such accuracy is not achieved, the batch or lot should be rejected or patient results obtained with the antimicrobial agent(s) in question should not be reported (see below). Similarly, if selected uninoculated plates or trays fail the sterility check after incubation, the batch or lot should be rejected. In addition to these formal quality control procedures that use reference strains, careful review of susceptibility results obtained during daily testing of clinical isolates is important to identify aberrant or unusual susceptibility patterns possibly indicative of reagent or technical problems.

Quality Control Frequency
In addition to batch and lot testing, quality control tests should be performed daily, or at least every day that the plates or trays are being used to test clinical isolates. When quality control is performed on each day of testing, performance is considered satisfactory if no more than 3 of 30 consecutive results for each drug-reference strain combination are outside the acceptable limits. If this frequency is exceeded, the laboratory must perform corrective action to determine the source of the error and to correct it as described below. However, if daily quality control testing does not reveal an excessive rate of errors, daily testing may be replaced by weekly testing as outlined below (1, 10).

To convert to a weekly quality control testing interval, each drug-reference strain combination is tested for 20 or 30 consecutive testing days to obtain a total of 20 to 30 MIC values for each combination. If no more than 1 of 20 or 3 of 30 MICs per combination are outside the accuracy range, weekly testing may replace daily testing. Alternatively, a streamlined 15-replicate series may be performed by testing three replicates (separate inocula) of each relevant QC strain for 5 days (1). If 0 or 1 value is out of range, conversion to weekly QC testing is permitted. If 2 or 3 are out of range, testing of an additional 15 replicates is required. Recently, CLSI has recommended that the 20 to 30 tests do not have to be conducted prospectively. Instead, results of consecutive individual tests performed in the last 12 months may be tallied and the above calculation performed (1). During weekly testing, a single MIC outside the acceptable range requires that the test be repeated once. If the repeat value is within the approved range, no further action will be needed. If the single repeat value is again out of range, daily testing must be performed for five consecutive days to document a return to in control values or measures taken to resolve the problem (1, 10).

DISK DIFFUSION TESTING
The disk diffusion method of susceptibility testing allows categorization of most bacterial isolates as susceptible, intermediate, or resistant to a variety of antimicrobial agents. To perform the test, commercially prepared filter paper disks impregnated with a specified single concentration of an antimicrobial agent are applied to the surface of an agar medium that has been inoculated with the test organism. The drug in the disk diffuses through the agar. As the distance from the disk increases, the concentration of the antimicrobial agent decreases logarithmically, creating a gradient of drug concentrations in the agar medium surrounding each disk. Concomitant with the diffusion of the drug, the bacteria that were inoculated onto the surface and were not inhibited by the concentration of the antimicrobial agent in the agar continue to multiply until a lawn of growth is visible. In areas where the concentration of the drug is inhibitory, no growth occurs, forming a zone of inhibition around each disk.

The disk diffusion procedure has been standardized primarily for testing common, rapidly growing bacteria (2, 38). This method should not be used to evaluate antimicrobial susceptibilities of bacteria that show marked strain-to-strain variability in growth rates, e.g., some fastidious or anaerobic bacteria. The test, however, has been modified to allow reliable testing of certain fastidious bacterial species by incorporation of enriched media and modified incubation conditions (detailed in chapter 74).

The diameter of the zone of inhibition is influenced by the rate of diffusion of the antimicrobial agent through the
agar, which may vary among different drugs depending upon the size of the drug molecule and its hydrophilicity. The zone size, however, is inversely proportional to the logarithm of the MIC, measured as discussed earlier in this chapter. Criteria currently recommended for interpreting zone diameters and MIC results for commonly used antimicrobial agents are listed in Table 2 and published annually by the CLSI (10).

Establishing Zone-of-Inhibition Diameter Interpretive Criteria

The first step in determining interpretive criteria for the disk diffusion test is selection of MIC breakpoints that define susceptibility and resistance categories for each antimicrobial agent. Zone of inhibition diameters that correspond to these breakpoints are initially established by testing 300 or more bacterial isolates by both dilution and disk diffusion methods and correlating the diameters of the zones of inhibition with the MIC values determined for each drug tested. These isolates tested should include not only those commonly encountered in clinical laboratories but also those with resistance mechanisms pertinent to the class of antimicrobial agent being tested. Organisms evaluated should be those most likely to be tested with the antimicrobial agent in question. The data from these studies are analyzed by preparing a scattergram of values (see the example in chapter 21) by convention, each MIC value (log scale) is plotted on the y axis, and the corresponding zone of inhibition diameter (arithmetic scale) is plotted on the x axis. Regression analysis can be performed, and a straight regression line showing the best fit is drawn. From this line, an approximation of the MIC can be inferred from any zone diameter. For antimicrobial agents to which isolates are either susceptible or resistant and only infrequently intermediate, regression analysis is not valid. In such cases, the data are plotted as a scattergram, and the interpretive standards are selected so as to allow optimal separation of resistant and susceptible populations. This approach, often called the error-rate-bounded method, may also be employed to minimize interpretive errors that can ensue from strictly applying the linear regression formula to a data set.

Antimicrobial Agent Disks

The amounts of antimicrobial agents in the disks used for the disk diffusion method are standardized, and in the United States, only a single concentration of each drug is recommended. The optimal amount of an antimicrobial agent per disk is determined early in the development of a new drug by testing disks with several different drug contents that can be evaluated by using scattergrams and regression lines. The most desirable concentration of a drug per disk is that which produces a zone-of-inhibition diameter of at least 10 mm with resistant isolates and a zone diameter of no larger than 30 mm with susceptible isolates.

Commercially prepared antimicrobial disks usually are supplied in separate containers, each with a desiccant. They must not be used beyond the specified expiration date and should be stored under refrigeration or frozen in a non-frost-free freezer at \(-20^\circ C\) or colder until needed. Disks containing a \(\beta\)-lactam agent should always be stored frozen to ensure that they retain their potency, although a small supply may be stored in the refrigerator for up to 1 week. Unopened disk containers should be removed from the refrigerator or freezer 1 to 2 h before use. This allows the disks to equilibrate to room temperature before the container is opened, thus minimizing the amount of condensation that will occur when warm air contacts the cold disks. A commercially available, mechanical disk-dispensing apparatus can be used and should be fitted with a tight cover, supplied with an adequate desiccant, stored in the refrigerator when not in use, and warmed to room temperature before being opened.

Agar Medium for Disk Diffusion

The recommended medium for disk diffusion testing in the United States is Mueller-Hinton agar (2). This unsupplemented medium has been selected by the CLSI for several reasons: (i) it demonstrates good batch-to-batch reproducibility for susceptibility testing; (ii) it is low in sulfonamide, trimethoprim, and tetracycline inhibitors; (iii) it supports the growth of most nonfastidious bacterial pathogens; and (iv) years of data and clinical experience regarding its performance have been accrued. Fastidious bacteria, such as Haemophilus species, Neisseria gonorrhoeae, Neisseria meningitidis, and streptococci, do not grow satisfactorily on unsupplemented Mueller-Hinton agar but can be tested by the disk method by using supplemented or modified test media as discussed in chapter 21.

Plates of Mueller-Hinton agar may be purchased, or the agar may be prepared from a commercially available dehydrated base according to the manufacturer’s directions. If the agar is prepared, only formulations that have been tested according to, and have met, acceptance limits recommended by the CLSI should be used. The prepared medium is autoclaved and immediately placed in a 45 to 50°C water bath. When cool, it is poured into round plastic flat-bottomed petri dishes on a level surface to give a uniform depth of about 4 mm (67 to 70 ml of medium for 150-mm-diameter plates and 26 to 30 ml for 100-mm-diameter plates) and allowed to cool to room temperature. Agar deeper than 4 mm may cause false resistance results (excessively small zones), whereas agar less than 4 mm deep may be associated with excessively large zones and false susceptibility.

Each batch of Mueller-Hinton agar should be checked when the medium is prepared to ensure that the pH is between 7.2 and 7.4 at room temperature, which means that the pH must be measured after the medium has solidified. This can be done by allowing a small amount of agar to solidify around the tip of a pH electrode in a beaker or a cup, by macerating a sufficient amount of agar in neutral distilled water, or by using a properly calibrated surface electrode. A pH outside the range of 7.2 to 7.4 may adversely affect susceptibility test results. If the pH is too low, drugs such as the aminoglycosides, macrolides, and fluoroquinolones will appear to lose potency, whereas others (for example, the penicillins and tetracyclines) may appear to have excessive activity. The opposite effects are possible if the pH is too high.

Freshly prepared plates may be used the same day or stored in a refrigerator (2 to 8°C); if refrigerated, they should be wrapped in plastic to minimize evaporation. Just before use, if excess moisture is visible on the agar surface, plates should be placed in an incubator (35°C) or, with lids ajar, in a laminar-flow hood at room temperature until the moisture evaporates (usually 10 to 30 min). At the time the medium is to be inoculated, no droplets of moisture should be visible on the agar surface or on the petri dish lid.

Various components of or supplements to Mueller-Hinton medium may affect susceptibility test results; therefore, appropriate quality control procedures (see “Quality Control” below) must be performed and zone diameters must be within acceptable limits. For example, media containing excessive amounts of thymidine or thymine can reverse the
inhibitory effects of sulfonamides and trimethoprim, causing zones of growth inhibition to be smaller or less distinct. Organisms may therefore appear to be resistant to these drugs when in fact they are not. Variation in the concentrations of divalent cations, primarily calcium and magnesium, affects results of aminoglycoside and tetracycline tests with *P. aeruginosa* isolates (2). A cation content that is too high reduces zone sizes, whereas a cation content that is too low has the opposite effect. Sheep blood should not be added to Mueller-Hinton medium for testing of nonfastidious organisms because the blood can significantly alter the zone diameters with several agents and bacterial species (19).

**Inoculation Procedure**

To ensure reproducibility of disk diffusion susceptibility test results, the inoculum must be standardized (2, 38). The inoculum may be prepared by the growth method or by direct suspension from colonies on the agar plate, as described above for dilution testing.

When trimethoprim-sulfamethoxazole is tested by the direct inoculum suspension method, colonies from blood agar medium may carry over enough trimethoprim or sulfonamide antagonists to produce a haze of growth inside the zones of inhibition with susceptible isolates.

The Mueller-Hinton agar plate should be inoculated within 15 min after the inoculum suspension has been adjusted. A sterile cotton swab is dipped into the suspension, rotated several times, and gently pressed onto the inside wall of the tube above the fluid level to remove excess inoculum from the swab. The swab is then streaked over the entire surface of the agar plate three times, with the plate rotated approximately 60° each time to ensure even distribution of the inoculum. A final sweep of the swab is made around the agar rim. The lid may be left ajar for 3 to 5 min, but no longer than 15 min, to allow any excess surface moisture to be absorbed before the drug-impregnated disks are applied.

**Antimicrobial Disks**

Within 15 min after the plates are inoculated, selected antimicrobial agent disks are distributed evenly onto the surface, with at least 24 mm (center to center) between them. Disks are placed individually with sterile forceps or, more commonly, with a mechanical dispensing apparatus and then gently pressed down onto the agar surface to provide uniform contact. No more than 12 disks should be placed onto one 150-mm-diameter plate, and no more than 5 disks should be placed onto a 100-mm-diameter plate to avoid overlapping zones. Some of the antimicrobial agent in the disk diffuses almost immediately; therefore, once a disk contacts the agar surface, the disk should not be moved.

**Incubation**

No longer than 15 min after disks are applied, the plates are inverted and incubated at 35°C in ambient air. A delay of more than 15 min before incubation permits excess prediffusion of the antimicrobial agents. The interpretive standards for nonfastidious bacteria are based on results of test samples incubated in ambient air, and the zone-of-inhibition diameters for some drugs, such as the aminoglycosides, macrolides, and tetracyclines, are significantly altered by CO$_2$; therefore, plates should not be incubated in atmospheres with increased CO$_2$. Testing isolates of some fastidious bacteria, however, requires incubation in 5% CO$_2$, and zone diameter criteria for those species have been established on that basis (see chapter 74).

**Interpretation and Reporting of Results**

Each plate is examined after incubation for 16 to 18 h for all nonfastidious bacterial isolates except staphylococci and enterococci, which should be incubated for a full 24 h if oxacillin and vancomycin, respectively, are tested (2). If plates are inoculated correctly, the diameters of the zones of inhibition are uniformly circular and the lawns of growth are confluent. Growth that consists of individual isolated colonies indicates that the inoculum was too light, and the test must be repeated. The diameters of the zones of complete inhibition, including the diameter of the disk, are measured to the nearest whole millimeter with calipers or a ruler. With unsupplemented Mueller-Hinton agar, the measuring device is held on the back of the inverted petri dish, which is illuminated with reflected light located a few inches above a black, nonreflecting background.

The zone margin is the area where no obvious growth is visible with the naked eye. When isolates of staphylococci or enterococci are tested, any discernible growth (especially a haze of pinpoint colonies) within the zone of inhibition around the oxacillin disk (for staphylococci) or vancomycin disk (for enterococci) is indicative of likely resistance. For other bacteria, discrete colonies growing within a clear zone of inhibition may indicate testing of a mixed culture that should be subcultured, reidentified, and restested. However, the presence of colonies within a zone of inhibition may also indicate selection of high-frequency mutants predicting eventual resistance to that agent, e.g., *Enterobacter* spp. with penicillins and cephalosporins. Such small in-growth colonies are frequently seen when testing fosfomycin but do not appear to reflect pending resistance to that agent. With *Proteus* species, a thin film of swarming growth is visible in an otherwise obvious zone of inhibition, the margin of heavy growth is measured and the film is disregarded. With trimethoprim, the sulfonamides, and the combination of the two agents, antagonists in the medium may allow some minimal growth; therefore, the zone diameter is measured at the obvious margin, and slight growth (20% or less of the lawn of growth) is disregarded.

The zone diameters measured around each disk are interpreted on the basis of guidelines published by the CLSI, and the organisms are reported as susceptible, intermediate, susceptible-dose dependent, or resistant (or in some cases “nonsusceptible” when no resistance breakpoint has been defined) to the antimicrobial agents tested (Table 2) (10). The clinical interpretation of the categories of susceptible, intermediate, susceptible-dose dependent, and resistant has already been provided above under “Dilution Methods.” Computer programs are available that accompany some automated zone size reading devices to allow MICs to be derived from the linear regression equation with selected antimicrobial agents and bacterial isolates (41, 42) (see also chapter 72).

**Advantages and Disadvantages**

The disk diffusion test has several advantages: (i) it is technically simple to perform and very reproducible, (ii) the reagents are relatively inexpensive, (iii) it does not require any special equipment, (iv) it provides susceptibility category results that are easily understood by clinicians, and (v) it is flexible regarding selection of antimicrobial agents for testing. The primary limitation of the disk diffusion test is the spectrum of organisms for which it has been standardized. There have not been adequate studies to develop reliable interpretive standards for disk testing of bacteria not listed in the CLSI disk diffusion document (2) or the CLSI...
guideline for infrequently isolated or fastidious bacteria (43).

It is also important to note that only certain drugs have been validated for disk diffusion testing of Stenotrophomonas maltophilia and Burkholderia cepacia (10). The disk test is inadequate for detection of vancomycin-intermediate-S. aureus (2, 44, 45) and is no longer recommended for testing staphylococci, does not detect daptomycin resistance in staphylococci and enterococci (24, 46) or colistin resistance in Gram-negative bacilli other than possibly P. aeruginosa (6), and in the past, prior to the recommendation to test cefoxitin, was reported to have difficulties in the detection of oxacillin-heteroresistant staphylococci (47) and enterococci with low-level (Van B-type) vancomycin resistance (45, 48). A potential disadvantage of disk diffusion susceptibility testing is that it provides only a qualitative result, and a quantitative result indicating the degree of susceptibility (MIC) may be needed in some cases, e.g., those involving penicillin and cephalosporin susceptibilities of S. pneumoniae and certain viridans group streptococci (see chapter 74).

Quality Control
The goals of a quality control program for disk diffusion tests are to monitor the precision and accuracy of the procedure, the performance of the reagents (medium and disks), and the performance of persons who do the testing and read, interpret, and report results. To best achieve these goals, reference strains are selected for their genetic stability and their usefulness in the disk diffusion test.

Reference Strains
Reference strains recommended by the CLSI for quality control of the disk diffusion procedure when nonfastidious bacteria are tested are E. coli ATCC 25922, P. aeruginosa ATCC 27853, S. aureus ATCC 25923 (not the same strain used for quality control of MIC tests), Enterococcus faecalis ATCC 29212, and E. coli ATCC 35218 (10, 49). E. coli ATCC 35218 is recommended as a control only for β-lactamase inhibitor combinations containing clavulanic acid, sulbactam, or tazobactam. Enterococcus faecalis ATCC 29212 can be used to ensure that the levels of inhibitors of trimethoprim or sulfonamides in Mueller-Hinton agar do not exceed acceptable limits and can also be used to control disks containing a high concentration of gentamicin or streptomycin (see chapter 73).

The reference strains listed above should be obtained from a reliable source, and stock cultures should be maintained in such a way that viability is ensured and the opportunity for selection of resistant variants is minimal. The procedures for maintaining and storing working stock cultures are described in the CLSI standard (2). If an unexplained result indicates that the inherent susceptibility of the strain has been altered, a fresh subculture of that organism should be obtained.

Zone-of-Inhibition Diameter Ranges
The ranges of zone diameters for reference strains used to monitor performance of the disk diffusion test are updated frequently and published annually; therefore, readers should refer to the most recent CLSI document for this information (10). Generally, results of 1 in every 20 tests in a series of tests might be out of the accepted limits. If a second result falls outside the stated limits, corrective action must be taken. The action taken and the results of that action must be documented.

Frequency of Testing
Each new batch or lot of Mueller-Hinton agar must be tested with the reference strains listed above before the medium is released for use with clinical specimens, and quality control must be done before or at the same time as a new lot of antimicrobial disks is placed in use. Appropriate reference strains also should be tested each day that the disk diffusion test is performed. The frequency of testing, however, may be reduced if satisfactory performance is documented for 20 or 30 consecutive days of testing; for each combination of drug and reference strain, no more than 1 of 20 or 3 of 30 zone-of-inhibition diameters may be outside the accepted limits published by the CLSI (10). The streamlined 15-replicate protocol described above for MIC testing is also an acceptable alternative approach for demonstrating proper performance prior to converting to weekly QC testing (10). When either of these criteria are fulfilled, each reference strain need be tested only once per week and any time a reagent component of the test is changed. However, if the diameter of a zone of inhibition falls outside the acceptable control limits, corrective action must be taken. If the problem appears to be caused by an obvious error such as use of the wrong disk or the wrong reference strain, contamination of the reference strain, or incubation in an incorrect atmosphere, or even if there is no obvious reason for an out-of-control value, repeating the test one time is acceptable. However, if the repeat value is again out of control, quality control must be performed daily for a period that will allow discovery of the source of the aberrant result and documentation of how the problem was resolved. This may be accomplished by the same approach described above under “Quality Control” in “Dilution Methods.”

Special Disk Tests
Two specialized applications of the disk test are described in detail in chapter 73. In brief, disk testing with cefoxitin is now the recommended method for detection of mecA-mediated oxacillin resistance in both S. aureus and coagulase-negative staphylococcal species (2, 10, 50, 51). Cefoxitin disk testing serves as a surrogate marker for the principal mechanism of oxacillin resistance in staphylococci and provides more reliable results than oxacillin disk testing itself. Secondly, inducible clindamycin resistance is not reliably detected by standard dilution or disk diffusion susceptibility testing without induction of the expression of erm-mediated macrolide-lincosamide-streptogramin B resistance in staphylococci, hemolytic streptococci, and S. pneumoniae (10, 52, 53). Such strains can be accurately detected only by induction of resistance expression by exposure to a macrolide. A disk approximation test in which erythromycin and clindamycin disks are placed in close proximity allows recognition of inducible resistance by truncating the clindamycin zone and giving rise to a positive “D-zone test” (10, 54). Alternatively, single-well microdilution tests have been described that include fixed concentrations of erythromycin and clindamycin in the same well for testing staphylococci or streptococci (53, 55, 56). When recognized through either method of induction testing, such strains should be regarded as resistant to clindamycin (10, 52).

ANTIBACTERIAL SUSCEPTIBILITY TESTING AND INTERPRETATIVE METHODS USED OUTSIDE THE UNITED STATES
The CLSI is best known for developing laboratory testing standards for use in the United States, including those for antimicrobial susceptibility testing (1, 2, 10). The CLSI standards are recognized as U.S. national standards by the American National Standards Institute and by federal regu-
lations, including the Clinical Laboratory Improvement Amendments (25), and as standard reference procedures by the Food and Drug Administration. However, the CLSI procedures are also used by an increasing number of laboratories outside the United States, including countries in North and South America and in several areas of Europe, Asia, and Australia. Some countries have national standards or professional committees comprising their own expert microbiologists that establish methods of susceptibility testing for their countries and interpretive criteria for those tests that may or may not be the same as those of the CLSI (57, 58), as described further in chapter 72.

Several variations on dilution and diffusion methods are used for routine susceptibility testing outside the United States (Table 3). Most non-U.S. methods are specific to individual countries, having developed and evolved locally over many years. Many of the non-U.S. methods differ from the CLSI procedures in the choice of media, inoculum preparation procedures, and, for diffusion methods, disk contents. There are also some variations between these methods in breakpoints and the approaches to establishing the breakpoints (59). Variation in test methods can cause considerable confusion in laboratories, especially if both CLSI and non-CLSI methods are used for different organisms. Thus, it is important that any method should be followed in all its detail for valid application of specific breakpoints.

There are continuing efforts to harmonize breakpoints internationally. In Europe, EUCAST has become a major force for developing and harmonizing methods and breakpoints for aerobic and facultative organisms. EUCAST has defined reference agar and broth microdilution MIC methods (www.eucast.org) for use in Europe (60) and is in the process of defining disk diffusion methods. The establishment of a global standard reference MIC susceptibility method (broth microdilution) developed through the ISO (Geneva, Switzerland) (3) in concert with the European Committee on Standardization (Brussels, Belgium) has also occurred recently. The global reference method is in essence the CLSI and EUCAST broth microdilution methods with a few differences harmonized in the ISO standard (3). This will hopefully provide a degree of international standardization for reference MIC determinations and allow a benchmark for assessment of the performance of commercial devices for susceptibility testing. In a second document, the ISO has established criteria for acceptable performance of susceptibility testing devices (61).

### International Dilution Methods

Both broth and agar dilution methods have been developed in multiple countries outside the United States. In the past, methods using a limited range of concentrations (often one or two), or so-called breakpoint methods, have been advocated (62). They are the standard form of susceptibility testing advocated by the Japanese Society for Chemotherapy (63, 64) and as an alternative to disk diffusion testing by the BSAC (65). Other MIC methods and standards include those of the BSAC (66) (see also http://www.bsac.org.uk), the Société Française de Microbiologie (CA-SFM—Comité de l’Antibiogramme de la SFM, http://sfm-microbiologie.org), the Deutsches Institut für Normung (DIN; documents are available through http://www.beuth.de), and the Swedish Reference Group for Antibiotics (SRGA; http://www.srga.org).

Breakpoint MIC methods (or more commonly, MIC methods with limited concentration ranges) are often used in larger laboratories because large numbers of isolates can be tested cost-effectively using replicators and the methods provide qualitative endpoints (i.e., susceptible, intermediate, and resistant). Optical readers are available to facilitate reading of agar dilution plates (e.g., Mastascan Elite; Mast Laboratories, Bootle, United Kingdom [http://www.mastascan.com]). However, there are considerable difficulties with quality control, including the lack of appropriate control strains for which the MICs are near the breakpoints, and the complexity of quantifying drug concentrations prior to use (67). In addition, problems have been reported in the past with the use of Iso-Sensitest agar (68, 69) and with the incorporation of inhibitors to prevent swarming of *Proteus* spp., such as p-nitrophenylglycerol (70), or increased agar content for the same purpose (71). In turn, the choice of Mueller-Hinton by the CLSI has been criticized for not providing luxuriant growth of all organisms (72), suggesting

that there is no ideal medium. As the best-studied, most widely used medium for susceptibility testing, Mueller-Hinton broth was chosen for the ISO reference method (3) and is supported by the EUCAST (see below).

**International Diffusion Methods**

A wide variety of diffusion methods have been developed in different countries over the years. They are quite diverse in their approaches. With the exception of the Danish method, which uses 9-mm tablets containing the antimicrobial agents, the other international diffusion methods use disks similar to CLSI. Almost all have been maintained primarily because of the cost-effectiveness and flexibility of diffusion testing. Many, including CA-SFM and the newly developed EUCAST disk diffusion method (www.eucast.org) are similar to the modified Kirby-Bauer method (38) advocated by the CLSI (2). As pointed out above, disk methods are inexpensive and flexible and have become more popular with the use of automated zone readers and interconnected computers for interpretation of zone diameters (42, 68). Some of the automated readers also contain “expert” software for antibiogram interpretation.

The Stokes’ method, which had previously been recommended by the BSAC, differed from other diffusion methods in that susceptibility categorization was achieved by comparison with a control strain rather than by reference to a defined set of zone diameters (73). This technique attracted criticism because it was not based upon or derived from correlations with MICs (74) and has now been replaced by a correlated diffusion method (66), which is now well developed and updated periodically (http://www.bsac.org.uk). For the new BSAC method, Iso-Sensitest (Oxoid, Basingstoke, United Kingdom) is the recommended agar, supplemented for the growth of fastidious bacteria with whole defibrinated horse blood, with or without NAD. Mueller-Hinton supplemented with 5% sodium chloride is recommended for the detection of methicillin and oxacillin resistance in staphylococci. The inoculum is prepared to produce semifluid growth only, rather than the confluent lawn of growth as recommended in the CLSI method. One important change in the newer British method is the elimination of an intermediate category for most organism-antimicrobial agent combinations (75).

Since 1980, the CA-SFM has put considerable effort into standardization of susceptibility testing, including regular updates with breakpoints for new drugs that are published frequently (76) (see also http://sfm-microbiologie.org). Like the CLSI, the CA-SFM has selected Mueller-Hinton as the testing medium. For diffusion testing, plates can be inoculated either by flooding or swabbing with a standardized inoculum of cells. In most other aspects, this method resembles that of the CLSI, including the use of control organisms and the choice of disk strength. The CA-SFM provides zone diameter breakpoints for drugs available in France and elsewhere that are not approved for clinical use in the United States, e.g., fusidic acid and pristinamycin (76). The French breakpoints often differ from those advocated by CLSI and place greater emphasis on the detection of emerging resistance. Thus, they are more likely to classify organisms as resistant (or nonsusceptible) than CLSI methods.

The German standards organization, DIN, published methods for diffusion susceptibility testing as early as 1979, with intermittent updates since then (77, 78). They too use Mueller-Hinton agar but will include the use of other media provided that the MIC-zone diameter relationships have been determined for those media. Like the CA-SFM method, the DIN method has much in common with the CLSI method.

The SRGA (79, 80) method uses Iso-Sensitabs, and it is based on the methodology developed by the original International Collaborative Study (81) that was the first to provide a sound theoretical basis to diffusion susceptibility testing. The breakpoints for susceptibility were restructured in 1981 into the more conventional susceptible, intermediate, and resistant categories (80) and were subsequently updated (82).

A method developed by a commercial firm in Denmark differs technically if not in principle from the other methods. As noted above, this method employs Neo-sensitabs that are compressed tablets, 9-mm in diameter, into which the antimicrobial agent has been incorporated (Rosco Diagnostica, Taarstrup, Denmark; http://www.rosco.dk). The method and the interpretive zone diameter criteria are updated and published by the manufacturer periodically. Not only are the tablets larger and thicker than conventional 6-mm-diameter paper disks, they usually contain larger amounts of antimicrobial agent to be tested, resulting in significantly larger zones of inhibition with most drugs. This has the disadvantage of reducing the number of tablets that can be put on a single plate and still produce readable zones. However, the system does have the advantage that the tablets can be stored at room temperature for up to 4 years, obviating the need for storage under refrigeration or freezing. This is an obvious benefit for laboratories in developing countries where reliable refrigeration and power can be a problem.

The calibrated dichotomous sensitivity (CDS) disk diffusion method developed in Australia in 1975 (83, 84) is still widely used in that country and has a number of unique features. The CDS method employs Sensitab agar and an unusual method for inoculum preparation and is unique in defining just two categories of susceptibility: susceptible and resistant. To simplify test result reading, each new drug is calibrated against the MIC breakpoint to yield, wherever possible, a zone diameter of 18 mm. This is achieved by adjusting disk strengths, which in most cases are substantially lower than those used with other methods. The lack of an intermediate category, which increases the risk of serious interpretive errors (e.g., susceptible instead of resistant), the absence of some common drugs from the test range, and some unusual use of surrogate drugs for testing have restricted the adoption of this method outside Australia. The interpretative criteria are updated regularly and can be found on the Internet (http://web.med.unsw.edu.au/cdstest/).

**EUCAST Methods**

Outside CLSI, EUCAST is probably the most widely recognized breakpoint setting organization. EUCAST is a standing committee of the European Society for Clinical Microbiology and Infectious Diseases (ESCMID) and the European Centre for Disease Prevention and Control (ECDC). It consists of two bodies: the EUCAST Steering Committee and the EUCAST General Committee. EUCAST emerged as a concerted effort to harmonize susceptibility testing across Europe into a single unified approach (66). Although there are many similarities between EUCAST and CLSI methods, there are also some differences. Both methods are based on the use of cation-adjusted Mueller-Hinton broth for broth microdilution and Mueller-Hinton agar for disk diffusion. For more fastidious organisms, EUCAST has developed a single medium, MH-F (Mueller-Hinton-Fastidious), Mueller-Hinton supplemented with 5% mechanically
defibrinated horse blood and 20-mg/liter β-NAD in place of CLSI’s Haemophilus test medium, and Mueller-Hinton broth and agar supplemented with 5% sheep or horse blood for other fastidious organisms (e.g., streptococci). For disk diffusion, EUCAST has also selected lower disk masses for certain organism-antimicrobial agent combinations. Quality control procedures are very similar, with essentially the same control strains and quality control ranges, except for disk diffusion, where the test medium and/or disk masses differ.

In recent years, there has been a growing consensus between EUCAST and CLSI about data sets and methods for breakpoint setting. Both organizations agree that microbiological, pharmacokinetic-pharmacodynamic, and clinical outcome data are major considerations when selecting breakpoints. In addition, EUCAST has formulated its approach to establishing epidemiological (wild-type) cutoff values (59) (see http://www.eucast.org), while this is implicit in CLSI’s approach. However, while there has been a slow convergence of breakpoints themselves, there are still a number of differing breakpoints for a range of reasons apart from methodological ones (such as different disk masses or test medium). These reasons include (i) differing standard dosing regimens within Europe and between Europe and the United States, (ii) access to different data sets during the breakpoint setting process, and (iii) differences in the time that the breakpoint setting process occurred (some CLSI breakpoints were set before the full suite of data sets were available, especially the more recent information on pharmacokinetics-pharmacodynamics). It is likely that breakpoints will continue to converge as methods for breakpoint setting become more standardized internationally.

COMMON SOURCES OF ERROR IN ANTIBACTERIAL SUSCEPTIBILITY TESTING

Potential sources of error in antibacterial susceptibility testing may be categorized as those that relate to the test system and its components, those associated with the test procedure, those peculiar to certain organism and drug combinations, and those that relate to reporting (16, 85, 86). The most common sources of error encountered in clinical microbiology laboratories are reviewed in the following paragraphs.

Various components of the susceptibility test system may be a source of error. First, the test system itself may have limitations regarding the organisms that should be tested. For example, the disk diffusion method should be used only to test rapidly growing bacterial pathogens that have consistent growth rates (those for which interpretive criteria have been developed and published by the CLSI). Second, the medium used may be a source of error if it fails to conform to recommended composition and performance. Factors common to both agar-based and broth-based systems are the pH of the medium, which for Mueller-Hinton agar or broth should be between 7.2 and 7.4, and their cation content. The concentration of magnesium and calcium in the broth medium should be that recommended by the CLSI to ensure reliable results (1). The Mueller-Hinton agar should be 3 to 4 mm deep for agar dilution and 4 mm deep for disk diffusion (1, 2). Third, the components of the system (antimicrobial disks, agar plates, and trays) must be stored properly, and they should not be used beyond the stated expiration date.

Steps in the susceptibility test procedure that may be a source of error if they are not performed correctly include inoculum preparation, incubation (conditions and duration), endpoint interpretation, and performance of appropriate quality control. The inoculum must be a pure culture, and it must contain an adequate density of bacteria. With rare exceptions, all systems should be incubated in ambient air at 35°C. The incubation time, however, varies. For conventional dilution and disk diffusion systems, incubation for 16 to 20 h and 16 to 18 h, respectively, is recommended, except in tests of staphylococci with oxacillin and vancomycin (MIC only) and enterococci with vancomycin, in which systems must be incubated for a full 24 h (1, 2, 87). The endpoints for all susceptibility tests must be measured accurately, following guidelines published by the CLSI (1, 2). If endpoints are interpreted by an instrument, the reliability of that instrument must be monitored and calibrated periodically. Moreover, with all susceptibility test systems, appropriate reference strains must be tested at regular intervals, any problems that occur must be thoroughly investigated, and corrective action must be well documented.

Testing of certain antimicrobial agents with some bacteria may yield misleading results because in vitro results do not necessarily correlate with in vivo activity. Examples include aminoglycosides and narrow- and expanded-spectrum cephalosporins tested with Salmonella spp. and Shigella spp., all β-lactam agents except penicillin, oxacillin, cefoxitin, and cefotaxime with staphylococci; cephalosporins, aminoglycosides (except concentrations used to detect high-level resistance), clindamycin, and trimethoprim-sulfamethoxazole tested with enterococci; and cephalosporins tested with Listeria spp. (1, 2, 10). Therefore, for these combinations of organisms and drugs, results should not be reported. Other errors associated with reporting include possible transcriptional errors for laboratories that use a manual recording and reporting system and possible errors in transmission of data for laboratories in which an automated susceptibility test system is interfaced with the laboratory and/or hospital information system. For several species of bacteria, resistance to a commonly tested antimicrobial agent is expected. For example, several species of Enterobacteriaceae, including Klebsiella, Citrobacter, and Enterobacter spp., among others, should test as ampicillin resistant (10). Likewise, Stenotrophomonas maltophilia should test as resistant to carbapenems, and Pseudomonas aeruginosa should test as resistant to trimethoprim-sulfamethoxazole (10). A susceptible result for any of these bacterium-antimicrobial combinations could indicate an error in antimicrobial susceptibility testing or bacterial identification, and the tests (including identification when necessary) should be repeated.

PROBLEM ORGANISMS AND RESISTANCE MECHANISMS

The dilution and diffusion methods described in this chapter have been developed through careful studies and standardized by national professional organizations and diagnostic device manufacturers. Despite this, there are still some organisms for which methods have not yet been standardized (e.g., coryneform bacteria and some fastidious bacteria in the case of disk testing) or which fail to provide reliable results with some of the standard tests (e.g., Stenotrophomonas maltophilia and Burkholderia cepacia in the case of disk diffusion testing of some drugs).

Other problems occur with detecting resistance mechanisms in isolates that may possess inducible resistance (e.g., clindamycin resistance in staphylococci and some streptococci, Van B-type resistance in some enterococci or AmpC-type β-lactamase in some Gram-negative species). Similarly, there are issues with detection of resistance mechanisms
that result in subtle phenotypic expression under standard inoculum and test conditions (e.g., extended-spectrum β-lactamase [ESBL] or carbapenemase expression in some Enterobacteriaceae). Special methods to detect these resistance mechanisms are outlined in chapter 73. Controversy has existed regarding the need to identify the resistance mechanisms such as ESBLs or carbapenemases for making treatment decisions. For example, revised CLSI cephalexin, aztreonam, and carbapenem interpretive criteria that are consistent with recent pharmacokinetic and pharmacodynamic data and the most common dosing regimens obviate the need for ESBL or carbapenemase confirmation before a treatment decision is made (10). It is the MIC that seems most predictive of therapeutic outcome in an individual patient as opposed to the resistance mechanism present in the patient’s infecting strain. However, there may still be a need to identify certain resistance mechanisms (especially those that are plasmid mediated) for epidemiological and infection prevention purposes.

There has not previously been uniform agreement regarding what level of accuracy is acceptable when selecting a testing method or system for performing antimicrobial susceptibility testing (17). However, general guidelines for acceptable performance (e.g., rates of essential agreement and category agreement) now have been developed through an international consensus effort (ISO) (3). However, it is important to keep in mind that new resistance mechanisms or decreases in susceptibility to important therapeutic agents can arise at any time to challenge our methods of susceptibility testing, e.g., the emergence of carbapenemase-mediated resistance in Enterobacteriaceae (88). Thus, susceptibility testing methods must continue to evolve and develop over time as new challenges are presented.

Antimicrobial Susceptibility Testing Systems*

JAMES A. KARLOWSKY AND SANDRA S. RICHTER

Commercial antimicrobial susceptibility testing (AST) systems were introduced into clinical microbiology laboratories during the 1980s and have been used in the majority of laboratories since the 1990s (1). Manual and semiautomated broth microdilution systems are utilized for small volumes of susceptibility testing, while larger laboratories often choose an automated broth microdilution system. Most AST systems also perform organism identification as described in chapter 69. Only one semiautomated system for disk diffusion testing is marketed in the United States; additional systems are available in other countries. The AST systems include data management software that may be interfaced with a laboratory information system (LIS) and offer various levels of expert system and epidemiological analyses (2).

The U.S. Food and Drug Administration (FDA) provides regulatory oversight for AST systems marketed in the United States. Susceptibility test systems are classified as class II medical devices (subject to general controls) and require premarket notification with a 510(k) submission for FDA clearance (3, 4). Automated short-incubation (<16 h) AST systems are subject to additional special controls (4).

A 510(k) submission must demonstrate that a device is substantially equivalent to other devices marketed in the United States. The FDA (4) recommends a multicenter comparison of an AST system to the Clinical and Laboratory Standards Institute (CLSI) reference method (5, 6). The level of performance considered acceptable for each antimicrobial agent-organism combination is >89.9% categorical agreement (same susceptible, intermediate, or resistant classification using FDA breakpoints), >89.9% essential agreement (MIC results within 1 dilution of the reference method), ≤1.5% very major errors (VME; false susceptibility based on the number of resistant organisms), and ≤3% major errors (ME; false resistance based on the number of susceptible isolates) (4). Any antimicrobial agent-organism combination not meeting these standards must be listed as a limitation in the package insert with a recommendation to use an alternative method. Limitation statements are also required if the evaluation did not include a sufficient number of resistant organisms, showed unacceptable (<95%) reproducibility, or showed an elevated “no growth” rate (>10%) for an organism group (4). It is important to consult individual instrument/panel package inserts for specific antimicrobial agent-organism limitations, as significant differences exist between systems.

The reporting of AST results for antimicrobial agents without proven clinical efficacy against the specific organisms listed in the pharmaceutical package insert is discouraged (4). Manufacturers apply FDA interpretive standards when evaluating AST results (4). When FDA interpretive criteria change, manufacturers must perform a comparative study, and if the new breakpoints affect device performance, a new 510(k) submission is required (7). Changes to existing FDA interpretive criteria are generally driven by CLSI interpretative criteria changes and, subsequently, clinical laboratory expectations. If an appropriate validation is completed, laboratories may report results using interpretive criteria other than those published in the AST device label (8). Current information describing FDA regulations and a list of approved devices may be found at http://www.fda.gov/MedicalDevices/DeviceRegulationandGuidance.

This chapter focuses primarily on commercial susceptibility testing systems currently available in the United States. The broth microdilution AST systems are manufactured by four companies: bioMérieux (Durham, NC; http://www.biomerieux-usa.com), Siemens Healthcare Diagnostics (Deerfield, IL; http://www.siemens.com), Becton Dickinson Diagnostics (Sparks, MD; http://www.bd.com), and Thermo Scientific (Cleveland, OH; http://www.thermoscientific.com; formerly TREK Diagnostic Systems). The BIOMIC V3 system, manufactured by Giles Scientific (Santa Barbara, CA; http://www.biomic.com), has FDA clearance to read disk diffusion zone sizes and broth microdilution panel wells. Readers should be aware that susceptibility testing system components are constantly changing in response to new technology and problems that are discovered.

SEMIAUTOMATED INSTRUMENTATION FOR DISK DIFFUSION TESTING

The advantages of the disk diffusion method of susceptibility testing include simplicity, reliability, low cost, and a high degree of flexibility in selection of agents tested (1). Semiautomated systems available for reading and interpreting disk diffusion inhibition zones are listed in Table 1. For all systems, agar plates are manually inserted into an instrument after incubation for image acquisition and measurement of the zone of inhibition. Despite advances in imaging technol-

d recountability of results that are consistent with known resistance phenotypes. In general, these instruments provide reproducible and accurate results. In evaluations of the systems, bacteria with faint growth accounted for most discrepancies (10, 11, 12).

MANUAL BROTH MICRODILUTION SYSTEMS

The manual broth microdilution systems listed in Table 1 facilitate the visual reading and recording of MICs. The panels are frozen (Thermo Scientific custom plates) or dehydrated (MicroScan and Sensititre microwell trays). Devices for rehydration and inoculation of dehydrated trays include the manual RENOK device (MicroScan), the microprocessor-controlled Sensititre automated inoculation delivery system, and the Sensititre multichannel electronic pipette.

After offline incubation, the MicroScan data management system (LabPro) displays an image of the tray configuration for recording manual results directly on the computer. The Sensititre Vizion system magnifies a digital image of the 96-well susceptibility plate on a computer screen with superimposed templates to guide the reading of endpoints that are transferred to the data management system (SWIN, Sensititre Windows software) with expert analysis. The SWIN data management system is also available for recording of manual results without the Sensititre Vizion instrument.

Most manufacturers offer standard Gram-positive, Gram-negative, Streptococcus species, and extended-spectrum β-lactamase (ESBL) confirmatory panels. Thermo Scientific offers a more extensive menu of FDA-cleared Sensititre plates (Haemophilus influenzae and yeast [YeastOne]) and "research use only" panels (mycobacteria [rapid and slow growers], Campylobacter, and anaerobic) that can be read with the Vizion system or manually.

SEMI-AUTOMATED BROTH MICRODILUTION SYSTEMS

The semiautomated broth microdilution systems listed in Table 1 utilize automated devices to read susceptibility and identification tests after offline incubation. The results are transferred to a data management system that may include expert system analysis using the same software as available for the automated systems. Further information regarding MicroScan and Sensititre panels is presented in the section on automated systems.

AUTOMATED BROTH MICRODILUTION SYSTEMS

Automated AST systems do not require further manual intervention to obtain results after placement of the test panel in an instrument where incubation and reading of endpoints occur. An overview of the automated systems currently available in the United States is presented in Table 2. The VITEK, MicroScan WalkAway, and Phoenix systems provide AST results after short-term incubation (<16 h); the currently available Sensititre ARIS panels and some MicroScan WalkAway panels require overnight incubation. Manufacturers should be consulted regarding the current antimicrobial agents available for each system.

VITEK Systems

The first VITEK instrument developed for the provision of rapid MIC results was introduced in the 1980s. The VITEK 1 is still used in a number of laboratories; however, bioMérieux has stopped further development of new cards and software updates and no longer supports the maintenance of this instrument. The more automated VITEK 2 received FDA clearance in 2000. The AST panels are thin plastic 64-well cards with one to six concentrations of 9 to 20 antimicrobial agents. An identification card for common Gram-positive or Gram-negative bacteria may be run simultaneously with each AST card. The Smart Carrier Station includes a bar code scanner and base unit with microproces-

**Overview of automated broth microdilution susceptibility testing instrumentation**

自动化的琼脂扩散法抗性测试仪器的概述

**摘要**

自动化的琼脂扩散法抗性测试仪能够在短时间内完成测试，从而提高了结果的准确性。这些仪器包括MicroScan、VITEK 2和BioMérieux等。

**MicroScan WalkAway**

MicroScan WalkAway系统是在20世纪80年代末期开发的，并在2005年首次上市。该系统最初提供两种主要类型的AST面板：常规面板进行光度计读数后在20小时后读取结果，而快速面板则在15小时内读取结果。这些面板包括(i) MIC面板（涵盖多种抗微生物剂的稀释范围），(ii) MIC组合面板（某些稀释用于鉴别），以及(iii) 碱点组合面板（识别一种有限范围的抗微生物剂的稀释，用于分类结果为敏感、中介或耐药）。MicroScan WalkAway系统已由BioMérieux公司开发。

**VITEK 2 Compact**

VITEK 2 Compact系统于2005年推出，该系统可以容纳15、30或60张卡片。VITEK 2 Compact系统比VITEK 2系统更简单且更经济。

**VITEK 2**

VITEK 2系统在早期的20世纪80年代提供，并在20世纪90年代开始使用。VITEK 2系统能够读取光度计读数和氧化还原指示读数。

**Synergies Plus**

Synergies Plus是BioMérieux公司开发的一个模块，可以与VITEK 2系统结合使用，以生成抗微生物剂的联合抗药性结果。

**BacT/ALERT**

BacT/ALERT是一个血培养检测系统，可以与VITEK 2系统结合使用，生成抗生素敏感性的结果。

**AST Results**

AST结果可用于创建基于VITEK 2和VITEK MS的抗微生物剂数据的抗微生物剂敏感性结果。

**Antimicrobial Susceptibility Testing**

抗微生物剂敏感性测试通常用于检测抗生素对细菌的敏感性。

**Antibacterial Agents and Susceptibility Test Methods**

**Antimicrobial Susceptibility Testing?**

抗微生物剂敏感性测试通常用于检测抗生素对细菌的敏感性。
requiring longer incubation (turbidimetric reading), and identification (fluorometric results within 2.5 h).

The fourth-generation WalkAway plus system includes an incubator-reader unit, a personal computer unit, a LIS interface, and a printer. Fluid level sensors, a directional light-emitting diode system, and larger-capacity reservoirs have reduced the time needed to perform maintenance. Two instrument sizes accommodate 40 or 96 panels. The Prompt Inoculation System (available for overnight panels) incorporates a wand to prepare a standard inoculum without turbidity adjustments that is stable for 4 h. A manual device (RENOK) rehydrates and inoculates panels. The humidified incubator-reader unit has a bar code scanner, rotating carousel, and robotics to position panels under a central photometer or fluorometer for readings.

The data management system, LabPro, interprets results, generates patient reports, and archives data to allow production of user-defined reports (antibiograms, trend analysis, and epidemiology reports). Since 2002, the data management system has been able to be coupled with an expert system (LabPro Alert) that incorporates >100 rules and may be customized.

**BD Phoenix**

The BD Phoenix System has been available in Europe since 2001 and the United States since 2004. The instrument holds up to 100 test panels. The panels are polystyrene trays containing 136 wells dedicated entirely to AST (Emergence panel: 28 antimicrobial agents plus ESBL test wells) or divided into a 51-well identification (ID) side and an 85-well AST side with 14 to 22 antimicrobial agents.

The Phoenix AP instrument was introduced in 2008 to reduce the hands-on time required to set up Phoenix panels and to standardize inoculum preparation. Placement of EpiCenter workstations with bar code printers at each technologist bench maximizes work flow efficiency. Each ID broth is labeled with an EpiCenter-generated bar code label and then inoculated with a heavy isolate suspension. The ID broth and corresponding AST broth for five isolates are placed in a rack that is loaded on the AP instrument for automated standardization of the ID broth inoculum, inoculation of AST broth, and addition of the AST redox indicator. The rack is manually transferred to an inoculation station where the ID broth bar code label and a Phoenix panel are scanned. After the ID and/or AST broth is poured into the appropriate site, each panel is sealed with a plastic cap and placed on the Phoenix instrument.

The Phoenix instrument reads panels every 20 min using both a redox-indicator colorimetric change and turbidity to determine bacterial growth. Growth (metabolic activity) causes the redox indicator to change from an oxidized (blue) state to a reduced (pink) form. A full range of antimicrobial agent concentrations and a “growth” or “no growth” reading for each well allow the system to provide direct rather than calculated MICs. Susceptibility results are completed in 6 to 16 h.

The BDXpert system applies rules that incorporate CLSI or other standards to interpret AST results. Results can be finalized at the Phoenix instrument, the BD EpiCenter or the laboratory LIS. The BD EpiCenter is data management software for analyzing epidemiological trends and generating reports using information from multiple BD instruments (Phoenix, BACTEC blood culture, MGIT 960, and Bruker matrix-assisted laser desorption–ionization Biotyper systems). Features of BD EpiCenter include a bidirectional LIS interface, software that allows BDXpert system analysis of manual offline AST results, and tools to create user-specific rules for analyzing AST results.

**Sensititre ARIS 2X**

The Sensititre ARIS (automated reading and incubation system) was introduced in the United States in 1992 and provides overnight AST results (13, 14). The latest ARIS 2X version with hardware and software upgrades was released in 2004. The ARIS 2X instrument fits on the Sensititre AutoReader and holds up to 64 plates (standard 96-microwell trays) available as MIC panels or separate ID plates. Plates are rehydrated and inoculated with the Sensititre AIM automated inoculation system or a handheld multi-channel electronic pipette before placement in the instrument’s carousel. In 2012, the inoculum transferred from McFarland suspensions to 11-mL Sensititre Mueller-Hinton broth tubes used to inoculate MIC susceptibility plates and JustOne strips for testing Gram-negative and Gram-positive nonfastidious isolates was increased from 10 μL to 30 μL to improve the detection of resistant subpopulations of bacteria. The Sensititre MycoTB plate uses a microtiter plate MIC format for susceptibility testing of Mycobacterium tuberculosis complex isolates against first- and second-line antituberculosis agents and produces results approximately 1 week earlier than the 1% indirect agar proportion reference method (15). An internal bar code scanner identifies the plate type to assign the appropriate time of incubation. After 16 to 24 h of incubation, each AST plate is transported to the OptiRead automated fluorometric plate reading system for reading of endpoints. The data management software (SWIN) provides expert analysis of results. The SWIN epidemiology module enables laboratories to monitor trends and generate antibiogram reports.

**Advantages of Automated Systems**

Advantages of automated AST systems include labor savings, reproducibility, data management with expert system analysis, and the opportunity to generate results more rapidly. A work flow and performance evaluation of the VITEK 2 and Phoenix systems reported a longer mean setup time per isolate for Phoenix (3 min) than for VITEK 2 (1.5 min) but more monthly maintenance time for VITEK 2 (63.2 min) than for Phoenix (21.2 min) (16). The new Phoenix AP instrument reduced setup time by 50%, with a manual manipulation time per isolate that was 11.5 s less than for VITEK 2 work flow (P < 0.001) for batches of 14 isolates (17).

The overall mean time to generate AST results was higher for Phoenix (12.1 ± 2.7 h) than for VITEK 2 (8.4 ± 2 h) (P < 0.001) (16). Ligoizi et al. reported that the time required for VITEK 2 AST for Gram-positive cocci was 6 to 17 h, with 90% of results available as follows: 8 h, *Staphylococcus aureus*; 11 h, coagulase-negative staphylococci (CoNS); 9 h, enterococci; 7 h, *Streptococcus agalactiae*; and 9 h, *Streptococcus pneumoniae* (18). There are limited data showing financial and clinical benefits in association with the rapid provision of AST results. Doern et al. reported lower mortality rates and cost savings (fewer diagnostic tests and days in intensive care) associated with the rapid reporting of AST results (19). Barenfanger et al. also demonstrated reduced lengths of stay and cost savings for patients with rapid reporting of AST results that were attributed to earlier adjustments in antimicrobial therapy (20).

The time required to complete AST testing may eventually be reduced further with the application of molecular techniques. Rolain et al. described a real-time quantitative PCR method to measure the effect of antimicrobial agents...
on bacterial growth with a shorter time needed to generate results (4 h for Gram-positive cocci and 2 h for Gram-negative rods) (21). Additional research, increased automation, and lower cost are needed to make this molecular technology available for clinical laboratories (21). Direct inoculation of automated AST systems with positive blood culture bottles has also been reported and may be validated for laboratory reporting in conjunction with rapid identification (22, 23).

Effective communication of the results to clinicians and pharmacists is essential to realizing the potential benefits of rapid testing. Communication may be enhanced by software packages that interface with medication records and alert clinicians or pharmacists when adjustments in antimicrobial therapy are needed.

**Disadvantages of Automated Systems**

Disadvantages of automated systems include a higher cost for equipment and consumables than with manual methods, predetermined antimicrobial panels, an inability to test all clinically relevant bacteria and antimicrobial agents, and problems with detection of heteroresistant isolates and some resistance phenotypes (24, 25). In addition, laboratories must validate reformulated antimicrobial agents and use additional testing and reporting methods for agents where FDA breakpoints have not kept pace with changes to CLSI guidelines. Reports of AST performance for detecting problematic resistance phenotypes are discussed below. Current performance of a system may not be accurately reflected by studies utilizing panels and software that are no longer available. A higher error rate should be accepted for evaluations using challenge strains with difficult-to-detect phenotypes than for studies that test populations of isolates usually encountered in the clinical laboratory.

**Ability of Automated Systems To Detect Resistance**

Vancomycin Resistance in Enterococci

Problems with the detection of low-level vancomycin resistance (vanB and vanC) among enterococci by automated systems have been demonstrated in multiple studies (26). A VITEK 2 evaluation only reported difficulty detecting vanC2 (Enterococcus casseliflavus) strains (27). Other VITEK 2 and Phoenix studies have demonstrated accurate detection of vancomycin-resistant enterococci, but rigorous studies comparing systems are lacking (28–31). An FDA limitation for E. casseliflavus and Enterococcus gallinarum requires Phoenix users to determine vancomycin susceptibility for those species with an alternate method (29). MicroScan overnight panel studies reported detection of all isolates except those containing vanC that are difficult for all AST systems since their MICs (4 to 16 μg/ml) span susceptible and intermediate categories (32).

High-Level Aminoglycoside Resistance in *Enterococcus* spp.

The detection of high-level aminoglycoside resistance in enterococci by overnight and short-incubation AST systems has been improved by changes in growth medium and extended incubation (33). Initial problems detecting high-level streptomycin resistance (HLSR) in MicroScan overnight panels appear to have been resolved after a broth reformulation (34). A study reporting a higher VME rate for MicroScan detection of HLSR (32) may not have performed the recommended 48-h read for isolates that appear streptomycin susceptible after overnight incubation. Separate VITEK 2 and Phoenix evaluations testing different strains reported VME rates of 0 to 5.2% and ME rates of 0 to 7.3% for the detection of HLSR or high-level gentamicin resistance (28–31).

Linezolid Resistance in Enterococci and Staphylococci

Reading endpoints when testing linezolid can be difficult due to trailing growth. The low prevalence of linezolid resistance limits the ability of manufacturers to optimize detection with AST systems. Linezolid susceptibility testing of 50 enterococcal and 50 staphylococcal challenge isolates (included 32 non-linezolid-susceptible strains) demonstrated categorical agreements of 96.0% (MicroScan), 93.0% (VITEK 2), 89.6% (Phoenix), and 85.9% (VITEK 1) in comparison to CLSI broth microdilution results (35). Brignate et al. reported 89.0% categorical agreement of Phoenix linezolid results compared to Etest determinations for 100 enterococci (28).

Penicillin Resistance in *Staphylococci*

Staphylococcal isolates for which the penicillin MIC is ≤0.12 μg/ml require an induced β-lactamase test (coagulase-negative staphylococci) or a penicillin zone edge test (S. aureus) to be negative before being reported as penicillin susceptible (8). The sensitivity of phenotypic methods for penicillinase detection performed on 197 S. aureus isolates for which the VITEK 2 penicillin MICs were ≤0.12 μg/ml ranged from 39% (induced nitrocefin test) to 71% (zone edge determination method) when blaZ PCR was used as the reference standard (36). Since the prevalence of penicillin-susceptible staphylococcal isolates is low and β-lactamase production may not be detected using phenotypic methods, testing of subsequent isolates from the patient (8) or use of a molecular method (36) should be considered before relying on penicillin for treatment of serious infections.

Oxacillin Resistance in *Staphylococci*

Most of the studies discussed below used mecA PCR as the gold standard when evaluating the accuracy of a system for detection of oxacillin resistance in staphylococci. Multiple studies have demonstrated excellent sensitivity and specificity of automated systems for detecting methicillin-resistant *S. aureus* (MRSA) (18, 29, 30, 37, 38). However, heterogeneous resistant populations may not be detected with routine oxacillin testing (39, 40). Manufacturers of the MicroScan, Phoenix, and VITEK 2 systems have improved MRSA detection by adding cefoxitin to panels (40–44). For the detection of oxacillin resistance among CoNS, MicroScan, Phoenix, and VITEK 2 evaluations have demonstrated excellent sensitivities (96 to 99.4%), with lower specificities (66 to 96%) (18, 30, 45–49). Isolates with false-resistant results often have oxacillin MICs of 0.5 to 2 μg/ml that would have been considered susceptible under previous CLSI CoNS oxacillin breakpoints that were lowered to ≤0.25 μg/ml in 1999 (50). Some of the ME were for *Staphylococcus lugdunensis* isolates with oxacillin MICs now considered susceptible based on the CLSI 2005 decision to apply S. aureus breakpoints (≤2 μg/ml) to this species of CoNS (45, 46). The lower CoNS oxacillin breakpoint is most accurate for detecting mecA carriage in *Staphylococcus hominis*, *Staphylococcus haemolyticus*, and *Staphylococcus epidermidis* isolates, but may overcall oxacillin resistance for other CoNS species (50). An evaluation of the VITEK 2 cefoxitin screen found it to be more specific than the VITEK 2 oxacillin test for detection of mecA-mediated resistance in CoNS (51).
Reduced Glycopeptide Susceptibility in Staphylococci

The initial failure of automated AST systems to reliably detect vancomycin-resistant *S. aureus* led to a temporary requirement for a supplemental vancomycin agar screening plate until the systems were optimized for vancomycin-resistant *S. aureus* detection (52, 53). An evaluation of four commercial AST systems for the detection of vancomycin-intermediate *S. aureus* reported sensitivities of 64 to 100%; the two systems with 100% sensitivity incorrectly categorized 12% (MicroScan) and 24% (Phoenix) of susceptible isolates as vancomycin-intermediate *S. aureus* (54). Reports of vancomycin MIC “creep” among MRSA appear to depend upon the method of testing and storage of isolates (55). Unreliable AST system detection of CoNS with reduced glycopeptide susceptibility has also been reported (56). CLSI encourages laboratories to confirm nonsusceptible vancomycin results with a second method and to send any *S. aureus* isolate with a vancomycin MIC of ≥8 µg/ml or isolate of CoNS with a vancomycin MIC of ≥32 µg/ml to a reference laboratory (8).

Inducible Clindamycin Resistance

Staphylococci and beta-hemolytic streptococcal isolates that are macrolide resistant and clindamycin susceptible may be assessed for inducible clindamycin resistance using the CLSI disk diffusion or broth microdilution test (8). The inoculum purity plates from an automated broth AST system may be used to perform the disk induction (D-zone) test (57). Recently, FDA-cleared tests for inducible clindamycin resistance in staphylococci have become available for all of the automated systems in Table 2. An evaluation of the Phoenix test for inducible clindamycin resistance performed on 194 macrolide-resistant, clindamycin-susceptible staphylococcal isolates reported a sensitivity of 99% and a specificity of 97% (58). A multicenter study of the VITEK 2 inducible clindamycin resistance test using challenge and local strains of *S. aureus* with 244 tests performed reported a sensitivity of 98% and a specificity of 99% (59). A more recent comparison using fresh clinical isolates reported Phoenix (100% sensitivity; 99.6% specificity) to be more sensitive than VITEK 2 (91.1% sensitivity; 99.8% specificity) at detecting inducible clindamycin resistance (60). Another study found the inducible clindamycin resistance test on the VITEK 2 AST-P612 card to generate false-negative results at a rate of one in four for bacteria not susceptible to erythromycin (61).

*Streptococcus* spp. Resistance

Evaluations of the Phoenix and VITEK 2 panels for testing *Streptococcus* species demonstrated reliable results despite the shorter incubation (28, 62–64). Overnight *S. pneumoniae* strains available from MicroScan and Sensititre provided accurate results for agents other than trimethoprim-sulfamethoxazole (discrepancies were attributed to trailing endpoints) (65). The detection of emerging resistance by commercial AST systems is often suboptimal. For example, a VITEK 2 study in Japan, using AST-P546 cards, was only able to detect 50% of 28 strains of *Streptococcus agalactiae* with reduced susceptibility to penicillin, as tested by agar dilution, suggesting that these rare isolates of *S. agalactiae* may be misclassified as susceptible to penicillin G (66).

Other Resistance in Gram-Positive Bacteria

Daptomycin results generated by MicroScan, using panel PC29, for *Enterococcus faecium*, *Enterococcus faecalis*, and *S. aureus* have a high rate of false nonsusceptibility that cannot be confirmed by Etest or reference broth microdilution testing (67). These and other unusual resistance phenotypes require confirmation prior to reporting (8).

ESBL-Producing *Enterobacteriaceae*

Implementation of revised (2010) cephalosporin (cefazolin, cefotaxime, ceftaxizone, ceftriaxone, and ceftazidime) and aztreonam CLSI breakpoints for *Enterobacteriaceae* makes ESBL testing unnecessary unless there is consideration of using a cephalosporin for which interpretive criteria were not recently evaluated (cefonicid, cefamandole, cefoperazone, or moxalactam) (8). Some laboratories may continue to perform ESBL testing for infection control purposes. Confirmation ESBL tests that typically measure the inhibitory effect of clavulanate on ceftazidime and cefotaxime are available for all of the automated systems listed in Table 2. Two comparative evaluations of ESBL detection among *Escherichia coli* and *Klebsiella* spp. revealed sensitivities of 74 to 91% (VITEK 2) and 92 to 96% (Phoenix), with specificities of 81 to 85% (68, 69). Evaluations of a single AST system (VITEK 2 or Phoenix) have reported specificities of 94 to 100% and sensitivities of 96 to 99.7% for ESBL detection (70–75). Evaluations of the MicroScan ESBL panels have demonstrated sensitivities of 88 to 100% and specificities of 77 to 98% (76–79). False-positive ESBL results for K1-hyperproducing *Klebsiella oxytoca* isolates have been reported for MicroScan (79) and Phoenix (72, 80) systems. An evaluation performed on a collection of *E. coli* isolates with CTX-M phenotypes found that ESBL detection by VITEK 2 occurred for only 68% of the 137 isolates tested (81).

Carbapenem Resistance

Failure of automated AST systems to recognize emerging carbapenem resistance among *Klebsiella pneumoniae* and non-*Klebsiella pneumoniae Enterobacteriaceae* isolates has been reported primarily in studies that applied CLSI MIC interpretative guidelines from 2009 or earlier (71, 82–85). The addition of ertapenem to AST system panels improved detection of *bla_kpc*-positive *Enterobacteriaceae* isolates due to relatively lower CLSI breakpoints (in comparison to those for meropenem and imipenem) with a higher sensitivity for carbapenem production. The 2009 CLSI recommendation to perform the modified Hodge test for detection of carbapenemase production in *Enterobacteriaceae* isolates with elevated carbapenem MICs still in the susceptible range also enhanced *bla_kpc* detection (8). Subsequent studies have reported that this issue may be largely, although not entirely, rectified by application of the 2010 CLSI update to carbapenem breakpoints and to be highly test system dependent (83, 86, 87). The meropenem wells on VITEK 2 cards have been reformulated since a study showed problems with the detection of resistance for meropenem (AST-GN28 card) tested against KPC-producing *K. pneumoniae* (88). Difficulties in identifying carbapenem resistance in *Acinetobacter baumannii* have been reported for Phoenix, MicroScan, and VITEK 2 (84, 89, 90). Problems with false resistance when determining carbapenem susceptibility have also been noted (91, 92). The CDC could only confirm 9% of 123 *Enterobacteriaceae* and 74% of 325 *Pseudomonas aeruginosa* isolates initially reported as non-imipenem susceptible by 44 U.S. hospital laboratories during the period from 1996 to 1999 (91). The lack of a clear explanation for this overdetection of carbapenem resistance led the authors to recommend that laboratories consider using a second AST method to confirm non-carba-
penem-susceptible results (91). Antimicrobial agent deterioration in test panels and technical errors are factors that may contribute to the over detection of carbapenem resistance by AST systems (91, 92).

Other Resistance in Gram-Negative Bacteria
Two evaluations directly comparing the accuracies of automated AST systems for testing clinical and challenge isolates of *P. aeruginosa* found unacceptable levels of error for imipenem, piperacillin-tazobactam, cefepime, ceftazidime, and aztreonam (93, 94). Susceptibility testing of clinical isolates of *P. aeruginosa* using only VITEK 2 identified three agents with categorical agreement of <90% (ceftazidime, cefotaxime, and gentamicin) that were predominantly minor errors (95). A VITEK 2 study utilizing *P. aeruginosa* isolates selected to represent specific β-lactam resistance phenotypes revealed elevated error rates for all β-lactam agents tested (96). A VITEK and MicroScan study concluded that automated commercial AST systems were contraindicated for testing isolates of *P. aeruginosa* from cystic fibrosis patients and attributed the poor correlation with reference methods to slow growth and mucoid strains (97). Phoenix studies have reported low categorical agreement for nonfermenting Gram-negative bacillus isolates primarily due to minor errors and ME with β-lactams, ciprofloxacin, and trimethoprim-sulfamethoxazole (75, 98, 99).

A study from Korea comparing commercial methods used to test colistin against 213 bloodstream isolates of *Acinetobacter* spp. found, compared to agar dilution, excellent categorical agreement for VITEK 2 (99.1%) compared to 87.3% using MicroScan (100). VITEK 2 has also been reported to provide high (97%) essential and categorical agreement with broth microdilution for tigecycline tested against clinical isolates of *E. coli* but not other species of *Enterobacteriaceae* (essential agreement, 81%; categorical agreement, 59%) (101).

A study from Korea comparing commercial methods used to test colistin against 213 bloodstream isolates of *Acinetobacter* spp. found, compared to agar dilution, excellent categorical agreement for VITEK 2 (99.1%) compared to 87.3% using MicroScan (100). VITEK 2 has also been reported to provide high (97%) essential and categorical agreement with broth microdilution for tigecycline tested against clinical isolates of *E. coli* but not other species of *Enterobacteriaceae* (essential agreement, 81%; categorical agreement, 59%) (101).

**COMPUTERIZED EXPERT SYSTEMS**

Expert systems to assist in the critical review of AST results are available for all commercial susceptibility systems currently marketed in the United States. Expert systems can enhance work flow by identifying the subset of results that require human expert attention and may also improve the quality of AST results reported from smaller laboratories that may lack a human expert (2, 102). By continuous monitoring, the algorithms allow more rapid recognition of incorrect results and more uniform reporting. However, the software must be frequently updated to reflect the emergence of new resistance and changes in reporting guidelines recommended by national organizations such as CLSI. Users must be aware of what rules and comments are activated in their system and work closely with manufacturer-provided specialists to customize the expert system for their laboratory. The degree of customization allowed varies among AST systems. Ideally, an expert system will report actual MICs with categorical interpretation before and after recommended changes. Expert systems may also deduce the susceptibility of an isolate to agents not tested and detect inconsistencies between bacterial ID and AST results (2, 102).

Most expert systems use a rules-based approach focusing on AST results for one drug at a time without considering results for other agents tested simultaneously. The VITEK 2 AES differs by performing an “interpretive reading” that compares the MICs for multiple agents to a large database of known resistance phenotypes and MIC distributions for different species (2, 103, 104). The rationale for interpretive reading with phenotype assignment is that a single mechanism typically mediates resistance to multiple agents (105). Excellent concordance of VITEK 2 AES interpretive reading with resistance genotypes has been reported in multicenter studies (103, 106). When the AES was compared to human expert analysis of VITEK 2 results for 259 consecutive clinical isolates in a university-based microbiology laboratory, there was disagreement for only 5 of the 65 isolates (8%) with AES corrections (102). A limitation that has been noted for the AES is an inability to interpret multiple inconsistent results as being caused by a single problem (102, 107). Nakasone et al. reported inaccurate resistance genotype reporting by the AES for vancomycin-resistant enterococci and macrolide-resistant *S. pneumoniae* (108). In 2011, Winstanley and Courvalin published a detailed review of VITEK 2, Phoenix, MicroScan, and other expert systems (2).

**CRITICAL REVIEW OF AST RESULTS**

Regardless of whether a laboratory is using a commercial expert system, it is important to be aware of unusual “resistant” and “susceptible” results that require verification of the organism’s ID and repetition of the susceptibility test by the same or a different method (8, 105). An example of an unprecedented phenotype that should prompt retesting is an *Enterobacteriaceae* or *P. aeruginosa* isolate that appears more resistant to piperacillin-tazobactam than to piperacillin (109). There are a number of antimicrobial agents that may appear active in vitro but lack clinical efficacy (Table 3); therefore, the isolates should be reported as resistant (8). The most recent CLSI M100 document should be consulted for current recommendations regarding agents to test for specific bacteria, methodology, interpretive criteria, results that may be inferred without testing a specific agent, antimicrobial agents to report based on the site of infection, and unusual results requiring verification (8). Expert rules

*Implementation of the revised (2010) cephalosporin and aztreonam CLSI breakpoints for Enterobacteriaceae makes routine ESBL testing unnecessary unless there is consideration of using the agents listed. If ESBL testing is performed and results are positive, the organisms should be reported as resistant to these agents.*
to assist with the interpretation of AST results are also available at the European Committee on Antimicrobial Susceptibility Testing (EUCAST) website (http://www.eu cast.org/expert_rules/).

**SELECTING AN AST SYSTEM**

Factors to consider when selecting an AST system include cost, performance, work flow, data management capabilities, ability to interface with other LIS and hospital information system components, and manufacturer technical support (110). Performance may be assessed by comparing dilutions of FDA-cleared antimicrobial agents and limitations (antimicrobial agent or bacteria listed in package inserts that require an alternative method) of panels from different manufacturers. Current users of systems and publications in peer-reviewed journals are important resources for assessing performance. Manufacturers should be asked if problems reported for particular antimicrobial agent-bacterium combinations have been resolved and what is under development. Manufacturer exhibits at national meetings offer demonstrations of systems and convenient access to industry representatives. Poster presentations at conferences provide the opportunity to interact with recent system users and acquire new information regarding performance. Another method of assessing the performance of AST systems is participation in proficiency testing surveys such as those of the College of American Pathologists (111), whose final critiques of AST methods used and problem antimicrobial agent-bacterium combinations with high error rates.

An AST system’s ability to perform ID is also important because expert rules are linked to bacterial identity. Additional information regarding selection of an AST system and laboratory verification of performance as required by the Clinical Laboratory Improvement Amendments of 1988 (112) is in the Clinical Microbiology Procedures Handbook (110) and Cumitech 31A (113).

**SUMMARY**

AST systems provide accurate and reproducible results for many antimicrobial agent-bacterium combinations. Expert analysis may improve work flow as well as the quality of reported results. The labor savings attributed to automated AST systems are particularly important for laboratories in regions with current or projected technologist shortages. In addition, the provision of more rapid AST results with a short-incubation system may improve patient care and lower health care costs. Future advances in the development of AST systems may increase their clinical impact with the incorporation of molecular techniques that dramatically shorten the time required for results.

**REFERENCES**

Most of the tests described in this chapter are phenotypic tests that characterize an organism’s susceptibility or resistance to an antimicrobial agent by screening for a specific resistance mechanism or phenotype. Some of these can be used to guide therapy, whereas others are used for epidemiology or infection control purposes. We have tried to describe the appropriate use of each test in its description. As screening tests, these do not provide an MIC of the agent; however, some of these tests have sufficient sensitivity and specificity that confirmation of the result is unnecessary and the results of the screening test can be reported without additional testing. For example, screening tests for inducible clindamycin resistance in *Staphylococcus aureus* and *Streptococcus* spp. and MIC screening tests for high-level aminoglycoside resistance in enterococci have been shown to have reliability comparable to that of standard methods for detecting clinically significant resistance, so additional confirmatory tests are unnecessary. The tests described here may either supplement or replace traditional testing methods, depending on the organism and the assay. This chapter describes details of tests for detection of the following: high-level aminoglycoside resistance and acquired vancomycin resistance in enterococci; inducible clindamycin resistance in streptococci; penicillin, oxacillin, vancomycin, inducible clindamycin, and high-level mupirocin resistance in staphylococci; extended-spectrum-β-lactamase (ESBL) and carbapenemase production in *Enterobacteriaceae*; and β-lactamases in multiple organisms. The tests included are listed in Table 1. Other special phenotypic tests described in previous versions of this chapter, including those for determining the bactericidal activity or combined activities of antimicrobial agents, have not changed substantially and are thus not discussed here. If guidance on such testing is needed, please refer to previous editions of this Manual which included this section (1).

Quality control information is given for many of the tests in each section; however, guidelines for the frequency of quality control testing are not provided, because they either have not been defined or vary depending on laboratory circumstances. A practical approach would be to perform quality control testing each day that clinical isolates are tested, or less frequently (e.g., weekly) once a laboratory

**TESTS TO DETECT RESISTANCE IN ENTEROCOCCI**

Serious invasive enterococcal infections, such as endocarditis, are commonly treated with a cell wall-active agent (either a penicillin or a glycopeptide, such as vancomycin) and an aminoglycoside (usually gentamicin or streptomycin). These agents act synergistically to enhance killing (2, 3). However, when an enterococcal strain is resistant to the cell wall-active agent or has high-level resistance (HLR) to the aminoglycoside, there is no synergism and combination therapy will not provide a bactericidal effect (2). Because of this, it is important to determine the susceptibility to both the aminoglycoside and the cell wall-active agent individually in order to predict the likelihood of synergy. Methods for detection of aminoglycoside and vancomycin resistance are discussed here. Discussions of methods for detection of high-level penicillin and ampicillin resistance can be found in the relevant Clinical and Laboratory Standards Institute (CLSI) documents (4, 5).

**Detection of HLR to Aminoglycosides**

Because aminoglycosides have poor activity against enterococci (MICs range from 8 to 256 μg/ml), they cannot be used as single agents for therapy (2, 6). This intrinsic, moderate-level resistance is due to poor uptake of aminoglycosides by the cell (7). Acquired aminoglycoside resistance in enterococci is due either to mutations resulting in decreased binding of the agent to the ribosome, as occurs with streptomycin (called ribosomal resistance), or, more commonly, to the acquisition of new genes that encode enzymes that modify aminoglycosides (called acquired resistance). Acquired aminoglycoside resistance usually corresponds to MICs that are significantly above the concentrations normally tested in routine susceptibility tests, e.g., ≥2,000 μg/ml for streptomycin and ≥500 μg/ml for gentamicin, and is designated HLR (7) (see also chapters 23 and 69).

Synergy between an aminoglycoside and a cell wall-active agent can be determined directly by performing complex time-kill studies (8, 9) or can be predicted by using less cumbersome screening tests. Gentamicin and streptomycin are the only two agents that should be tested on a routine basis. Enterococci that are resistant to gentamicin are considered resistant to tobramycin and amikacin as well, because gentamicin resistance is most commonly due to the bifunctional enzyme encoded byaac(6′)-Ic-aph(2″)-Ia, which also confers resistance to other aminoglycosides except streptomycin. Resistance to streptomycin is mediated by a different resistance mechanism, and consequently, streptomycin resistance must be determined separately from gentamicin resistance. Isolates of Enterococcus faecium are intrinsically resistant to the synergistic actions of amikacin, kanamycin, tobramycin, and netilmicin with cell wall-active agents, irrespective of in vitro testing results for HLR (10). Enterococcus faecalis strains that are susceptible to gentamicin may be resistant to tobramycin, netilmicyn, kanamycin, and amikacin (11) by means of various other aminoglycoside-modifying enzymes, but optimal methods for testing have not been determined.

The following genes for three additional enzymes that mediate gentamicin resistance have been described:aph(2′)-Ic (33), aph(2′)-IId (238), and aph(2′)-Ib (12). All of these genes confer resistance to ampicillin-gentamicin synergism; however, the first蚜([aph(2′)-Ic] may not be detected using the screening methods described below, since its presence seems to lead to intermediate, not high-level, resistance. The second gene, aph(2′)-IId, if detected by the screening methods described here, would be assumed to be resistant to synergy with amikacin, although this may not be the case. Only time-kill or molecular studies for the specific enzymes will detect their presence. Methods for detection of HLR to aminoglycosides are summarized in Table 2 and discussed below.

Agar Dilution Screening Method
Agar plates are prepared with brain heart infusion (BHI) agar with addition of 500 μg of gentamicin per ml or 2,000 μg of streptomycin per ml. The plates are inoculated by spotting 10 μl of a suspension that is equivalent to a 0.5 McFarland standard, prepared from growth on an 18- to 24-h agar plate, giving a final inoculum of 10⁶ CFU per...

*CLSI disk diffusion method (5).
*If streptomycin is negative at 24 h, incubate for an additional 24 h.
*NA, not applicable.
*If the zone is 7 to 9 mm, then the test is inconclusive, and an agar or broth microdilution test should be performed to confirm susceptibility or resistance.

spot. The plates are incubated for a full 24 h in ambient air. The presence of more than one colony of growth should be read as presumptive resistance. For streptomycin, the plates should be incubated for an additional 24 h if there is no growth at 24 h. Mueller-Hinton agar (MHA), MHA plus 5% sheep blood, or dextrose phosphate agar may be substituted for BHI agar, but because growth is better on BHI agar, this is the preferred medium. Commercially prepared agar screening plates are available and have performed well (13–15).

**Broth Microdilution Screening Method**

Broth dilution tests are prepared using a single well or a tube containing BHI broth with the addition of 500 µg of gentamicin per ml or 1,000 µg of streptomycin per ml. The final inoculum concentration is that recommended for routine broth microdilution testing, i.e., 5 × 10⁵ CFU/ml. The plates are incubated for 24 h in ambient air. For streptomycin, the test samples should be incubated for an additional 24 h if there is no growth at 24 h. Any growth is interpreted as denoting resistance.

The recommended streptomycin concentration for use in the broth microdilution screen is half that used in the agar dilution screening test. Because this test is often included as part of a routine Gram-positive MIC panel, the inoculum is that commonly used in broth microdilution testing (5 × 10⁶ CFU/ml). The total number of cells tested in the agar dilution screening procedure (10⁶ CFU/spot) is 20-fold larger than that normally used in the broth microdilution test (5 × 10⁴ CFU/0.1 ml well). In order to provide a test that uses a small inoculum and at the same time maximizes the detection of HLR to streptomycin, it was necessary to lower the concentration recommended for testing streptomycin from 2,000 to 1,000 µg/ml in the broth microdilution test. Because of poorer growth and the smaller inoculum, Mueller-Hinton broth is inadequate for use in the broth microdilution screening test (16). The performance of other aminoglycosides in this test has not been evaluated.

**Disk Diffusion Screening Method**

The standard disk diffusion procedure (5) described in chapter 23 (with unsupplemented MHA) is used, except that special high-content disks (gentamicin at 120 µg and streptomycin at 300 µg) are required (17). Zones are measured after 18 to 24 h of incubation in ambient air at 35°C. Isolates for which the zone diameters are ≥10 mm are categorized as susceptible. The absence of a zone of inhibition corresponds to the presence of HLR. Strains for which the zones of inhibition are 7 to 9 mm usually display HLR, but a few are strains for which the MICs are only moderately elevated (16). Therefore, strains for which the zone diameters are 7 to 9 mm should be tested by either the standard agar or broth microdilution screening method to determine susceptibility or resistance. High-content gentamicin and streptomycin disks are available commercially.

**Quality Control**

For both gentamicin and streptomycin, E. faecalis ATCC 29212 is used as the susceptible control strain and E. faecalis ATCC 51299 is used as the resistant control strain (18). Only E. faecalis ATCC 29212 is used for control of disk diffusion tests. The expected quality control limits are 16 to 23 mm for gentamicin (120 µg) disks and 14 to 20 mm for streptomycin (300 µg) disks (19).

**Detection of Vancomycin Resistance in Enterococci**

As defined by CLSI, the MIC interpretive criteria for vancomycin are ≤4 µg/ml for susceptible, 8 to 16 µg/ml for intermediate, and ≥32 µg/ml for resistant. The three most common phenotypes of resistance are (i) high-level vancomycin resistance (MICs, ≥64 µg/ml) with accompanying teicoplanin resistance (MICs, ≥16 µg/ml) (VanA phenotype); (ii) moderate- to high-level vancomycin resistance (MICs, 16 to 512 µg/ml), most commonly without teicoplanin resistance (VanB phenotype); and (iii) intrinsic low-level resistance associated with Enterococcus gallinarum and Enterococcus casseliflavus (MICs, 2 to 32 µg/ml) (VanC phenotype) (20, 21). Both the VanA and VanB phenotypes are most commonly seen in E. faecalis and E. faecium but have been found in other species, including E. casseliflavus and E. gallinarum (20, 22). Additional genes conferring vancomycin resistance have also been described, including vanD (23, 24), vanE (25), vanG (26), vanL (17), vanN (27), and vanM (28). Detailed information that explains the phenotypes associated with these, including the usual MICs for vancomycin and teicoplanin and species in which they are found, is described in chapter 23.
Many methods commonly used by clinical laboratories, including disk diffusion and the Vitek (bioMérieux, Durham, NC) and MicroScan (Siemens Healthcare Diagnostics, Deerfield, IL) systems, originally had problems detecting low-level vancomycin resistance (both VanB and VanC types) (29–35). However, systems have improved (34, 36–39). The Vitek 2 and Phoenix systems perform very well for detection of vancomycin resistance in enterococci (40–46); however, a recent study cautioned that vanA- or vanB-containing E. casseliflavus and E. gallinarum may not be differentiated from the usual wild-type vanC-containing enterococci (43) with the Vitek 2 expert system. Disk diffusion testing requires 24 h of incubation and examination of zones under transmitted light.

The vancomycin agar screening test first described by Willey et al. (35) was adopted by CLSI in 1993 (47, 48) (Table 2). Sensitivity and specificity levels of 96 to 99% and 100%, respectively, were noted at that time. Commercially prepared plates also perform well (29, 49, 50). However, there may be some confusion about the characterization of susceptibility or resistance for the vanC-containing enterococci, E. gallinarum and E. casseliflavus, because their growth is less uniform on these screening plates. Both of these species intrinsically contain a vanC gene, but the MICs of vancomycin for them range from 2 to 32 μg/ml (20). Whether the presence of this gene is associated with therapeutic failures is not known. Since the vancomycin MICs for these strains are often >4 μg/ml, the strains are likely to grow on agar screening plates, where a larger inoculum and a richer medium may promote growth (14, 48, 49). Most strains of vanC-containing enterococci are motile at 30°C; E. casseliflavus is typically yellow pigmented. These characteristics have been used to distinguish vanC-containing enterococci from other species (49, 51, 52). However, some E. gallinarum and E. casseliflavus strains may be nonmotile. Because of this, a better test to differentiate them from E. faecalis and E. faecium is fermentation of 1% methyl-β-D-glucopyranoside (MGP). All vanC-containing enterococci acidify MGP, whereas E. faecium and E. faecalis do not (53) (see also chapter 23).

### Vancomycin Agar Screening Test

Agar plates are prepared with BHI agar supplemented with 6 μg of vancomycin per ml (BHI-V6). Using growth from an 18- to 24-h agar plate, a suspension equivalent in turbidity to a 0.5 McFarland standard is made and used to inoculate the plates by spotting 1 to 10 μl or swabbing an area of 10 to 15 mm in diameter. The final inoculum is 10⁷ to 10⁸ CFU per spot. After inoculation, the plates are incubated for a full 24 h in ambient air at 35°C. The presence of more than one colony of growth indicates presumptive resistance.

#### Quality Control

For quality control, E. faecalis ATCC 29212 (no growth, i.e., susceptible) and E. faecalis ATCC 51299 (growth, i.e., resistant) should be tested (216). Plates made with BHI agar from certain manufacturers may allow light growth of E. faecalis ATCC 29212, especially if the larger inoculum (10 μl) is used or the plates are held for longer than 24 h.

### Reporting Resistance in Enterococci

For any serious enterococcal infection (e.g., endocarditis), results of the screen for HLR to gentamicin and streptomycin should be reported in concert with the results of the testing of the cell wall-active agent (penicillin, ampicillin, or vancomycin), because synergy would not be expected if any one of the agents was reported as resistant. High-level aminoglycoside resistance determined by an MIC screening method can be reported without further confirmation. With the disk diffusion test, results can be reported unless the test is inconclusive, in which case an agar dilution or broth microdilution test should be done to clarify the result. Helpful suggestions on reporting the results of enterococcal tests are given by Hindler and Sahm (6).

### TESTS TO DETECT RESISTANCE IN STAPHYLOCOCCI

Because some of the phenotypic tests described here for S. aureus are not recommended for coagulase-negative staphylococci (CoNS), the two groups are discussed separately, as S. aureus and Staphylococcus lugdunensis and as CoNS (except S. lugdunensis), for detection of oxacillin resistance. Although S. lugdunensis is coagulase negative, it tends to behave more like S. aureus than like other CoNS with regard to oxacillin tests (54–56). This grouping may also work for other tests, although possible exceptions are noted in the discussions that follow. Tests for detection of resistance in this group are summarized in Table 3.

#### Detection of Penicillin Resistance in Staphylococci

Penicillin resistance in staphylococci is due to production of penicillinase, encoded by the blaz gene, which is usually plasmid mediated and inducible. Most staphylococci are now resistant to penicillin, so its use for treatment is rarely considered. The susceptibility breakpoint for penicillin resistance is ≤0.12 μg/ml; however, because rare isolates with penicillin MICs in the susceptible range may produce β-lactamase, current recommendations state that a β-lactamase test should be performed on staphylococcal isolates that test susceptible to penicillin before reporting of the isolate as penicillin susceptible (19, 57).

In the past, commercial β-lactamase tests utilizing a chromogenic cephalosporin, such as nitrocefin, were widely used. However, a recent study comparing phenotypic methods for detecting penicillinase in S. aureus strains that test susceptible to penicillin showed that nitrocefin-based methods lack sensitivity (58). In that study, blaz was detected by PCR in 28 of 197 S. aureus isolates with penicillin MICs of ≤0.12 μg/ml by a Vitek 2 system. When a nitrocefin-based method was used, only 11 of 28 (39%) isolates were detected as β-lactamase positive. The most sensitive nonmolecular β-lactamase detection method studied was the appearance of the penicillin zone edge as either sharp (β-lactamase positive) or tapered (β-lactamase negative) (59), which detected 20 of 28 (71%) blaz-positive strains.

Both CLSI and EUCAST recommend that the zone edge test be performed for S. aureus isolates with penicillin MICs or zone diameters within the susceptible range before reporting them as susceptible (19, 57). The zone edge test is not recommended for CoNS, but CLSI recommends that a nitrocefin-based test be performed before reporting of CoNS, including S. lugdunensis, as penicillin susceptible (19). Furthermore, CLSI also recommends that MIC and β-lactamase tests be performed on all subsequent Staphylococcus isolates from the same patient because of the possibility that rare strains that contain blaz but test as penicillin susceptible may become phenotypically resistant by both MIC and β-lactamase testing (19).

#### Detection of Oxacillin Resistance in S. aureus and S. lugdunensis

Strains of S. aureus resistant to oxacillin are still referred to as methicillin-resistant S. aureus (MRSA), even though...

<sup>a</sup>Applies to S. aureus only.
<sup>b</sup>Applies to both S. aureus and S. lugdunensis.
<sup>c</sup>Commercial β-lactamase tests may also be used, but if the test is negative, the penicillin disk diffusion zone edge test should be performed before reporting the isolate as susceptible.
<sup>d</sup>BAP, blood agar plate.
<sup>e</sup>Isolates with a vancomycin MIC of 8 μg/ml (intermediate) will also grow.
methicillin is no longer available; the abbreviation MRSA has persisted and therefore is also used here. At least four different resistance mechanisms can confer resistance to oxacillin in S. aureus: (i) expression of the acquired chromosomal mecA gene to produce a supplemental penicillin-binding protein (PBP), designated PBP 2a, with decreased affinity for penicillins; (ii) production of a different PBP variant by the recently described mecC gene, found in isolates recovered from livestock; (iii) inactivation of the drug by increased production of β-lactamase; and (iv) production of modified intrinsic PBPs with altered affinity for the drug (60–65).

Resistance mediated by mecA is by far the most common mechanism of oxacillin resistance worldwide, and it is the most-studied and most-characterized type. Rapid and reliable detection of mecA-mediated resistance is recognized as a crucial component of laboratory testing, and numerous laboratory methods for this purpose have been described. Since its description in 2011, mecC-mediated resistance has been identified in S. aureus from human, livestock, and other animal isolates, but it appears to have a low prevalence overall, especially in persons with high rates of animal exposure (66–69). Although studies to determine the prevalence of other resistance mechanisms have not been done, it is assumed that resistance that is not mediated by a mec gene occurs only rarely in S. aureus, and such mechanisms have not been found at all in S. lugdunensis. MRSA isolates have historically demonstrated resistance to multiple classes of antimicrobial agents, including erythromycin, clindamycin, chloramphenicol, tetracycline, trimethoprim-sulfamethoxazole, older fluoroquinolones, and aminoglycosides. However, some contemporary MRSA isolates, especially community-associated strains (CA-MRSA), are frequently not multidrug resistant (70–72).

Strains that possess mecA (classic resistance) are either heterogeneous or homogeneous in their expression of resistance. With homogeneous expression, virtually all cells express resistance when tested by standard in vitro test methods. However, testing of a heteroresistant isolate results in a subpopulation of cells that appear to be susceptible and others that appear to be resistant. Often, only 1 in 10⁶ to 1 in 10⁸ mecA-positive cells in the test population express resistance (73–75). Oxacillin MIC interpretive criteria for S. aureus and S. lugdunensis are ≤2 μg/ml for susceptible and ≥4 μg/ml for resistant (19, 57). Heterogeneous expression occasionally results in MICs near the breakpoint (oxacillin MICs of 2 to 8 μg/ml) and consequently may be misinterpreted as susceptible.

Non-mecA-mediated resistance due to hyperproduction of β-lactamase (borderline oxacillin-resistant S. aureus [BORSAs]) or production of modified PBPs (MOD-SA resistance) also results in oxacillin MICs near the breakpoint. BORSA-type resistance can usually be distinguished from the classic type (mecA positive) of resistance or MOD-SA resistance by the addition of a β-lactamase inhibitor (e.g., clavulanic acid) to the oxacillin MIC test, which lowers the MIC by 2 dilutions or more. Isolates that are resistant by either the BORSA or the MOD-SA mechanism usually do not have multiple-drug resistance, similar to CA-MRSA.

Incomplete induction of mecA expression by oxacillin can result in light or hazy growth within the zone of inhibition, which in turn affects interpretation of oxacillin zone diameters, leading to performance concerns with both sensitivity and specificity (56, 76, 77). Therefore, if oxacillin is tested against staphylococci, only MIC-based methods are recommended for use (19). Phenotypic tests described below for the S. aureus group include (i) the use of cefoxitin as a surrogate for oxacillin in routine susceptibility testing methods and (ii) the oxacillin-salt agar screening test.

Detection Using Cefoxitin as a Surrogate for Oxacillin

The use of cefoxitin has been validated extensively since it was first proposed by investigators in France (78, 79). When used as a surrogate for prediction of oxacillin resistance in S. aureus, it has been shown to be equal in sensitivity to oxacillin-based tests, but with better specificity, because it is easier to read than tests with oxacillin, especially for disk diffusion tests (56, 80).

Both cefoxitin MIC and disk diffusion methods are described for S. aureus and S. lugdunensis (Table 3). The cefoxitin disk test is performed using routine disk diffusion for S. aureus and S. lugdunensis: results of ≤21 mm are reported as oxacillin resistant, and those of ≥22 mm are considered oxacillin susceptible (19). The test is easy to read using reflected light and does not require careful examination of the disk diffusion zones for light growth or small colonies. Following validation in a multilaboratory study (80), cefoxitin MIC breakpoints for prediction of mecA-mediated oxacillin resistance in S. aureus and S. lugdunensis were included in CLSI document M100 (81); cefoxitin MICs of ≤4 μg/ml are interpreted as oxacillin susceptible, and those of ≥8 μg/ml are considered oxacillin resistant. The cefoxitin screen for oxacillin resistance is also endorsed by EUCAST (57). Cefoxitin MIC and disk diffusion tests are read after 16 to 18 h of incubation (19).

Oxacillin-Salt Agar Screening Test for S. aureus

The oxacillin-salt agar screening test (Table 3) has been used widely, although it has been shown to be less sensitive than the cefoxitin disk diffusion test (78, 82, 83). Its use for detection of the presence of mecA in S. lugdunensis has not been studied, but theoretically it should work because oxacillin MICs for mecA-positive strains are ≥16 μg/ml (84, 85). Some investigators examined the use of 4 μg/ml cefoxitin in an agar dilution screen similar to the oxacillin-salt agar screen (77, 86, 87), and they demonstrated sensitivities and specificities equivalent to or better than those obtained with oxacillin-salt agar (87–89), although this method has not been endorsed by CLSI as a screening test.

MHA supplemented with 4% sodium chloride and 6 μg of oxacillin per ml is used for the agar screening method recommended by CLSI (4). For this test, inoculum suspensions are prepared by selecting colonies from overnight growth on a nonselective agar plate. The colonies are transferred to broth (e.g., tryptic soy broth) or saline to produce a suspension that matches the turbidity of a 0.5 McFarland standard. This suspension is used to inoculate the oxacillin agar screening plate by either (i) dipping a cotton swab into the test suspension, expressing the excess liquid from the swab, and inoculating an area of 10 to 15 mm in diameter (or streaking the swab onto a quadrant of the agar surface); or (ii) spotting an area of 10 to 15 mm in diameter with a 1-μl loop that has been dipped in the suspension (90). Test plates are incubated for a full 24 h at 33 to 35°C in ambient air and examined for growth of more than one colony, which indicates resistance. It is important that the incubation temperature not exceed 35°C, as MRSA may not be detected with this method if plates are incubated at warmer temperatures (4).

Quality Control

S. aureus ATCC 29213 (oxacillin susceptible) and S. aureus ATCC 43300 (oxacillin resistant) are the recommended quality control strains.
Limitations of Methods for Detection of Oxacillin Resistance in S. aureus

For S. aureus, growth of an isolate on an oxacillin agar screening plate generally means that the isolate is mecA positive. When performed properly, the oxacillin agar screening method will detect most mecA-positive S. aureus strains. Occasionally a heteroresistant mecA-positive strain is not detected, which may in part be due to a low frequency of resistance expression (91, 92) or to lot-to-lot or manufacturer-to-manufacturer variation in the test medium (93, 94). The test may also not detect borderline-resistant strains with non-mecA-mediated resistance mechanisms.

Early comparisons of the oxacillin agar screening test and the cefoxitin disk diffusion test for S. aureus found an increased sensitivity for detecting mecA-mediated resistance for the cefoxitin disk diffusion test (82, 95). In more recent comparisons of the two methods, using the revised disk diffusion breakpoints, the tests performed equally, with sensitivities of 98 to 100% for cefoxitin disk diffusion and 100% for the oxacillin-salt agar screen (96–98). Cefoxitin disk diffusion testing has been shown to perform well for detection of borderline resistance caused by mecA (76, 78), but it will not detect other types of borderline oxacillin resistance, i.e., MOD-SA or BORSA strains. In one study, reference and commercial methods for detection of mecA were studied with a collection of S. aureus strains expressing either borderline oxacillin MICs (oxacillin MICs of 1 to 4 μg/ml) or for which previous results with oxacillin tests were discrepant by disk and MIC testing (77). In that study, MIC and disk diffusion tests using cefoxitin performed significantly better than those using oxacillin, including the oxacillin-salt agar screening test and oxacillin MIC tests for detection of mecA-mediated resistance.

Although the cefoxitin-based tests demonstrate the best performance for detection of mecA-mediated resistance in S. aureus, only tests using oxacillin will work for the detection of resistance due to MOD-SA or BORSA (mechanisms not mediated by mec genes). The rarity of this type of resistance (typically associated with oxacillin MICs of 2 to 16 μg/ml) precludes a clear understanding of its clinical relevance, but experimental studies suggest that it may not have a significant impact on outcomes (99–101).

Recently, a novel mec gene, mecC, was described among Staphylococcus species in Europe. This was originally described as a novel mecA allele, termed mecA_LGA235, but since it shares only 69% nucleotide identity and 63% amino acid similarity to mecA, it has now been designated a distinct gene (102). Like mecA, mecC encodes an alternate PBP that confers resistance to β-lactam agents. MRSA strains carrying mecC were originally identified among S. aureus strains associated with bovine mastitis, but subsequent studies have identified such strains among humans and animals in Europe, as both colonizers and causes of infection (69, 103–105). Although mecC appears to be most common in S. aureus, it has also been described for Staphylococcus xylosus (106).

As with MOD-SA and BORSA, mecC-mediated resistance is reliably detected by antimicrobial susceptibility tests, but unlike the case with MOD-SA and BORSA, mecC is more reliably detected with cefoxitin than with oxacillin (107, 108). The discrepancy between oxacillin and cefoxitin resistance among mecC-producing S. aureus isolates is so striking that some have even suggested using the oxacillin-susceptible but cefoxitin-resistant phenotype as a first-line screen for the presence of mecC (108). As one would expect, mecC cannot be detected with assays targeting mecA or PBP 2a (107). Since mecC is both clinically significant and conferred by a single gene, molecular tests have been developed for mecC surveillance and detection (109–111), and additional mechanism-specific diagnostic methods will likely be developed in the future.

Using only cefoxitin-based methods for detection of oxacillin resistance may eliminate the possibility of finding strains that are either phenotypically oxacillin resistant but mecA and mecC negative (such as BORSA or MOD-SA) or phenotypically oxacillin susceptible but mecA positive (112, 113). However, until it is shown that these patterns are clinically significant, using a cefoxitin-based test alone is a reasonable approach, with the understanding that should therapy with a β-lactam agent be ineffective, additional testing, including testing of the specific agent used for treatment or appropriate molecular tests, might be required.

Detection of Oxacillin Resistance in CoNS except S. laguensis

Of the different resistance mechanisms that have been described for S. aureus, only mecA- and mecC-mediated oxacillin resistance has been described to occur in CoNS. However, detection of oxacillin resistance by using standard methods can be more difficult than it is for S. aureus, due in part to the more heteroresistant expression of resistance in CoNS (114). With CLSI reference methods, the sensitivity of detection of oxacillin resistance in this group improved when the MIC breakpoints were adjusted downward in 1999 by CLSI (115), to ≤0.25 μg/ml for susceptible and ≥0.5 μg/ml for resistant. However, correlation of these interpretive criteria with the presence or absence of mecA is optimum only for Staphylococcus epidermidis, Staphylococcus haemolyticus, and, possibly, Staphylococcus hominis (116–118). For other species of CoNS (e.g., Staphylococcus saprophyticus and Staphylococcus sciuri), oxacillin breakpoints tend to be less specific, i.e., mecA-negative strains are categorized as resistant by oxacillin disk and MIC methods (55, 117–121).

In 2009, CLSI removed oxacillin disk diffusion breakpoints for CoNS from document M100 (81) because the test lacks specificity and the cefoxitin disk diffusion test more accurately predicts the presence or absence of mecA. The oxacillin-salt agar screening test cannot be used for detecting oxacillin resistance in CoNS because it uses 6 μg of oxacillin per ml, which is higher than the breakpoint for CoNS (55, 122, 123). Therefore, the only methods now recommended by CLSI and EUCAST for detection of oxacillin resistance in CoNS are the standard oxacillin MIC test and the cefoxitin disk diffusion test as a surrogate for oxacillin (19, 57).

With CoNS, the cefoxitin disk diffusion test generally provides equal sensitivity but greater specificity than that of the oxacillin MIC test for detection of strains harboring the mecA gene (76, 124, 125), although there is some evidence that performance may be somewhat species-dependent. The cefoxitin disk diffusion test fails to reliably classify mecA-positive strains of Staphylococcus simulans as resistant (76, 126); the reason for this is unknown. For S. saprophyticus, cefoxitin disk diffusion testing reliably separates mecA-positive from mecA-negative isolates, but one study suggests that specificity is improved if S. aureus breakpoints rather than CoNS breakpoints are used for interpretation (127).

The cefoxitin disk diffusion test is performed using the routine disk diffusion procedure, with breakpoints of ≤24 mm for oxacillin resistant and >25 mm for oxacillin susceptible. The use of a cefoxitin MIC breakpoint for prediction of mecA-mediated resistance in CoNS was recently investigated in a multilaboratory study, but because of performance differences between broths from different manufacturers and
overlap of the oxacillin-susceptible and -resistant populations, its performance for MIC testing was not better than that of oxacillin (80), so cefoxitin MIC breakpoints were not adopted. Quality control is the same as that recommended for standard disk diffusion and MIC methods (19).

Limitations of Methods for Detection of Oxacillin Resistance in CoNS except S. lugdunensis Except for S. simulans (see above), cefoxitin disk diffusion testing provides good sensitivity and greater specificity than that of oxacillin tests for prediction of mecA-mediated resistance in CoNS.

Oxacillin MIC tests lack specificity for non-S. epidermidis isolates, so CLSI recommends that for serious infections with CoNS other than S. epidermidis, isolates with oxacillin MICs of 0.5 to 2 μg/ml (i.e., MICs that are resistant using the CoNS breakpoints but susceptible using those for S. aureus) be tested for mecA or PBP 2a. However, this would require that identification of CoNS to the species level be performed.

To improve detection of oxacillin resistance in CoNS, several methods have been proposed, including lowering the concentration of oxacillin to 4 μg/ml in the salt agar screening test (87); using cefoxitin in an agar dilution screen (87); and using a combination of results, for example, oxacillin-salt agar screening and cefoxitin disk diffusion test results (124), oxacillin agar dilution and cefoxitin disk diffusion test results (128), and oxacillin MIC and moxalactam MIC results (129). Other investigators have recommended that CoNS strains with oxacillin zone diameters of 17 to 27 mm or cefoxitin zone diameters of 24 to 31 mm be tested for mecA or PBP 2a (130).

Clearly, methods for detection of oxacillin resistance in this group are less than ideal and deserve further study. Since there is discrepancy between the appropriate tests for S. epidermidis and non-S. epidermidis isolates, species identification, MIC testing of the specific agent being used, and molecular testing for mecA or PBP 2a should be considered for CoNS strains isolated from patients for whom therapy choices are limited.

Other Tests for Detection of Oxacillin Resistance in Staphylococci

Other commercial methods for the rapid detection of oxacillin resistance in staphylococci include (i) direct culture of patient specimens (usually nasal swabs) onto agar media containing antimicrobial agents with a chromogenic indicator, (ii) detection of the presence of PBP 2′ by latex agglutination testing, and (iii) automated PCR assays.

Several selective chromogenic agars are now FDA cleared for detection of MRSA from surveillance specimens, including MRSA Select (Bio-Rad, Redmond, WA), Spectra MRSA (Remel, Lenexa, KS), CHROMagar MRSA II (BD, Sparks, MD), ChromID MRSA (bioMérieux, Hazelwood, MO), and, most recently, HardyCHrom MRSA (Hardy Diagnostics, Santa Maria, CA). The exact components of these media are proprietary and vary by manufacturer, but they typically contain both chromogenic and selective components. The chromogenic indicator results in S. aureus colonies demonstrating a characteristic color that differentiates them from other Staphylococcus species on the medium, and the selective component inhibits growth of bacteria that are not oxacillin resistant. These media can be used for direct plating from surveillance swabs and interpreted as early as 24 hours postincubation; in this way, they can reduce the time to MRSA detection compared to that of traditional culture by 1 to 3 days. Although the performances of specific chromogenic agars vary, numerous studies have demonstrated good correlations compared to both conventional culture-based methods and PCR screening tests for detection of MRSA colonization (131–133) and similar performances between different commercial chromogenic agars (132, 134–136). However, when their use was compared to the use of molecular methods, molecular methods were found to have increased sensitivity and rapidity of detection, but at a higher cost (136–138).

The impact of such agars has been especially dramatic for surveillance cultures performed for specific patient populations, such as cystic fibrosis patients, in whom co-colonization with methicillin-resistant S. aureus or multiple bacterial species is likely. In two recent studies, the inclusion of chromogenic agar improved the sensitivity by 9% to 50% and decreased the turnaround time by 24 to 48 hours (131, 139). However, some have pointed out that addition of a broth enrichment step prior to plating on MRSA-selective agar is important to maximize the sensitivity of selective chromogenic agars, especially when the colonization burden is low (132, 140).

Although not all chromogenic agars are FDA cleared for clinical use in the United States, studies have validated the performance of these media for detection of MRSA in clinical specimens. In one study of specimens that are typically polymicrobial, including superficial wounds, endotracheal aspirates, and sputum, inclusion of chromogenic agar improved detection of MRSA by 21% overall and decreased the turnaround by 1 day (141). Another study of clinical specimens demonstrated better performances of chromogenic selective agar than of traditional methods across multiple specimen types, including wounds, respiratory specimens, stools, and positive blood cultures (142). In studies focusing only on positive blood cultures containing Gram-positive cocci, MRSA-selective chromogenic agar demonstrated excellent sensitivity and specificity (142–143) and enabled detection of MRSA 12 to 24 h earlier than by conventional methods (143–145). Only Spectra MRSA (Remel) has FDA approval for direct detection of MRSA from positive blood culture bottles containing Gram-positive cocci (http://www.accessdata.fda.gov/cdrh_docs/reviews/k092407.pdf).

Commercial rapid methods that detect the presence of PBP 2′ in staphylococci by using latex agglutination include the MRSA-Screen test (Denka Seiken Co., Ltd., Tokyo, Japan), the PBP 2′ latex agglutination test (Oxoid Limited, Basingstoke, United Kingdom), the Mastalex test (Mast Diagnostics, Bootle, United Kingdom) (146), and the Slidex MRSA detection test (bioMérieux). The first three tests have been cleared by the FDA. The MRSA-Screen test, cleared for use only with S. aureus, has been evaluated widely and has a high sensitivity and specificity for that species (83, 147–149). Detection of resistance in CoNS by the MRSA-Screen test has been less successful, requiring induction, an increased inoculum, or an increased agglutination time for adequate sensitivity (118, 149–151). The Oxoid PBP 2′ latex agglutination test was approved by the FDA for testing of both S. aureus and CoNS, with the latter requiring induction with oxacillin or cefoxitin. Although not extensively evaluated, its use for same-day reporting of MRSA from blood cultures (152) and of teicoplanin-resistant CoNS (153) has been described.

In addition to these, automated commercial methods that allow the detection of oxacillin resistance genes by PCR include the GeneOhm MRSA (BD, Franklin Lakes, NJ) and Xpert MRSA (Cepheid, Sunnyvale, CA) tests. Molecular analysis may also be performed by standard PCR
when confirmation of the presence of the mecA gene is required (see chapter 77).

**Reporting Results of Tests for Oxacillin Resistance**

CLSI recommends that oxacillin-resistant staphylococci be reported as resistant to all β-lactam agents, including penicillins, cephalosporins except cephalosporins with anti-MRSA activity (i.e., all cephalosporins, including cephamycins), β-lactam–β-lactamase inhibitor combination agents, and carbapenems. These agents are clinically ineffective against oxacillin-resistant staphylococcal infections, even though they may demonstrate activity in vitro (4, 5, 19). Newer β-lactam agents were recently developed that have activity against MRSA (154–156). Only ceftriaxone has received FDA approval, and both ceftriaxone and cefotaxime are included in CLSI quality control tables and are listed in the CLSI document M100 glossary, in a new class labeled “cephalosporins with anti-MRSA activity” (19). Such agents should not be reported as resistant based on the oxacillin result but must be tested directly if they are reported for isolates that test resistant to oxacillin or cefoxitin (19).

Isolates of *S. aureus* that appear oxacillin resistant by an alternative test method that uses oxacillin but fail to grow on the agar screening plate are probably borderline resistant and lack mecA (92, 157, 158). Much less is known about borderline resistance than about mecA-positive resistance because there have been few clinical studies (159). In animal model studies, isolates with β-lactamase-mediated oxacillin resistance appeared to be treated effectively with β-lactam agents (61, 99, 101, 160); therefore, if a phenotypically oxacillin-resistant *S. aureus* strain isolated from a seriously ill patient does not contain mecA, this information should be conveyed to the patient’s medical provider. The incidence of phenotypically susceptible mecA-positive strains of *S. aureus* is not known. However, should phenotypically susceptible strains be isolated from serious infections in patients with a history of MRSA infection, confirmation by another method, such as detection of PBP 2a by latex agglutination testing, should be considered (113, 148, 161).

Most automated susceptibility panels now use both oxacillin and cefoxitin for determination of oxacillin resistance, but the final results are determined by algorithms within the expert system; commercial systems are validated by the device manufacturers and cleared by the FDA (see chapter 72). In general, if both oxacillin and cefoxitin tests are used and discrepancies occur, oxacillin-susceptible, cefoxitin-resistant results should be assumed to indicate mecA-mediated resistance. Oxacillin-resistant, cefoxitin-susceptible results, on the other hand, are likely not due to mecA but should occur only rarely. Current CLSI standards recommend a conservative approach to handling these discrepancies by suggesting that if both agents are tested and either one yields a resistant result, the isolate should be reported as MRSA. This is also true for isolates that test as mecA positive but oxacillin or cefoxitin susceptible (19).

### Detection of Vancomycin Resistance in Staphylococci

In January 2006, CLSI vancomycin interpretive categories for *S. aureus* were changed to ≤2 μg/ml for susceptible, 4 to 8 μg/ml for intermediate, and ≥16 μg/ml for resistant. Interpretive categories for CoNS were not changed and are ≥4 μg/ml for susceptible, 8 to 16 μg/ml for intermediate, and ≥32 μg/ml for resistant (19, 162). Unlike the case for oxacillin and cefoxitin testing, *S. lugdunensis* results for vancomycin testing should be interpreted using the break-points for CoNS. The rationale for lowering the *S. aureus* intermediate breakpoint to include 4 μg/ml was that (i) isolates with a vancomycin MIC of ≥4 μg/ml, although rare, likely represent a population of organisms with heterogeneous resistance; and (ii) limited outcome data suggested that infections with these isolates were likely to fail vancomycin monotherapy (163). Vancomycin-intermediate *S. aureus* strains (MICs of 4 to 8 μg/ml) are commonly referred to as VISA, and those that are vancomycin resistant (MICs of ≥16 μg/ml) are known as VRSA. CoNS with reduced susceptibility to vancomycin are referred to here as VISS, for vancomycin-intermediate *Staphylococcus* species other than *S. aureus*.

As of January 2014, 13 VRSA strains have been documented in the United States; 8 were from Michigan, 3 from Delaware, 1 from New York, and 1 from Pennsylvania (23, 164, 165). There are also reports of VRSA from countries outside the United States, including India, Pakistan, Iran, Portugal, and Brazil (166–170). All VRSA isolates identified to date contain the vanA gene and were isolated from patients who had underlying medical conditions, including pneumonia or colonization with MRSA and/or vancomycin-resistant enterococci (VRE); most patients also had received previous vancomycin therapy. The vancomycin MICs for VRSA strains range from 32 to 1,024 μg/ml; all display no zone of inhibition with a 30-μg vancomycin disk.

Resistance in VISA is not due to acquisition of a van gene but is thought to be due to changes in the cell wall that render such strains less susceptible to vancomycin (171). At present, no single genetic change has been linked to the VISA phenotype, and it is believed that several different mutations can lead to VISA. The incidence of VISA strains is greater than that of VRSA strains, although the true prevalence is difficult to know because when VISA first began to appear, some routine susceptibility testing methods failed to detect vancomycin-intermediate staphylococci (172–174).

No van gene-mediated vancomycin resistance has been reported for VISS, but the 1% of CoNS isolates with elevated vancomycin MICs (175–180) that are also thought to be due to cell wall changes (181). An early study that reviewed the prevalence of VISS found it to be very low (i.e., <1%), except in one institution (171). In a 2009 report of a large surveillance study of isolates from 33 countries, the incidence of VISS was documented to still be <1.0% (182).

The CLSI reference broth microdilution method is reliable for detection of VISA and VRSA, and presumably VISS. However, the disk diffusion test cannot detect VISA or VISS because these isolates produce zone diameters within the susceptible range (≥15 mm). Because of this, all parameters for the disk diffusion test were removed from document M100 in 2014. However, a vancomycin disk diffusion test result of 6 mm (no zone) can still detect *S. aureus* isolates that contain vanA; if such results are encountered, both the purity and the identity of the isolate should be confirmed, and a vancomycin MIC test should be performed. The use of BHI-V6 screening agar, used to detect VRE, is a sensitive method for detection of *S. aureus* isolates for which the vancomycin MICs are ≥8 μg/ml, but its performance is variable for detection of *S. aureus* isolates for which the vancomycin MIC is 4 μg/ml (183), and it cannot be used to detect VISS. Most available susceptibility testing methods can now detect VRSA strains, although accurate detection of VISA strains is still problematic (see below).

Although reduced susceptibility to vancomycin can occur in both *S. aureus* and CoNS, the occurrence in *S.
 aureus is more concerning because this species is more frequently a cause of serious infections. It is for this reason that the Centers for Disease Control and Prevention (CDC) recommends the use of BHI-V6 screening agar for detection of S. aureus with reduced susceptibility to vancomycin (http://www.cdc.gov/HAI/settings/lab/visa_vrsa_lab_detection.html). This recommendation is for laboratories that may miss these isolates by using their primary susceptibility testing method (i.e., those that routinely use disk diffusion testing). Laboratories may consider limiting this testing to MRSA strains, since these are the isolates in which resistance is of greatest clinical relevance.

**BHI-V6 Screening Agar Test Method**
The recommended method for inoculating the agar is using a 10-μl drop of a suspension equivalent to a 0.5 McFarland standard delivered with a micropipette. Alternatively, a swab can be used to spot inoculate an area of 10 to 15 mm in diameter. The agar plate should be read after 24 h of incubation and carefully examined with transmitted light. The presence of more than one colony or a light film of growth is considered positive (4, 19).

**Quality Control**
As mentioned above, BHI-V6 agar is the same screening agar as that used to detect VRE, and the quality control strains recommended for the VRE test can also be used for the S. aureus test (4). These strains are vancomycin-susceptible *E. faecalis* ATCC 29212 and vanB-mediated vancomycin-resistant *E. faecalis* ATCC 51299. Since the amount of inoculum applied for the VRE test (1 to 10 μl of a suspension equivalent to a 0.5 McFarland standard) spans the recommended inoculum for the S. aureus test, a laboratory that uses this medium for both purposes need perform quality control only once for both tests, either daily or weekly.

**Limitations of Methods for Detection of Vancomycin Resistance**
Standard broth microdilution MIC tests are reliable for detection of any reduced vancomycin susceptibility (i.e., intermediate or resistant susceptibility) in staphylococci. Most commercial methods and routine disk diffusion tests also detect vancomycin resistance (i.e., MICs of ≥16 μg/ml). The detection of intermediate vancomycin resistance by other methods is more challenging. In a recent study looking at the ability of commercial and reference susceptibility testing methods to detect VISA strains, the essential agreement (percentage of results within ±1 dilution) of all methods compared to the reference broth microdilution method was excellent except for disk diffusion testing, which detected no intermediate strains, and use of BHI-V6 screening agar, which failed to identify 12 of 33 strains with a vancomycin MIC of 4 μg/ml (183). This finding was also noted in an earlier study (174). However, in the more recent study, although the essential agreement was excellent, the categorical agreement was not, ranging from 64.8% to 92.2% for the commercial methods tested, with some methods missing VISA stains and others overcalling resistance in susceptible strains (185). This may have been due to differences in the media used in the systems, as it has been shown that recognition of VISA may be medium dependent (174).

Recent studies have shown that the Etest (bioMérieux) method tends to result in slightly higher vancomycin MICs than those obtained by broth microdilution (183, 184), and it may characterize susceptible strains as VISA strains. This was also true of some other commercial systems in the study mentioned above, which compared commercial and reference methods for detection of VISA strains. However, all methods in that study generated vancomycin MICs of ≥2 μg/ml for the VISA isolates tested; therefore, to increase detection of VISA strains, a laboratory might consider further testing of any isolate with an MIC of 2 μg/ml by an alternate method. Etest might be considered for use as the alternate method, since it was successful in detecting 44 of 45 (98%) of the VISA isolates; however, it may also categorize some susceptible strains as intermediate (183, 184).

**Reporting Results of Vancomycin Testing**
Growth of *S. aureus* on BHI-V6 agar is presumptive for either VISA or VRSA (4, 19; http://www.cdc.gov/HAI/settings/lab/visa_vrsa_algorithm.html). Additional testing is needed to confirm vancomycin resistance. First, the identity and purity of the isolate should be confirmed. The MIC of the isolate should then be determined using a validated method. For many laboratories, the most available method is Etest. It is recommended that any *S. aureus* isolate for which the vancomycin MIC is ≥8 μg/ml be sent to a reference laboratory for confirmation. In the United States, several states recommend VISA and VRSA be reported to the public health authority.

**Detection of hVISA**
Heteroresistant vancomycin-intermediate *S. aureus* (hVISA) isolates are isolates of *S. aureus* that normally test susceptible by standard methods but contain a subpopulation of cells (typically 1 in every 10^3 to 10^6 cells) for which the vancomycin MICs are nonsusceptible, i.e., ≥4 μg/ml. This phenomenon was first described in 1997 (185). Some hVISA isolates are detected by standard methods because the population MICs is 4 μg/ml; some, however, continue to be missed because the population MIC is ≤2 μg/ml. There is no agreement in recent reports about the incidence of hVISA or their clinical significance (163). The “gold standard” for detection of hVISA is population analysis/area-under-the-curve analysis, a technique that is unsuitable for routine use (186). No standardized technique that will detect these isolates is available to clinical laboratories. However, there are two Etest methods that have been developed: (i) the macro Etest and (ii) Etest GRD. The macro Etest uses a large inoculum spread onto BHI agar plates and separate vancomycin and teicoplanin strips; MICs of ≥8 μg/ml for either agent or ≥12 μg/ml for teicoplanin alone are considered positive (187). Several studies evaluating the macro Etest for hVISA detection found it to be relatively insensitive (range of 57 to 89% sensitivity, with positive predictive values ranging from 21 to 71%) (188–190). Etest GRD is performed by using MHA with 5% sheep blood, an inoculum equivalent to 0.5 McFarland standard, and a single strip impregnated with both vancomycin and teicoplanin; specific MICs of the two agents are then interpreted as positive or negative (191). Published sensitivities of Etest GRD range from 57 to 100%, with positive predictive values of 16 to 80% (188–190, 192).

**Detection of Inducible Clindamycin Resistance in Staphylococci**
Although erythromycin and clindamycin are in separate antimicrobial agent classes, i.e., macrolides and lincosamides, respectively, their mechanisms of action (inhibition of protein synthesis) and mechanisms of resistance are similar. The two main mechanisms of macrolide resistance are (i) an efflux pump that affects only macrolides and (ii) a
methylose that alters the ribosomal binding site for both antimicrobial agents. The efflux mechanism of resistance, which confers resistance to macrolides (designated M-type resistance, for macrolide), is mediated in staphylococci by msrA. The target modification type of resistance, which confers resistance to macrolides, lincosamides, and streptogramin B agents (designated MLSB-type resistance, for macrolide-lincosamide-streptogramin B), is mediated by an erm gene (usually ermA or ermC). In staphylococci, MLSB-type resistance can be either constitutive or inducible; if it is inducible, the isolate appears to be susceptible to the lincosamide (i.e., clindamycin) by routine testing methods unless it is induced by a macrolide (i.e., erythromycin). It is important to determine if resistance (whether inducible or constitutive) to clindamycin exists when it is being considered for therapy. A detailed explanation of these resistance mechanisms can be found in chapter 69.

Phenotypically, if an isolate has M-type resistance, it is resistant to erythromycin but susceptible to clindamycin. If an isolate has MLSB-type resistance, it is erythromycin resistant and may test as susceptible or resistant to clindamycin, depending on whether expression is constitutive or inducible for that drug. For strains that are erythromycin resistant but clindamycin susceptible, it is important to determine whether inducible clindamycin resistance exists (due to an erm gene) or if the strain remains clindamycin susceptible (due to an efflux gene).

There are two test methods recommended for detecting inducible clindamycin resistance in staphylococci: (i) the D-zone test and (ii) a broth dilution test that uses a single well or tube containing 4 μg of erythromycin per ml and 0.5 μg of clindamycin per ml (Table 3). The test methods are described below.

**Test Methods**

**D-Zone Test**

Detection of inducible clindamycin resistance can easily be accomplished using a disk diffusion procedure by placing a 15-μg erythromycin disk adjacent to a 2-μg clindamycin disk and looking for a flattening of the clindamycin zone, which looks like the letter D and is therefore referred to as a D zone. For laboratories that are already performing disk diffusion testing, this may be done by placing the disks 15 to 26 mm apart (193), along with the other disks tested on an MHA plate. Some disk dispensers may position disks more than 26 mm apart even if the disks are placed in adjacent positions. Therefore, because dispensers may vary and the distance is critical, the distance should be verified before the test is adopted as a standard procedure. Placing the disks 15 to 20 mm rather than 26 mm apart may make the test more sensitive and easier to interpret (194–196), although to accomplish this one of the disks must be placed on the plates by hand instead of with a disk dispenser.

For laboratories that routinely perform antimicrobial susceptibility test methods other than disk diffusion testing, Jorgensen et al. have shown that the test can be performed on a standard blood agar plate used for purity checks (197) by streaking one-third of the plate for confluent growth and then streaking for isolation on the rest of the plate. In that study, the investigators showed that dilutions of up to 1:250 of inoculum equivalent to a 0.5 McFarland standard can be used. The disks are placed 15 mm apart on the portion of the plate where confluent growth would occur. In a later study, it was determined that the BBL Prompt system (BD, Sparks, MD) should not be used to inoculate the purity plate for D-zone determination (196). In that study, the

**Single-Well Broth Dilution Method**

The single-well broth dilution test is performed by preparing microdilution wells (containing no less than 100 μl per well) or tubes of cation-adjusted Mueller-Hinton broth (CAMHB) with a combination of 4 μg of erythromycin per ml and 0.5 μg of clindamycin per ml. The combination is prepared by combining equal amounts of 2× concentrations of the agents, i.e., 8 μg of erythromycin per ml and 1 μg of clindamycin per ml, and transferring the appropriate volume to a microdilution well or tube. The final concentrations in the well or tube are 4 μg/ml of erythromycin and 0.5 μg/ml of clindamycin. The wells or tubes are then inoculated by use of routine inoculation procedures for broth microdilution or macrodilution (38). The test should be interpreted only for those staphylococcal strains that are erythromycin resistant, i.e., with MICs of ≥8 μg/ml, and clindamycin susceptible or intermediate, i.e., with MICs of ≤0.5 μg/ml. Growth indicates inducible clindamycin resistance; no growth indicates no inducible clindamycin resistance.

**Quality Control and Quality Assessment**

Two strains have been designated for quality assessment purposes (e.g., for training, competency assessment, or test evaluation): S. aureus BAA-977, which has inducible ermA-mediated resistance, and S. aureus BAA-976, which has msrA-mediated resistance to erythromycin only. S. aureus ATCC 25923 should be used as the routine quality control strain for daily or weekly quality control testing of clindamycin and erythromycin disks, using MHA. If the test is performed as part of the purity check procedure, CLSI recommends that the disk content be verified using S. aureus ATCC 25923 on MHA (4). However, this would require that laboratories which do not routinely do disk diffusion testing have a supply of MHA plates on hand for quality control purposes only. An alternative to this would be to use the two quality assessment strains, BAA-977 and BAA-976, as quality control organisms at daily or weekly intervals, based on CLSI recommendations, when using the purity plate method.

For adequate quality control of the broth microdilution test, it is necessary to test both an inducibly clindamycin-resistant strain and one that is not inducibly resistant so that it can be confirmed that both the agents are in the well and performing as they should. The best way to do this is to avoid having to test both strains every time a test is performed is to test BAA-976 and BAA-977 once when the tubes or microdilution panels are prepared (or once for each new lot). For subsequent daily or weekly testing, S. aureus ATCC 29213 can be used as a susceptible control and BAA-977 as a resistant control. For further discussion, see reference 198.

**Reporting Results**

The incidence of inducible clindamycin resistance in staphylococci can be highly variable, both by geographic area and by organism group (i.e., hospital-associated MRSA,
CA-MRSA, and CoNS). CLSI now recommends that isolates that are D-zone test positive or grow in the combination well be reported as clindamycin resistant (4, 5, 19). Although some have suggested that clindamycin may be effective in some situations where inducible resistance is demonstrated (199), CLSI recommends that inducibly clindamycin-resistant strains be reported as resistant, with a comment stating that "this isolate is presumed to be resistant based on detection of inducible clindamycin resistance." If the test is not offered routinely, it should be available by request for cases in which clindamycin is being considered for therapy.

Detection of High-Level Mupirocin Resistance in Staphylococci

Mupirocin is a topical antibacterial agent that is used for treatment of skin infection and eradication of nasal carriage of S. aureus (200). Resistance to mupirocin is either low level, associated with MICs of 8 to 256 μg/ml, or high level, associated with MICs of ≥512 μg/ml (41). HLR usually implies the presence of the mupA gene, although strains with HLR have occurred without mupA (201) or have been created in the laboratory (202). More recently, HLR to mupirocin has been attributed to a different allele, mupB. The predicted MupB protein shares limited homology with MupA, but expression of mupB from a plasmid is sufficient to confer HLR to a naïve S. aureus strain (203). It has been shown that elimination of S. aureus colonizing strains with mupirocin HLR is not possible (204); whether colonizing strains with low-level resistance can be eliminated with mupirocin is debatable (41, 205).

Methods for the detection of HLR to mupirocin have been suggested by many investigators (206–211), and the British Society for Antimicrobial Chemotherapy recommends methods for testing mupirocin (http://www.bsac.org.uk). Based on data from a multilaboratory study (201), CLSI included methods for prediction of mupirocin HLR by use of disk diffusion or a single-well broth microdilution screen (4, 5, 19) (Table 3).

For disk diffusion testing, the standard disk diffusion procedure is used with a 200-μg mupirocin disk. The test plate is incubated at 35°C for 24 h; the absence of a zone of inhibition is indicative of mupirocin HLR, whereas any zone indicates the absence of HLR. (Note that disks for the test may not yet be available commercially but can be prepared in-house by the following method. Using a stock solution of mupirocin at 8,000 μg/ml and a microproprietor, add 0.025 ml to sterile 6-mm disks that have been spread out on a sterile surface. Allow the disks to dry in a laminar flow hood. When the disks are dry, transfer them to a small tube with desiccant and store at −20°C.) For the broth microdilution procedure, a single well containing 0.1 ml of 256-μg/ml mupirocin is inoculated using a standard inoculum (4) and incubated at 35°C for 24 h. Growth in the well indicates high-level mupirocin resistance; no growth indicates the absence of HLR.

Quality control parameters are given in CLSI document M100 (19). For both tests, S. aureus ATCC BAA-1708, a mupA-positive strain, is used as the resistant control and should show no zone of inhibition. For disk diffusion tests, S. aureus ATCC 25923 is used as the negative control (zone range, 29 to 38 mm), and for the MIC test, S. aureus ATCC 29213 (mupirocin MIC, 0.06 to 0.5 μg/ml) or E. faecalis ATCC 29212 (MIC, 16 to 128 μg/ml) can be used as the susceptible control.

TESTS TO DETECT RESISTANCE IN STREPTOCOCCI

Oxacillin Disk Screening Test for Detection of Penicillin Resistance in Pneumococci

A screening test in which a 1-μg oxacillin disk is used to detect penicillin resistance in pneumococci was first described following an outbreak caused by Streptococcus pneumoniae strains resistant to multiple antimicrobial agents in South Africa in the 1970s (212–214). Since then, this test has been used extensively and was shown to be highly sensitive but not specific for detection of penicillin-non-susceptible pneumococci (215). Strains identified as non-susceptible by this method may be penicillin susceptible, intermediate, or resistant. Penicillin MIC tests must be performed on any strain that produces a zone diameter of ≥19 mm to determine if it is resistant (215). For nonmeningitis strains that produce zone diameters of ≥20 mm, CLSI now recommends that they can be considered susceptible to ampicillin, ampicillin-sulbactam, amoxicillin, amoxicillin-clavulanic acid, cefaclor, cefdinir, cefepime, cefotaxime, cefpodoxime, ceftazidime, ceftriaxone, cefuroxime, doripenem, ertapenem, imipenem, meropenem, and oral and parenteral penicillins, with no further testing (19). MIC tests rather than the oxacillin disk screen should be used routinely on strains isolated from cerebrospinal fluid and blood.

Detection of Inducible Clindamycin Resistance

The importance of determining erythromycin and clindamycin resistance phenotypes and detecting inducible clindamycin resistance in streptococci follows the same logic as that described for staphylococci (see “Detection of Inducible Clindamycin Resistance in Staphylococci,” above); however, the genes responsible for the resistance differ from those in staphylococci and can occur in β-hemolytic streptococci, S. pneumoniae, and viridans group streptococci. The M phenotype (i.e., erythromycin resistance and clindamycin susceptibility) in streptococci is due to mepA, and the gene responsible for the MLSB type (constitutive or inducible) is usually ermB or, more rarely, ermTR (216). Although routine testing of β-hemolytic streptococci is not required because penicillin- or ampicillin-non-susceptible isolates are extremely rare (or in fact do not exist, for Streptococcus pyogenes), a recent publication documented the clinical significance of inducible clindamycin resistance in β-hemolytic streptococci by using an animal model (217). The authors recommended that tests to detect inducible resistance in streptococci be performed and reported routinely. The CDC also recommends that when susceptibility testing is clinically indicated, colonizing isolates of group B streptococci from penicillin-allergic pregnant women should be tested for inducible clindamycin resistance (218).

As for staphylococci, there are two test methods recommended for detecting inducible clindamycin resistance in β-hemolytic streptococci and S. pneumoniae: (i) the D-zone test and (ii) a broth dilution test that uses a single well or tube containing 1 μg of erythromycin per ml and 0.5 μg of clindamycin per ml (4, 5, 19). These are described below. A variation of the D-zone test has also been used successfully for detection of viridans group streptococci (219, 220) but is not described here.

Test Methods

D-Zone Test

Detection of inducible clindamycin resistance in β-hemolytic streptococci and pneumococci can be accomplished.
using a disk diffusion procedure similar to that for staphylococci by placing a 15-μg erythromycin disk adjacent to a 2-μg clindamycin disk and looking for a flattening of the clindamycin zone, which looks like the letter D and is therefore referred to as a D zone, as stated above. For laboratories that are already performing disk diffusion testing, the disks must be placed by hand at a distance of 12 mm from each other (221) on an MHA plate with 5% sheep blood, along with other disks being tested. A disk dispenser cannot be used to place the two disks, because they must not be separated by more than 12 mm (221). For laboratories that routinely perform other antimicrobial susceptibility test methods, the purity plate method suggested by Jorgensen et al. can also be performed on a standard blood agar plate used for purity checks (197,221) by streaking one-third of the plate for confluent growth and then streaking for isolation on the rest of the plate. The disks are then placed 12 mm apart on the portion of the plate where confluent growth would occur. Only the use of a suspension equivalent to a 0.5 McFarland standard has been evaluated for inoculation of the purity plate (221). For either method, after incubation at 35°C for 20 to 24 h in 5% CO₂, organisms that show a blunting or flattening of the clindamycin zone are considered D-zone test positive; those that show no flattening are D-zone test negative.

Single-Well Broth Dilution Method

The single-well broth dilution test is performed by preparing microdilution wells (containing no less than 100 μl per well) or tubes of CAMHB with 3% lysed horse blood with a combination of 1 μg/ml of erythromycin and 0.5 μg/ml of clindamycin. The original studies used only microdilution wells (222, 223), although theoretically tubes should also work if the test conditions are kept the same. The combination is prepared by combining equal amounts of 2× concentrations of the agents, i.e., 2 μg/ml of erythromycin and 1 μg/ml of clindamycin, and transferring the appropriate volume to a microdilution well or tube. The final concentrations in the well or tube are 1 μg/ml of erythromycin and 0.5 μg/ml of clindamycin. The wells or tubes are then inoculated using routine inoculation procedures for broth microdilution or macrodilution (4, 19). The test should be interpreted only for those streptococcal strains that are erythromycin resistant, i.e., with MICs of ≥1 μg/ml, and clindamycin susceptible or intermediate, i.e., with MICs of ≤0.5 μg/ml. Growth indicates inducible clindamycin resistance; no growth indicates no inducible clindamycin resistance.

Quality Control and Quality Assessment

Two strains have been designated as supplemental quality control strains for quality assessment (e.g., for training, competency assessment, or test evaluation) of the D-zone test: S. aureus BAA-977, which has inducible ermA-mediated resistance to clindamycin, and S. aureus BAA-976, which has msrA-mediated resistance to erythromycin only. S. pneumoniae ATCC 49619 should be used as the routine quality control strain for daily or weekly quality control testing of clindamycin and erythromycin disks, using MHA with 5% sheep blood. If the test is performed as part of the purity check procedure, ideally the disk content should be verified using S. pneumoniae ATCC 49619 on MHA with 5% sheep blood. However, this would require that laboratories which do not routinely do disk diffusion testing have a supply of MHA with 5% sheep blood on hand for quality control purposes only. An alternative to this would be to use the two quality assessment strains, BAA-977 and BAA-976, as quality control organisms, with testing daily or weekly.

For adequate quality control of the broth microdilution test, it is necessary to test both an inducibly clindamycin-resistant strain and one that is not inducibly resistant so that it can be confirmed that both the agents are in the well and performing as they should. The best way to do this to avoid having to test both strains every time a test is performed is to test BAA-976 and BAA-977 once when the tubes or microdilution panels are prepared (or once for each new lot). For subsequent daily or weekly testing, S. pneumoniae ATCC 49619 can then be used as a susceptible control, with BAA-977 as a resistant control.

Reporting Results

The incidence of inducible clindamycin resistance in β-hemolytic streptococci can be highly variable, both by geographic area and by organism group (216, 224-226). However, when inducible clindamycin resistance is detected, CLSI recommends that, as for staphylococci, isolates shown to be D-zone test positive or that exhibit growth in the microdilution well will be reported as clindamycin resistant. As a conservative approach, the CLSI has suggested that inducibly clindamycin-resistant strains may be reported as resistant, with a comment stating that “this isolate is presumed to be resistant based on detection of inducible clindamycin resistance.” Based on the recent publication by Lewis et al. establishing the clinical significance of inducible clindamycin resistance in streptococci, consideration should be given to routine testing and reporting (217). If the test is not offered routinely, it should be available by request for cases in which clindamycin is being considered for therapy.

TESTS TO DETECT RESISTANCE IN ENTEROBACTERIACEAE

Antimicrobial resistance among Enterobacteriaceae, and especially resistance to β-lactam agents, is of increasing concern worldwide. Whereas infections with Enterobacteriaceae were once very treatable, resistance to multiple classes of antibiotics among this family of bacteria, and even pan-resistance to all available therapeutic agents, has been described (227-231). Preserving effective antibiotic agents for treatment and preventing the spread of these organisms are increasingly recognized as high priorities throughout the continuum of patient care, and reliable detection of resistance in this group of organisms is essential for guiding therapeutic decisions and infection control interventions.

This is complicated, however, because β-lactam resistance in Enterobacteriaceae is not a straightforward issue; resistance occurs through multiple mechanisms, can be intrinsic or acquired, can be induced from low- to high-level expression, and can spread both through clonal expansion and through horizontal transmission of resistance genes.

In 2010, CLSI lowered the Enterobacteriaceae MIC interpretive criteria for cephalosporins and carbapenems. One impact of this change is that clinical laboratories using the lowered breakpoints are no longer instructed to perform tests for specific mechanisms of resistance and to change susceptibility testing reports accordingly. Instead, with the lower breakpoints in place, laboratories are instructed to report the interpretation for each antimicrobial agent according to the observed MIC (19, 57, 232). As such, the mechanism-specific tests described in this chapter may not be necessary for routine testing to guide reporting of susceptibility tests but are useful for purposes of surveillance and targeted infection prevention.
Tests for ESBLs

Enterobacteriaceae can produce β-lactamases capable of hydrolyzing penicillins and cephalosporins, including the extended-spectrum cephalosporins (e.g., ceftaxime, ceftriaxone, cefotaxime, and ceftazidime). These enzymes are referred to as ESBLs (233, 234) and are discussed in chapter 69. More than 200 different types of ESBLs have been identified among Gram-negative bacteria, and they are associated with a variety of in vitro antimicrobial susceptibility profiles (233, 234; http://www.lahey.org/Studies/). Although all ESBLs hydrolyze extended-spectrum cephalosporins, the activity against specific antimicrobial agents varies by enzyme type. For example, some of the TEM and SHV ESBLs demonstrate greater activity for ceftazidime than for ceftriaxone, whereas the CTX-M enzymes demonstrate greater activity for ceftriaxone and cefotaxime than for ceftazidime (234, 235). ESBLs do not hydrolyze carbenapenems, and therefore carbapenems have been the treatment of choice for infections with ESBL-producing isolates.

CLSI guidelines describe screening criteria and confirmatory tests for ESBL detection in Klebsiella spp., Escherichia coli, and Proteus mirabilis (19); EUCAST guidelines also include Salmonella spp. and Shigella spp. (57). Although ESBLs do occur in bacteria other than these species, the phenotypic ESBL confirmatory test can produce a false-negative result in the presence of an AmpC-type enzyme (236), so validation of the ESBL test in bacteria with a chromosomally encoded AmpC enzyme (e.g., Enterobacter spp. and Serratia spp.) is difficult. When ESBL testing was performed routinely, it was important to establish screening criteria for ESBL detection, because routine disk diffusion and MIC tests did not always identify isolates that produced ESBLs (237–240). Therefore, MIC and disk diffusion screening breakpoints were developed for aztreonam, cefotaxime, cefpodoxime, ceftazidime, and ceftriaxone for aid in detecting ESBL-producing isolates (57, 241). ESBL-producing clinical isolates may demonstrate HLR to one or more of the screening drugs (239, 242–246). Thus, the sensitivity of the screening test increases when more than one screening drug is used (240, 247, 248).

ESBLs are inhibited by clavulanic acid, and this property is used in laboratory tests to confirm ESBL production. These tests are based on enhanced drug activity when a cephalosporin (usually ceftazidime or cefotaxime) is tested with clavulanic acid compared to its activity when tested alone. Both a disk diffusion test and a broth microdilution MIC test have been described for confirmation of ESBL production. For broth microdilution, cefotaxime and ceftazidime are tested with and without 4 μg of clavulanic acid per ml. A decrease in the MIC of ≥3 doubling dilutions for the agents tested in combination with clavulanic acid compared to the values obtained for the agents tested alone indicates the presence of an ESBL. For disk diffusion testing, the same agents incorporated into disks with and without 10 μg of clavulanic acid are tested. An increase in the zone diameter of ≥5 mm for either of the disks with clavulanic acid indicates the presence of an ESBL. Klebsiella pneumoniae ATCC 700603 should be included for quality control purposes; accepted ranges are given in the current CLSI document M100 tables and at the EUCAST website (19, 57).

There are multiple explanations for a screen-positive, confirmatory test-negative result for an isolate. The isolate may be ESBL negative but demonstrate reduced susceptibility to the screening agents because of decreased porin production, hyperproduction of a normal-spectrum β-lactamase, such as TEM-1 or SHV-1, or production of another cephalosporin-hydrolyzing enzyme, such as an AmpC-type enzyme, which is not inhibited by clavulanic acid. Alternatively, the isolate may be ESBL positive but produce an additional β-lactamase, such as the AmpC-type enzyme, which can interfere with ESBL inhibition by clavulanic acid (236, 249). The addition of an AmpC inhibitor (i.e., cloxacillin) appears to improve the sensitivity of ESBL detection among strains that also produce an AmpC enzyme (250). In one version of such a test, the same disk diffusion method and interpretive criteria used for ESBL detection are performed on MHA containing cloxacillin to inhibit AmpC enzymes, thereby improving detection of ESBLs in the presence of both types of resistance (251).

In recent years, both CLSI and EUCAST revised the recommendations for when to perform ESBL screening and confirmation tests. These revised recommendations were made because the interpretive criteria or breakpoints for cephalosporins and aztreonam were also revised (57, 241). The new breakpoints, based upon pharmacokinetic/pharmacodynamic data and limited clinical outcome data, are meant to more accurately predict treatment outcomes by using the most commonly used dosages for the cephalosporins. When the current breakpoints are used, ESBL screening and confirmatory tests should be performed for infection control and epidemiological purposes rather than for changing interpretive criteria (e.g., changing a cephalosporin report from susceptible to resistant). In other words, it is possible for an isolate to produce an ESBL but still to test susceptible to one or more extended-spectrum cephalosporins. This recommendation seems to contradict previous recommendations to report all cephalosporins as resistant if an ESBL is detected (81), but the new pharmacokinetic/pharmacodynamic data suggest that previous practices may have resulted in reporting of false resistance (254).

Tests for Detection of Plasmid-Mediated AmpC-Type β-Lactamases

Genes encoding inducible AmpC-type β-lactamases occur on the chromosomes of several Gram-negative bacilli, such as Enterobacter cloacae, Citrobacter freundii, Serratia marcescens, and Pseudomonas aeruginosa (255). These enzymes confer resistance to a wide spectrum of β-lactams, and they are resistant to the commonly used β-lactamase inhibitors (see details in chapter 69). Genes encoding AmpC-type β-lactamases may also be located on transmissible plasmids in several bacterial species that lack an inducible chromosomally mediated enzyme, including E. coli, Klebsiella spp., Salmonella spp., and P. mirabilis (256). Like plasmids encoding ESBLs, plasmids encoding AmpC-type enzymes often carry resistance determinants for multiple classes of antimicrobial agents, and the combination of an AmpC-type enzyme with porin loss can result in carbapenem resistance (257, 258).

None of the phenotypic tests described below for AmpC detection can differentiate between genes located on the chromosome and those on a plasmid. Detection of an AmpC enzyme in members of the Enterobacteriaceae that do not typically carry a chromosomal enzyme gene is assumed to indicate a plasmid-mediated enzyme; in E. coli, which carries a chromosomally located but typically unexpressed AmpC enzyme gene, molecular studies are necessary to distinguish between plasmid and chromosomal enzyme genes. The detection of plasmid-mediated AmpC-type enzymes is helpful for infection control and epidemiological investigations (259–261), and most large studies evaluating methods for AmpC detection have focused on plasmid-mediated enzymes (262).
Several tests have been proposed for detection of AmpC-mediated resistance. Two assays, the modified three-dimensional extract test and the cefoxitin-agar medium-based test, are labor-intensive and difficult to implement in the clinical laboratory (263, 264). The more promising assays incorporate an inhibitor of AmpC enzymes incorporated into one of several confirmatory AmpC assays, described below. Two inhibitors that have been evaluated widely are cloxacillin and boronic acid, although proprietary inhibitors have also been evaluated for this purpose (265, 266). It is important that the boronic acid inhibitor is not specific for AmpC enzymes; boronic acid affects both class A (e.g., KPC) and class C (e.g., AmpC) enzymes, so additional testing must be performed to differentiate these (267, 268).

Phenotypic tests for AmpC production are generally performed on isolates that screen positive for potential AmpC production by testing nonsusceptible to the cephamycins (i.e., cefoxitin or cefotetan). Cefoxitin resistance demonstrates better sensitivity for this purpose, although cefotetan resistance is a more specific predictor of AmpC production (269–271). Others have suggested that a combination of resistance to cefotetan and resistance to ceftazidime or cefoxitin can improve specificity without decreasing sensitivity (272, 273). Isolates that screen as potential AmpC producers can be confirmed with a molecular test (see chapter 77) or one of the phenotypic confirmatory tests described below.

The double-disk synergy test has been evaluated widely for detection of both plasmid- and chromosome-encoded AmpC enzymes. This test involves a paper disk or tablet containing an antibiotic (typically cefotetan, ceftazidime, or cefotaxime) placed near an AmpC inhibitor (typically cloxacillin or boronic acid) on a lawn of the organism to be tested. The inhibitor inactivates the β-lactamase, resulting in a zone of inhibition around the antibiotic disk that is enlarged and distorted toward the inhibitor disk (274, 275). Numerous studies have reported this test to have good sensitivity (range of 85 to 90%), although its specificity is much less reliable (272, 276, 277). Ruppê et al. developed a modification of this approach that can be used to detect the AAC-1 β-lactamase, which is inhibited by oxacillin. Essentially, the double-disk synergy test is set up in duplicate with ceftazidime and cefotaxime, using cloxacillin as an inhibitor for one set and cefotaxin as the inhibitor for the other. Organisms producing an AAC-1 enzyme will demonstrate inhibition in both assays, while those producing other AmpC β-lactamases will demonstrate inhibition only with cloxacillin (275).

Another test incorporates a disk containing both a test drug (typically cefotaxin, but also cefotaxime or ceftazidime) and an AmpC inhibitor (cloxacillin or boronic acid) in a standard disk diffusion assay. The zone diameter of the test drug alone is compared to that obtained in the presence of the inhibitor; an increase in zone size (typically of ≥4 mm) is interpreted as positive (277, 278). Numerous studies have evaluated different combinations of β-lactams and inhibitors with this assay, and each has concluded that it demonstrates good sensitivity and specificity for confirmation of both plasmid- and chromosome-encoded AmpC enzymes (269–271, 278, 279). In one study evaluating the cloxacillin and boronic acid inhibitors, each compound performed well, but the best assay performance was observed when both compounds were combined with cefotaxin (278).

At least two commercial manufacturers have developed test systems based on various tests described here. Rosco NeoSensitabs and Mast antibiotic resistance detection sets both incorporate several disks or tablets into panels that can be used to decipher various β-lactam resistance mechanisms; these systems have generally performed well in a limited number of published studies (269, 277, 280). Etest also produces an AmpC assay (Etest AmpC) that follows a similar logic. Etest AmpC uses a double-ended strip containing a gradient of cefotetan on one end and a gradient of cefotetan plus cloxacillin on the other; the MIC for cefotetan alone is compared to the MIC with the inhibitor, and a ratio of ≥8 is considered positive, as is a deformation of the ellipse or formation of a phantom zone (http://www.ilexmedical.com/files/E-test-Package-Insert/Product_supplement.pdf).

Tests for Detection of Carbapenemases

Carbapenems are broad-spectrum β-lactam agents used for empiric treatment of very serious infections and for treatment of infections with multidrug-resistant organisms. As such, carbapenems are viewed as “agents of last resort,” and resistance to them is a significant clinical and public health concern. Carbapenemases are β-lactamases that can hydrolyze carbapenem antimicrobial agents (e.g., ertapenem, doripenem, imipenem, and meropenem). Typically, carbapenemases can also hydrolyze other β-lactam agents, such as the penicillins, β-lactam–β-lactamase inhibitor combinations, and cephalosporins, so isolates producing a carbapenemase can be resistant to all β-lactam drugs. Although carbapenemases can be chromosomally encoded, most are encoded on a plasmid that can also contain other resistance determinants. It is these features of carbapenemases that make identifying isolates harboring such resistance mechanisms a significant infection control concern.

Carbapenemases fall within the following three classes of β-lactamases: class A enzymes, including KPC, SME, IMI, NMC, and GES; class B enzymes, also known as the metallo-β-lactamases (MBLs), with NDM, VIM, and IMP being the most common types; and class D OXA enzymes (281, 282). These enzymes are described in chapter 69. Carbapenemases have been identified in many different Gram-negative bacilli, but their recent emergence among the Enterobacteriaceae represents a significant escalation of their clinical relevance. The KPC enzyme is the most commonly identified class A carbapenemase and is found among Enterobacteriaceae; it usually occurs in Enterobacteriaceae but has also been identified in Pseudomonas spp. (281, 283). In the past, MBLs were most often found in P. aeruginosa and Acinetobacter spp., and only occasionally in Enterobacteriaceae (284). In contrast to historic MBLs, the NDM mechanism has emerged primarily among Enterobacteriaceae, although it has also been described for Acinetobacter spp., Pseudomonas spp., and Stenotrophomonas maltophilia (285–287), and its presence was documented in numerous countries across several continents within the first few years of its description (285, 287). OXA carbapenemases are most commonly found in Acinetobacter spp., but the OXA-48 family of carbapenemases is found among Enterobacteriaceae (288). In January 2009, the CLSI guidelines recommended use of the modified Hodge test (MHT) for detection of carbapenemase activity in Enterobacteriaceae (81). This test is performed by inoculating a carbapenem-susceptible isolate, E. coli ATCC 25922, onto MHA as described for disk diffusion testing, with the exception that an inoculum equivalent to a 0.5 McFarland standard is diluted 1:10 prior to inoculation. A carbapenem disk (either 10 μg meropenem or 10 μg ertapenem) is placed on the plate, and then a loopful of the test isolate is streaked from the disk to the edge of the plate. After overnight incubation, the test is read at the intersection of the zone of inhibition for E. coli.
ATCC 25922 and the test isolate. Indented growth of E. coli ATCC 25922 toward the carbapenem disk is interpreted as a positive result; no indentation of E. coli ATCC 25922 growth from the zone of inhibition toward the disk is interpreted as a negative result. When a carbapenemase-producing isolate is streaked three or four times around one carbapenem disk, the multiple distortions of the zone of inhibition can resemble a clover leaf, and hence this test is sometimes called the cloverleaf test.

Initially, the MHT was recommended for the detection of carbapenemase production in Enterobacteriaceae isolates that demonstrated an elevated but susceptible carbapenem MIC (i.e., 2 μg/ml for ertapenem and 2 to 4 μg/ml for imipenem or meropenem) or zone diameter (i.e., 16 to 21 mm for ertapenem or meropenem) (81, 289–292). Additionally, it was recommended to report isolates that tested MHT positive as "carbapenemase-producing" isolates in the laboratory report, with a warning that the carbapenem therapeutic outcome was unknown. In 2010, the carbapenem breakpoints were revised; now the susceptible breakpoints are ≤1 μg/ml for doripenem, imipenem, and meropenem and ≤0.50 μg/ml for ertapenem (19). When these breakpoints are used, the susceptibility of the β-lactam agents is reported according to the interpretive criteria for the MIC obtained with each agent; the MHT is no longer recommended for routine reporting, and interpretive criteria are not changed according to the presence of carbapenem resistance. However, some laboratories may still choose to perform the MHT for special infection prevention strategies or to address specific epidemiologic questions related to the mechanism of resistance.

The advantages of the MHT are that it is easy to perform, multiple isolates can be tested on one agar plate, and carbapenemases of different classes can be detected using the same test (289, 293). The disadvantages are that reading the test is subjective and the test cannot differentiate between different carbapenemases, which can be useful epidemiologically. However, false-positive results have been reported for some isolates that produce AmpC-type enzymes or ESBLs when these noncarbapenemase mechanisms combine with chromosomal porin mutations (267, 294, 295). What is even more concerning is that NDM-producing Enterobacteriaceae may produce false-negative results (294, 296). Although the MHT performs well for class A and D enzymes and for detection of some MBLs, its poor performance for detection of isolates carrying the rapidly emerging NDM MBL is a significant limitation.

Another assay that is not specific for any particular class of carbapenemase is the Carba NP test, which relies on a pH-sensitive indicator to detect hydrolysis of the imipenem β-lactam ring by a carbapenemase (297). Several studies have demonstrated excellent sensitivity and specificity for detection of many different carbapenemase enzymes in both Enterobacteriaceae and P. aeruginosa (297, 298), although this test performs less well for the GES and OXA-48 families of carbapenemases (299). The Carba NP test is inexpensive, quick (1 to 3 h), and relatively easy to perform and interpret (297–299), all of which suggest that it may be a valuable tool for detection of carbapenemases. At least one commercial supplier provides reagents for the Carba NP test (Rosco Diagnostica, Taastrup, Denmark), but this test has not been FDA cleared and is not available commercially in the United States. Therefore, U.S. laboratories that wish to perform the Carba NP test must validate its performance and prepare testing reagents in-house, thus increasing the test complexity.

Researchers have also described carbapenemase detection through the use of matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) mass spectrometry. This technology is being introduced widely in clinical microbiology laboratories for the purpose of rapid and accurate bacterial identification, but it can also detect carbapenemases by detecting the hydrolyzed and decarboxylated metabolites of specific carbapenems (300, 301). This approach has been described as inexpensive, rapid, and applicable to several different types of carbapenemase, but the current state of this assay requires that the user be relatively savvy about operation of the MALDI-TOF instrument, as the systems placed in microbiology laboratories are typically optimized for bacterial identification rather than detection of drug metabolites.

In addition to the general tests described above, several tests have been described for detection and differentiation of specific carbapenemase types, including class A (e.g., KPC) and class B (i.e., MBL) carbapenemases. These tests may be useful for epidemiological studies but would likely require additional validation before they could be used for making treatment decisions. Class A and C enzymes are inhibited by boronic acid, and class B MBLs are inhibited by chelators, such as EDTA and 2-mercaptopyruvonic acid. Many tests that incorporate one or more of these inhibitors with a carbapenem have been described for differentiating the activity of one enzyme from that of another. The test formats fall into three general categories: a double-disk zone distortion test, a two-disk zone enhancement test, and a broth microdilution or gradient diffusion MIC reduction test.

Kim et al. (302) described a double-disk distortion test for detection of MBLs which uses a carbapenem disk (e.g., imipenem) and another disk containing Tris-EDTA and 2-mercaptopyruvonic acid chelators. These disks were placed 10 mm apart, edge to edge, on MHA inoculated with the test organism. After overnight incubation, MBL production of the test isolate was identified by distortion of the inhibition zone around the carbapenem disk toward the chelator disk, indicating that the removal of metal ions by the chelators inhibited carbapenemase activity. Doi et al. (303), Pasteran et al. (267), and Tsakris et al. (268) each described a two-disk potentiation test for detection of class A carbapenemases. In this test, one disk contains a carbapenem and the other disk contains a carbapenem plus 3-aminophenylboronic acid (APB), both of which are placed on MHA inoculated with the test organism. Production of a class A carbapenemase is indicated by an increase in the zone diameter around the carbapenem disk with APB compared to that around the carbapenem-only disk.

Tests for carbapenem MIC reduction in the presence of APB or a chelator have been described for detection of both class A carbapenemases and MBLs (267, 304), in addition to the use of the commercial Etest MBL strip. These tests are similar to the CLSI MIC confirmatory test for ESBLs in that they are positive for carbapenemase production if the carbapenem MIC is significantly lower in the presence of the inhibitor than the MIC without the inhibitor. The commercial Etest MBL strip, which has been evaluated in numerous studies, demonstrates substantial performance variability (305–307), but it is both convenient and familiar to most clinical laboratories. Broth microdilution-based MIC reduction tests have been evaluated less widely but have demonstrated good performance for sensitive and specific detection of common MBL enzymes in Enterobacteriaceae (267, 308).
These tests for detection of specific carbapenemases are generally convenient and easy to perform, and some have very favorable performance characteristics. However, significant disadvantages of the tests are that multiple tests would have to be performed routinely to detect carbapenemases of different classes, and none of these inhibitor-based tests can detect OXA carbapenemases.

**DIRECT TESTS FOR β-LACTAMASES**

In the clinical laboratory, β-lactamase tests can be used for two purposes. The first is to detect an underlying mechanism of resistance that may not be detected using routine susceptibility testing methods, and the second is to detect a mechanism of resistance that is an infection control concern and is epidemiologically important. These purposes are not mutually exclusive. Identification of a β-lactamase is often epidemiologically important, and in the health care setting, it can be an infection control concern. However, the use of a special test for enzyme detection does not always mean that the β-lactamase test should be used to predict treatment outcomes. For example, a β-lactamase-positive result for a *Neisseria gonorrhoeae* isolate means that the isolate is resistant to penicillin and that penicillin would not be an appropriate treatment choice (19). In contrast, the CLSI test for detection of ESBLs is a useful test for detecting a resistance mechanism with epidemiological and infection control significance, but with the recently revised CLSI cephalosporin breakpoints, this test is not recommended for prediction of cephalosporin treatment outcomes (19). Instead, it is recommended that laboratories use the results of routine susceptibility testing and apply the revised interpretive criteria. A list of the organisms for which β-lactamase tests are useful is given in Table 4.

In the direct β-lactamase test, a positive reaction indicates that the isolate is resistant to the β-lactam agents noted in Table 4, but a negative reaction is inconclusive, because other mechanisms of β-lactam resistance are possible. For example, most ampicillin-resistant *Haemophilus influenzae* isolates produce β-lactamases which can be detected by direct β-lactamase tests; however, rare strains are ampicillin resistant but β-lactamase negative (309-311). For the latter, conventional disk diffusion or dilution tests are needed to detect the resistance (see chapter 71). Three direct β-lactamase assays, the acidimetric, iodometric, and chromogenic methods, have been used widely in the past (312, 313), although the penicillin zone edge test is now recommended for *S. aureus*. Each method involves testing bacteria grown on nonselective media, and the results are available within 1 to 60 min. The acidimetric and iodometric methods use a colorimetric indicator to detect the presence of penicilloic acid in the reaction vessel following β-lactamase hydrolysis of penicillin. In the acidimetric method, the substrates are citrate-buffered penicillin and a phenol red indicator. A decreasing pH associated with the presence of penicilloic acid results in a color change from red (negative result) to yellow (positive result) (314). The substrates in the iodometric test are phosphate-buffered penicillin plus a starch-iodine complex. Penicilloic acid, if present, reduces the iodine and prevents it from combining with starch, resulting in a colorless reaction (positive); a bluish purple color corresponds to a negative result (315).

The chromogenic cephalosporin nitrocefin can be used in a test tube assay (316) but has been incorporated into several filter paper-type disk or strip products that are commercially available and widely used in clinical laboratories. β-Lactamase hydrolysis of the chromogenic cephalosporin molecule causes an electron shift that results in a colored product (316). Although the acidimetric and iodometric methods have varied in performance, perhaps due in part to a lack of experience with these methods, the chromogenic method has been reliable for detecting β-lactamases produced by all of the organisms indicated in Table 4 (317, 318).

The colorimetric β-lactamase tests rely on visualization of a colored product that presumably results from β-lactamase destruction of the substrate β-lactam molecule. However, these tests are not 100% specific, and other substances may yield colored endpoints. Serum may cause a colored reaction with the nitrocefin test (316), and if reagents are not stored properly, spontaneous degradation of penicillin may produce false-positive acidimetric or iodometric β-lactamase reactions. The penicillin zone edge test described above, in “Detection of Penicillin Resistance in Staphylococci,” demonstrated much better sensitivity for detecting β-lactamase production in *S. aureus* than any of the colorimetric tests described here; therefore, it is now the preferred phenotypic method for use on *S. aureus* (19, 57). The zone edge test has not been evaluated extensively for other bacterial species and is not recommended for routine use for species other than *S. aureus*.

While some bacteria (e.g., *H. influenzae*, *N. gonorrhoeae*, and enterococci) constitutively produce β-lactamases, others (e.g., staphylococci) may produce detectable amounts of enzyme only after exposure to an inducing agent, which may be generally a β-lactam (319). If staphylococci produce a positive β-lactamase result without induction, the results can be reported. However, if no β-lactamase is detected, then the test must be performed on cells that have been exposed to an inducing agent before a negative result is reported. This can be done by testing organisms that have been grown in the presence of subinhibitory concentrations of penicillin.

* A positive result indicates resistance to all penicillinase-labile penicillins, including amoxicillin, ampicillin, azlocillin, carbenicillin, mecloxacillin, ticarcillin, and ticarcillin; however, a negative result is inconclusive, since other resistance mechanisms may occur.

* Direct β-lactamase tests include chromogenic cephalosporin, acidimetric, and iodometric tests.
of a β-lactam agent (e.g., 0.25 μg of cefoxitin per ml) in a broth or agar system. Alternatively, growth from around a 1-μg oxacillin or 30-μg cefoxitin disk (e.g., a 1-μg oxacillin or 30-μg cefoxitin disk) can be tested. A positive result may take longer to develop for staphylococci than for other organisms, and the test should not be considered negative until it has been allowed to react for at least 60 min. Although a nitrocefin-based test can be performed for S. aureus, a negative result should be confirmed by the more sensitive zone edge test described above (19).

Although penicillin resistance in enterococci is not reliably detected with standard susceptibility tests, direct β-lactamase tests using nitrocefin-based assays are effective. However, because β-lactamase-producing enterococci are rare, it is not necessary to perform such testing routinely (19).

β-Lactamase testing by the chromogenic nitrocefin method with anaerobic Gram-negative bacilli other than those from the Bacteroides fragilis group may be performed prior to susceptibility testing (320). It is not necessary to test members of the B. fragilis group because they characteristic produce β-lactamases and should be considered penicillin resistant. As with aerobes, resistance to β-lactam drugs among anaerobic bacteria is not always mediated by β-lactamase production (e.g., in some strains of Parabacteroides distasonis and B. fragilis) (252, 253, 320).

The S. aureus strains recommended by CLSI for quality control of routine disk diffusion and dilution tests (19) can be used for quality control of β-lactamase tests. S. aureus ATCC 25923 is β-lactamase negative, whereas S. aureus ATCC 29213 is β-lactamase positive (19).

Susceptibility Test Methods: Fastidious Bacteria*

ROMNEY M. HUMPHRIES AND JANET A. HINDLER

Most fastidious bacteria do not grow satisfactorily in standard in vitro susceptibility test systems that use un-supplemented media. For certain fastidious species that are more frequently encountered, such as Haemophilus influenzae, Neisseria gonorrhoeae, Neisseria meningitidis, Streptococcus pneumoniae, and other Streptococcus spp., slight modifications have been made to standard Clinical and Laboratory Standards Institute (CLSI) disk diffusion and MIC methods to allow reliable testing of these bacteria. The modifications generally involve the use of a test medium with added nutrients and sometimes extended incubation times and/or incubation in an atmosphere with increased levels of CO₂ (Table 1). Specific zone diameter and MIC interpretive criteria have been developed by the CLSI for these bacteria, as have acceptable ranges for recommended quality control (QC) strains (1). The CLSI also published an approved guideline for testing infrequently isolated or fastidious bacteria, including Abiotrophia spp., Granulicatella spp., Aeromonas spp., Plesiomonas spp., Bacillus spp. (not Bacillus anthracis), Campylobacter jejuni, Corynebacterium spp., Erysipelothrix rhusiopathiae, the HACEK group (Aggregatibacter [formerly the aphrophilus group of Haemophilus and Actinobacillus], Cardiobacterium, Eikenella, and Kingella spp.), Helicobacter pylori, Lactobacillus spp., Leuconostoc spp., Listeria monocytogenes, Moraxella catarrhalis, Pasteurella spp., Pedicoccus spp., and Vibrio spp. Standard MIC methods for testing potential agents of bioterrorism (Bacillus anthracis, Yersinia pestis, Burkholderia mallei, Burkholderia pseudomallei, Francisella tularensis, and Brucella spp.) are also included in CLSI document M45 (2), and conditions for testing these are listed in Table 2. Interpretive criteria for the organisms in the CLSI M45 guideline were primarily adapted from those for organisms included in CLSI standards (1), taking into consideration information in the literature and the experiences of authors of the guideline. This is in contrast to the extensive microbiological, clinical, and pharmacodynamic databases normally used for development of interpretive criteria that appear in CLSI antimicrobial susceptibility testing standards. The classification of M45 as a guideline rather than a standard was based on this fact. A summary of the testing conditions for these organisms appears in Table 3. There are no specific recommendations for other fastidious bacteria such as Bordetella spp. and Legionella spp. This is because in part (i) infections caused by these bacteria usually respond to drugs of choice, (ii) isolates are infrequently recovered from patients infected with these organisms, and (iii) isolates are often difficult to grow and special media are required.

In addition to conventional MIC test methods (e.g., agar dilution or broth dilution methods), the Etest MIC determination method (bioMérieux, Marcy L’Etoile, France) has been used to test many types of fastidious bacteria. The Etest approach allows placement of strips on special media and the use of various incubation conditions. The limitations of this method include its cost and lack of clearance by the U.S. Food and Drug Administration (FDA) for testing many less commonly encountered fastidious bacteria. Prior to use of the Etest for clinical testing in the United States, the FDA clearance status for the particular organism-antimicrobial agent combination should be determined. If FDA clearance has not been granted, laboratories should perform a verification study to meet the requirements of the Clinical Laboratory Improvement Amendments to allow use of this test for organisms off-label, and the results should be qualified on the patient report. However, for organisms not included in CLSI document M100 or M45, this is complicated by the absence of a defined method with which to compare results. Laboratories may consider exchanging isolates with a reputable laboratory as a means by which to perform such a verification study, in this instance. This chapter summarizes the standard methods recommended by the CLSI for antimicrobial susceptibility testing of Streptococcus spp. (including S. pneumoniae), H. influenzae, N. gonorrhoeae, and N. meningitidis. Methods for testing the infrequently isolated or fastidious bacteria included in CLSI document M45 are summarized to include testing potential agents of bioterrorism. Test methods and indications for testing and the reporting of results are provided. In the past, regional and global surveillance studies for antimicrobial resistance among respiratory pathogens, including H. influenzae, S. pneumoniae, and M. catarrhalis, were conducted regularly. However, the numbers of these studies have declined, and it is somewhat difficult to get an accurate global picture of the incidence of resistance in these organisms. Similarly, for more infrequently encountered and fastidious bacteria, surveillance studies are rarely performed, and resistance rates are predominantly reported only in single institutional studies and case series and reports. Nonetheless, the incidence of resistance among contemporary isolates is also provided, as available in the cur-

decline in 2007, before release of PCV-13, in the United States (11), it remains the most commonly identified pneumococcal serotype in colonized children (10).

Three sets of penicillin breakpoints exist for pneumococci: one for meningitis, one for nonmeningitis, and one applicable to therapy with oral penicillin G (1, 12). The breakpoints for pneumococcal meningitis are ≤0.06 μg/ml for susceptibility and ≥0.12 μg/ml for resistance, with no intermediate category. For nonmeningitis, ≤2 μg/ml is considered susceptible, 4 μg/ml is considered intermediate, and ≥8 μg/ml is considered resistant. The breakpoints for oral penicillin are ≤0.06 μg/ml for susceptibility, 0.12 to 1 μg/ml for the intermediate category, and ≥2 μg/ml for resistance (1). The SENTRY antimicrobial surveillance program recently reported on the 14-year antimicrobial susceptibility trends for more than 18,900 S. pneumoniae isolates from patients with community-acquired respiratory infections and bacteremia at 9 U.S. medical centers between 1998 and 2011 (8). In 2011, 85% of isolates were susceptible to penicillin by the nonmeningitis breakpoints and 56% by the meningitis breakpoints; in contrast, 97% and 72% susceptibility, respectively, was identified by this study in 1998 (8). In parts of the world where the PCV-7 vaccine has not been widely used, penicillin resistance rates remain high and serotype 19A has increased in incidence for reasons other than serotype replacement disease among a vaccinated population (5). In particular, penicillin susceptibility was found to be only 54% by the nonmeningitis breakpoint in an international study of more than 3,300 isolates recovered from various specimen sources among pediatric patients between 2004 and 2011 (13). In a study of isolates collected from 20 hospitals in Taiwan between 2006 and 2010, only 11.7% of isolates were susceptible to penicillin by the

meningitis breakpoints, and 63.2% of isolates were susceptible by the nonmeningitis breakpoints (14). Among 616 isolates collected in 2010 from the Asia-Pacific region and South Africa, the rates of penicillin resistance by the nonmeningitis breakpoints were found to be ≥50% in Hong Kong, Korea, South Africa, and Thailand (15).

Strains of S. pneumoniae that are susceptible to penicillin generally are susceptible to other β-lactam agents; however, as the penicillin MIC increases, the MICs of other β-lactams also increase (16). Current rates of resistance to the extended-spectrum cephalosporins vary by location (6, 8, 13, 15). In the international survey of pediatric isolates mentioned above, 93% of all isolates were susceptible to ceftriaxone (MIC, ≤1.0 μg/ml) (13). Ceftaroline, an antimicrobial recently approved by the FDA for the treatment of community-acquired bacterial pneumonia, displays the most potent activity among the β-lactams against S. pneumoniae. The SENTRY U.S. study documented 94.5% susceptibility in 2011 by the FDA breakpoint, which at the time was ≤0.25 μg/ml, among penicillin-resistant (MIC, ≥2 μg/ml) isolates (8). The current CLSI and FDA susceptibility breakpoint for ceftaroline is ≤0.5 μg/ml (1).

Resistance has been described for all other classes of antimicrobial agents that are usually considered for treating pneumococcal infections, except for the glycopeptides. Resistance to macrolides and clindamycin has increased in the United States in the post-PCV-7 era (6) and appears to be influenced by macrolide use. The SENTRY study found that 82% of isolates were macrolide susceptible (MIC, ≤0.25 μg/ml) just prior to the introduction of PCV-7, whereas in 2011 macrolide susceptibility had declined to 55.2%. In the same study, clindamycin susceptibility declined from 96.2% pre-PCV to 78.2% in 2011 (8). Resistance to macrolides in Asian-Pacific countries is much higher than in the United States, exceeding 75% in some areas (15). Erythromycin MICs for pneumococci with macrolide-lincosamide-streptogramin B (MLS)-type resistance (encoded by the ermB gene) are usually ≥64 μg/ml, and clindamycin MICs are ≥8 μg/ml, whereas for isolates with the M phenotype (encoded by the mefA gene), erythromycin MICs are 1 to 32 μg/ml and clindamycin MICs are ≥0.25 μg/ml. The clinical significance of the lower-level macrolide resistance expressed by the M phenotype was once debated; however, treatment failures have been documented with such strains (18). Erythromycin resistance but clindamycin susceptibility may also be an indicator of the presence of an inducible ermB gene (19). There is a theoretical risk of spontaneous conversion from inducible to constitutive resistance in these isolates during extended clindamycin therapy, although this has not specifically been demonstrated for pneumococci. Susceptibility and resistance to azithromycin, clarithromycin, and dirithromycin among S. pneumoniae isolates can be predicted by testing erythromycin (1). Telithromycin, a ketolide, is considerably more active than macrolides against S. pneumoniae, with less than 1% of isolates showing resistance in...

<sup>a</sup>Suspension is in Mueller-Hinton broth or saline standardized to a 0.5 McFarland standard. For broth dilution, the final organism concentration is 5 × 10<sup>5</sup> CFU/ml. CHOC, chocolate agar; SBA, sheep blood agar.

<sup>b</sup>Incubation temperature, 35°C (except for *C. jejuni* and *C. coli*).

<sup>c</sup>*E. coli* ATCC 35218 is used for QC when testing β-lactam–β-lactamase inhibitor combination drugs.

<sup>d</sup>Suspension is in saline standardized to a 2.0 McFarland standard.

<sup>e</sup>For halophilic species, prepare inoculum in 0.85% NaCl (normal saline).
North America in 2003 and 2004, the most recent year for which susceptibility data for this agent are available (20).

Resistance rates for trimethoprim-sulfamethoxazole (TMP-SMX) range from 35 to 47% in the United States in the pre- and post-PCV-7 eras and are similar outside the United States (8, 21). Resistance rates for fluoroquinolones have remained low (6, 8, 22), but resistance is more frequent in elderly patients (22, 23). Resistance has only rarely been documented by surveillance studies for linezolid, tigecycline, and quinupristin-dalfopristin (6, 24).

Reference Test Methods

The CLSI describes both a broth microdilution method and a disk diffusion procedure for testing pneumococci. Details of these methods are listed in Table 1. The broth microdilution method may be used to test all of the antimicrobial agents recommended by the CLSI for pneumococci. With the exception of the oxacillin disk screening test for penicillin susceptibility, the disk diffusion method does not work reliably for testing β-lactam agents, including the cephalosporins. When used to predict penicillin susceptibility, oxacillin disk diffusion zone diameters of ≥20 mm indicate that the isolate is susceptible to penicillin using the nonconservative meningitis or oral penicillin breakpoints (1). However, strains with zone diameters of ≤19 mm cannot be readily categorized as resistant, and at a minimum the MICs of penicillin and an extended-spectrum cephalosporin or meropenem should be determined. It should be noted that the oxacillin screening procedure should be used only for isolates from patients with non-life-threatening infections.

If clindamycin testing is performed, it should include a screen for inducible clindamycin resistance. This can be accomplished via either the D-zone disk diffusion test or by a single-well broth microdilution test. For the D-zone test, a 15-μg erythromycin disk and a 2-μg clindamycin disk are placed 12 mm apart on Mueller-Hinton agar (MHA) supplemented with sheep blood (5%, vol/vol); a flattening of the clindamycin zone of inhibition adjacent to the erythromycin disk is indicative of inducible clindamycin resistance. For the broth microdilution test, 1 μg/ml of erythromycin and 0.5 μg/ml of clindamycin are combined in a single well (1); growth is indicative of inducible clindamycin resistance.

Increased use of tetracyclines, in particular doxycycline, as alternative agents for the treatment of community-acquired pneumonia in ambulatory and penicillin-allergic patients prompted the CLSI to revise the S. pneumoniae tetracycline susceptibility breakpoint from ≤2 μg/ml to ≤1 μg/ml, concomitant with introduction of doxycycline-specific breakpoints in 2013 (1). Prior to this change, doxycycline susceptibility was inferred from tetracycline testing, although doxycycline is more active than tetracycline against S. pneumoniae (25, 26). Currently, the CLSI has not assigned minocycline breakpoints for S. pneumoniae, and susceptibility is inferred from tetracycline testing (1).

Commercial Methods for Testing

Several options are available for determining MICs of various antimicrobial agents with pneumococci. The Etest method has been extensively evaluated (27, 28). Etest strips have been cleared by the FDA for all drugs recommended by the CLSI for testing of S. pneumoniae except doxycycline and telithromycin. The accuracy of the Etest has been reported to be >90% for most relevant drugs (27, 28), although the number of minor errors with penicillin is relatively high and Etest penicillin MICs are slightly lower than those determined by reference broth microdilution (27). Since it is recommended that the Etest be incubated in CO₂, the MICs of the macrolides and ketolides tend to be 1 or 2 dilutions higher than those by the reference broth method, in which incubation is conducted in ambient air. This is because these agents are less active at lower pH, which occurs with CO₂ incubation.

Other commercially available FDA-cleared panels or systems specifically designed for testing pneumococci include MicroScan (Siemens Healthcare Inc., West Sacramento, CA), Phoenix (BD Diagnostic Systems, Sparks, MD), Sensititre (Trek Diagnostic Systems, Inc., Cleveland, OH), and VITEK 2 (bioMérieux, Inc., Durham, NC). The MicroScan MICrOSTREP, Sensititre, VITEK 2, and Phoenix systems have been evaluated and found to show MICs that are comparable to those obtained with the CLSI broth microdilution reference method (28–30).

Strategies for Testing and Reporting of Results

The CLSI stipulates that S. pneumoniae isolates from cerebrospinal fluid (CSF) should be routinely tested by a reliable MIC method to determine susceptibilities to penicillin and cefotaxime, ceftriaxone, or meropenem (1). For CSF isolates, and with penicillin, only interpretations using the meningitis breakpoints should be reported for cefotaxime and ceftriaxone; for isolates from other sites, both meningitis and nonmeningitis interpretations should be reported for these agents (1). In addition, vancomycin can be tested by either an MIC or a disk diffusion method on isolates from CSF. Along with penicillin, the CLSI recommends primary testing and reporting of erythromycin and TMP-SMX for isolates from non-CSF sources; these drugs can be tested by either an MIC or a disk diffusion method (1). MIC testing of penicillin, cefotaxime or ceftriaxone, and/or meropenem, and MIC or disk diffusion testing of vancomycin, a fluoroquinolone, and tetracycline or doxycycline would also be appropriate for strains isolated from non-CSF sources. Other drugs that might warrant testing if being considered for treatment of infections other than meningitis include cephalosporins, clindamycin, and telithromycin. For isolates that are resistant to erythromycin and susceptible or intermediate to clindamycin, screening for inducible clindamycin resistance should be performed prior to reporting an isolate as clindamycin susceptible (1).

STREPTOCOCCI OTHER THAN PNEUMOCOCCI

Incidence of Resistance

Because there are significant differences in susceptibility of β-lactam agents in viridans group versus β-hemolytic streptococci, there are separate ampicillin, penicillin, cephalaxine, ceftriaxone, and cefepime interpretive criteria for the two organism groups (1). The viridans group of streptococci includes the mutans group, salivarius group, bovis group, anginosus group (previously “Streptococcus milleri” group), and mitis group. The anginosus group includes small-colony-forming β-hemolytic strains with group A, C, F, or G antigens. The β-hemolytic group includes the large-colony-forming β-hemolytic strains with group A (Streptococcus pyogenes), C, or G antigens and strains with group B (Streptococcus agalactiae) antigen.

Although β-hemolytic streptococci have been uniformly susceptible to penicillin (MIC ≤ 0.12 μg/ml), two reports have described penicillin MICs of 0.25 to 0.5 μg/ml for S. agalactiae (31) and group C streptococci (32). Kimura et al. from Japan reported 14 isolates of Streptococcus agalactiae...
collected from 1995 to 2005 with penicillin MICs of 0.25 to 1.0 μg/ml. These isolates harbor a point mutation in the PBP 2x gene, and introduction of this organism’s PBP 2x into penicillin-susceptible strains through allelic exchange resulted in elevated penicillin MICs (33). The clinical significance of the elevated penicillin MICs in these β-hemolytic streptococci is not known. These isolates also demonstrated fluoroquinolone nonsusceptibility and were more frequently macrolide resistant than fully penicillin-susceptible isolates (34). Similar isolates with altered PBP 2x and elevated penicillin MICs have subsequently been reported in the United States (35) and Canada (36, 37). High-level aminoglycoside resistance has been described on rare occasions for S. agalactiae.

The MLS-type macrolide resistance due to erm genes in β-hemolytic streptococci may be either inducible or constitutive. If the resistance is inducible, the strains will be resistant to erythromycin (and the other 14- and 15-membered macrolides) but appear susceptible to clindamycin unless resistance is induced. The rate of erythromycin resistance was recently reported to be 23% and that of clindamycin resistance to be 12.6% from an international surveillance study of 763 β-hemolytic streptococci isolated from skin and soft tissue, respiratory tract, and bloodstream infections in 2010 (38). Rates of resistance to erythromycin and clindamycin among 155 S. pyogenes isolates from U.S. patients in 2011 were 13.5% and 3.9%, respectively (39). In contrast, rates of erythromycin and clindamycin resistance among 153 S. agalactiae U.S. isolates were 54% and 33%, respectively (39). Resistance to erythromycin and clindamycin among contemporary isolates of S. agalactiae is significantly lower in Canada (40) and Europe. S. agalactiae strains colonizing pregnant women and isolated as part of prenatal screening are more likely to be erythromycin and clindamycin susceptible than those isolated from clinical infections (41).

Resistance rates among β-hemolytic streptococci vary for tetracyclines and remain low for fluoroquinolones. In several recent large surveillance studies, some international, resistance was not observed for daptomycin or linezolid (40, 42). Penicillin resistance in viridans group streptococci has been described, and resistance rates among bloodstream isolates can be >50% (43, 44), particularly for S. mitis, S. oralis, and S. sanguinis. Resistance has been described for some viridans group streptococcal isolates for macrolides, lincosamides, and tetracyclines (43–45), quinupristin-dalfopristin (44, 45), and fluoroquinolones (45). Single reports of resistance to vancomycin have been noted for S. gallolyticus (46) and S. mitis (47), and resistance to linezolid has been reported on rare occasions (48). In an European surveillance study, two viridans group Streptococcus isolates showed a daptomycin MIC of 2 μg/ml, which indicates nonsusceptibility according to CLSI criteria (49), and a case of daptomycin-nonsusceptible S. anginosus bacteremia was recently described for a patient with prior daptomycin exposure (50). Among a large international collection of bloodstream isolates, all were susceptible to tigecycline (44).

**Reference Test Methods**

The disk diffusion test may be used to determine the penicillin susceptibility of β-hemolytic streptococci; however, it is unreliable and should not be used for viridans group streptococci (51). For either group, carbapenems and daptomycin should be tested only by an MIC method, whereas other agents may be tested by either the MIC or disk method (1). Aminoglycoside MICs of >1,000 μg/ml for streptococci have been described; however, there are no published methods for screening for high-level aminoglycoside resistance in streptococci.

CLSI standards describe a D-zone test for inducible resistance to clindamycin in β-hemolytic streptococci, which is performed in the same manner as the D-zone test described above for S. pneumoniae. Alternatively, a single-well erythromycin (1 μg/ml) plus clindamycin (0.5 μg/ml) combination broth microdilution test can be performed, which displays >95% sensitivity and specificity compared to those of the D-zone test, for the detection of inducible clindamycin resistance (52).

**Commercial Test Methods**

There have been several reports demonstrating that the BD Phoenix performs reliably for susceptibility testing of Streptococcus spp. (30). Two studies have evaluated the performance of the MicroScan MICrOSTREP plus antimicrobial panel for testing antimicrobial susceptibility of streptococci (53); one study demonstrated reliable performance of the system for the β-hemolytic streptococci. However, numerous minor errors were noted in the second study with viridans group streptococci for ampicillin and penicillin (54). For the other test systems, there are no peer-reviewed publications, although it might be expected that systems capable of testing pneumococci would also perform adequately for other streptococci. The MicroScan, Phoenix, and Sensititre systems are cleared by the FDA for the testing of Streptococcus spp. The VITEK 2 system received FDA clearance in 2013 for the AST-ST01 card, with expanded species coverage that includes S. pneumoniae, as well as the viridans group and β-hemolytic streptococci. Etest has not been extensively evaluated but does appear to be a possible alternative to the reference methods for testing Streptococcus spp. (55, 56).

**Strategies for Testing and Reporting of Results**

Routine testing of β-hemolytic streptococci is unnecessary since there have been only sporadic reports of decreased susceptibility to penicillin, primarily in S. agalactiae (31–33, 35–37). However, if erythromycin is being used to treat infections caused by S. pyogenes and treatment failure is suspected, testing might be considered. Similarly, if clindamycin is being considered for prophylaxis of pregnant women who are highly allergic to penicillin, in an effort to prevent perinatal group B streptococcal disease, testing for erythromycin and clindamycin, including inducible resistance, should be performed. Erythromycin is not reported but tested only to determine if an isolate has the erythromycin-resistant and clindamycin-susceptible phenotype, in which case a test for inducible clindamycin would be required prior to reporting the isolate as clindamycin susceptible. For viridans group streptococci, penicillin MICs should be determined for strains isolated from blood, especially for patients with infective endocarditis.

**H. INFLUENZAE**

**Incidence of Resistance**

Ampicillin resistance in H. influenzae is primarily due to a plasmid-borne β-lactamase. TEM-1 is the most common enzyme, and ROB-1 contributes to less than 5% of β-lactamase-producing strains (57). It was recently shown among 11 H. influenzae isolates from several countries containing blaROB-1 that the plasmid on which blaROB-1 is commonly found is mobilized at a low frequency, which might account
for the infrequency of blaROB-1 compared to the rate of occurrence of blaTEM-1 (58). Ampicillin resistance can also result from altered penicillin-binding proteins in β-lactamase-negative, ampicillin-resistant (BLNAR) strains. Resistance in BLNAR strains is primarily associated with mutations of the ftsI gene that encodes PBP 3 (59, 60), which is the sole essential PBP in H. influenzae (59). A singular N526K mutation has been shown to result in a 2-fold increase in the MIC of ampicillin and a 2- to 8-fold increase in resistance to various cephalosporins. This mutation is relatively common in BLNAR isolates, although other mutations have been described (61–63). Isolates of BLNAR H. influenzae express lower levels of resistance to ampicillin, with MICs generally ranging from 0.5 to 8 μg/ml. Compared with β-lactamase-producing or ampicillin-susceptible H. influenzae, BLNAR isolates are slightly less susceptible to amoxicillin-clavulanic acid and to various cephalosporins, such as cefaclor and cefotaxime (64–66). Some strains may possess this β-lactam resistance mechanism and also produce β-lactamase; these strains are referred to as β-lactamase-producing amoxicillin-clavulanic acid-resistant (BLPACR) (61). Ampicillin MICs for β-lactamase-producing H. influenzae and BLPACR isolates are as high as 512 μg/ml (61, 63).

A study in the United States showed that 27% of 1,545 isolates collected from 2008 to 2010 were β-lactamase positive (67). Similar rates were noted in a global surveillance study in 2010 (38) in which 24% of isolates were β-lactamase positive and in another study of isolates from the Asia-Pacific region and South Africa in which 22% were reported as β-lactamase positive (15). From 2009 to 2010, 43% of 174 isolates from Taiwan were reported to be β-lactamase positive (68). However, the reported incidences of H. influenzae strains that are BLNAR and BLPACR vary considerably. From 2009 to 2012, 9.8% of H. influenzae isolates (n = 266) from patients with community-acquired pneumonia in 6 cities in China were β-lactamase producing and 9.0% were BLNAR (66). A study conducted in a single hospital in Thailand between September 2005 and March 2008 reported rates of β-lactamase-positive and BLNAR H. influenzae isolates of 40.9% and 18.2%, respectively (69). Investigators in Sweden noted a significant increase in β-lactam-resistant invasive isolates of H. influenzae over the last decade, mainly due to an increase in BLNAR isolates (70). Among 2,206 isolates collected from children aged ≤5 years in France between 2001 and 2008, 27.5% were β-lactamase positive, while 16.9% were BLNAR and 6.5% were BLPACR. Authors of that study noted a statistically significant decrease in β-lactamase-producing strains (P < 0.0001) and a statistically significant increase in BLNAR in isolates from 2001 to 2008 (64). A decrease in β-lactamase-producing isolates has also been documented in North America and Europe. In Japan, BLNAR strains are prevalent and more common than β-lactamase-producing strains (17, 65).

Resistance among H. influenzae isolates to broad-spectrum oral cephalosporins (e.g., cefixime and cefpodoxime) (64, 71) and to extended-spectrum cephalosporins (e.g., ceftriaxone) (15, 38, 64, 67, 72) is rare. All 453 H. influenzae isolates from the Asia-Pacific region and Africa were susceptible to the newer extended-spectrum cephalosporin ceftaroline when a CLSI susceptibility breakpoint of ≤0.5 μg/ml was used; however, when a EUCAST breakpoint of ≤0.03 μg/ml was used, only 93.4% were susceptible (15). For 515 H. influenzae isolates from Europe, 100% were susceptible to ceftaroline using CLSI breakpoints and 97.7% were susceptible with EUCAST breakpoints (72). In a U.S. study of 1,545 isolates, 99.9% were susceptible to ceftriaxone using the FDA breakpoint at that time of ≤0.12 μg/ml (67). All 3 studies included at least 25% β-lactamase-producing isolates. Use of the various breakpoints emphasizes the need to check this detail when evaluating antimicrobial surveillance data.

Of 1,545 isolates of H. influenzae collected from 2008 to 2010 in the United States, 77.2% were susceptible to TMP-SMX (67), and 68% of 360 isolates in a global study were TMP-SMX susceptible (38). Resistance to fluoroquinolones remains rare in H. influenzae (15, 67, 72); however, investigators in Taiwan recently described the emergence of polyclonal levofloxacin- and moxifloxacin-resistant H. influenzae isolates among residents of a nursing home where nearly half of the 48 isolates recovered from 30 patients were resistant to fluoroquinolones (73). A surveillance study in Asia noted nearly 6% levofloxacin resistance in Taiwan but rates of less than 1% fluoroquinolone resistance in several other Asian countries (68). Resistance to newer macrolides is uncommon, with less than 3% of isolates examined in various studies showing resistance to azithromycin (15, 38, 67).

### Reference Test Methods

β-Lactamase production in H. influenzae can easily be detected by the chromogenic cephalosporin, acidometric, or iodometric β-lactamase test methods (see chapter 73). The CLSI has developed broth microdilution MIC and disk diffusion methods for testing H. influenzae, and these methods can also be used to test H. parainfluenzae. Testing of the more unusual Haemophilus spp., including Aggregatibacter aphrophilus (formerly H. aphrophilus and H. paraphrophilus) and Aggregatibacter segnis (formerly H. segnis), is now addressed in CLSI document M45 (2). Specific variables related to each of the methods for testing H. influenzae and H. parainfluenzae are listed in Table 1. Haemophilus test medium (HTM) is recommended and consists of a Mueller-Hinton base, 15 μg of hematin per ml, 15 μg of NAD per ml, and 5 mg of yeast extract per ml. Cation-adjusted Mueller-Hinton broth (CAMHB) is used with the components listed above for the preparation of HTM broth, which contains 0.2 IU of thymidine phosphorylase per ml when testing sulfonamides or trimethoprim. Although HTM agar is transparent, difficulties in measuring zones and poor growth of some strains have been noted. Broth microdilution tests with HTM generally give clearer endpoints. The problems most often noted with both the disk diffusion and the broth microdilution methods are equivocal endpoints with BLNAR strains with several β-lactams. Because of this, the CLSI recommends that BLNAR strains (which are best detected by tests with ampicillin) be considered resistant to amoxicillin-clavulanic acid, ampicillin-sulbactam, cefaclor, cefamandole, cefetamet, cefonicid, cefprozil, cefuroxime, loracarbef, and piperacillin-tazobactam and that the activities of these agents against BLNAR strains not be tested (1). Some have suggested the use of disks with an ampicillin concentration lower (63, 74) than the 10 μg recommended by the CLSI (1). In addition to the CLSI, the EUCAST (http://www.eucast.org/) describes methods and interpretive criteria for both MIC and disk diffusion testing of Haemophilus influenzae. The methods are nearly identical to the CLSI methods, with the exception of the test media, which are MHA with 5% defibrinated horse blood and 10 mg/liter of β-NAD for disk diffusion and Mueller-Hinton broth supplemented with 5% lysed horse blood and 20 mg/liter of β-NAD for MIC testing. Recently, investigators tested 89 H. influenzae isolates with various ampicillin resistance mech-
nisms by disk diffusion with 12 β-lactam drugs. The main genotypes of β-lactam-resistant strains were separated by using the EUCAST disk diffusion method; however, there was some overlap among ampicillin-susceptible and BLNAR strains (74).

Commercial Test Methods
Currently, the only FDA-cleared broth microdilution system for testing *Haemophilus* spp. is Sensititre (Trek). The Etest has been cleared by the FDA for testing *H. influenzae* with most drugs that would be used for treating *Haemophilus* infections, and Etest generally demonstrates results comparable to those obtained by CLSI reference methods. However, Billal et al. reported that Etest produces considerably higher MICs than broth microdilution when testing ampicillin, amoxicillin-clavulanic acid, and cefixime and perhaps other β-lactams (76). This is a particular concern with BLNAR and BLFACR strains.

**Strategies for Testing and Reporting of Results**

**β-Lactamase testing** detects the most common type of clinically significant resistance in *H. influenzae*. β-Lactamase-positive isolates are ampicillin and amoxicillin resistant. To detect BLNAR strains, an ampicillin disk diffusion or MIC test is required. To detect BLFACR strains, both a β-lactamase test and amoxicillin-clavulanic acid disk diffusion or MIC test are required, as these strains are β-lactamase positive and show decreased susceptibility to amoxicillin-clavulanic acid. Since the incidence of BLNAR is currently low in many geographic areas, such tests may not be routinely needed and for practical purposes, a negative β-lactamase test result translates into ampicillin susceptibility. However, for laboratories where the incidence of BLNAR is unknown because routine susceptibility tests are not performed on *H. influenzae* isolates, it would be reasonable to perform susceptibility tests, at a minimum, on isolates from sterile sources with ampicillin (for β-lactamase negative strains) and ceftriaxone or any other agent that might be considered for therapy. Testing should be considered for TMP-SMX, and the CLSI suggests that this agent be tested and reported routinely (1). Other oral agents that might be considered, such as amoxicillin-clavulanic acid, the oral cephalosporins, newer macrolides, and fluoroquinolones, are predictably active against *H. influenzae* and are often prescribed empirically. Consequently, routine testing of these drugs is generally not useful. However, these and other agents may be tested for surveillance or epidemiological purposes (1).

**N. GONORRHOEAE**

**Incidence of Resistance**
Antimicrobial resistance among *N. gonorrhoeae* isolates is a significant concern, and resistance to penicillin, tetracycline, and the fluoroquinolones has precluded the use of these drugs as primary agents for the treatment of gonococcal infections in most countries. In 2012, emerging resistance to the oral cephalosporins among *N. gonorrhoeae* isolates in the United States led the CDC to recommend combination therapy with ceftriaxone and azithromycin or doxycycline as the first-line regimen for the treatment of uncomplicated gonorrhea (77).

Penicillin resistance in *N. gonorrhoeae* occurs via either the production of a plasmid-associated TEM-1 or TEM-135 β-lactamase (penicillinase-producing *N. gonorrhoeae* [PPNG]) or multifactorial mutations to the chromosome (chromosomally mediated resistant *N. gonorrhoeae* [CMRNG]). CMRNG arises through stepwise acquisition of mutations to various genes that result in penicillin resistance. These include mutation to the primary penicillin targets, PBP 1 and PBP 2, the membrane porin PorB1h; and the promoter and coding sequence of the transcriptional repressor of the MtrCDE efflux pump, mtrR. While the spectrum of activity for the TEM β-lactamases expressed by PPNG is restricted to the penicillins (78), CMRNG may show decreased susceptibility to other β-lactams.

Strains of *N. gonorrhoeae* with reduced susceptibility to the cephalosporins (e.g., cefixime [MIC ≥ 0.25 μg/ml] and ceftriaxone [MIC ≥ 0.125 μg/ml]) emerged in Japan in 2007 (79) and have now spread to many parts of the world (80–82). Whereas penicillin-resistant CMRNG isolates harbor only 4 to 8 mutations to penA, the gene that encodes PBP2, isolates with elevated cephalosporin MICs harbor a mosaic penA gene that encodes more than 60 amino acid polymorphisms compared to the wild-type PBP 2 (83). The mosaic penA gene is thought to have arisen from DNA recombination with the penA genes of multiple saprophytic *Neisseria* spp. Overexpression of the MtrCDE efflux pump system and mutation of the PorB1h porin result in additional resistance to extended-spectrum cephalosporin MICs, and at least one unknown resistance determinant also exists in these isolates (84). Oral cephalosporin treatment failures have been confirmed for patients infected with these strains (84), but injectable ceftriaxone appears to maintain activity. The Gonococcal Isolate Surveillance Program (GISP), which tests urethral isolates from male clients visiting sexually transmitted disease clinics throughout the United States, reported 133 isolates with decreased susceptibility to cefixime (MIC ≥ 0.25 μg/ml) between 2005 and 2010, and in 2011, 1.3% of more than 5,500 isolates tested had a cefixime MIC of ≥0.125 μg/ml, which is significantly above the wild-type MIC. Only 57 isolates with reduced susceptibility to ceftriaxone (MIC ≥ 0.125 μg/ml) were identified in the GISP in the United States during this period (85). In contrast, decreased gonococcal susceptibility to ceftriaxone was observed more frequently by the World Health Organization’s Gonococcal Antimicrobial Surveillance Program (GASP) in 2010 in China (55.8% of 1,398 isolates tested), Korea (29.3% of 82 isolates tested), Japan (20.3% of 403 isolates tested), Hong Kong (23.3% of 947 isolates tested), and India (10.8% of 37 isolates tested) (86). Disturbingly, high-level cefixime-resistant (MIC, 8 μg/ml) and ceftriaxone-resistant (MIC, 4 μg/ml) *N. gonorrhoeae* strains have been reported in Japan (87), France (88), and Spain (89) and were associated with likely ceftriaxone treatment failures. These strains harbor a novel mosaic penA allele, with several unique mutations not previously described for isolates with elevated extended-spectrum cephalosporin MICs (88, 90). In particular, the PBP A510P mutation was found to be an important determinant of ceftriaxone resistance (90). The mosaic PBP 2 from one of these strains, when introduced into a wild-type *N. gonorrhoeae* isolate, resulted in a 500-fold increase in ceftriaxone MIC (90). These strains are the first extensively drug-resistant *N. gonorrhoeae* isolates, as, in addition to ceftriaxone and cefixime, they are resistant to the tetracyclines and fluoroquinolones (90). To date, these strains have not been identified in the United States. In vitro, ertapenem appears to have activity against these isolates, with MICs ranging from 0.016 to 0.064 μg/ml, although the ertapenem MIC parallels that of ceftriaxone in isolates with mosaic penA alleles other than the ceftriaxone-resistant PBP A510P (91).

Tetracycline resistance in *N. gonorrhoeae* can be plasmid or chromosomally mediated, but plasmid-mediated resis-
tance results in higher MICs. Gonococcal fluoroquinolone resistance occurs primarily via spontaneous mutations to the quinolone resistance-determining regions (QRDRs) of gyrA and parC. Efflux-mediated resistance can also occur, again by mutation to mtrR; overexpression of the MtrCDE efflux system is also associated with elevated MICs for tetracyclines and macrolides (including azithromycin). In the United States in 2011, 22.7% of GISP isolates were resistant to tetracycline. Ciprofloxacin resistance peaked in the United States in 2007 at 14.8%, and in 2011, 13.3% of isolates in the GISP tested resistant to ciprofloxacin. However, ciprofloxacin resistance is much more commonly encountered in isolates recovered from men who have sex with men; for such isolates, the rate of ciprofloxacin resistance was 26% in 2011. The Western Pacific and Southeast Asian regions in the GASP reported an overall 59% fluoroquinolone resistance rate among 9,744 N. gonorrhoeae isolates in 2010 (86). In many countries, including Cambodia, Hong Kong, Korea, Philippines, Vietnam, Bhutan, India, and Thailand, >95% of isolates were fluoroquinolone resistant (86).

Isolates with azithromycin MICs of ≥2 µg/ml (reduced susceptibility) were uncommon in 2011 in the United States, documented for 0.3% of GISP isolates. Five of these isolates had MICs of 8 µg/ml and 1 had an MIC of 16 µg/ml. In the Western Pacific and Southeast Asian regions in the GASP, azithromycin resistance was low in all countries (e.g., <1%), with the exception of Mongolia, where azithromycin resistance was documented for 34% of gonococcal isolates in 2010 (86).

Reference Test Methods
Routine β-lactamase tests readily detect PPNG and can reliably be performed by either the chromogenic cephalosporin, acridimetric, or iodometric method.

The CLSI recommends the use of GC agar base for disk diffusion and agar dilution MIC testing. For both tests, a 1% defined growth supplement must be added; however, in agar dilution tests with imipenem or clavulanic acid, the growth supplement must be free of cysteine to avoid inhibition of the activities of these two agents (1, 92, 93). The agar dilution method is preferred to the broth dilution method for MIC testing because N. gonorrhoeae has a tendency to autolyze in liquid media. For other details of testing, see Table 1. Liao and colleagues evaluated the performance of disk diffusion on chocolate agar for 163 unique N. gonorrhoeae isolates, as compared to CLSI reference GC agar dilution (94). While performances for ciprofloxacin and ceftriaxone were equivalent on both media, improved categorical agreement with agar dilution was found when chocolate agar was used as opposed to GC agar for penicillin disk diffusion testing (84.1% versus 65% categorical agreement).

Recently, the use of cepodoxime disk diffusion on chocolate Columbia blood agar was proposed as a screen for the detection of mosaic PBP 2 isolates with decreased cefixime and ceftriaxone MICs. A zone diameter of ≥11 mm was predictive of a mosaic PBP 2 with 98.7% sensitivity and 65% specificity (95).

Commercial Test Methods
The only commercial method currently available for susceptibility testing of N. gonorrhoeae is Etest, which has been shown to produce results comparable to those of CLSI reference agar dilution methods. One study demonstrated several major errors for tetracycline, although essential agreement with CLSI reference disk diffusion was 94.6% for 295 isolates of N. gonorrhoeae tested (96). Another study of 163 N. gonorrhoeae isolates demonstrated better Etest performance for ceftriaxone when chocolate agar as opposed to GC agar was used (94); in that study, the values for essential agreement with reference agar dilution were 53.8% for GC agar and 82.8% for chocolate agar.

Strategies for Testing and Reporting Results
Generally, routine antimicrobial susceptibility testing is not necessary for clinical isolates of N. gonorrhoeae. However, the CDC recently recommended performing culture and susceptibility testing for N. gonorrhoeae isolated from patients with suspected treatment failures with the recommended combination therapy regimens (77). Thus, laboratories should, at a minimum, identify a reliable reference laboratory for this testing, if culture and susceptibility testing of N. gonorrhoeae is infrequently performed. Primary agents for testing include ceftriaxone, cefixime, ciprofloxacin, and tetracycline.

Complicating N. gonorrhoeae antimicrobial susceptibility testing is the widespread use of nucleic acid amplification tests (NAATs) for the diagnosis of N. gonorrhoeae. NAATs remain the test of choice for the diagnosis of N. gonorrhoeae from genital sources because they are much more sensitive than culture, but these tests do not yield an isolate for susceptibility testing. Several investigators have evaluated molecular methods by which to detect important resistance determinants, such as the mosaic PBP 2 sequence and mutations to gyrA and parC, directly from patient specimens that tested positive for N. gonorrhoeae by a NAAT (97–99). These assays do not yet have widespread use, although the ability to rapidly detect key resistance determinants in N. gonorrhoeae may soon enhance both culture-based antimicrobial resistance surveillance and allow for tailored patient treatment regimens.

N. MENINGITIDIS
Incidence of Resistance
The modal MIC for penicillin and N. meningitidis is 0.06 μg/ml. However, N. meningitidis isolates from the United States, Europe, and elsewhere with reduced susceptibility to penicillin (MICs, 0.12 to 1.0 μg/ml) have been recognized for nearly two decades, and the incidence of these strains is increasing (100–107). A study of 4,735 N. meningitidis isolates from 19 Latin American countries and the Caribbean between 2006 and 2010 noted that 29.1% of isolates were penicillin intermediate (MICs, 0.12 to 0.25 μg/ml). There were also 14 isolates categorized as fully penicillin resistant (MIC ≥ 0.5 μg/ml), and these were associated with an outbreak of disease in a Mexican prison (100). In contrast, only 2.8% of penicillin-intermediate isolates and 1,447 strains from invasive infections were reported during a similar time frame in South Africa (104). Diminished penicillin and ampicillin susceptibility in meningococci is due to polymorphisms in PBP 2 that result from point mutations of the penA gene encoding that PBP (107). Recently, 290 nonsusceptible meningococcal strains isolated between 2000 and 2010 in Belgium were examined for their genetic diversity, and 41 different alleles of penA were identified (101). The clinical significance of isolates with elevated penicillin MICs is uncertain, and infections caused by isolates with reduced susceptibility to penicillin have successfully been treated with high doses of penicillin in several cases, although rare reports cited clinical failure in meningitis when a dose of penicillin lower than recommended was used. Two independent groups examined outcomes in
patients infected with isolates with reduced susceptibility to penicillin and concluded that the serogroup rather than the penicillin MIC is the microbiological parameter most predictive of mortality (103, 108). High-level resistance due to β-lactamase production was observed in a few isolates in the 1980s and 1990s; additional isolates have not been documented for more than a decade (107).

The extended-spectrum cephalosporins (e.g., ceftriaxone and cefotaxime) remain highly active against isolates with elevated penicillin MICs (101–103, 105, 106, 109) and are often used as first-line therapy for meningococcal meningitis in developed countries. However, a report of eight ceftriaxone-non-susceptible serogroup A isolates from India is concerning. Ceftriaxone MICs ranged from 0.25 to 8 μg/ml in these isolates (110).

Regarding agents used for prophylaxis, resistance to sulfonamides occurs frequently (104–106, 111), and the incidence of resistance to rifampin is low but has been documented on several occasions following exposure to that agent (100, 105, 111–113). A comprehensive study of 392 isolates from diverse geographic locations collected over 25 years, including 61 isolates with rifampin MICs of >0.25 μg/ml, showed that isolates of N. meningitidis displaying rifampin MICs of >1 μg/ml possess spolB alleles with mutations that are absent in the alleles found in all isolates with rifampin MICs of ≤1 μg/ml (112).

Of the greatest concern is the increasing frequency of diminished fluoroquinolone susceptibility in meningococci from several countries. These isolates generally have ciprofloxacin MICs of 0.125 to 0.5 μg/ml, rather than demonstrating high-level resistance. Resistance has been attributed to mutations in the gyrA gene, similar to the situation in gonococci (114, 115). A single isolate from Venezuela has been reported to be resistant to both ciprofloxacin and a second agent that could be used for prophylaxis, azithromycin (116), and three meningococcal isolates recovered in Spain were ciprofloxacin nonsusceptible and rifampin resistant (117).

### Strategies for Testing and Reporting of Results

The CLSI has published standards for MIC testing of N. meningitidis that utilize either the broth microdilution method and CAMHB with 2.5 to 5% lysed horse blood (CAMHB-LHB) or the agar dilution method and MHA with 5% sheep blood, both with incubation in 5% CO₂ (1, 92).

Interpretive criteria are listed for agents such as penicillin, cefotaxime, and ceftriaxone that might be prescribed for treating a meningococcal infection. In addition, interpretive criteria are listed for agents such as ciprofloxacin, rifampin, and azithromycin that might be used for prophylaxis of meningococcal case contacts. Strains with diminished fluoroquinolone susceptibility may best be detected by testing with nalidixic acid by MIC or disk methods (105). The CLSI describes a disk diffusion method for testing N. meningitidis that utilizes MHA with 5% sheep blood and CO₂ incubation. As with MIC tests, interpretive criteria are listed for several therapeutic and prophylactic agents. Unfortunately, these do not include breakpoints for ampicillin and penicillin, as disk testing results obtained with these agents were unreliable (1, 93).

Several investigators have examined modified penicillin disk diffusion methods by using 2- and 10 IU penicillin disks and 1-μg oxacillin disks and also determined that these cannot reliably distinguish N. meningitidis isolates that are susceptible from those that have decreased ampicillin and penicillin susceptibility (118). Therefore, disk diffusion testing should not be used for these drugs. One possible exception might be testing of mecillinam (aminocillin) by the disk method as a screen for isolates with penA polymorphisms (105).

Because of the lack of clinical failures with the drugs of choice for the treatment of meningococcal infections, susceptibility testing is not warranted in most situations. Although the Etest has not been cleared by the FDA for testing N. meningitidis, several studies have shown it to be suitable for testing meningococci and to perform best by using MHA with 5% sheep blood incubated in CO₂ (118, 119). However, in a 14-laboratory study, Vazquez et al. noted some difficulties in obtaining reliable Etest results with rifampin (119).

### POTENTIAL BACTERIAL AGENTS OF BIOTERRORISM

Several bacterial agents are identified as potential agents of bioterrorism by the CDC (http://www.bt.cdc.gov/agent/index.asp). These include Bacillus anthracis, Yersinia pestis, Francisella tularensis, Burkholderia mallei, Burkholderia pseudomallei, and Brucella spp. The antimicrobial susceptibility patterns for most of these organisms are predictable; susceptibility testing of naturally occurring isolates is often not necessary. However, it is possible for antimicrobial resistance to spontaneously occur among these organisms, and in the case of a bioterrorism event, there is the possibility of engineered resistance. To detect any potential resistance, standardized broth microdilution susceptibility testing methods and interpretive criteria were established and published by the CLSI (2).

Acquired resistance to antimicrobial agents commonly used for treatment of infections caused by B. anthracis, Y. pestis, F. tularensis, B. mallei, B. pseudomallei, and B. suis is rare. In contrast to other species of Bacillus which produce bla1 and bla2 β-lactamases that confer resistance to penicillin, most isolates of B. anthracis are susceptible to penicillin. Penicillin-susceptible strains of B. anthracis produce an anti-sigma factor, RsfA, that sequesters the sigma factor required for transcription of the β-lactamase genes. In a naturally occurring penicillin-resistant strain, a single nucleotide deletion in the RsfA gene resulted in truncated β-lactamase genes. As a result, sigma factor sequestration does not occur, and the β-lactamase genes are transcribed (120). However, amoxicillin is recommended for anthrax prophylaxis only when the isolate has been determined to be susceptible to penicillin, and this recommendation is limited to young children and pregnant women (121). Laboratory-generated fluoroquinolone resistance in B. anthracis was described, but fluoroquinolone resistance in clinical isolates has not been reported (122, 123).

There are reports of two spontaneously occurring drug-resistant Y. pestis isolates recovered in Madagascar (124, 125). Both isolates acquired conjugative plasmids. In one isolate, the plasmid carried resistance determinants for ampicillin, chloramphenicol, tetracycline, kanamycin, streptomycin, and sulfonamide. In the other isolate, the plasmid conferred resistance to streptomycin. The concern for multidrug resistance encouraged a recent study of 392 Y. pestis isolates from 17 countries in the Americas, Africa, and Asia. Eight antimicrobial agents used for treatment or prophylaxis of plague were tested, and no resistance was reported (126). In another study, screening of 713 isolates of Y. pestis from North America failed to demonstrate the backbone plasmids that conferred resistance in the Madagascar strains (127).

B. pseudomallei is intrinsically resistant to many antimicrobial agents, including gentamicin, streptomycin, rifampi-
cin, erythromycin, and many β-lactams (128). Susceptibility studies of B. pseudomallei and B. mallei indicate that using CLSI interpretive criteria (2), most isolates are susceptible to amoxicillin-clavulanic acid, ceftazidime, imipenem, tetracycline, doxycycline, and TMP-SMX (129–131). However, some isolates of B. pseudomallei have elevated ceftazidime MICs (i.e., MIC ≥8 μg/ml) (130–132) and elevated amoxicillin-clavulanic acid MICs (i.e., MIC ≥8 μg/ml) (130–132). Resistance to ceftazidime and amoxicillin-clavulanic acid can be due to class A PenA β-lactamase (130).

Clinical isolates of Brucella spp., with reduced susceptibility to rifampin and TMP-SMX (133–136) have been reported. In these publications, the susceptibility testing methods used were either not clearly defined or different from the methods currently recommended by the CLSI. Also, resistant isolates were not characterized for resistance determinants or mutations. However, mutations in the rpoB gene, the target for rifampin activity, have been observed in vitro in Brucella mutants (137, 138).

Isolates of F. tularensis demonstrate β-lactamase activity, and they are resistant to β-lactams, including cephalosporins and carbapenems (139–142). Resistance to aminoglycosides, tetracyclines, fluoroquinolones, and chloramphenicol has not been reported.

B. anthracis, B. mallei, B. pseudomallei, and Y. pestis demonstrate sufficient growth with commonly used broth microdilution MIC testing medium and incubation conditions (Table 2). However, the recommended testing medium for F. tularensis is CAMHB with a 2% concentration of a defined growth supplement. This is the same cysteine-containing defined growth supplement as is added to GC agar base for susceptibility testing of Neisseria gonorrhoeae. Some isolates of Brucella spp., particularly isolates of B. abortus, require CO2 incubation. However, incubation in CO2 may increase the MICs of aminoglycosides and decrease the MICs of tetracyclines. The streptomycin susceptibility breakpoint is one doubling dilution higher (i.e., increased from 8 μg/ml to 16 μg/ml) when panels are incubated in CO2 (143). For the slower-growing organisms, F. tularensis, Y. pestis, and Brucella spp., 48 h of incubation may be needed to achieve sufficient growth.

There are few studies comparing alternative susceptibility testing methods to the standard CLSI reference broth microdilution methods. One study compared Etest to broth microdilution for testing B. anthracis (144). In that study, Etest MICs were within a single doubling dilution of the broth microdilution MICs for ceftiraxone, chloramphenicol, ciprofloxacin, clindamycin, erythromycin, rifampin, tetracycline, and vancomycin but not for penicillin. Penicillin MIC values for Etest tended to be lower than those obtained by broth microdilution. A similar trend for penicillin MICs was noted for B. anthracis in a study comparing Etest to agar dilution (145). These results suggest that Etest is acceptable for susceptibility testing of B. anthracis with antimicrobial agents other than penicillin. More recently, Etest was shown to be reliable for testing 26 diverse strains of Y. pestis with ciprofloxacin, doxycycline, gentamicin, levofloxacin, streptomycin, and tetracycline but not with chloramphenicol and TMP-SMX (146).

In addition to routine phenotypic methods, Weigel et al. combined a modified broth microdilution susceptibility testing method with real-time quantitative PCR for testing for ciprofloxacin and doxycycline with B. anthracis, which allowed reliable results to be available following 6 h versus the standard 16 to 20 h of incubation (147). Others have examined molecular methods, including pyrosequencing and single nucleotide polymorphism (SNP)-based PCR assays, to detect ciprofloxacin resistance in Bacillus anthracis, Yersinia pestis, and Francisella tularensis (148, 149). SNP-based PCR assays have also been used for characterization of doxycycline resistance in the three species (149).

Susceptibility testing of potential agents of bioterrorism raises safety concerns for clinical microbiology laboratories. All of the above-mentioned organisms require at least biosafety level 2 (BSL2) practices, containment, and facilities. BSL3 conditions are recommended for activities with a high potential for aerosol production (150). Since the inoculum preparation for susceptibility testing has the potential for aerosol production, all susceptibility testing procedures must be performed in a BSL3 facility. Laboratories without BSL3 facilities should send isolates to an appropriately equipped reference laboratory that has select-agent clearance status, such as reference laboratories within the Laboratory Response Network and at the CDC (http://www.selectagents.gov/).

**ABiotrophia species and Granulicatella species**

For Abiotrophia spp. and Granulicatella spp., resistance to agents from several different antimicrobial classes, including penicillins, cephalosporins, carbapenems, macrolides, lincosamides, fluoroquinolones, and tetracyclines, has been reported. In a study of 20 blood isolates by Murray et al., MICs for specific agents were as follows: penicillin, 0.5 μg/ml; cefotaxime, 4 μg/ml; cefepime, ≥8 μg/ml; meropenem, 0.5 μg/ml; erythromycin, 16 μg/ml; clindamycin, 0.25 μg/ml; and tetracycline, 2 μg/ml (151). Murray et al. also noted an isolate of levofloxacin-resistant Abiotrophia eleanora (currently known as Granulicatella eleanora) which was obtained from a patient who had received 10 days of levofloxacin prophylaxis (151). Among isolates from 28 patients with infections with nutritionally variant streptococci (19 Granulicatella adiacens, 8 Abiotrophia defectiva, and 1 G. elegans isolate) treated at a university hospital in Taiwan, 50% had penicillin MICs of 0.25 to 2 μg/ml and 10 isolates were not susceptible to cefotaxime, with 7 fully resistant at MICs of ≥4 μg/ml. Three isolates had cepfepime MICs of ≥8 μg/ml; these isolates were susceptible to imipenem (0.12 μg/ml) and that for meropenem was 0.5 μg/ml (152). When CAMHB-LHB with 0.001% pyridoxal was used to test 27 Granulicatella (Abiotrophia) adiacens and 12 Abiotrophia defectiva isolates, 41%, 51%, and 8% were found to be penicillin susceptible, intermediate, and resistant, respectively. Interestingly, G. adiacens was substantially more susceptible to penicillin than was A. defectiva (55% versus 8%) in this study (153). Little is known about mechanisms of resistance in these bacteria. There is one report of an Abiotrophia defectiva isolate with a conjugative, Tn916-like transposon, Tra3872 (154). The transposon carried ermB and tetM resistance determinants, which conferred resistance to erythromycin and tetracycline, respectively. In another study that examined 15 isolates from pediatric patients (6 Abiotrophia and 9 Granulicatella isolates), 8 were resistant to erythromycin. Five of these were clindamycin susceptible and harbored mefA, and three that were clindamycin resistant were positive for ermB and also tetM. One of the ermB-positive Granulicatella spp. also had mefA (155). These findings demonstrate that these bacteria are able to acquire and transfer mobile genetic elements which confer antimicrobial resistance.
by Namdari et al., a procedure for adding pyridoxal to an inoculum prepared with the Prompt system and a MicroScan dried Gram-positive panel is described (156). It should be noted that susceptibility testing of aminoglycosides against Abiotrophia spp. and Granulicatella spp. is not recommended even though aminoglycosides are commonly used in combination therapy with an agent active against the cell wall, such as penicillin or vancomycin, for treating serious infections caused by these organisms. Since the aminoglycoside acts synergistically with the agent, in vitro susceptibility to aminoglycosides does not predict in vivo susceptibility.

**AEROMONAS HYDROPHILA COMPLEX (A. CAVIAE, A. HYDROPHILA, A. JANDAEI, A. SCHUBERTII, AND A. VERONII) AND PLESIONOMAS SHIGELLOIDES**

Aeromonas spp. are typically resistant to ampicillin, show variable results with β-lactam–β-lactamase inhibitor combinations, and are resistant to narrow-spectrum cephalosporins (157–160). Inducible β-lactamases in Aeromonas spp. have been noted, and resistance may emerge during therapy with a β-lactam agent (161). Among 172 isolates of Aeromonas spp. tested as part of a global surveillance program conducted from 2003 to 2007, >90% were susceptible to extended-spectrum cephalosporins, 98.8% were susceptible to meropenem, but only 63.7% were susceptible to piperacillin-tazobactam (162). In contrast, among 260 isolates of Aeromonas spp. isolated in the Asia-Pacific region, 78% were susceptible to ceftazidime, the only expanded-spectrum cephalosporin tested, and 68.8% were susceptible to imipenem (163). Aeromonas spp. that express metallo-β-lactamases have been recently described, including an Aeromonas hydrophila isolate carrying an integron-borne blαIM,4 gene isolated from a patient in Hungary (164) and an Aeromonas caviae isolate carrying a plasmid-borne blαMP,19 isolated from a patient in France (165). The metallo-β-lactamase CphA is also frequently found in Aeromonas spp.

In Taiwan, where Aeromonas spp. are frequently encountered, results from 234 isolates in 1996 found species-based differences in overall antimicrobial susceptibility, noting that Aeromonas sobria was more susceptible than either A. hydrophila or A. caviae (158). Similar results were noted by Vila et al. from Spain in 2002 (159). Tobramycin susceptibility may be more common in Aeromonas veronii, with one study finding less than 30% susceptibility, whereas other species tested susceptible to this agent (157). Aeromonas spp. are generally considered susceptible to fluoroquinolones (158), although Aeromonas caviae isolated from the stools of patients with diarrhea was shown in two independent studies to be more frequently fluoroquinolone resistant than other Aeromonas spp. (166, 167). Resistance to fluoroquinolones appears to be increasing in the Asia-Pacific region, more than doubling, from 8% to 17%, between the periods of 2003 to 2006 and 2007 to 2010 (163). Fluoroquinolone resistance in Aeromonas is associated with mutations to the QRDR of gyrA and parC (166, 167). In the United States, two reports have documented ciprofloxacin-resistant A. hydrophila infections following leech therapy when patients were treated prophylactically with ciprofloxacin (168, 169). Aeromonas spp. are typically resistant to ampicillin and other penicillins, including piperacillin, and susceptible to β-lactamase inhibitor combinations and several other classes of antimicrobial agents (170, 171).

Although Aeromonas spp. and Plesiomonas shigeloides cause diarrheal disease, otherwise healthy individuals with diarrhea due to these bacteria usually recover spontaneously without treatment (159, 170), and routine antimicrobial susceptibility testing of isolates from fecal specimens is not recommended (2). However, both genera can cause a variety of other infections for which treatment may be necessary (157, 158, 160, 161, 170, 171). Consequently, for isolates from extraintestinal sources, antimicrobial susceptibility testing may be warranted. These organisms show growth characteristics similar to those of Enterobacteriaceae, which led the CLSI to recommend disk diffusion or broth microdilution MIC testing using the same methods as recommended for Enterobacteriaceae.

**BACILLUS SPECIES**

Bacillus spp. other than B. anthracis are common contamintants in the clinical laboratory, but these bacteria can cause serious disease, including catheter-associated infections, traumatic wound infections, and corneal ulcers. Since the susceptibility profiles of Bacillus spp. are quite variable, susceptibility testing should be considered when Bacillus spp. are isolated from normally sterile body sites or serious or refractory infections. Isolates of Bacillus spp. can express β-lactamases that confer resistance to penicillins and possibly cephalosporins. Bacillus cereus is the most common species found in clinical specimens, and most isolates are resistant to penicillin and extended-spectrum cephalosporins, although penicillin resistance does not always predict cephalosporin resistance (145, 172). Penicillin and cephalosporin resistance also occurs in other species of Bacillus, but it is less common. Resistance to other agents has been reported. These agents include aminoglycosides, erythromycin, clindamycin, chloramphenicol, tetracycline, fluoroquinolones, TMP-SMX, and even vancomycin (145, 172, 173). When 70 isolates of Bacillus spp. from a variety of clinical specimens were examined, daptomycin was found to have activity against vegetative cells but not against spores (173). In the same study, 2 strains (vegetative cells) had ciprofloxacin MICs of >4 μg/mL and 10 strains were resistant to erythromycin. A case of fatal septicemia caused by Bacillus cereus resistant to carbapenems was reported for a patient treated with meropenem (174); the resistance mechanism was not determined for this isolate.

Standard susceptibility testing methods for nonfastidious bacteria can be used for testing Bacillus spp. The CLSI provides guidelines for broth microdilution testing (Table 3) (2). Agar dilution and Etest methods using MHA were compared in a study by Turnbull et al. (145). In this study, Etest MICs were similar to agar dilution MICs for several agents, including cefotaxime, ciprofloxacin, erythromycin, gentamicin, penicillin, tetracycline, and vancomycin. Two commercial β-lactamase tests, nitrocefin (Oxoid, Basingstoke, England) and IntraLactam strips (Mast Diagnostics, Merseyside, United Kingdom), were evaluated in a study by Andrews and Wise (175); both tests failed to detect β-lactamase activity in four of five penicillin-resistant isolates of B. cereus. Therefore, β-lactamase testing is not recommended for predicting penicillin susceptibility in Bacillus spp.

**CAMPYLOBACTER**

Resistance to the fluoroquinolones, which are agents commonly used for treating gastrointestinal infections caused by Campylobacter jejuni and Campylobacter coli, has been reported with increasing frequency in the United States among both human and animal isolates of these two species.
over the past two decades. The National Antimicrobial Resistance Monitoring System (NARMS) noted no ciprofloxacin resistance among _C. jejuni_ human isolates in 1990, but rates of 18% resistance in 2001 and 24% resistance in 2011 were noted (176). Only 1.8% of human isolates were erythromycin resistant in 2011, and 45% were tetracycline resistant. Similar resistance was noted by the NARMS for _C. coli_ in 2011, with 23.5% resistance to ciprofloxacin, 1.7% resistance to erythromycin, and 46% resistance to tetracycline (176). Resistance among animal isolates, which may subsequently be transmitted to humans, has been associated with the addition of macrolides and fluoroquinolones to animal food as growth-promoting agents (177). In the United States in 2004, the FDA reversed its approval for 

United States in 2004, the FDA reversed its approval for _tetracycline_ (176). Resistance among animal isolates, which 

over the past two decades. The National Antimicrobial Resistance Monitoring System (NARMS) noted no _C. jejuni_ human isolates of _C. jejuni_, remains to be determined. Unlike _Escherichia coli_ and _Salmonella_, which require multiple mutations to the QRDR of _gyrA_ to achieve high-level quinolone resistance, a single mutation, T85I, in _gyrA_ yields high-level resistance to both nalidixic acid and fluoroquinolones in _Campylobacter_ (180). Despite reports of enhanced fitness associated with this mutation in _Campylobacter_ in chicken models of infection (179), Wassenaar and colleagues concluded that fluoroquinolone-resistant _Campylobacter_ infections are no more severe than infections caused by susceptible isolates following an extensive review of previous studies and nearly 11,000 new cases (181).

Because of the increasing incidence of resistance, testing of isolates from individual patients with severe illness or prolonged symptoms may be warranted, and isolates might also be tested for epidemiological purposes. Susceptibility testing by broth microdilution in CAMHB-LHB and incubation in a microaerobic atmosphere (Table 3) is suggested by the CLSI (2). Interpretive criteria for ciprofloxacin, erythromycin, doxycycline, and tetracycline are provided. The CLSI also describes a disk diffusion method for ciprofloxacin and erythromycin in which the absence of a zone indicates resistance. However, due to wide variations in measured zones that occur as a result of hazy or film-like growth, criteria for interpreting results other than resistant are not provided (2). Gaudreau et al. suggested that ciprofloxacin, erythromycin, and tetracycline disk diffusion tests can be used to identify both resistance and susceptibility to these three agents in _C. jejuni_ and _C. coli_. However, for the ciprofloxacin results, a nalidixic acid disk must also be tested to ensure detection of fluoroquinolone resistance (182, 183). The Etest correlated well with agar dilution in a study by Baker when ciprofloxacin, erythromycin, and tetracycline were tested (184).

Currently, no testing methods have been validated, or interpretive criteria developed, for _Campylobacter_ spp. other than _C. jejuni_ or _C. coli_.

**CORYNEBACTERIUM SPECIES AND CORYNEFORMS**

The many _Corynebacterium_ spp. may exhibit a variety of susceptibility profiles, and many strains are highly suscepti-

ble (185-189). However, most isolates of _C. amycolatum_, _C. jeikeium_, _C. resistent_, and _C. urealyticum_ are multiresistant to antimicrobial agents often considered for therapy of _G_ram-positive infections, including penicillins, cephalosporins, macrolides, aminoglycosides, fluoroquinolones, tetracyclines, and clindamycin. Resistance to daptomycin was reported recently for a _C. striatum_ isolate causing native valve endocarditis in a patient with 12 weeks of prior daptomycin therapy for the treatment of methicillin-resistant _Staphylococcus aureus_ bacteremia and osteomyelitis (190), but as a whole the _Corynebacterium_ spp. remain susceptible to teicoplanin, vancomycin, linezolid, daptomycin, and tigecycline (185, 187). Most isolates of _C. urealyticum_ are resistant to fluoroquinolones, which has important implications for empirical therapy for urinary tract infections due to this species (187, 191). Mutation to _gyrA_ has also been associated with quinolone resistance in _C. striatum_, _C. amycolatum_, and _C. macginleyi_ (192). Macrolide resistance is frequently found in clinical isolates of _Corynebacterium_ and is mainly associated with the presence of an _ermX_ methylase gene (193).

A significant antimicrobial resistance is rare for _C. diphtheriae_, and very few reports of nonsusceptibility to either penicillin or macrolides exist (194-196). In a study of 410 isolates from around the world, 5 showed reduced susceptibility to macrolides and ketolides (194). Using Etest to evaluate 47 isolates of _C. diphtheriae_, investigators in Brazil reported that the penicillin MICs ranged from 0.002 to 0.38 μg/ml, the penicillin MIC₉₀ was 0.19 μg/ml, and the penicillin resistance rate was 14.8%. However, in that study, a penicillin breakpoint of ≤0.12 μg/ml was used to categorize isolates as penicillin susceptible, rather than the breakpoint of ≤1 μg/ml for susceptibility that is currently recommended by the CLSI (2, 195). Poor bactericidal activity of penicillins for _C. diphtheriae_ has been reported. Von Hunolstein demonstrated penicillin tolerance among 17 of 24 _C. diphtheriae_ isolates from patients with pharyngitis or tonsillitis (197). A paradoxical effect (e.g., decreasing bactericidal activity with increasing antibiotic concentration) with amoxicillin has also been demonstrated with two strains of _C. diphtheriae_ isolated from patients with endocarditis (198). The authors of the study suggested that poor bactericidal activity of penicillins at high doses may contribute to poor outcomes when penicillins are included in the therapeutic regimen for _C. diphtheriae_ endocarditis (198). Monoresistance to the folate pathway inhibitors trimethoprim, sulfamethoxazole, and co-trimoxazole has been reported, most recently for a _C. diphtheriae_ bv. mitis isolated from a patient in Mayotte (199). This isolate harbored a class 1 integron with the _dfrA_ gene that conferred resistance to trimethoprim.

Growth characteristics among the _Corynebacterium_ spp. may vary, and previous studies have used a variety of methods, media, and incubation conditions for antimicrobial susceptibility testing. Prior to the publication of CLSI document M45, the absence of interpretive criteria specifically for _Corynebacterium_ spp. led to inconsistencies in interpreting results when CLSI interpretive criteria for other _G_ram-positive organisms (e.g., streptococci and _Staphylococcus_) were applied (186, 188, 194). This continues to be a problem if investigators are unaware of CLSI M45 (195). The CLSI recommends broth microdilution with CAMHB-LHB and incubation in ambient air (Table 3). Some strains grow satisfactorily after 24 h of incubation, but others require 48 h of incubation for sufficient growth. The 48-h incubation period is particularly important for detecting resistance to β-lactams, and it is recommended, if growth is not satisfactory or if an isolate
appears susceptible to β-lactams at 24 h, that the test be reincubated and final β-lactam results be read after 48 h of incubation (2). Currently, disk diffusion testing of Corynebacterium spp. is not recommended by the CLSI. Several investigators have used Etest satisfactorily for testing Corynebacterium spp. (185, 195), and Engler et al. used Etest to confirm the reduced susceptibility to macrolides and ketolides that was initially identified by agar dilution testing of C. diphtheriae (194).

Testing and reporting recommendations in CLSI M45 are applicable to other coryneforms, including the genera Arcanobacterium, Brevibacterium, Cellulomonas, Dermabacter, Leifsonia, Microbacterium, Oerskovia, Rothia, and Turicella (2). Scarce data are available in the literature regarding antimicrobial susceptibility of these organisms, and methods used to test for this vary between studies. However, macrolide resistance has been noted for isolates of Brevibacterium, Dermabacter, and Turicella, and fluoroquinolone resistance has been noted for Brevibacterium and Dermabacter (187).

Some isolates of Arcanobacterium haemolyticum may display tetracycline resistance (200) but are reportedly susceptible to other agents that might be considered for treatment. One study has reported A. haemolyticum and Oerskovia turbata harboring the vanA gene on a plasmid; both isolates were vancomycin resistant (201). A study of 50 clinical isolates of Microbacterium spp. demonstrated variable susceptibility profiles, but notably, only 56% of isolates were susceptible to ciprofloxacin; 1 isolate, a Microbacterium resistance, was resistant to vancomycin, which is typical for this species (202). Turicella oitidis is susceptible to most β-lactams, ciprofloxacin, rifampin, tetracyclines, and gentamicin, but significant resistance to macrolides and lincosamides has been reported (203, 204). Susceptibility testing of Corynebacterium spp. and other coryneforms is warranted when the organisms are isolated from normally sterile sites.

ERYSIPELOTHRIX RHUSIOPATHIAE

Erysipelothrix rhusiopathiae is an intrinsically vancomycin-resistant Gram-positive bacillus. Other agents that have little to no activity against isolates of this species are aminoglycosides and TMP-SMX. Antimicrobial susceptibility studies of isolates from a number of sources have shown all isolates of E. rhusiopathiae to be susceptible to penicillins, cephalosporins, carbapenems, and fluoroquinolones (205–207). Resistance to clindamycin, erythromycin, and tetracycline does occur. In one study of 66 isolates from swine in Japan, 94% were susceptible to erythromycin (206). In that study, the authors found that 71% of the isolates had an MIC of 28 µg/ml to tetracycline, which they assigned as resistant, although no CLSI interpretive criteria exist to date for E. rhusiopathiae and the tetracyclines (206). Isolates with elevated tetracycline MICs were previously shown to be positive for tetM (208). Recently, all four clinical isolates tested with daptomycin had MICs of ≤0.125 (209).

Isolates of E. rhusiopathiae are fastidious, so CAMHB-LHB is recommended for broth microdilution testing (2). There are also reports of agar dilution testing using either MHA supplemented with 5% horse blood or un supplemented MHA (205–207). The CLSI provides susceptibility only breakpoints for the penicillins, cepheps, carbapenems, and fluoroquinolones, whereas resistance and intermediate status interpretive criteria are provided for erythromycin and clindamycin. When organisms are isolated from sterile sites, laboratories should primarily test ampicillin or penicillin (2).

HACEK GROUP

There are limited antimicrobial susceptibility test data on the HACEK group of organisms (i.e., Aggregatibacter formerly the aphrophilus group of Haemophilus and Actinobacillus, Cardio bacterium, Eikenella, and Kingella spp.), in part because these organisms are infrequently encountered and often difficult to grow. Members of the HACEK group are susceptible to extended-spectrum cephalosporins and fluoroquinolones and are often susceptible in vitro to ampicillin and penicillin (51, 210, 211), although occasional isolates of Actinobacillus actinomycetemcomitans, Cardio bacterium hominis, Eikenella corrodens, and Kingella spp. produce β-lactamase (211). Coburn and colleagues noted that 22.9% of 68 isolates belonging to the HACEK group were nonsusceptible to penicillin, but 95.8% of isolates remained susceptible to ampicillin and all but two isolates were susceptible to amoxicillin-clavulanic acid (211). One E. corrodens isolate tested resistant to penicillin and ampicillin but tested negative for the presence of β-lactamase by the Cefinase dish method. American Heart Association recommendations for treatment of patients with endocarditis caused by HACEK organisms suggest that HACEK organisms be considered ampicillin resistant, largely because of difficulties in performing antimicrobial susceptibility testing and the potential failure by the laboratory to identify ampicillin-resistant strains (51).

Both microdilution with CAMHB-LHB can be used for testing HACEK organisms. Some isolates may require 48 h of incubation to obtain adequate growth, as evidenced by substantial turbidity in the positive growth control well. Some isolates may not grow satisfactorily in CAMHB-LHB; in a recent study of 174 HACEK isolates, 59.8% failed to grow sufficiently in CAMHB-LHB to allow susceptibility testing (211). In particular, poor growth was noted for A. actinomycetemcomitans (83.3% of isolates), Aggregatibacter aphrophilus (60.7%), and C. hominis (60%). Susceptibility testing may be warranted for isolates from normally sterile sites, and β-lactamase testing should be performed on HACEK isolates (2), although laboratories should be aware that not all ampicillin resistant isolates may be detected by this testing (211).

H. PYLORI

Incidence of Resistance

H. pylori is intrinsically resistant to glycopeptides, polymyxins, nalidixic acid, trimethoprim, and sulfonamides. The rates of resistance for H. pylori vary considerably among the first-line agents recommended for therapy, with resistance to metronidazole the highest, followed by clarithromycin. Resistance to amoxicillin, tetracyclines, and quinolones is low (212–214).

Routine surveillance for H. pylori resistance is no longer performed in the United States; however, between 1998 and 2002, the CDC conducted the Helicobacter pylori Anti microbial Resistance Monitoring Program, which evaluated antimicrobial susceptibility of H. pylori isolated over this period. Among 347 isolates tested, 25% were resistant to metronidazole, 13% to clarithromycin, and less than 1% to amoxicillin; no resistance to tetracycline was found (215). More recently, a study of 531 H. pylori isolates obtained between 2000 and 2008 from an Alaskan Native population with high seroprevalence of infection documented 42% metronidazole resistance, 30% clarithromycin resistance, 19% levofloxacin resistance, and less than 2% amoxicillin and tetracycline resistance (214). Studies in other developed
countries reveal much higher rates of metronidazole and clarithromycin resistance among contemporary *H. pylori* isolates. A German study of 5,296 *H. pylori* isolates collected between 2006 and 2011 found 67.1% resistance to metronidazole and clarithromycin, and 24.9% resistance to ciprofloxacin and levofloxacin, whereas resistance to tetracycline and rifampin was rare and amoxicillin resistance was not detected (212). A surveillance study in the United Kingdom of isolates collected between 2009 and 2010 revealed 88% metronidazole resistance and 68% clarithromycin resistance among 109 *H. pylori* isolates from patients evaluated at a reference laboratory; 61% of the isolates were resistant to both drugs (213). In contrast, that study documented 22% and 3% resistance to metronidazole and clarithromycin, respectively, when isolates from patients seen at a general hospital were tested. Prior treatment with metronidazole and clarithromycin was associated with increased risk of resistance to these drugs in both patient populations. Similarly, <4% of 3,707 *H. pylori* isolates in Japan between 2002 and 2005 were resistant to metronidazole, which may be related to infrequent use of metronidazole in this country (216).

**Reference Test Method**

The CLSI describes an agar dilution MIC method for testing *H. pylori*. The test medium is MHA supplemented with 5% (vol/vol) aged (≥2-week-old) sheep blood. The inoculum is prepared from 72-h-old growth on a blood agar plate to obtain a final concentration of bacteria approximating 10⁵ CFU/spot. Incubation is for 3 days at 35°C in a microaerobic atmosphere produced by a gas-generating system typically used for campylobacters. *H. pylori* ATCC 43504 has been designated a QC strain, and currently there are interpretive criteria only for clarithromycin. Other antimicrobial agents that have been studied and for which there are CLSI QC ranges include amoxicillin, metronidazole, telithromycin, and tetracycline (2). The EUCAST has defined clinical interpretive criteria, based on epidemiological cut-off values, for metronidazole, amoxicillin, levofloxacin, tetracycline, and rifampin; these are similar to those used in many studies that have evaluated *H. pylori* antimicrobial resistance. The exception is amoxicillin, for which the EUCAST defines MICs of >0.12 μg/ml as resistant (http://www.EUCAST.org), whereas many studies utilize >1 μg/ml to denote amoxicillin resistance. Although there are currently no CLSI interpretive criteria for metronidazole, many investigators have used an MIC of >8 μg/ml for resistance. The European *Helicobacter pylori* Study Group has published an agar dilution method that is similar to the CLSI method; however, they recommend horse blood-supplemented MHA and a higher inoculum (217). Although there is no standard method for disk diffusion testing, Grignon et al. have demonstrated that this method is reliable for testing clarithromycin (218), the drug that is usually of greatest interest. Because point mutations in specific genes have been implicated in resistance, genotypic methods are also used, especially for clarithromycin (219).

**Commercial Test Methods**

Although no commercial methods are FDA cleared for antimicrobial susceptibility testing of *H. pylori*, several investigators have examined the performance of Etest. Drawing a conclusion for the performance of Etest across studies is complicated by the fact that significant differences in methods, including medium types, inoculum concentration, and incubation conditions, exist. One study found an essential agreement (i.e., results within ±1 doubling dilution) between Etest and agar dilution of 84.6% for amoxicillin, 94.1% for clarithromycin, 89.9% for metronidazole, and 89.1% for tetracycline (220). In a prospective study, categorical agreement between Etest and agar dilution was 93% for both clarithromycin and metronidazole (221); a second multilaboratory found >98% agreement between Etest and agar dilution for clarithromycin (217). However, two large studies reported significant discrepancies between agar dilution and Etest MICs for metronidazole (222). The Etest manufacturer now recommends alternative incubation conditions for *H. pylori* when testing metronidazole, e.g., incubation in an anaerobic environment for 24 h, followed by 48 h of incubation in a microaerophilic environment (Etest package insert, 2012, bioMérieux). This preincubation in anaerobic environment was shown to significantly improve Etest agreement with agar dilution (223), although MHA supplemented with 5% horse blood as opposed to aged sheep blood was used for agar dilution in this study. Several studies have evaluated Etest determination of clarithromycin resistance compared to detection of 23S mutations. These studies demonstrate an imperfect relationship between phenotypic and genotypic resistance. In particular, a study by De Francesco and colleagues found 74% concordance between clarithromycin resistance determined by Etest and the presence of a 23S mutation. That study demonstrated an 85.7% cure rate in patients with phenotypic susceptibility but genetic resistance, in contrast to a 71.4% cure rate when phenotypic resistance but genetic susceptibility was documented. Cure rates were significantly poorer if a resistant result was documented by either method (224).

**Strategies for Testing and Reporting of Results**

Growth requirements and complex antimicrobial susceptibility testing recommendations for only a limited number of drugs make testing of *H. pylori* impractical for the routine clinical laboratory. However, because of the significant resistance noted for metronidazole and clarithromycin, testing may be required in selected situations, in which case a reliable reference laboratory should be used. Kim et al. identified discordant susceptibility results for clarithromycin, metronidazole, and tetracycline when testing multiple isolates from different locations in 101 control and 101 disease patients (225). A similar finding was reported by Osato et al. (222) for metronidazole susceptibility. These results suggest that resistant isolates are not evenly distributed throughout the stomach, and susceptibility results for isolates from a single biopsy sample may not be representative of the entire population, an important consideration when evaluating results of susceptibility testing for *H. pylori*. Testing of isolates from multiple gastric sites may be indicated, although no studies have demonstrated this to correlate with patient outcomes.

**LACTOBACILLUS, PEDIOCoccus, AND LEUCONOSTOC SPECIES**

*Pediococcus* spp., *Leuconostoc* spp., and most *Lactobacillus* spp. are intrinsically vancomycin resistant. *Lactobacillus gasseri*, *L. delbrueckii*, and *L. acidophilus* may be vancomycin susceptible (226–229).

For *Lactobacillus* spp. the MICs of piperacillin-tazobactam, imipenem, erythromycin, and clindamycin are generally low, but the MICs of penicillin and cephalosporins for these organisms can vary (226–230). In a study of 85 blood isolates, MICs ranged from 0.06 to 4 μg/ml for penicillin and from 0.25 to ≥256 μg/ml for ceftiraxone, with *L. casei* and *L. rhamnosus* being among the species with the least
susceptible to these agents (229). Fluoroquinolones have poor activity against most Lactobacillus spp. (226, 227, 229, 230).

Lactobacillus spp. are usually susceptible to clindamycin and erythromycin, and penicillin MICs are generally less than 0.5 μg/ml (230–232). Ceftriaxone MICs have been shown to vary from 1 to >128 μg/ml, and elevated imipenem MICs (>0.5 μg/ml) and meropenem MICs (>8 μg/ml) have been described (230–233). There is one report of an imipenem therapeutic failure for a central nervous system infection due to Lactobacillus with an imipenem MIC of 4 μg/ml (234). Daptomycin MICs for Lactobacillus spp. are low (<0.5 μg/ml), and linezolid MICs range from 2 to 8.0 μg/ml (235).

Pediococcus spp. are generally susceptible to clindamycin and erythromycin (228, 230, 231, 236) but can be resistant to both of these (231). A penicillin MIC of 0.5 μg/ml was reported for 49 isolates (228), but penicillin MICs as high as 2 μg/ml have been noted (231). MICs for ceftriaxone are generally ≥16 μg/ml; however, most isolates are very susceptible to imipenem (MICs ≤0.25 μg/ml) (230, 231). Pediococcus spp. are resistant to ciprofloxacin (230, 231, 236). Gentamicin, which would only be used in combination therapy, has variable activity against isolates of all three genera (228, 230, 231, 236).

The medium recommended by the CLSI for broth microdilution testing of Lactobacillus spp., Pediococcus spp., and Leuconostoc spp. is CAMHB-LHB (Table 3) (2). Some have performed susceptibility testing by agar dilution using either unsupplemented MHA or MHA with 5% sheep blood (230). If testing by agar dilution, incubation in 5% CO₂ may be necessary to achieve sufficient growth.

**L. MONOCYTOGENES**

Clinical isolates of *L. monocytogenes* remain susceptible to the drugs of choice, including ampicillin (or penicillin) and TMP-SMX. With the exception of occasional resistance to tetracyclines, expressed by a tetM or tetS gene, and ciprofloxacin, mediated by active efflux (237), *L. monocytogenes* is typically susceptible in vitro to other agents active against Gram-positive bacteria, including chloramphenicol, vancomycin, and macrolides (237, 238). Daptomycin MICs are elevated (MIC₉₀ 4 μg/ml), and linezolid MICs range from 1 to 2 μg/ml (238). Although *L. monocytogenes* may appear susceptible to cephalosporins in vitro, these agents are not effective clinically. Antimicrobial susceptibilities of 4,668 clinical isolates of *L. monocytogenes* were evaluated in France between 1989 and 2007 (237). Only 61 isolates were found to be resistant to at least one clinically relevant antibiotic, most commonly tetracycline (0.7% of isolates) and ciprofloxacin (0.4% of isolates), which emerged in the 1980s and 1990s, respectively. In addition, 1 isolate was resistant to trimethoprim, 1 to erythromycin, and 1 to chloramphenicol, and 2 were resistant to streptomycin. However, some studies have recently reported an increased rate of resistance to one or more clinically relevant antibiotics in *L. monocytogenes* isolated from food and food processing environments (239). Overexpression of efflux systems has been shown to be selected for by the disinfectant benzalkonium chloride, used in commercial food production facilities (240).

*Listeria* infections are generally treated empirically, and antimicrobial susceptibility testing is usually not necessary. Only criteria for susceptibility (MIC ≤2.0 μg/ml) are listed for ampicillin and penicillin in the CLSI guidelines because clinical isolates of *L. monocytogenes* have not been noted to have results other than those indicating susceptibility (2). *L. monocytogenes* is not truly fastidious, and testing in Mueller-Hinton broth without the blood supplement has been done satisfactorily. However, the CLSI recommends using CAMHB-LHB. It is important to remember that cephalosporins should not be tested or reported for *L. monocytogenes* because some isolates may, for example, have ceftriaxone MICs as low as 8 μg/ml, which could suggest false susceptibility (241). This cautionary measure is emphasized in CLSI documents (2) and illustrates why it is inappropriate to indiscriminately report susceptibility results for any agent without knowing if it would be a reasonable therapeutic option. Because cephalosporins are frequently used empirically for the treatment of meningitis, the laboratory should quickly communicate smear or culture findings suspicious for *Listeria* whenever they occur.

**M. CATARRHALIS**

*M. catarrhalis* has maintained a high degree of susceptibility to all antimicrobial agents that might be used to treat infections caused by this organism. The exception is penicillin, susceptible penicillins. More than 90% of *M. catarrhalis* isolates produce β-lactamase and are resistant to amoxicillin, ampicillin, and penicillin (66–68, 72, 242). These isolates remain susceptible to amoxicillin-clavulanic acid, which is often prescribed for *M. catarrhalis* infections.

Most isolates produce one of two types of β-lactamases: BRO-1 or BRO-2 (242–247). Both enzymes are encoded by chromosomal genes and are phenotypically identical and membrane associated. BRO-1-producing strains are up to 10-fold more prevalent than BRO-2-producing strains, and ampicillin and penicillin MICs for BRO-1-producing strains are often higher (e.g., ≥4–16 μg/ml) than those for BRO-2-producing strains (e.g., ≤0.5 μg/ml) (242–247). Because of the low MICs for the latter strains, the clinical significance of their response to β-lactamase-labile penicillins is questionable. When 1,440 isolates of *M. catarrhalis* from children and adults were examined as part of a global surveillance study, BRO-negative isolates were more commonly isolated from children than from children and oral cephalosporins had consistently higher MICs for isolates from the Far East than for isolates from the rest of the world (243). Resistance rates for TMP-SMX are less than 5% in most studies (67, 72, 242-244, 246). Hsu et al. reported that 18.5% of 314 isolates from 11 hospitals in Taiwan were resistant to TMP-SMX (242). Resistance to macrolides and tetracyclines is generally low (<1% from isolates in the Western Hemisphere from 2009 to 2011) (15, 38, 66, 68, 242). In the Asia-Pacific region, rates of clarithromycin and tetracycline resistance were 7.6% and 3.2%, respectively (248).

Only the chromogenic cephalosporin method has reliably detected the β-lactamases produced by *M. catarrhalis*. Routine β-lactamase testing may not be necessary because of the high incidence of β-lactamase-positive strains. Nevertheless, some advocate reporting of β-lactamase results to highlight the fact that this pathogen is generally unresponsive to some agents (e.g., amoxicillin) commonly prescribed for the treatment of respiratory tract infections. MIC testing without β-lactamase testing can be problematic, as there is some overlap in amoxicillin and amoxicillin MICs in β-lactamase-positive and -negative strains. Since *M. catarrhalis* typically responds to the drugs of choice, testing beyond the β-lactamase test is rarely indicated. CLSI document M45-A2 addresses MIC testing of *M. catarrhalis*, and the recommended test medium is CAMHB (2). Recommendations for disk diffusion testing of amoxicillin-clavulanic acid,
azithromycin, clarithromycin, erythromycin, tetracycline, and TMP-SMX using MHA and incubation in 5% CO₂ are included in CLSI document M45-A2 (Table 3). These were adopted following studies performed by Bell et al. which demonstrated a high correlation of disk diffusion results with results obtained by MIC testing (244).

**PASTEURELLA SPECIES**

Human isolates of *Pasteurella* spp. are generally susceptible to penicillin, with MICs of ≤0.5 μg/ml (249–252). Sporadic reports of human infections with β-lactamase-producing isolates demonstrated positive reactions with a nitrocefin-impregnated disk test, amoxicillin MICs of 8 to 64 μg/ml, and amoxicillin-clavulanic acid MICs of 0.25 μg/ml to 1 μg/ml (253, 254). For one of these isolates, the β-lactamase was characterized as a plasmid-borne TEM-1 (254), whereas two other cases were associated with plasmid-borne ROB-1 β-lactamases (253). *Pasteurella* spp. are generally very susceptible to antimicrobial agents commonly used for the treatment of acute bacterial skin and skin structure infections; a recent study documented very low MICs for cefazolin, ceftriaxone, ampicillin-sulbactam, ertapenem, azithromycin, doxycycline, and TMP-SMX among 156 *Pasteurella* spp. isolated from patients with animal bite wounds (255). No studies have documented resistance among clinical isolates for parenteral cephalosporins, fluoroquinolones, tetracyclines, chloramphenicol, or TMP-SMX (249–252). Resistance to erythromycin can occur, and there is at least one report of a failure of erythromycin to cure a cat bite victim who subsequently developed meningitis (256).

Broth microdilution and disk diffusion methods are described by the CLSI for testing *Pasteurella* spp. (Table 3). Due to the absence of nonsusceptible strains, there are only susceptibility interpretive criteria for agents that might be tested, with the exception of erythromycin. Susceptibility testing may be warranted for isolates from normally sterile sites, and β-lactamase testing should be done on these isolates as well as those from respiratory sources (2). Testing of isolates from bite wounds is not necessary since bite wound infections are generally treated empirically with agents (e.g., amoxicillin-clavulanic acid) that would cover a variety of organisms likely to be implicated in the infection.

**VIBRIO SPECIES**

Both *Vibrio cholerae* and the noncholera *Vibrio* spp. are often susceptible to most antimicrobial agents, including newer cephalosporins, aminoglycosides, fluoroquinolones, and tetracyclines; however, resistance to one or more of these can occur (257).

In parts of the developing world, rates of resistance among *V. cholerae* vary considerably both geographically and year to year. Resistance to tetracyclines, fluoroquinolones, and TMP-SMX, drugs commonly prescribed when therapy is needed, has been documented (258). Multidrug-resistant *V. cholerae* has been attributed to the presence of genetic elements harbored on an R plasmid (259), whereas the integrating conjugative resistance element SXT encodes resistance to trimethoprim, sulfamethoxazole, and streptomycin and has been observed among *V. cholerae* strains from multiple cholera outbreaks (257, 260). Wang et al. recently reported the antimicrobial susceptibilities of 550 *V. cholerae* El Tor biotype O1 isolates collected in China between 1961 and 2010; these isolates demonstrated significant increases in resistance to TMP-SMX (from 0 to 38.5%), tetracycline (from 0 to 89%), and nalidixic acid (0 to 45.9%) over this period (261). In contrast, a study of 340 *V. cholerae* O139 isolates collected in China between 1995 and 2009 displayed high rates of resistance to nalidixic acid (83.1%), tetracycline (83.4%), azithromycin (50.3%), and TMP-SMX (90.7%) (262). Recently, a *V. cholerae* El Tor Ogawa strain was isolated from a child in India that harbored both the *bla*<sub>TEM</sub> and *bla*<sub>NDM-1</sub> genes, with resistance to third-generation cephalosporins by Etest and agar dilution (263).

When a double-blind randomized study was conducted to determine the equivalence of azithromycin and ciprofloxacin, 78% of 97 patients had a bacteriologic cure with azithromycin, compared with only 10% of 98 patients who received ciprofloxacin. The 168 isolates from these patients were found to be susceptible to both azithromycin and ciprofloxacin when tested by disk diffusion and Etest, but the median ciprofloxacin MIC for 91 *V. cholerae* serogroup O1 isolates was 0.25 μg/ml, which is significantly above the wild-type MIC (264). The elevated MICs and poor outcomes suggest the possibility of a resistance mechanism not detectable when an MIC of ≤1 μg/ml is used to define ciprofloxacin susceptibility. Indeed, isolates from the 2010 Haitian *V. cholerae* O1 outbreak were found to have reduced susceptibility to ciprofloxacin (0.25 to 1.0 μg/ml), which was associated with mutation to the QRDR of gyrA and parC (75).

Since 2009, the CDC has been annually tracking antimicrobial resistance in *Vibrio* spp. other than *V. cholerae*. In each year studied, *V. parahaemolyticus* represented the largest number of isolates submitted to the CDC for testing, followed by *V. alginolyticus* and *V. vulnificus*. Fewer than 50 isolates of other species were submitted for testing. In 2011, 95.1% of *V. alginolyticus* isolates were resistant to amoxicillin, in contrast to 40.3% of *V. parahaemolyticus* and 4.8% of *V. vulnificus* isolates. No isolates of *Vibrio* tested were resistant to quinolones or tetracycline, and 0.3% of isolates were resistant to TMP-SMX (176).

Antimicrobial therapy is not required to manage cholangitis, but such therapy may shorten the duration and reduce the severity of disease. Similarly, although the noncholera *Vibrio* spp. cause diarrheal disease, otherwise healthy individuals with diarrhea due to these bacteria usually recover spontaneously without treatment. When *Vibrio* spp. are isolated from sources associated with serious infections, antimicrobial susceptibility testing is warranted. The CLSI suggests use of broth microdilution or disk diffusion using methodology similar to that for testing *Enterobacteriaceae*. In 2010, an MIC test for detecting azithromycin in *Vibrio* spp. was added to the CLSI guidelines, and an MIC of ≤2 μg/ml is considered susceptible; no criteria for interpreting resistance are described. For testing of the halophilic *Vibrio* spp., some have suggested use of MHA containing 1% NaCl. However, the CLSI recommends preparation of the inoculum suspension in 0.85% NaCl solution for both disk diffusion and broth microdilution MIC testing with MHA and CAMHB (both without NaCl supplementation), respectively (2).

**CONCLUSION**

With the exceptions of serious streptococcal infections, extraintestinal *Aeromonas* or *Vibrio* infections, and device-associated coryneform infections, infections caused by many of the fastidious bacteria discussed in this chapter are treated empirically, as these bacteria are often susceptible to the drugs of choice. Consequently, susceptibility testing is infrequently needed for many of these organisms. In certain circumstances testing may be warranted, such as when there appears to be clinical failure, patient intolerance to the...
drug(s) of choice, or serious infections for which there are limited appropriate drugs that might be prescribed. Additionally, susceptibility testing may aid in species identification (e.g., differentiating C. jeikeium from other Corynebacterium species). If a physician seems unsure about requesting antimicrobial susceptibility testing on a fastidious organism, he or she should be encouraged to seek assistance from an infectious diseases clinician or pharmacist.

The Etest has been examined for testing a variety of fastidious bacteria and their strengths and limitations. If fastidious bacteria are often for isolates associated with serious infections, and MIC results are likely to be more useful than qualitative results. The disk diffusion test should be used only for bacteria for which there are CLSI or EUCAST interpretive criteria. It is important for laboratory workers to maintain an awareness of the methods available for testing fastidious bacteria and their strengths and limitations. If testing must be performed, it should be done by a laboratory familiar with these methods and their limitations.

Infections due to anaerobic bacteria are common and can be serious or even life threatening. Severe infections due to anaerobic bacteria may lead to high morbidity and mortality if appropriate antibiotic therapy is not started (1). Since anaerobes are part of the normal human microbiota, infections due to anaerobic bacteria are typically endogenous in nature. Anaerobic infections are usually polymicrobial. For instance, three to five anaerobes, on average, can be involved in a single case of suppurative anaerobic surgical infection (2).

Susceptibility testing for anaerobes can be problematic for many reasons, including the fastidious nature and slow growth of the organism. For this reason, empirical therapy for infections has often been instituted long before results of susceptibility testing are available. Additionally, anaerobic susceptibility testing can be difficult to perform due to the manipulation required under anaerobic conditions. The use of empirical broad-spectrum antimicrobial therapy has led some clinicians and laboratories away from performing susceptibility testing. Thus, a correlation between clinical outcomes and decreased susceptibility of isolates may be difficult to document.

However, anaerobic bacterial resistance is increasing globally, as demonstrated by multiple surveys in Europe, the United States, Canada, New Zealand, and other areas of the world (3–6). Moreover, resistance patterns differ by geographic location, not only between countries but also within countries and even among hospitals located within the same city. Resistance patterns in one area of the world cannot always be predicted by published reports of resistance from another area. Differences in susceptibility among individuals may be due to various testing methods, selective antibiotic pressures on the bacteria secondary to patterns of antimicrobial usage in distinct areas, and lack of uniformity in adoption of interpretive breakpoints.

Certain resistance patterns are well known and well spread across geographic areas, such as β-lactamase production by almost all Bacteroides spp. and two-thirds of Prevotella spp. (5). Yet other resistance mechanisms are currently being recognized, and certain organisms are becoming more resistant to various classes of drugs, such as the decreasing susceptibility to clindamycin in the Bacteroides fragilis group (3). Clinicians and laboratorians can no longer assume susceptibility of anaerobes without performing the testing.

The Clinical and Laboratory Standards Institute (CLSI) has provided laboratories with procedural guidelines for anaerobic susceptibility testing as well as various antimicrobial choices for testing on certain organisms (7, 8). This chapter outlines the CLSI and other susceptibility testing methodologies available, emphasizing the advantages and disadvantages of each. As current resistance patterns guide the choice of antimicrobials to test, the main categories of resistance are emphasized for Gram-negative and Gram-positive anaerobes. Pertinent trends of increasing resistance among each group are noted. Finally, specific recommendations for antibiogram testing and reporting are reviewed.

### SUSCEPTIBILITY TESTING METHODS AND QC

#### Reference Test Methods

**Agar Dilution**

The CLSI reference agar dilution procedure (also called the Wadsworth method) is the recommended reference testing method for anaerobic organisms (7). The agar dilution method is the method by which other susceptibility testing methods are compared to assess their validity. Briefly, 2-fold dilutions of each antimicrobial are added to molten agar, poured into a petri dish, and allowed to solidify (9). Standardized inocula of microorganisms are applied onto the surface of each plate. Within 30 min of inoculation of the plates and after the bacteria have absorbed into the media, the plates are inverted and incubated in an anaerobic atmosphere. After approximately 48 h of incubation, the plates are examined visually. The MIC is defined as the lowest concentration of each antimicrobial agent at which growth of the organism is inhibited. Although it is the “gold standard” of susceptibility testing for anaerobes, the agar dilution method requires considerable time, labor, and expertise. For these reasons, it can be difficult for routine clinical microbiology laboratories to perform as the sole susceptibility testing method for an individual isolate recovered from an anaerobic infection.

**Medium**

The recommended medium is brucella agar supplemented with hemin (5 μg/ml), vitamin K₁ (1 μg/ml), and 5% (vol/vol) laked (lysed) sheep blood. This medium supports the growth of essentially all anaerobes (10). Details

---

*This chapter contains information presented by Diane M. Citron and David W. Hecht in chapter 72 of the 10th edition of this Manual.
concerning the preparation of this agar and its composition can be found in the appendixes of CLSI document M11-A8 (7). Stock solutions of hemin, vitamin K₁, and laked sheep blood can be prepared and stored ahead of time. Hemin and vitamin K₁ are added to brucella agar base, autoclaved, and stored as prepared tubes of supplemented brucella agar. On day of testing, the supplemented brucella agar is melted and cooled to 48 to 50°C. The appropriate antimicrobials and the sterile laked sheep blood are added to the molten agar. Samples are then gently mixed, taking care not to introduce bubbles, and the plates are poured. Solidification of the media usually takes approximately 15 to 20 min. Plates should be placed in an incubator or laminar flow hood to be allowed to dry for 30 to 45 min after solidification. The CLSI recommends that the plates can be stored seven or fewer days in sealed plastic bags at 2 to 8°C. However, a 72-h storage limit should be applied for more stringent research or other purposes. Due to instability, plates containing imipenem (but not meropenem, ertapenem, or doripenem) or β-lactam–β-lactamase inhibitor combinations containing clavulanic acid cannot be stored and should be used on the day of preparation. If such plates are stored and used beyond the date of preparation, the antibiotic may break down and the antimicrobial MICs will appear higher than they truly are.

Inoculum Preparation

The inoculum can be prepared by suspending colonies from a 24- to 72-h brucella blood agar plate into brucella broth or another clear broth and obtaining a 0.5 McFarland standard density. Alternatively, the inoculum may be prepared by adding five or more colonies into enriched thioglycolate or other supportive broth medium and incubating them for 4 to 24 h to obtain a 0.5 McFarland standard density. Although the equivalence of a 0.5 McFarland standard may be assessed using either a photometer or by visual inspection, certain broth media may affect photometer readings. Thus, quality control (QC) should be performed in such situations, as mentioned below.

Inoculation Procedure

The organism suspensions should be applied onto the surface of the agar with an inoculum-replicating apparatus (also known as Steer’s replicator) (Multiple Inoculator; CMI-Promex, Inc., Pedricktown, NJ) (11). The final inoculum on the agar is approximately 10⁵ CFU per spot for B. fragilis and Bacteroides thetaiotaomicron. For species with larger cells, such as Clostridium difficile ATCC 29741, C. difficile ATCC 700507, and Eggerthella lenta ATCC 43055. A chart of QC MIC ranges for anaerobes by the agar dilution method is included in CLSI document M100 (8).

Two QC strains should be used for each assessment when using the agar dilution procedure. Detailed suggestions are included in the CLSI document M11 (7). Dilution blanks of sterile, distilled water or buffer should be set up when preparing antimicrobial agents. Brucella plates with no antibiotic should be prepared when pouring the agar. An antimicrobial-free control plate should be incubated aerobically to check for aerobic contamination of the inoculation process, while another should be incubated under anaerobic conditions. If thioglycolate or another agar-containing broth medium is used for inoculum preparation, additional control plates should be inoculated with antibiotic-free broth since inoculum residue can occasionally be confused with growth of an organism on final reading of the plates. The CLSI also advises performance of colony counts on inoculum suspensions to ensure that the final inoculum is appropriate. It is also suggested that the inoculum concentration be verified for 5 to 10% of tests by performing colony counts when using broth media which may affect photometer readings. Different organisms may demonstrate variations in colony counts. For example, Veillonella and Parvimonas micra, which are composed of smaller cells than are most anaerobes, may have higher colony counts for a standard McFarland measure than do bacteria with larger cells, such as Clostridium perfringens.

Interpretation and Result Reporting

The MIC endpoint, as defined by the CLSI, is the minimum concentration at which a marked reduction of growth occurs on the test plate compared to the anaerobic growth control. A color pictorial guide of various MIC end points for anaerobes is included for guidance in CLSI document M11 (7). It is important to compare the antimicrobial-containing plates to the antimicrobial-free control plate when reading the tests, as different species of anaerobic bacteria can look different on the agar dilution plate. Other antimicrobial-organism combinations may be particularly difficult to interpret, such as Gram-negative organisms tested against ceftizoxime and piperacillin. Additionally, many strains of fusobacteria produce L forms (cell wall-deficient bacterial forms) which grow as transparent hazes on the surface of the agar and appear even at the highest MICs of β-lactam antibiotics.

Interpretive categories for MICs for anaerobic bacteria are listed in CLSI document M100 (8). The European Committee on Antimicrobial Susceptibility Testing (EUCAST) publishes its breakpoints, which do not match CLSI breakpoints in all cases (EUCAST; http://www.euCAST.org/clinical_breakpoints). EUCAST also does not specify a single susceptibility testing method for anaerobes. The CLSI states

Quality Control

A QC program is designed to monitor accuracy and precision of the susceptibility testing process, including procedures, performance of reagents and equipment, and competency of persons conducting the tests. QC must be performed to demonstrate that any new medium adequately supports growth of the test organisms and that the antimicrobial agents have not deteriorated during shipping or storage. These tests must be a part of any testing program using any of the methods described above. QC strains that most closely resemble the tested organisms should be included. Recommended QC strains for the agar dilution procedure include B. fragilis ATCC 25285, B. thetaiotaomicron ATCC 29741, C. difficile ATCC 700507, and Eggerthella lenta ATCC 43055. A chart of QC MIC ranges for anaerobes by the agar dilution method is included in CLSI document M100 (8).
that the intermediate category for anaerobes was established due to the difficulty in reading endpoints (8). Isolates for which the antimicrobial agent MICs are in the intermediate range may respond to therapy when maximum dosages are used alongside appropriate ancillary therapy, such as drainage or debridement. However, clinical responses should be carefully monitored. An overview of the agar dilution method, including advantages and disadvantages, is presented in Table 1.

**Broth Microdilution**

The broth microdilution method is easier to perform than agar dilution and offers certain advantages, such as the ability to test multiple antimicrobials at one time. With this method, small volumes of broth liquid media containing drugs in serial 2-fold dilutions are prepared on rounded or conical wells of sterile, plastic microdilution trays or plates. A standard amount of the bacteria is inoculated into each well. MIC determinations are obtained in a manner similar to that used for agar dilution. If panels are made in-house, laboratories can design their own drug panels. Panels may be freshly prepared and then frozen, or they may be purchased commercially as lyophilized or frozen panels. If antimicrobials to the plates, but volumes differ based upon the CLSI only for *B. fragilis* group organisms at this time (8).

**Medium**

The recommended medium is brucella broth supplemented with hemin (5 μg/ml), vitamin K₁ (1 μg/ml), and 5% (vol/vol) laked (lysed) horse blood. Microdilution trays may be freshly prepared and then frozen, or they may be purchased commercially as lyophilized or frozen panels. If trays are to be frozen, antimicrobial agents should be added before freezing. Details concerning the preparation of broth microdilution plates are covered in CLSI document M11 (7). Dispensing devices or pipettes may be used to add the antimicrobials to the plates, but volumes differ based upon the device used. Each well should contain at least 0.1 ml of broth. Volumes lower than 0.1 ml are not recommended due to evaporation. Certain antimicrobials such as imipenem and clavulanic acid are more labile than other antibiotics, and panels containing these antimicrobials must be stored at lower temperatures. Trays should not be stored in a self-defrosting freezer, as repeat freeze-thaw cycles lead to antibiotic degradation.

**Inoculum Preparation**

Inoculum preparation is similar to that used for agar dilution. A 0.5 McFarland standard density inoculum can be prepared by suspending colonies from a 24- to 72-h brucella blood agar plate into brucella broth or another clear broth, or by incubating enriched thioglycolate or other supportive broth medium with several colonies until the desired turbidity is reached. Optimally, the inoculum suspension should be diluted in broth or saline within 15 min of obtaining the correct McFarland density, for a final approximation of 1 × 10⁵ CFU in each well. Dilution techniques vary depending upon the method of tray inoculation (7).

**Inoculation Procedure**

Frozen trays should be brought to room temperature before use. Inoculation may be accomplished by use of a mechanical dispenser, an inoculator, or a pipette. Placement of the trays in a reducing environment for 2 to 4 h prior to inoculation may aid in the growth of oxygen-sensitive strains, but *B. fragilis* is relatively oxygen tolerant (9). Trays should be prereduced if metronidazole is included in the panel, since activity of metronidazole is dependent upon an active intermediate, which requires a reduced atmosphere. If metronidazole is not prereduced, rapidly growing or nonfastidious strains can appear falsely resistant.

**Incubation Conditions**

Trays should be incubated for 46 to 48 h at 35 to 37°C in an anaerobic atmosphere. Trays should not be stacked more than four high to ensure uniformity of incubation temperature of the trays. In addition, trays should not be sealed with sealing tape, since this decreases the diffusion of gas to the inoculum and may lead to poor growth or false resistance to metronidazole. However, evaporation of the broth can be problematic if the trays are not incubated in a humidified environment with a cover tray. Alternatively, the trays may be placed in a self-sealing plastic bag which is left open slightly to allow for gas exchange. It is also permissible to use perforated tape with holes for each well.

**Quality Control**

QC of the broth microdilution process is similar to that described for agar dilution and is described in detail in CLSI document M11 (7). Recommended QC strains for the broth microdilution procedure include *B. fragilis* ATCC 25285, *B. thetaiotaomicron* ATCC 29741, *C. difficile* ATCC 700057, and *E. lenta* ATCC 43055. A chart of QC MIC ranges for anaerobes by the broth microdilution method is included in CLSI document M100 (8). When testing an individual

strain, one QC strain should be included. Each tray should include a growth control well and a sterility well that is uninoculated. It is also suggested to incubate uninoculated microdilution trays from each batch that is prepared in-house in order to confirm sterility (12). Purity checks of the inoculum suspension should be performed by incubating aliquots aerobically and anaerobically. Colony counts on inoculum suspensions should also be performed to ensure that the final inoculum is appropriate.

**Interpretation and Result Reporting**

Determination of the MIC may be made by viewing the plates from the bottom using a magnifying mirror viewing stand with reflective light. As for agar dilution, the MIC is the concentration at which the most significant reduction of growth is observed. A trailing effect may be seen with some antimicrobial-organism combinations, and a color pictorial guide of various MIC determinations for broth microdilution is included in CLSI document M11 (7). If there is poor growth in the drug-free positive control well, the test should not be read. Currently, CLSI breakpoints for broth microdilution and agar dilution for *B. fragilis* group organisms are the same (5). A summary of the advantages and disadvantages of the broth microdilution technique is provided in Table 1.

**Commercial Test Methods**

**MIC Gradient Diffusion Method**

The Etest (bioMérieux, Durham, NC) and M.I.C.Evaluator (M.I.C.E.) strips (Thermo Fisher Scientific, Basingstoke, United Kingdom) are convenient gradient diffusion methods and are generally easier to use in routine clinical microbiology practice than are agar dilution and broth microdilution. The Etest was introduced in 1994 and until recently was the only gradient diffusion method available for clinical laboratories. In a 2008 survey of 150 U.S. hospitals, Goldstein and colleagues reported that 65% of hospital laboratories with access to anaerobe susceptibility testing performed such testing using Etest (13). Forty percent of hospital laboratories used microbroth dilution, and none used agar dilution.

Various antimicrobial Etests are commercially available for use in the United States. Both the Etest and M.I.C.E. are thin plastic strips which are impregnated on one face with an increasing gradient concentration of an antimicrobial agent. A 1.0 McFarland is swabbed onto a plate, usually a prereduced brucella plate supplemented with hemin and vitamin K₁. The MIC is determined by the intersection of the lower part of the ellipse with the corresponding number on the test strip. The strips are generally read at 48 h; however, clostridial species and *B. fragilis* group isolates may grow well enough to be read at 24 h. The advantages of these strips are that multiple drugs can be tested on one plate, and the method is flexible in allowing laboratories to tailor antimicrobial testing according to their needs. Large overlapping inhibitory zones of certain organisms may render the test difficult to read, unless the strips are located far apart on the plate. Users should refer to the Etest package inserts for QC organism suggestions. When testing an individual strain with Etest, one QC strain should be included.

Etest strips cost approximately $2 to $3 (U.S.) apiece, and testing can be expensive if several Etests are used at one time. The complete list of current U.S. Food and Drug Administration (FDA)-approved antimicrobial agents for anaerobe testing can be found in the various package inserts for the drugs. Table 1 lists the advantages and disadvantages of the MIC gradient diffusion methodology.

Comparative studies of Etest performance against agar dilution have demonstrated high categorical agreement, approximately 98%, averaged across all anaerobes and essential agreement of 85% or higher (14–17). In one study of 197 anaerobic organisms tested by both agar dilution and Etest, intermethod correlations of all drugs were high, with penicillin showing the lowest correlation, at 91.8% (18). It has been well documented that Etest can overestimate metronidazole resistance of organisms compared to agar dilution if anaerobiosis is not adequate (19). However, this phenomenon can be avoided by preincubating the test plates in an anaerobic environment overnight prior to their use. Other studies have shown a very high major error (VME) rate (false susceptibility) of 3.2% for Etests of certain antimicrobial-microorganism combinations, such as clindamycin and ceftriaxone tested against *B. fragilis* group and *Clostridium* spp., compared to agar dilution (16).

In a comparative study of agar dilution, Etest, and M.I.C.E. using 102 clinical strains of anaerobes, Rennie et al. reported that the essential and categorical agreement between Etest and M.I.C.E. was >90% for the four drugs tested: amoxicillin-clavulanate, imipenem, metronidazole, and penicillin (20). Compared to agar dilution, a high VME rate was noted for both Etest and M.I.C.E. for penicillin (8 to 9% VME) and metronidazole (13 to 14% VME). Agar dilution MICs were generally higher for all species of anaerobes and antibiotics. The VME discrepancies were again observed among *B. fragilis* group strains and clostridia, including *C. perfringens*.

**Commercially Available Broth Microdilution Panels**

Two commercially available panels for anaerobic susceptibility testing are available currently, both offered by Thermo Fisher Scientific (Cleveland, OH). The first is the dried anaerobic Sensititre panel (ANO2B; Trek Diagnostic Systems, now owned by Thermo Fisher), which is available with 15 antimicrobials and is marketed for research use only ([http://www.trekds.com/products/sensititre/c_anaerobe.asp](http://www.trekds.com/products/sensititre/c_anaerobe.asp)). Sensititre can also design custom panels, either frozen or dried, to suit the needs of an individual laboratory. A frozen anaerobic susceptibility panel is also available through Oxoid (also now owned by Thermo Fisher) (ANA MIC panel, catalog number R8320100; [http://www.thermoscientific.com/en/product/oxoid-ana-mic-panel-minimal-inhibitory-concentration-mic-susceptibility-system.html](http://www.thermoscientific.com/en/product/oxoid-ana-mic-panel-minimal-inhibitory-concentration-mic-susceptibility-system.html)). There are limited studies on the performance of such panels for anaerobic susceptibility testing. Dowickz and colleagues compared mero- penem on the Sensititre panel to agar dilution for 47 anaerobes and demonstrated overall agreement of 93% (± 1 2-fold dilution) between the two methods (21). Each drug on the panels must be FDA approved for use in anaerobic infections in order for the entire panel to be approved. Since this is not the case, FDA approval is not available for either company’s panels.

**β-Lactamase Testing**

Anaerobes may be tested for β-lactamase production by the β-lactamase disk test using a chromogenic cephalosporin. Such disks are available through BD Diagnostics, Hardy Diagnostics, and Thermo Fisher Scientific. Hydrolysis of
the β-lactam ring by β-lactamases causes the disk to change from yellow to red. Most reactions occur within 5 to 10 min. Since some β-lactamase-positive strains of Bacteroides spp. or other anaerobes may react more slowly (up to 30 min), it is suggested to hold the chromogenic cephalosporin disks for a full 30 min before calling the test negative. Members of the B. fragilis group are presumed to be resistant to ampicillin, amoxicillin, and penicillin due to β-lactamases, so β-lactamase disk testing need not be performed. Other Gram-negative anaerobes, such as Prevotella, Porphyromonas, and Bacteroides, may be tested by the nitrocefin disk, but it is important to realize that resistance to β-lactam drugs is not always mediated by β-lactamase production. Therefore, if an isolate is negative by the chromogenic cephalosporin disk, resistance may still be present due to other mechanisms such as alterations of penicillin-binding proteins, as with some strains of Parabacteroides (previously Bacteroides) distasonis and B. fragilis (22). Gram-positive anaerobes may also be screened for β-lactamase activity by the chromogenic cephalosporin disk test. If the isolate is β-lactamase positive, the isolate should be reported as resistant to penicillin and ampicillin, regardless of the MIC result.

Disk Diffusion
According to CLSI, disk diffusion tests are not suggested as an antimicrobial testing method for anaerobes, as the susceptibility testing results are inaccurate and do not correlate with the results of the agar dilution method (8).

RESISTANCE PATTERNS IN ANAEROBIC BACTERIA
Resistance patterns differ by geographic region and have changed significantly over time. Various authors have emphasized the screening of anaerobes for certain resistance patterns which are rising in incidence and are clinically important (23). Such patterns which deserve close attention include (i) resistance to the β-lactam–β-lactamase inhibitor combinations among the B. fragilis group; (ii) increasing clindamycin resistance in all anaerobes; (iii) metronidazole resistance, which is no longer confined to the B. fragilis group, but now includes Gram-positive cocci and Gram-positive rods; and (iv) resistance of Clostridium to glycopeptides and lipopeptides, such as vancomycin and dapto mycin. Each of these patterns is described below.

Bacteroides fragilis Group
The B. fragilis group consists of 24 species (including five Parabacteroides species). Of this group, B. fragilis is generally the most susceptible to antibiotics. P. distasonis demonstrates high MICs for β-lactams, and B. thetaiotaomicron also demonstrates higher rates of resistance to various antimicrobials than do other members of the B. fragilis group. A survey conducted by Snydman and colleagues of B. fragilis group isolates collected from 10 U.S. medical centers demonstrated trends in susceptibilities using agar dilution over 1997 to 2004 (4). Species distribution of 6,574 isolates included 51% B. fragilis, 19% B. thetaiotaomicron, 10% Bacteroides ovatus, 6% Bacteroides vulgatus, and 5% P. distasonis, with the remaining composed of a variety of species. Susceptibility rates of antibiotics within the B. fragilis group varied by species. Specifically, compared to other members of the B. fragilis group, B. ovatus was more resistant to the carbapenems, B. vulgatus was more resistant to piperacillin-tazobactam and showed the highest rates of resistance to moxifloxacin (54%), P. distasonis was more resistant to ampicillin-sulbactam and cefoxitin, and B. ovatus and Bacteroides uniformis showed higher rates of resistance to moxifloxacin (39% and 41%, respectively). These patterns of resistance by species have been mirrored by other studies (24–26).

Greater than 97% of all Bacteroides isolates are resistant to penicillin and ampicillin principally due to β-lactamase production (27). Resistance to penicillins and cephalosporins is mediated primarily by the cepA or cfxA gene. The cepA gene encodes a chromosomal cephalosporinase which renders the organism resistant to cephalosporins and aminopenicillins, but the isolate remains susceptible to piperacillin and β-lactam–β-lactamase inhibitor combinations. When cepA gene expression is enhanced by an upstream promoter, the MICs of all β-lactams increase, with the exception of carbapenems (23). However, the additional presence of a membrane modification such as a porin loss may lead to a 4-fold increase in the MICs of the β-lactams and β-lactam–β-lactamase inhibitor combinations. Currently, β-lactams–β-lactamase inhibitor combinations, such as ticarcillin-clavulanate and piperacillin-tazobactam, are active against nearly all strains of B. fragilis group, with >90% susceptibility in most reports (3, 28, 29). However, recent studies from various areas of the world, including the United States, Europe, Taiwan, and Kuwait, have emphasized increasing resistance to ampicillin-sulbactam or piperacillin-tazobactam of Bacteroides species (3, 28–32). Authors from one study characterized a B. thetaiotaomicron strain with a porin loss which contributed to amoxicillin-clavulanate resistance (33). This pattern of decreasing susceptibility of B. fragilis group isolates is important, since the number of therapeutic choices is narrowing and β-lactam–β-lactamase inhibitor combinations are not infrequently used in anaerobic infections.

The cfxA gene encodes a broad-spectrum β-lactamase which is responsible for high-level resistance to cefoxitin and other β-lactam drugs (26, 34). Although the principal mechanism of resistance to penicillins is β-lactamase production, penicillin-binding proteins can also lead to resistance (35). Piperacillin and other uredopenicillins are more active than penicillin, but more than half of isolates are resistant to the former (36). Oxacillin, nafcillin, and the first-generation cephalosporins are not active against the B. fragilis group.

Cefoxitin and cefotetan are generally active against B. fragilis. However, cefotetan has lower activity against members of the B. fragilis group other than B. fragilis (32). Rates of resistance to cefoxitin and cefotetan are rising, and susceptibility testing should be performed if these antimicrobials are to be used for therapy (3). With the exception of cefotaxime, broad-spectrum cephalosporins show poor activity against B. fragilis group organisms (37).

Carbapenems (imipenem, ertapenem, meropenem, and doripenem) are generally active against members of the B. fragilis group, and most studies report susceptibility rates of >95% (4, 25). Carbapenem resistance is usually mediated by a zinc metallo-β-lactamase enzyme encoded by the cfxA gene that confers resistance to all current β-lactams and β-lactam–β-lactamase inhibitor combination agents (38). The cfxA gene is present in small numbers in Bacteroides but is silent unless insertion sequence elements activate the gene (39). Metallo-β-lactamase enzymes can be detected phenotypically with use of a chelating compound such as...
EDTA, which inactivates the enzyme and renders the isolate susceptible to the carbapenem. Alarming, carbapenem resistance is increasing as well but at low rates (25, 28, 31). In a surveillance trend study of B. fragilis group organisms, Snydman and colleagues reported a decrease in carbapenem susceptibility from 2006 to 2009 (29). Carbapenem susceptibility rates in the study were 97.5 to 98.9%, and the susceptibility rate for the β-lactam-β-lactamase inhibitor combination agents was approximately 95%. Seifert et al. reported 95% carbapenem susceptibility of the B. fragilis group isolates associated with intra-abdominal infections in their multicenter German study (25). Interestingly, a report from Turkey noted only 90% susceptibility to carbapenems in a group of 66 B. fragilis group isolates, the majority of which were confirmed positive by PCR for the presence of the cfiA gene (40).

Clindamycin resistance is increasing worldwide in the B. fragilis group and approaches 40% (3, 4, 29, 31). Resistance is mediated by erm genes, which are frequently located on transferable plasmids and can be linked to transferable tetracycline resistance as well (41).

Metronidazole resistance is linked to the nim (nitroimidazole reductase) gene. Although rare, metronidazole-resistant strains of B. fragilis group isolates have been reported from numerous areas of the world (3, 28, 38). In 2011, Sherwood and colleagues published on a strain of B. fragilis from a leg wound which was resistant to metronidazole and numerous other drugs (38). The isolate was confirmed by PCR to possess the nim gene located on a potentially transferable plasmid. Moxifloxacin and linezolid were the only antimicrobials to which the organism displayed MICs in the susceptible range. Approximately 95 to 97% of B. fragilis isolates in France are susceptible to metronidazole (using the EUCAST susceptible breakpoint of ≤4 mg/liter, which is one 2-fold dilution lower than the CLSI susceptibility breakpoint), and other countries have published reports of similar susceptibility (3, 23, 28). Expression of this gene leads to reduction of the nitrate residue of metronidazole into an amino derivative, thus decreasing the effect of the antibiotic on the bacterium. Of 206 B. fragilis isolates in one study, the nim gene was detected in 24%, and metronidazole MICs of the nim-positive isolates ranged from 1.5 to >256 mg/liter, spanning the range of susceptible to highly resistant (42). Metronidazole MICs must therefore be measured, as the nim gene can be found in metronidazole-resistant strains. Although many nim-positive Bacteroides strains do not develop a high level of resistance, they can be induced by subinhibitory concentrations of the antibiotic to express high MICs (43). Thus, metronidazole treatment could potentially select for a subpopulation of nim-positive organisms which may express resistance and decrease clinical response to the drug. Metronidazole resistance is spreading geographically to other genus and species of anaerobes, highlighting the transmissibility of this type of plasmid-mediated resistance.

Moxifloxacin can be distinguished from levofloxacin by its added activity against anaerobes and is FDA approved for complicated intra-abdominal infections caused by anaerobes. However, rates of susceptibility to moxifloxacin are highly variable across studies, and isolates appear to be acquiring resistance rapidly. In a recent study, Snydman et al. reported resistance rates of >80% to moxifloxacin for B. fragilis group isolates (29). In a multicenter European surveillance study, susceptibility to moxifloxacin decreased between 2003 and 2009 from 91 to 86.4% (3). Resistance is mediated by gyrA mutations, efflux pumps, or modifications of topoisomerase genes.

The FDA has approved MIC breakpoints for tigecycline (susceptibility breakpoint, 4 μg/ml) for use in treatment of complicated intra-abdominal infections due to anaerobes. Although resistance at this time is relatively low in surveillance studies, there have been reports of susceptibility rates ranging from approximately 95 to 98.5% in some studies (6, 44).

In conclusion, Bacteroides carries various resistance mechanisms which can complicate treatment of infections. Studies have shown that susceptibility patterns of Bacteroides species are linked to outcome, even in the presence of mixed infections (4, 45). Therefore, B. fragilis group isolates from significant sites should be tested for susceptibility against a variety of antibiotics.

**Prevotella and Porphyromonas**

Fewer data are available for Prevotella and Porphyromonas susceptibility profiles than for Bacteroides. Overall, Prevotella and Porphyromonas are more susceptible to antimicrobials used to treat anaerobic infections than the B. fragilis group, while Prevotella is more resistant than Porphyromonas. Most Prevotella spp. are resistant to penicillin and ampicillin due to β-lactamase production. In a New Zealand surveillance study from 1999 to 2003, susceptibility rates among 45 strains of Prevotella spp. were as follows: 18% to penicillin, 89% to ceftriaxone, and 96% to clindamycin (5). Susceptibility rates for cefoxitin and cefotetan range from 70 to 99%, and piperacillin susceptibility rates are lower, at 55 to 80% (30, 31, 46). Liu and colleagues also reported in their study that Prevotella spp. demonstrated decreasing susceptibility to imipenem from 100% in 2002 to 94% in 2006 (31). Authors of a German antimicrobial surveillance study reported that 90.5% of Prevotella spp. tested susceptible to clindamycin. A recent Belgian study of Prevotella spp. and miscellaneous Gram-negative anaerobes documented decreasing clindamycin susceptibility from 91% susceptible in 1993 to 94%, 82% susceptible in 2004, and 69% susceptible in 2012 (47). Nine percent of Prevotella isolates showed intermediate moxifloxacin MICs (25).

Porphyromonas, on the other hand, appears more susceptible to β-lactams and other drugs than do Prevotella spp. However, susceptibility reports of clinically significant Porphyromonas spp. in surveillance studies are rare. Bahar and colleagues reported susceptibility profiles of 45 Porphyromonas isolates as measured by Etest (48). In their study, Porphyromonas demonstrated 94% susceptibility to penicillin and 97% susceptibility to cefoxitin, with 100% susceptibility to the remaining antibiotics, including ampicillin-sulbactam, imipenem, clindamycin, and metronidazole. Production of β-lactamase is rare, although clindamycin resistance has been observed in a minority of strains (49).

Both genera are almost uniformly susceptible to carbapenems, metronidazole, and tigecycline. Rare reports of metronidazole resistance in Prevotella spp. have been published (46). A report from France describes reduced susceptibility to metronidazole in 3 of 188 Prevotella spp., which also showed resistant subpopulations, similar to the findings with B. fragilis group organisms (50). In another study, cefobiprole was tested against 42 strains of Porphyromonas and Prevotella (51). The cefobiprole MICs of most Porphyromonas spp. were ≤0.125 μg/ml, while Prevotella bivia and Prevotella melaninogenica were less susceptible.
Other Gram-Negative Bacilli

Penicillin resistance among *Fusobacterium* spp. is relatively rare. Four of 36 (11%) *Fusobacterium* isolates in a Taiwan survey were positive for β-lactamase, as reported by Liu and colleagues (31). All *Fusobacterium* spp. were susceptible to metronidazole, piperacillin-tazobactam, cefmetazole, doripenem, and ertapenem. On the other hand, imipenem and meropenem nonsusceptibility rates were 4 to 8%, respectively, which were increased in comparison to previous years. Moxifloxacin susceptibility was shown in 81% of *Fusobacterium* isolates. Susceptibility rates vary somewhat by species. Over 90% of *Fusobacterium nucleatum* and *Fusobacterium necrophorum* isolates are susceptible to cephalosporins and cephapemycins, while *Fusobacterium mortiferum* is resistant to cephapemycins (32).

*Bilophila wadsworthia* usually produces a β-lactamase and is therefore resistant to penicillin and ampicillin but is generally susceptible to remaining antibiotics, including clindamycin, cefoxitin, β-lactam–β-lactamase inhibitor combinations, carbapenems, and metronidazole (53, 54).

*Campylobacter gracilis* was previously thought to be resistant to many β-lactam agents, but studies have shown that a more resistant organism, *Sutterella wadsworthensis*, was often misidentified as *C. gracilis* in published reports (55). When properly identified and tested, *C. gracilis* is susceptible to most agents, including β-lactam–β-lactamase inhibitor combinations, cefoxitin, and clindamycin (56). *S. wadsworthensis*, on the other hand, not uncommonly displays resistance to clindamycin, piperacillin, and/or metronidazole (57).

Gram-Positive, Non-Spore-Forming Bacilli

The “*Eubacterium*” group, *Actinomyces*, *Propionibacterium*, and *Bifidobacterium* are usually susceptible to β-lactam agents, including the penicillins, cephalosporins and cephamycins, carbapenems, and β-lactam–β-lactamase inhibitor combinations (58, 59). One exception is *Eggerthella lenta* (formerly *Eubacterium lentum*), for which the MICs of third-generation cephalosporins are elevated. There are currently no CLSI clinical breakpoints for vancomycin and anaerobes; however, this agent shows in vitro activity against the “*Eubacterium*” group, *Propionibacterium* spp., and *Actinomyces* spp. (57). Although most lactobacilli which grow well in ambient air are vancomycin resistant (e.g., *Lactobacillus casei*, *Lactobacillus rhamnosus*, *Lactobacillus plantarum*, *Lactobacillus salivarius*, and *Lactobacillus fermentum*), vancomycin shows some activity against the majority of lactobacilli which grow only anaerobically (*Lactobacillus acidophilus* group, *Lactobacillus crispatus*, *Lactobacillus gasseri*, *Lactobacillus johnsonii*, and *Lactobacillus jenseni*) (60). The lactobacilli which grow aerobically should be tested for susceptibility aerobically, as outlined in CLSI document M45 guidelines for infrequently isolated or fastidious bacteria (61). On the other hand, if the lactobacilli grow only anaerobically (as is common for most vaginal lactobacilli), or if the lactobacilli are recovered from a specimen from which other anaerobes are recovered, it is currently suggested that susceptibility testing be followed based on the anaerobic guidelines in CLSI document M11 (7). This testing approach may change as more data are generated. *Lactobacillus* spp. are generally susceptible to erythromycin and clindamycin but show variable susceptibilities to cephalosporins, imipenem, vancomycin, and penicillin according to the species (62, 63).

Most non-spore-forming Gram-positive anaerobes, with the exception of the “*Eubacterium*” group, are resistant to metronidazole. The newer antimicrobial agents, such as linezolid, daptomycin, dalbavancin, oritavancin, and ramoplanin, show activity against Gram-positive aerobic organisms and also exhibit excellent in vitro activity against most anaerobic Gram-positive species (60, 64–66).

Gram-Positive, Spore-Forming Bacilli

C. *perfringens* isolates are almost universally susceptible to penicillin and clindamycin (5, 59). However, a recent Canadian population-based surveillance study of bacteriaemia due to *Clostridium* spp. from 2000 to 2006 demonstrated that 8/58 (14%) *C. perfringens* isolates were resistant to clindamycin (67). All *C. perfringens* isolates in the study were susceptible to penicillin and metronidazole. *C. perfringens* is typically susceptible to metronidazole, although resistant strains have been described (68). Non-*perfringens* *Clostridium* spp., including *C. difficile*, show variable patterns of susceptibility to a variety of glycopeptides and related antibiotics (69). Most clostridia are inhibited by 2 mg/liter of vancomycin and daptomycin and by 1 mg/liter of teicoplanin or dalbavancin (65). However, the “RIC” group of clostridia—namely, *Clostridium ramosum*, *Clostridium innocuum*, and *Clostridium clostridioides*—is intrinsically resistant to several antibiotics. *C. clostridioides*, which appears Gram negative in cultures, produces β-lactamase, shows low-level resistance to teicoplanin and dalbavancin, is resistant to daptomycin, but is susceptible to vancomycin (23, 70). On the other hand, *C. innocuum* is resistant to cefoxitin and cefotetan, retains high MICs (8 to 32 μg/ml) for vancomycin, but is susceptible to tigecycline and metronidazole. Finally, *C. ramosum* is resistant to vancomycin and daptomycin and shows low-level resistance to linezolid (MIC, 8 μg/ml), in contrast to other clostridial species. Goldstein and colleagues reported on the activity of cefotiboprole against clostridial species and demonstrated that most clostridia (including *C. perfringens*, *Clostridium cadaveris*, and *Clostridium subterminale*) were susceptible at ≤1 μg/ml, excluding *C. perfringens* and *C. clostridioides* (51). The authors’ findings differed from the findings of Wootton et al. who reported an MIC of 4 μg/ml for the group of 48 mixed species of clostridia (71).

*C. difficile* may be resistant to many β-lactam agents, including cephalosporins, fluoroquinolones, and clindamycin, but the organism usually demonstrates low MICs to metronidazole and vancomycin (72). Strains resistant to rifampin or rifaximin have been reported in laboratory surveys, and some were confirmed by clinical failures (72, 73). Metronidazole-resistant strains are rare but have been documented (74, 75). Fidaxomicin shows excellent activity against *C. difficile*, but reduced susceptibility has been documented in vitro and has been associated with mutations leading to target modifications (76).

Gram-Positive Cocci

The great majority of Gram-positive cocci are susceptible to β-lactams, β-lactam–β-lactamase inhibitor combinations, cephalosporins, carbapenems, and metronidazole (32). However, many Gram-positive cocci are resistant to clindamycin, including 30% of *Finegoldella magna* and *Peptostreptococcus* spp. (77). *Peptococcus niger* is highly susceptible to β-lactams, β-lactam–β-lactamase inhibitor combinations, cephalosporins, carbapenems, chloramphenicol, metronidazole, and tigecycline (52, 60, 78).

*Reprinted with permission from the Clinical and Laboratory Standards Institute from reference 8. Data were generated from unique isolates from patient specimens submitted to three referral laboratories: Tufts New England Medical Center, Boston, MA; Loyola University Medical Center, Maywood, IL; and R.M. Alden Research Laboratory, Culver City, CA. Testing was performed by the agar dilution method. Breakpoints, in micrograms per milliliter, are in parentheses after the category (S, susceptible; R, resistant). The intermediate category is not shown but can be derived by subtraction of the percent susceptible and percent resistant for each antimicrobial agent from 100%.

*Anaerobic Gram-positive cocci include Peptococcus, Peptostreptococcus, Finegoldia, Peptoniphilus, and Anaerococcus species.

*Calculated from fewer than the CLSI document M39 (81) recommendation of 30 isolates.

*Clostridium difficile isolates are from intestinal sources; these results do not imply efficacy for intraluminal infections. Vancomycin MICs for all isolates were <4 μg/ml.
The accuracy of reported susceptibilities of the anaerobic Gram-positive cocci may have been limited in the past by misidentifications. For instance, *Peptoniphilus harei* (*Pt. harei*) may have been misidentified in past studies as *Peptoniphilus asaccharolyticus* (*Pt. asaccharolyticus*) (79). Veloo and colleagues from the Netherlands report differing susceptibilities among the three most common Gram-positive cocci identified by genotypic methods in their study: *P. micra*, *F. magna*, and *Pt. harei* (80).

Metronidazole resistance among Gram-positive cocci is extremely rare (80). If such resistance is encountered in an anaerobic Gram-positive isolate, the identity of the organism should be confirmed. Strains of streptococci such as the *Streptococcus anginosus* group and *Streptococcus maltolactis* may initially be identified as anaerobic Gram-positive cocci and will test resistant to metronidazole.

**STRATEGIES FOR TESTING AND REPORTING OF SUSCEPTIBILITY DATA**

**Antimicrobial Testing Guideline**

For individual patient management, susceptibility should be performed when (i) selection of an active agent is critical for disease management, (ii) long-term therapy is considered for clinical management, (iii) anaerobes are recovered from specific sterile body sites (e.g., blood, brain, bone, or joint), or (iv) the usual treatment regimen fails (Table 2). Since most anaerobic infections are polymicrobial in nature and are likely to include both β-lactamase-negative and β-lactamase-positive strains, susceptibility testing should be reported at least for the most resistant organism. Some anaerobic organisms, such as *C. perfringens*, *Clostridium septicum*, or *Clostridium sordellii*, may be the sole source of infection. In such cases, susceptibility testing should be performed, since these organisms are usually β-lactamase negative and therapy may be narrowed.

The CLSI lists certain antimicrobial agents to be considered for testing and reporting on anaerobic organisms (Table 3). The listing of antimicrobials is based upon many factors, including resistance rates and resistance mechanisms. The type of anaerobe (Gram negative versus Gram positive) guides the choice of antimicrobial testing. As noted in Table 3, certain antibiotics are listed as a cluster within one box, and only one of the agents in the box needs to be tested under usual circumstances. Antibiotics listed in the same box demonstrate similar clinical efficacy, and interpretive results (susceptible, intermediate, or resistant) are also similar. For Gram-negative anaerobes, penicillin or ampicillin may be tested and/or reported selectively for all except the *B. fragilis* group, which are almost uniformly resistant and need not be tested. For Gram-negative anaerobes other than those in the *B. fragilis* group, penicillin or ampicillin MICs may be obtained. If the β-lactamase test is positive for Gram-negative anaerobes, report the isolate as resistant to penicillin and ampicillin. However, it is important to recognize that Gram-negative anaerobes which are negative by the β-lactamase disk test may be resistant to β-lactams by another mechanism (8). Thus, a negative β-lactamase disk test should be followed by penicillin or ampicillin MIC testing if such drugs may potentially be used for treatment.

For Gram-positive anaerobes, many non-spore-forming Gram-positive rods are resistant to metronidazole, such as *Actinomyces*. Ampicillin and penicillin are recommended for primary testing for Gram-positive anaerobes, as many are β-lactamase negative. As with Gram-negative anaerobes, report the isolate as resistant to penicillin and ampicillin if the β-lactamase test is positive, regardless of the MIC result. Although CLSI MIC amoxicillin breakpoints have not been established, they are considered equivalent to ampicillin breakpoints (8). Some laboratories do not routinely perform susceptibility testing on *C. perfringens* isolates, since isolates retrieved from human infections are almost universally susceptible to penicillin and clindamycin (5, 59).

The remaining supplemental or alternative antimicrobials listed for possible testing or reporting are helpful for those patients or institutions with strains which are resistant to primary drugs. Alternative testing may also be helpful for treatment of patients who are allergic to primary drugs or for treatment of unusual isolates.

**Antibiograms**

Individual hospitals should perform periodic surveillance of anaerobes to monitor resistance rates in their system, if possible. Establishment of an antibiogram outlining patterns of resistance for certain anaerobes on a periodic basis would be helpful for empirical coverage of the patient with antibiotics. CLSI guideline M39 provides recommendations outlining the proper collection, analysis, and presentation of cumulative antimicrobial susceptibility test data (81). It is recommended to gather data from at least 30 isolates collected over the period of a year from each group in order to obtain a reasonable number of isolates upon which to estimate the percent susceptible. At the same time, clinically relevant organisms which are not frequently isolated can be included. However, for optimal surveillance, testing of 75 to 100 isolates is preferred, including members of the *B. fragilis* group and *Clostridium* spp. If possible, *Prevotella* spp., *Fusobacterium* spp., and other frequently isolated pathogens should be considered for inclusion. Examples of cumulative antimicrobial susceptibility reports are included for *B. fragilis* group and for anaerobic organisms other than *B. fragilis* group (Tables 4 and 5). Reported antimicrobial agents should generally be based upon the hospital’s formulary, although one agent from each antimicrobial class should be tested even if not on the hospital formulary, in order to detect resistance. Such data could be important as part of the cumulative susceptibility report if and when the hospital drug formulary was changed. It is important to recognize that neither national nor even local data from other institutions within the region are sufficient to predict susceptibility of anaerobes to antimicrobial agents at one’s own hospital.

**CONCLUSIONS**

A variety of susceptibility testing methodologies are available which allow for accurate surveillance of susceptibility trends or testing of individual isolates. As antimicrobial resistance among anaerobes has become a significant problem in recent years, there is an even greater need to perform susceptibility testing and gather data to monitor trends in changing resistance patterns.

mycin, and metronidazole against Clostridium perfringens, Propionibacterium acne, and anaerobic Gram-positive cocci. Anaerobe 11:93–95.

The World Health Organization (WHO) has described drug-resistant tuberculosis (TB) as "a major public health threat that threatens TB control" (1). Approximately 500,000 cases of multidrug-resistant (MDR) TB occur each year worldwide (2). MDR TB is defined as a case caused by tubercle bacilli that are resistant to isoniazid (INH) and rifampin (RIF), the two most effective drugs in the standard regimen. Although most of the cases of TB and drug-resistant TB occur in developing countries, a significant percentage of these diseases also occur in industrialized countries, where immigrants may make up the majority of new TB cases. Drug-resistant TB is therefore a worldwide problem. Fortunately, at the same time that the threat of drug-resistant TB is emerging, new tools are being developed for more rapid detection of drug resistance. Among the new tools endorsed by WHO for the diagnosis of TB and detection of drug resistance are liquid culture, Cepheid GeneXpert MTB/RIF, and molecular line probe assays (1, 3). In the United States, a task force was convened to plan to combat and control drug-resistant TB. The report of this task force was published in early 2009 (4). This report emphasizes the need to develop and enhance laboratory capacities to rapidly and accurately detect drug-resistant TB. Along with the advances in new technologies, new drugs are becoming available to help meet the challenges of this changing situation.

Recently, attention has been focused on cases of TB that exhibit resistance not only to INH and RIF but also to quinolones and injectable drugs such as amikacin, kanamycin, or capreomycin. These cases, described as extensively drug-resistant TB (XDR TB), present serious challenges for diagnosis, treatment, and control of the disease (5). Successful treatment of XDR TB is possible with individualized treatment based on results of drug susceptibility testing (DST), including second-line drugs, adverse-event management, and nutritional and psychological support (6). However, most patients with XDR TB succumb to this disease because of delays in diagnosis, inability to test for susceptibility to second-line drugs, coinfection with HIV, unavailability of second-line drugs, or combinations of these factors. Again, enhancing the capacity of laboratories to quickly detect drug resistance and test for susceptibility to second-line drugs is a key component in efforts to combat this ominous new development.

This chapter includes a description of nonradioactive broth culture systems and rapid molecular systems for detection of drug resistance, as well as the standard agar proportion method. The molecular drug susceptibility testing (MDST) methods are revolutionizing the way in which drug-resistant TB is detected, creating a new standard of turnaround time—hours or days—to provide results, rather than the weeks or months previously required. We also include the method, the microscopic observation drug susceptibility (MODS) (7, 8), which does not require frequent importation of proprietary materials and represents an inexpensive technique desirable in resource-limited settings.

As described in earlier chapters, nontuberculous mycobacteria (NTM) and aerobic actinomycetes can also be causes of significant disease in humans. As goals are met for elimination of TB, NTM will constitute an increasing proportion of causative agents of human mycobacterial diseases. DST of many NTM and aerobic actinomycetes may provide useful guidance in the treatment of these infections and is also discussed in this chapter.

**ANTIMICROBIAL AGENTS**

Although a variety of antimicrobial agents are available for treating mycobacterial diseases, not all agents are suitable for treating all types of infections. Furthermore, in the face of antimicrobial resistance, the choice of alternative therapies can be problematic and clinical experience becomes a prevailing factor. For uncommon mycobacterial infections, the physician is not infrequently faced with a dilemma in choosing a treatment regimen because of a lack of clinical precedence or unclear efficacy. The situation is confounded further by the need to treat mycobacterial infections with a combination of agents to improve efficacy, to prevent resistance, or to overcome intrinsic resistance.

The antimicrobial agents that are used in treating mycobacterial infections are discussed below. The primary nontuberculous agents are discussed first, followed by other drugs in alphabetical order. Recommended treatments for TB and the most commonly encountered NTM infections are summarized in Table 1 (9, 10). For TB, first-line drugs are less toxic, able to be given orally, and usually used to treat uncomplicated cases. The Clinical and Laboratory Standards Institute (CLSI) document on DST of mycobacteria (11) currently recommends that first-line testing include...
INH, RIF, ethambutol (EMB), and pyrazinamide (PZA). In the United States, streptomycin (STR) was moved to second-line testing several years ago. Second-line drugs are used when first-line therapy fails or is inappropriate. These agents include injectable drugs such as amikacin (AMK), capreomycin (CAP), kanamycin (KAN), STR, viomycin, quinolones such as ofloxacin (OFX), levofloxacin (LVX), and moxifloxacin (MXF), oral drugs such as ethionamide (ETH), p-aminosalicylic acid (PAS), cycloserine, linezolid (LZD), amoxicillin-clavulanate, amithiozones, and bedaquiline (BDQ). These drugs are often accompanied by more-severe side effects, and for some of them, the efficacy for treating TB is not clear.

Drug resistance in Mycobacterium tuberculosis complex (MTBC) occurs randomly and at a low frequency and is usually a result of single-step mutations. Two types of drug resistance are seen: primary and acquired. Primary drug resistance occurs in an individual who is infected with a drug-resistant strain before drug treatment is initiated. Acquired resistance can emerge against any of the antimicrobial agents during chemotherapy as a result of inadequate treatment.

Genes that are known to be associated with antibiotic resistance in MTBC are summarized in Table 1 (12). Although drug resistance mechanisms in MTBC are not fully understood, five categories are found in mycobacteria. These include decreased uptake of drug such as seen in dormant acid-fast bacilli, drug inactivation by constitutive \( \beta \)-lactamas (i.e., b-lactam resistance), increased efflux as seen in fluoroquinolone resistance, alteration of the target as described below with RIF and INH, and reduced prodrug-activating enzymes as exhibited in INH and PZA resistance (12).

### Isoniazid

INH, a synthetic antimicrobial agent introduced in 1952 for the treatment of TB, is remarkably specific and potently bactericidal for tubercle bacilli. INH has comparatively low toxicity and is active against virtually all wild-type strains of MTBC. While the mechanism of INH activation is not completely understood, it is likely that the process involves an oxidation reaction catalyzed by a catalase-peroxidase encoded by the katG gene (13). The oxidized form of INH can then covalently bind to the nicotinamide moiety of NAD(H) to form INH-NAD(H) adducts, which in turn compete with NAD(H) for binding to an enoyl-acyl carrier protein reductase encoded by the inhA gene (14).

The primary effect of INH is on mycolic acid synthesis, as evidenced by the increased fragility of the mycobacterial cell, increased intracellular viscosity, decreased cellular hydrophobicity, and loss of acid fastness of INH-resistant isolates (15). The mycolic acids are produced by the fatty acid synthesis (FAS I and II enzyme systems, the latter of which synthesizes the species-specific long-chain mycolic acids. Activated INH targets one of the FAS II enzymes, the enoyl-acyl carrier protein (ACP) reductase of InhA. INH also may interfere with NAD metabolism, energy metabolism, and macromolecular synthesis (16, 17).

The mechanism of action of INH correlates with the known mechanisms of INH resistance. Banerjee et al. (18) reported that INH and ETH resistance in MTBC correlated with a missense mutation in the inhA gene. Other studies showed that katG mutations account for 30 to 60% of INH resistance (19) and that mutations in inhA promoter conferring a low level of INH resistance may not always be clinically significant (20). Mutations in the \( \alpha/bpC \) promoter, which regulates the expression of an alkyl hydroperoxide reductase (21, 22), are also associated with INH resistance.

INH is active only against replicating tubercle bacilli in the presence of oxygen. Resistance to INH develops rapidly when patients are given monotherapy, and the frequency of INH resistance within a population of tubercle bacilli ranges from \( 10^{-5} \) to \( 10^{-9} \). Adverse drug reactions include infrequent, age-related hepatitis and, less frequently, peripheral neuropathy, hypersensitivity reactions such as fever and rash, and arthralgias.

### Rifampin

Rifampin (rifampicin, introduced in 1968, affects intracellular, slowly replicating tubercle bacilli in caseous lesions as well as the actively replicating bacilli in open cavities. RIF is also active against several other slowly growing mycobacteria but is inactive against the

</table>
rapidly growing mycobacteria. It easily diffuses through the mycobacterial cell membrane due to its lipophilic nature. RIF inhibits transcription by binding to the β-subunit of the DNA-dependent RNA polymerase. Drug resistance develops when mutations occur in the rpoB gene encoding the β-subunit of the RNA polymerase (23). Studies showed that >96% of RIF resistance could be attributed to mutations within an 81-bp core region of the rpoB gene (24). With increasing use of MDST for detection of TB drug resistance, several rpoB mutations have been found to alter susceptibility to RIF, but these may not increase the MIC sufficiently to cause the TB bacilli to test as resistant in standardized methods such as the Mycobacterial Growth Indicator Tube (MGIT) system. The clinical significance of these mutations is not clear, but some association with treatment failure has been reported (25).

Adverse drug reactions include hepatotoxicity, gastrointestinal, and hypersensitivity reactions, and a red-orange discoloration of urine, tears, other body fluids, and soft contact lenses. RIF also induces increased hepatic metabolism and may result in subtherapeutic levels of the antiviral agents (26).

**Rifabutin and Rifapentine**

Rifabutin (RFB; ansamycin), a spiropiperidyl rifamycin, and rifapentine (RFP), a cyclopentyl rifamycin, have potent in vitro activity against MTBC. RFB also is very active against the *Mycobacterium avium* complex (MAC) (27). The mode of action and mechanism of resistance of both drugs appear to be identical to those of RIF; however, approximately 30% of RIF-resistant MTBC isolates are susceptible to RFB and RFP. The latter observation correlates with certain specific mutations in the rpoB gene (28). Yang et al. analyzed clinical strains of MTBC for cross-resistance to rifamycins and found that alterations at codons 513 and 531 correlate with resistance to RIF and RFB; and point mutations at codons 516 and 529, deletion at codon 518, and insertion at codon 516. Of particular concern is the interaction of RFB and, to a somewhat lesser degree, rifabutin (RFB) with protease inhibitors, which leads to enhanced hepatic metabolism and may result in subtherapeutic levels of the antiviral agents (26).

**Ethambutol**

EMB, introduced in 1961, is a synthetic antituberculous compound that is active only against growing bacilli. Its activity against slowly growing NTM is more variable. The primary mechanism of action of EMB is bacteriostatic inhibition of cell wall synthesis, while evidence points to a specific effect on arabinogalactan synthesis (31). In MTBC, the frequency of mutation to EMB resistance is on the order of 10⁵—there is evidence that some EMB resistance correlates with a specific mutation (at PZA codon 306) in the embB gene, which encodes an arabinosyltransferase (32, 33). While mutations in the embB gene result in high-level resistance in MTBC, this mutation accounts for only 70% of resistant strains; thus, mutations in other genes are likely to play an additional role (12). Mutations at embB codon 306 may also affect susceptibility to other drugs used in the treatment of TB (34).

Many MAC isolates have high EMB MIC values, but it has been shown that the MIC value does not correlate with clinical response (35). It appears that EMB affects the permeability of the MAC cell wall and perhaps increases the intracellular concentration of the other, potentially more active drugs (36).

The most important adverse effect associated with EMB is decreased visual acuity due to optic neuritis, which is related to both the dose and the duration of treatment. EMB is not recommended for the treatment of children too young to be monitored for changes in vision, unless no other drug is appropriate because of resistance. The effects on vision are generally reversible when the drug is discontinued.

**Pyrazinamide**

PZA is a synthetic derivative (pyrazine analog) of nicotinamide and, in combination with INH, is rapidly bactericidal for replicating and nonreplicating forms of *M. tuberculosis*. PZA is inactive against other *Mycobacterium* species, including *M. bovis*, although rare PZA-susceptible *M. bovis* isolates have been described. PZA is active only at an acidic pH; therefore, the pH of the growth medium must be adjusted for accurate measurements of the in vitro activity of the drug. It is most likely that PZA is active only in the acidic milieu of the phagolysosome and, depending on the concentration achieved at the site of the infection, may be bacteriostatic or bactericidal. PZA is hydrolyzed in the liver to the active metabolite pyrazinoic acid, and although the mechanism of action of PZA is not fully understood, its activity depends on this conversion. *M. tuberculosis* produces a pyrazinamidase, and most strains of PZA-resistant *M. tuberculosis* lack this enzyme; however, some PZA-resistant isolates retain enzyme activity, suggesting that there are other mechanisms of resistance such as drug efflux (37).

The lack of pyrazinamidase activity and its correlation with PZA resistance have been associated with mutations in the pncA gene, which encodes the enzyme (38). Indeed, it now appears that 72 to 97% of PZA resistance can be attributed to mutations in the pncA gene (Table 2).

**Aminoglycosides**

The aminoglycosides that are used for the treatment of mycobacterial infections include STR, KAN, and AMK. The aminoglycosides are bactericidal at the usual concentrations attained in serum, and tobramycin is active only against *M. chelonae*.

The primary mechanism of action of the aminoglycosides is inhibition of the post- to pretranslocation step of protein synthesis by blocking the binding of the aminoaacyl-tRNA...
(e-type binding). Cross-resistance among the aminoglycosides often occurs when resistance mutations develop in \( \text{rrs} \) after treatment with amikacin, but resistance to STR or KAN may not cause cross-resistance to amikacin (39). KAN-resistant, AMK-susceptible isolates may have mutations in the \( \text{eis} \) promoter region (Table 2). AMK often is used in combination with one or more other agents for treatment of serious infections caused by rapidly growing mycobacteria or by MAC.

The molecular basis of STR resistance in MTBC (Table 2) results from mutations in the gene that encodes ribosomal protein S12 or from mutations in the 16S rRNA region, which is structurally linked to the S12 protein in the assembled ribosome (40, 41). Finken et al. (40) showed that mutations in the \( \text{rpsL} \) gene, coding for the S12 protein, were present in 20 of 38 STR-resistant strains and that there was a mutation in the \( \text{rpsL} \) gene, encoding 16S rRNA, in 9 strains. Nair et al. (41) determined the nucleotide sequence of the \( \text{rpsL} \) gene and showed that STR resistance, in a small number of isolates, appeared to be a result of point mutations at codon 43 of this gene. Adverse drug reactions associated with aminoglycosides include hearing loss, tinnitus, loss of balance, and renal failure.

**Amithiozone**

Amithiozone (thiacetazone, tibione, or panthrene) is a thiosemicarbazole that is active against MTBC. Resistance develops quickly when monotherapy is given. Adverse drug reactions are gastrointestinal irritation and bone marrow suppression, and hepatotoxicity can occur in patients receiving concomitant INH. Additionally, there appears to be an association of Stevens-Johnson syndrome and severe epidermal necrolysis in HIV-infected patients with TB treated by regimens containing amithiozone (42). Consequently, it is recommended that amithiozone not be used to treat patients known or suspected to be infected with HIV. Amithiozone is not available in the United States and is not used in Europe because of the adverse effects, but it has been used successfully in combination with INH for the treatment of TB in some African countries, where adverse effects are believed to be less severe.

**Bedaquiline**

The antituberculous potential of diarylquinoline drugs was reported in 2005 (43). One of these drugs, TMC207, or bedaquiline (BDQ), appears to reduce the time to conversion to a negative sputum culture for patients with MDR TB (44). BDQ was approved by the U.S. FDA at the end of 2012 for treatment of tuberculosis (45). Diaryquinolines have a new mechanism of antituberculous action, i.e., inhibition of mycobacterial ATP synthase. Standardized protocols for laboratory testing to detect BDQ resistance have not been developed at the time of the writing of this Manual. Resistance has been linked to mutations in the \( \text{rpsL} \) gene, including Asp28Gly, Asp28Ala, Leu95Val, Glu61Asp, Ala63Pro, and Ile66Met mutations. These ATP synthase mutations are associated with increases in MIC, from 0.03 \( \mu \text{g/ml} \) in wild-type strains to 0.25 to 4 \( \mu \text{g/ml} \) in strains with the above-mentioned mutations, using a broth dilution susceptibility testing method (46). However, some resistant strains that do not have ATP synthase mutations have been developed in the laboratory, indicating the presence of other resistance mechanisms (47).

**Capreomycin**

CAP, a macrocyclic polypeptide antibiotic isolated from *Streptomyces mutabilis* subsp. *capeorus*, is an important injectable drug used for treating drug-resistant TB. The mechanism of action is similar to that of the aminoglycosides: it interferes with translation. CAP is generally considered to be a bacteriostatic agent but has been shown to be bactericidal in vitro against nonreplicating TB bacilli (48). Mutations in the 16S rRNA gene (\( \text{rrs} \)) or \( \text{inhA} \) gene can confer resistance to CAP (49).

**Clofazimine**

Clofazimine is a substituted iminophenazine, bright red dye. It has weak bactericidal activity against *M. leprae* but is used in combination with RIF and dapsone as a conventional treatment regimen for leprosy. However, it may take up to 50 days of treatment before there is evidence of tissue antimicrobial activity, which may influence the length of time before there is a clinical response in the treatment of leprosy.

The mechanism of action of clofazimine is unknown; however, it is highly lipophilic and binds preferentially to mycobacterial DNA. The half-life is extraordinarily long (estimated to be 70 days), and the drug tends to be deposited in fatty tissues and cells of the reticuloendothelial system. Adverse drug reactions are limited primarily to a pink or red discoloration of the skin, conjunctiva, cornea, and body fluids and gastrointestinal intolerance.

**Cycloserine**

\( \text{D-CS} \) is an analog of \( \text{d}-\text{alanine} \) that inhibits the synthesis of \( \text{d}-\text{alanyl-} \text{d}-\text{alanine} \), an essential component of the mycobacterial cell wall. CS is active against all mycobacteria as well as several other types of bacteria. Although it is one of the secondary drugs for treatment of TB, in vitro susceptibility testing is not recommended due to technical problems with the test (11). There are significant adverse drug reactions associated with CS treatment, notably, peripheral neuropathy and central nervous system dysfunction including seizures and psychotic disturbances.

**Dapsone**

Dapsone (diaminodiphenyl sulfone) is a synthetic compound that was shown to be active against *M. leprae* in the early 1940s. Dapsone is an antifolate that, like other inhibitors of folic acid synthesis, exerts primarily a bacteriostatic effect and is only weakly bactericidal. Common adverse drug reactions include nausea, vomiting, anorexia, and methemoglobinemia; hematuria, rash, pruritus, and fever also can occur. Traditionally, dapsone is used in combination with RIF and clofazimine for the treatment of leprosy. Acedapsone is a diacetlylated form of dapsone with an extraordinarily long half-life of 46 days; as a result, this drug is administered infrequently (e.g., five injections per year), with peak concentrations in tissue occurring 20 to 35 days after administration. Acedapsone is relatively inactive against *M. leprae*, but in vivo it is deacetylated to the parent compound.

**Ethionamide**

ETH is a derivative of isonicotinic acid and, like INH, blocks mycolic acid synthesis. Isolates of MTBC that are resistant to high concentrations of INH are susceptible to ETH, suggesting that the site of action may be different from that of INH. However, mutations in the promoter of the \( \text{inhA} \) gene have been associated with ETH resistance (18). Side effects associated with ETH include gastrointestinal irritation and neurologic symptoms.
Macrolides

Azithromycin and clarithromycin are the most important agents in the treatment of MAC disease and are effective and approved prophylactic agents for preventing disseminated disease in HIV-infected persons (50, 51). These drugs also are useful in the treatment of disease caused by M. marinum, M. haemophilum, M. kansasii, M. simiae, and rapidly growing mycobacteria other than M. fortuitum. Indeed, they are viewed as potential cornerstones in the treatment of NTM infections (9, 10). Azithromycin, an azalide (a subclass of macrolides), and clarithromycin are structurally similar to erythromycin and have modifications that improve their acid stability and increase their potency, half-life, achievable concentrations in tissue, and bioavailability without causing toxicity. These macrolides are bacteriostatic agents and inhibit the growth of microorganisms by binding to the 50S subunit of the prokaryotic ribosome, blocking protein synthesis at the peptidyltransferase step. Meier et al. (52) showed that both clarithromycin- and azithromycin-resistant mutants of M. intracellulare have a single-base mutation at adenine 2058 in the 23S rRNA gene, a site of mutation or methylation that has been associated with macrolide resistance in other bacteria (53). The same genetic basis for macrolide resistance was found in M. chelonae and M. abscessus (54).

The ability of azithromycin to concentrate in tissues most likely accounts for its therapeutic activity in animal studies and humans (14, 55). Its level in polymorphonuclear leukocytes is nearly 1,000-fold higher than the levels in serum (56). Similarly, the concentrations of clarithromycin in tissue are 4 to 5 times greater than the concentrations in serum, and the concentration in macrophages is 20 to 30 times greater.

p-Aminosalicylic Acid

PAS is an antifolate that is active against MTBC but inactive against most other mycobacteria. There is some evidence that PAS also may affect iron transport in MTBC and salicylic acid metabolism. PAS is incompletely absorbed in the gastrointestinal tract and is associated with significant gastrointestinal side effects.

Quinolones

OFOX, LVX, and MFX are fluorinated carboxyquinolones with good in vitro activity against both fully susceptible and drug-resistant MTBC and many NTM (57–59). LVX (the L-isomer of OFX) is approximately twice as active against MTBC as ofloxacin in vitro and therefore may be the preferred drug for susceptibility testing. MFX is especially useful in the treatment of multidrug-resistant TB (60). The efficacy of fluoroquinolones in the treatment of pulmonary TB may relate, in part, to the observation that these quinolones concentrate in lung tissue to levels at least four times greater than the concentration in serum.

The mechanism of action of all fluorinated quinolones is inhibition of DNA synthesis as a result of binding to the DNA gyrase (bacterial topoisomerase II) (61). Takiff et al. (62) showed that quinolone resistance in MTBC can be ascribed to mutations in the gyrA and gyrB genes, which encode the DNA gyrase subunits (Table 2). In MTBC, fluoroquinolones function by binding to the bacterial enzyme-DNA complex, with suggested mechanisms being strand breakage, SOS-mediated autolysis, and replication blockage. While there are no reports of cross-resistance between quinolones and other classes of antimycobacterial agents, there is cross-resistance within the quinolone class, such that reduced susceptibility to one quinolone may likely confer reduced efficacy to all quinolones (59). Adverse effects with fluoroquinolones may be less severe than with the other secondary agents (63).

New Anti tuberculous Drugs

Several new classes of drugs, including nitroimidazole and oxazolidinone drugs, have shown promise for the treatment of pansusceptible as well as drug-resistant TB. These new drugs have unique and new action mechanisms, and there is no cross-resistance between these new drugs and the existing anti-TB drugs. Some show stronger bactericidal effects than currently used drugs, which may result in shorter therapy durations. Furthermore, for treating HIV and TB coinfection, the new drugs seem to have lower interaction with protease inhibitors. These are potential advantages that remain to be proven by clinical trials. At the time of preparation of this chapter, no information was available about susceptibility testing for these drugs.

The nitroimidazole drug PA-824 is in phase II clinical testing and has been shown to be effective in enhancing bactericidal activity when combined with RIF and/or PZA in a murine model of TB (64). The oxazolidinone drug linezolid has been demonstrated to be effective in treatment of TB, including MDR TB (65, 66). However, its cost and the frequent occurrence of side effects including neuropathy and anemia may limit its usefulness. Alternative dosing regimens may prove useful in reduction of treatment durations.

Drugs Used for Susceptibility Testing

Antimicrobial agents for susceptibility testing (reference powders) can be obtained directly from the manufacturer or from commercial sources. In the United States, most antimicrobial agents are also available from U.S. Pharmacopeial Convention, Inc., Reference Standards Order Department, 12601 Twinbrook Parkway, Rockville, MD 20852. The reference powder should be accompanied by information about its assay potency (in micrograms per milligram), expiration date, lot number, and storage condition, as well as the stability and solubility of the agent. Preparations formulated for therapeutic use in humans or animals should not be used. Unopened vials of powders should be stored as specified by the manufacturer, and opened containers should be stored in a desiccator at the recommended temperature. Stock solutions of most agents at 1,000 µg/ml or greater remain stable for at least 6 months at −20°C and for 1 year at −70 to −80°C. Directions provided by the drug manufacturer should be followed in addition to these general recommendations. Paper disks impregnated with standardized amounts of the primary and secondary anti-TB drugs are available from commercial sources for use in the disk elution modification of the proportion method. Use of these disks obviates errors in weighing and dilution, as well as errors in labeling, because the disks are coded with the drug name and concentration. This technique provides results equivalent to those obtained with solutions prepared from reference powders. Quality control (QC) testing should be performed with each new batch of antimicrobial agent.

Drug Susceptibility Testing of M. tuberculosis Complex

Drug Resistance

In the early 1960s, the WHO organized two meetings that led to the description of reliable criteria and techniques for
testing MTBC for resistance to antituberculous drugs (67, 68). The critical proportion (percentage of resistant cells associated with treatment failure) for resistance on Löwenstein-Jensen slants varied according to the drug, e.g., 1% for INH and RIF and 10% for STR, EMB, PZA, ETH, KAN, and CS. However, based on the experience of Russell and Middlebrook with 7H10 agar (69), the Centers for Disease Control and Prevention (CDC) recommended Middlebrook 7H10 agar and 1% as the critical proportion for all drugs (70).

Resistance is fundamentally a phenomenon linked to large initial bacterial populations. In pulmonary TB, the greatest populations are those prevailing in cavities, which can contain $10^7$ to $10^9$ organisms, whereas the populations found in hard caseous foci, the most common type of lesion, generally do not exceed $10^2$ to $10^7$ organisms (71). The greater frequency of resistance during treatment of cavity TB was shown as early as 1949 (72, 73). David at CDC (74) demonstrated the probability distribution of drug-resistant mutants and in a fluctuation test showed that M. tuberculosis spontaneously mutated to resistance to INH, STR, EMB, and RIF. The highest proportions of mutants observed for INH at 0.2 μg/ml, STR at 2.0 μg/ml, EMB at 5.0 μg/ml, and RIF at 1.0 μg/ml were $3.5 \times 10^{-6}$, $3.8 \times 10^{-6}$, 0.5 $\times 10^{-4}$, and $3.1 \times 10^{-4}$, respectively. Thus, the proportion of mutants resistant to INH and RIF would be in the order of $10^{-13}$. Implicit in all the studies of the genetic basis of antimicrobial resistance in M. tuberculosis is that the MDR TB phenotype is the result of accumulative mutations rather than the acquisition of an MDR transfer factor (24).

**Unique Features of TB That Affect Drug Susceptibility Testing**

According to the generally accepted theory, resistance appearing during drug treatment is due to selection and multiplication of the resistant mutants preexisting in the tubercle bacillus population of the host. Inasmuch as the susceptible bacilli are the predominant part of the population, initial killing involves a greater number of microorganisms. The consequence is a sharp fall in the population of bacilli during the initial period of treatment. The rise due to multiplication of the resistant mutants occurs later. This “fall-and-rise” phenomenon, as demonstrated in the patient's sputum, was described in the late 1940s (75, 76). In 1979, Mitchison (77) suggested the “special-populations” hypothesis to explain the action of the major antituberculous drugs against the various subpopulations of tubercle bacilli. The subpopulations include (i) rapidly growing bacilli in the pulmonary lesions; (ii) bacilli that grow in short metabolic spurts and that might be susceptible to RIF, but not INH; (iii) bacilli that reside in the acidic environment of the caseous lesions; and (iv) dormant, non-replicating bacilli. The hypothesis was developed to explain in part the basis of the early bactericidal activity and the later sterilizing activity of antituberculous agents. One of the reasons for the success of the conventional multiple-drug regimen for TB is that the different drugs each make a unique contribution in eradicating tubercle bacilli within each of these special populations. Thus, the use of multiple drugs in the treatment of TB is aimed at both preventing drug resistance and achieving a maximum therapeutic effect. The existence of subpopulations with differing metabolic status also means that conventional pharmacokinetic studies do not predict the effectiveness of treatment regimens for TB (78).

**Critical Concentrations**

The criteria for defining drug-resistant MTBC were established on an empirical basis, i.e., that there is a certain proportion of drug-resistant mutants above which therapeutic success is less likely to be realized. The procedures used to perform drug susceptibility tests and the criteria for interpreting the results take into account two factors: (i) the critical proportion of drug-resistant mutants and (ii) the critical concentration of the drug in the test medium. On the basis of clinical and bacteriologic studies, the significant proportion of bacilli resistant to an antituberculous drug above which a clinical response is unlikely was generally set at 1%. The critical concentration of a drug is the concentration that inhibits the growth of most cells within the population of a wild-type strain of tubercle bacilli without appreciably affecting the growth of the resistant mutant cells that might be present. In other words, if the proportion of tubercle bacilli that are resistant to the critical concentration of a drug exceeds 1%, it is unlikely that the use of that drug will lead to a therapeutic success. It should be noted that this concentration may not have a direct relationship to the peak level of the drug in serum. The critical concentrations of antituberculous drugs, in different media, are given in Table 3 (11, 79–83).

**Low versus High Drug Concentrations**

On occasion, the agar proportion method or commercial broth systems may indicate that an isolate of MTBC is resistant to INH or EMB at the critical concentration of the drug (Table 3). When this occurs, reflexively testing the higher concentration is recommended, although there is not uniform consensus regarding the clinical relevance of the results of testing at a higher concentration when two concentrations are used (11).

For INH, low-level resistance may be suggestive of resistance to ETH (18). Additionally, when an isolate is resistant to the low INH concentration but susceptible to the high concentration, therapeutic effect may be achieved with an adjustment in INH dosage. The CLSI recommends that the following comment be appended to the results (11):

> These test results indicate low-level resistance to INH. A specialist in the treatment of drug-resistant tuberculosis should be consulted concerning the appropriate therapeutic regimen and dosages.

**Service Referral**

While the rate of occurrence of TB is decreasing in the United States and some other industrialized countries, drug-resistant TB is increasing in countries that are sources for immigration. Mycobacteriology laboratories may experience reduced numbers of patient cultures or specimens requiring DST at the same time that new rapid molecular technologies are becoming available. These changing conditions may warrant a reexamination of which laboratories should be performing DST. Laboratories that are unable to maintain expertise or cost-effectiveness due to low volumes of testing and laboratories that are unable to take advantage of new, more rapid technologies should consider referring specimens or cultures to reference laboratories. The time lost due to referring cultures to a reference laboratory may be more than offset by the use of rapid techniques in the reference laboratory.

**When To Perform Drug Susceptibility Tests**

The CDC and CLSI guidelines recommend that the first isolate of MTBC obtained from each patient be tested for

- Where more than one concentration for an agent is listed, the lower concentration is the “critical concentration.”
- The concentrations shown are from reference 11.
- About 30% of RIF-resistant isolates are rifabutin susceptible.
- INH and EMB may first be tested at the critical concentration. When INH or EMB has tested resistant at the critical concentration, the higher concentration of the drugs may be tested with other second-line agents.
- NR, not recommended.

susceptibility to the primary drugs (11, 84). This ensures the most effective treatment for a patient and contributes to the surveillance database for TB control. Susceptibility testing should be repeated if cultures fail to convert to negative after 3 months of therapy or if there is clinical evidence of failure to respond to therapy. If a laboratory is unable to provide this service, then isolates should be referred to another laboratory for timely testing.

Second-line DST should be performed when resistance to RIF or any two first-line drugs is detected. In addition, when an isolate exhibits monoresistance to the critical concentration of INH, it should also be tested for susceptibility to secondary agents if the clinician is planning to include a fluoroquinolone in the treatment regimen (11).

When To Report Drug Resistance

Drug susceptibility results should be reported as soon as possible. When drug resistance is detected and it is verified that the resistance is not due to contamination or mixing with NTM, the attending physician should be notified as soon as possible in addition to sending a written report. If repeat testing is required to confirm the drug resistance, a preliminary report indicating that drug resistance has been detected and retesting is in progress should be issued as soon as possible, and the physician should also be notified. Once the initial resistance has been confirmed, a final report should be issued. When delay in DST is anticipated due to culture impurity, a preliminary report indicating so should be issued.

Methods of Drug Susceptibility Testing of M. tuberculosis Complex

The methods generally accepted for determining the antimicrobial susceptibility of MTBC are based on the growth of the microorganisms on solid or in liquid medium containing a specified concentration of a single drug. Four culture-based methods have been described: the agar proportion method, the modified proportion method using commercial broth systems, the absolute-concentration method, and the resistance ratio method (85, 86). Only the agar proportion and the commercial broth methods are discussed further in this chapter; the last two are described elsewhere (86). There are two FDA-cleared, automated, and nonradiometric broth systems: the MGIT 960 system (Becton Dickinson) (87, 88) and the VersaTREK Mycobacteria Detection and Susceptibility Testing (Thermo Scientific). VersaTREK also developed a microtiter plate MIC method. Based on the CLSI guidelines (11), a rapid broth susceptibility testing method should be used in conjunction with rapid methods of primary culture and identification to provide drug susceptibility results within 28 days of receipt of the specimens in the laboratory (84). Before implementing any such rapid broth system, one should validate the system by using a standardized reference method.

Agar Proportion Method

The agar proportion method for DST of MTBC was developed in the early 1960s by G. Canetti (67, 68). The method was subsequently modified and standardized and has been considered the standard method of susceptibility testing of MTBC to all drugs except PZA in the United States and many European countries for years. The agar proportion method is not suitable for testing PZA, because the medium often fails to support growth of TB bacilli when prepared at the required pH of 5.5 (79). The preferred medium for agar proportion is Middlebrook 7H10 agar. Drugs can be either prepared from reference powders (agar diffusion) or added as drug-impregnated discs (disc elution) (79).

Media

In an effort to provide uniformity in the DST of MTBC by the agar proportion method, Middlebrook 7H10 agar
supplemented with oleic-acid-albumin-dextrose-catalase (OADC) is the recommended standard medium (11, 79). Most isolates of M. tuberculosis grow on this medium, and under a dissection microscope, the transparency of 7H10 agar facilitates the recognition of mixed mycobacterial species or the presence of contaminants. Occasionally, the drug susceptibility test may be invalid due to insufficient growth of drug-resistant strains of MTBC on 7H10 medium. To test those isolates, 7H11 medium may be substituted for 7H10, and higher concentrations of some drugs should be used, as shown in Table 3 (89). QC of the medium, especially the OADC supplement, is critical.

**Inoculum and Incubation**

The source of the inoculum for a susceptibility test by agar proportion may be growth from a primary culture or a subculture of a solid medium or broth (indirect method) or a smear of the clinical specimen. A typical dilution scheme according to the number of organisms observed in the stained smear. To ensure adequate but not excessive growth until sufficient growth is obtained. Positive broth cultures should be used or the isolate should be subcultured in broth containing quadrant by the colony count on the control quadrant. When the percent resistance is greater than 1%, the isolate is considered resistant to the drug.

**Reading and Interpreting Results**

The criterion for resistance in MTBC is based on the fact that when the proportion of resistant mutants to a drug exceeds 1%, the drug does not have adequate therapeutic efficacy (68). In the proportion method, the percent resistance is obtained by dividing the colony count on the drug-containing quadrant by the colony count on the control quadrant. When the percent resistance is greater than 1%, the isolate is considered resistant to the drug.

For a valid test, the control quadrant of the lower dilution should have at least 50 colonies. If there are fewer than 50 colonies on the control quadrant of the lower dilution (10⁻² or 10⁻¹) by 3 weeks, this indicates insufficient growth, and the test is invalid and should be repeated. The total incubation period is 3 weeks; however, if mature colonies appear in the lower quadrant in less than 3 weeks, resistant results can be reported. Susceptible results should not be reported until week 3. If cultures are incubated beyond 3 weeks, false resistance may result due to degradation of the antimicrobial compound.

**Colonial morphology and pigmentation should be carefully examined grossly and microscopically for compatibility with MTBC and the absence of NTM or other organisms. This is especially critical when the susceptibility test is performed by the direct method. Small colonies of rapid growers, as well as the rough, dry colonies of some MAC strains, may appear similar to MTBC colonies on 7H10 agar. Also, rapidly growing mycobacteria may be slow to grow on primary isolation media, and they will appear as MDR TB when tested against primary antituberculous agents. Susceptibility testing results by the direct method**

* Dilutions of a concentrated specimen are prepared based on the number of bacilli observed in the initial acid-fast smear. Sterile distilled water is used to prepare the dilutions; the carbol fuchsin stain is examined with the oil immersion objective (1,000×), and the fluorochrome stain is examined with the high-dry objective (450×). If the patient is receiving therapy, not all bacilli observed in the smear may be viable; therefore, the undiluted specimen should be tested as well as the appropriate dilution based on the microscopic criteria given in this table.

* From reference 79.
must never be reported without a preliminary identification of the organism.

Microcolonies may be observed when using the agar proportion method, especially when testing EMB. Several possibilities may account for the presence of microcolonies: growth of susceptible organisms in the presence of degraded drug, true resistance, or partial resistance. One study reported that most strains that had microcolonies in the EMB quadrant had EMB-susceptible results when tested with the BACTEC 460 method (90). The significance of microcolonies is unknown, and each laboratory should determine how to best report these findings, based on its own in-house experience. With advances in molecular technologies, testing for the presence of drug-resistance-associated mutations may help differentiate true resistance from growth of susceptible organisms due to degraded drugs.

Quality Control
A reference strain of *Mycobacterium tuberculosis*, H37Rv (ATCC 27294), which is susceptible to all primary and secondary antituberculous drugs, is recommended for QC. Strains of *M. tuberculosis* that are resistant to INH, RIF, and/or other drugs are available from the American Type Culture Collection; however, these strains are resistant to high concentrations of the respective drugs and are not ideal for QC testing. Ideally, a strain of MTBC that shows resistance at or near the cutoff values of a particular drug should be used for QC. A number of strains used in the CDC's Model Performance Evaluation Program offer these characteristics. Also, for safety considerations, it is not advisable to use a single MTBC strain that is resistant to more than two drugs. Aliquots of suspensions of QC strains of *M. tuberculosis*, adjusted to match a 1.0 McFarland standard in 7H9 broth, can be stored at −70°C for up to 6 months. QC testing of all agar components should be performed with each new batch of medium or antimicrobial agent, and media should be checked for sterility and shown to support adequate growth.

The MGIT 960 System for Drug Susceptibility Testing
In 1995, the MGIT was introduced for the growth and detection of mycobacteria from clinical specimens. Each MGIT tube contains modified Middlebrook 7H9 broth, and in the bottom is a fluorescence-quenching-based oxygen sensor (silicon rubber impregnated with ruthenium pentahydrate). When actively growing organisms utilize the dissolved oxygen, the reduced oxygen concentration enables the generation of fluorescence, which is then measured and expressed as growth units (GU). The MGIT 960 system is a fully automated system that continuously monitors the growth of microorganisms hourly through fluorescence detection. The system uses a nonradiometric medium and does not require the use of needles for addition of growth supplement or inoculation of organisms. In 2002, the system was approved by the FDA for susceptibility testing of MTBC to STR, INH, RIF, and EMB (SIRE) and PZA. Several studies showed that the performance of the MGIT 960 system for testing primary drugs is equivalent to that of the radiometric BACTEC 460 system (no longer commercially available) and the agar proportion method and that the time to results is comparable to that for the BACTEC 460 (87, 91–95).

The MGIT SIRE drug kit containing lyophilized INH, RIF, EMB, and STR and the SIRE supplement is specifically designed for testing susceptibility to these four drugs with the MGIT 960 system. The MGIT 960 employs a two-tier test protocol; SIRE drugs and PZA are tested separately. STR is a secondary agent and not necessary to test. PZA is discussed later. The first-tier drugs and their concentrations are as follows: STR, 1.0 μg/ml; INH, 0.1 μg/ml; RIF, 1.0 μg/ml; and EMB, 5.0 μg/ml. If resistance to INH or STR is detected at the first-tier DST, the laboratory may choose to test INH at 0.4 μg/ml and STR at 4 μg/ml in addition to the initial concentrations. MGIT 960 is not FDA approved for testing second-line agents, but several studies validated the use of MGIT 960 for testing the susceptibility of MTBC, including multidrug-resistant strains, to several secondary agents (81–83, 92, 96).

Inoculum and Incubation
The inoculum for DST may be prepared from either liquid or solid media. To ensure accuracy and reproducibility of results, strict adherence to the guidelines of the manufacturer is imperative. An MGIT DST set contains a growth control tube (without drugs) and drug-containing tubes. The preinoculation preparation includes the addition of 0.8 ml of the SIRE supplement to each MGIT tube in the set and 0.1 ml of a drug solution to the tube designated for that specific drug.

A positive MGIT tube can be used as a source of inoculum. According to the manufacturer's package insert, the MGIT tube, after being detected positive by MGIT 960, needs to incubate for an additional 1 to 2 days, and DST should be set up within 1 to 2 days of incubation. The MGIT tube must be mixed well and used to inoculate the drug-containing MGIT tubes. The inoculum for the growth control is a 1:100 dilution of the inoculum used for the drug-containing MGIT. The volume of the inoculum is 0.5 ml. If DST cannot be set up within 1 to 2 days of incubation after being positive, it can be tested with a 1:5 dilution of the MGIT tube following 3 to 5 days of incubation after being positive. After 5 days, the growth in the MGIT tube is too heavy for DST. A new MGIT tube must be seeded and incubated; the seeded MGIT tube can be tested following the manufacturer's time schedule described above. The proper inoculum for seeding is 0.5 ml of a 1:100 cell suspension equivalent to 0.5 McFarland standard. If the growth of the seeded MGIT tube is detected in <4 days, the growth is too heavy or the culture is not pure.

Growth from a solid medium can also be used as a source of inoculum. The isolate must not be older than 14 days after the first appearance of colonies on the medium. To ensure obtaining diverse populations, growth should be taken from different parts of the medium. The suspension is adjusted to a 0.5 McFarland standard and then diluted 1:5 with sterile normal saline before inoculation into the drug-containing MGIT tubes. The inoculum for the growth control is a 1:100 dilution of the inoculum used for the drug-containing tube.

After inoculation, the MGIT DST set must be registered in the MGIT 960 system with a proper drug panel. It is important to select a panel that matches the DST set being inoculated. The growth in each MGIT tube is automatically monitored hourly by the MGIT 960 system.

Reading and Interpreting Results
When the GU of the growth control reaches 400 within 4 to 13 days, the MGIT 960 system flags the completion of the drug susceptibility test and interprets the DST results based on the following rules. An isolate is called resistant to a drug when the GU of the drug-containing MGIT tube is greater than 100, and it is called susceptible when the
GU of the drug-containing MGIT tube is equal to or less than 100. The test is invalid if the GU of the growth control reaches 400 in less than 4 days, indicating that the growth is too fast (the inoculum is either too heavy or contains contaminants), or in more than 13 days, indicating that the growth is too light.

When the drug susceptibility test is completed, the MGIT 960 system allows the user to print the DST report. It is important to verify the drug order of the MGIT tubes against the drug order on the report, especially when the report contains resistant results. It is pivotal to verify any resistant result by excluding apparent resistance due to the presence of NTM or other bacteria before a preliminary report is issued. The following steps are helpful for verification of resistant results. First, examine the turbidity of the MGIT tube with a resistant result. MTBC usually grows as small clumps and settles at the bottom of the tube, and the broth usually remains clear. Without disturbing the MGIT tubes, if the broth appears turbid, the presence of NTM or other bacteria may be suspected. Second, make a smear from an MGIT tube and perform acid-fast staining to confirm that the observed morphology is compatible with that of MTBC and without presence of NTM or other bacteria. MTBC usually appears as cording or tight clumps. Although antituberculous agents may alter the typical cording morphology, a dispersed distribution of acid-fast bacilli or random loose clumps throughout the entire smear suggests the presence of NTM. When, on rare occasions, differentiating MTBC from NTM is difficult, it is advisable to make a subculture from the MGIT tube showing drug resistance onto 7H10 or 7H11. Examining the microscopic colonial morphology in a few days will help to differentiate MTBC from other mycobacteria.

When any DST result obtained with the MGIT 960 system is questionable, repeat testing of the isolate by agar proportion or with MGIT 960 should be performed. If a culture contains non-acid-fast bacteria or NTM, a pure culture of MTBC must be obtained before retesting is attempted. Because resolation of MTBC may take several weeks, molecular testing for drug resistance mutations should be considered. Each laboratory should determine its own policy with regard to the necessity of retesting to confirm initial resistant results. As a good practice of quality assurance, when a laboratory first implements the MGIT 960 system or microbiologists are newly trained to use the system, reproducibility of retesting results should be documented. In addition, retesting an isolate to confirm rarely occurring resistant results such as mono-RIF resistance or mono-EMB resistance should be considered.

Quality Control
A reference strain of M. tuberculosis such as H37Rv (ATCC 27294) that is susceptible to all primary drugs should be tested with each lot of SIRE drug kit and MGIT medium received. It should also be tested with each test run or once a week if multiple test runs are performed each week (11).

PZA Testing
PZA susceptibility testing by MGIT 960 became commercially available in 2002. The MGIT PZA testing uses the same platform as previously described for the SIRE drugs. Differences are as follows. (i) The broth in the MGIT PZA tube has a reduced pH. (ii) The PZA drug kit contains PZA and PZA supplement, which is not interchangeable with the SIRE supplement. (iii) The PZA growth control is inoculated with a 1:10 dilution of the inoculum to PZA-containing MGIT tubes. The preinoculation preparation includes the addition of 0.8 ml of MGIT PZA supplement to the tubes designated for the growth control and the PZA tube, and 0.1 ml of PZA solution only to the tube designated for PZA. Inoculation preparation from positive MGIT tubes or from a solid medium is the same as that for the SIRE drugs. The interpretation criteria are also the same as those for the SIRE drugs.

The procedure for verification of the instrument-determined resistance for the SIRE drugs applies to PZA resistance as well. Since mono-PZA resistance is rare for M. tuberculosis, retesting of PZA to confirm the initial resistance and further identification to the species level (i.e., M. tuberculosis versus M. bovis) is recommended.

The reproducibility of PZA susceptibility testing appears to be inferior to that obtained with other first-line drugs (97, 98). Inoculum preparation is critical, and it appears that a reduced inoculum of 0.25 ml may reduce false-resistance results compared with the standard inoculum of 0.5 ml (99). A combination of culture-based testing and pncA sequencing may provide the most reliable and accurate prediction of PZA susceptibility or resistance (100).

VersaTREK
VersaTREK is a fully automated, continuously monitoring system for growth and detection of mycobacteria, as well as susceptibility of MTBC to all primary drugs. VersaTREK technology is based on detection of pressure changes (oxygen consumption due to microbial growth) within the headspace above the broth medium in a sealed bottle. The medium consists of a Middlebrook 7H9 broth, which has been enriched with growth supplement (glycerol and Casitone), and contains cellulose sponges as a growth support matrix that increases the surface area for exposure to oxygen.

Inoculum and Incubation
The VersaTREK Myco susceptibility kit for testing INH, RIF, and EMB and the VersaTREK Myco PZA kit for testing PZA were FDA cleared for diagnostic use. They contain lyophilized drugs and the diluent. The working drug solutions are prepared by reconstituting the drugs with 25 ml of the diluent. Preparation of the bottles for DST requires the addition of 1.0 ml of growth supplement and 0.5 ml of antibiotic working solution using a syringe. The final concentrations in the Myco bottles are as follows: 0.1 μg/ml of INH, 1.0 μg/ml of RIF, and 5.0 μg/ml of EMB. INH and EMB can be tested at higher concentrations (0.4 and 8.0 μg/ml, respectively) if testing two levels of drug concentrations is desired or indicated. The final concentration for PZA is 300 μg/ml. The inoculum can be prepared from either solid media (e.g., Löwenstein-Jensen or 7H10/7H11) or liquid media (e.g., VersaTREK Myco or 7H9). The turbidity of the cell suspension is standardized to a 1.0 McFarland standard, and a 1:10 dilution of the suspension is used for inoculating the drug-containing VersaTREK Myco bottles and the control bottle. The inoculum is 0.5 ml. The inoculated Myco bottles are kept in the instrument at 35°C, and growth is automatically monitored every 24 minutes.

Reading and Interpreting Results
DST results are manually determined. A drug susceptibility test is valid for interpretation when the time to detection of growth in the control bottle (without drugs) is within 3 to 10 days of inoculation. Drug-containing bottles are monitored for another 3 days after the control bottle has turned positive. An isolate is considered resistant to a drug if the time to detection of growth in the drug-containing bottle is less than or equal to 3 days after that for the control
bottle. An isolate is considered susceptible if no growth occurs in the drug-containing bottle or if the time to growth detection is more than 3 days after that for the control bottle. A small number of studies demonstrate good agreement among the VersaTREK Myco system, the BACTEC 460TB, MGIT 960, and the agar proportion method. Detection times are very comparable to those obtained by the BACTEC 460TB and MGIT 960 (101–103).

Quality Control
Each new lot of the VersaTREK Myco Susceptibility kit and VersaTREK Myco PZA kit, Myco bottles, and growth supplement must be tested with strains of MTBC appropriate for QC. A pansusceptible strain of MTBC should be included with each test run (11).

Alternative Drug Susceptibility Testing by Other Approaches
Since 2000, DST of mycobacteria has become a very dynamic field, spawning many new technologies that may prove successful in clinical laboratories. Some of these techniques are based on improved methods for measuring inhibition of growth, while others are based on molecular detection of mutations associated with resistance (104–112).

TREK Sensititre MYCOTB MIC Plate Method
The TREK Sensititre MYCOTB MIC plate method uses a 96-well plate format with drug dilutions prepared in microbroth for testing both first-line and second-line drugs. As of the time of this publication, it has not received FDA clearance for diagnostic use; thus, it is for research use only. Biosafety precautions should be followed strictly when setting up DST using the microtiter plate, as with other procedures handling live MTBC organisms. The Sensititre MYCOTB MIC microtiter plate contains lyophilized antibiotics including AMK (0.12 to 16 μg/ml), CS (2 to 236 μg/ml), EMB (0.5 to 32 μg/ml), ETH (0.3 to 40 μg/ml), INH (0.03 to 4 μg/ml), KAN (0.6 to 8 μg/ml), MFX (0.06 to 8 μg/ml), OFX (0.25 to 32 μg/ml), PAS (0.5 to 64 μg/ml), RIF (0.12 to 16 μg/ml), RFB (0.12 to 16 μg/ml), RIF (0.12 to 16 μg/ml), and STR (0.25 to 32 μg/ml). It tests 12 drugs on a single MIC plate, and results are available within 10 to 21 days after the test setup. The DST setup requires growth from solid media for preparation of inoculum; this requirement may cause a delay for setting up a test. In comparison with the agar proportion method, the performance of this method is considered satisfactory to excellent with the categorical agreement from 94 to 100% in one study and 80 to 99% in another study with EMB, MFX, and cycloserine at the lower end of agreement (113, 152). PZA is not included in the panel due to a requirement for acidic testing conditions; it is necessary to use another method to test PZA. CAP is also not included in the panel; unavailability of testing CAP for MDR TB may be considered a drawback. With drug resistance prevalence at 10%, it is neither necessary nor cost-effective to test second-line drug susceptibility of all isolates, 90% of which are pansusceptible. However, the system has potential advantages. The availability of MIC values may provide an explanation for isolates of poor reproducibility with the agar proportion or MGIT methods, which may be associated with strains whose drug MIC values are close to the critical concentrations. Furthermore, emerging resistance may be able to be detected sooner by the increase of MIC values during the treatment course. While the Sensititre system represents a new way of performing DST for MTBC, the objectivity and reproducibility of reading MICs, the variability of agreement with the agar proportion method for various drugs, the cost-effectiveness, and the overall usefulness of the MIC approach on regimen formulation for treating TB patients are issues to be further investigated.

Microscopic Observation Drug Susceptibility
The MODS system is a culture-based DST method. Unlike the broth culture systems mentioned above, the MODS method does not require the use of proprietary culture media purchased from a single source. Middlebrook 7H9 broth medium, supplemented with OADC and a selective antibiotic/antifungal cocktail, is used in 24-well microtiter plates (7). As described by Moore et al., 12 wells are used for each specimen, including 4 control wells with no antituberculous drug and 8 drug-containing wells including low and high concentrations of INH, RIF, EMB, and STR. MODS results are read by examining each well with an inverted microscope. Growth of MTBC is indicated by the presence of cording clumps. The method enables rapid detection of growth and provides a quick indication of susceptibility or resistance to the primary drugs. Because proprietary media are not used and ingredients can be purchased from a variety of suppliers, the method is relatively inexpensive. Safety concerns regarding the use of the 24-well microtiter plate may have been addressed by the practice of enclosing the plates in sealed plastic bags and making the microscopic observations through the bags without opening them. MTBC can be tentatively identified, especially in high-prevalence settings, by the corded or clumped appearance of nonpigmented growth after more than 5 days of incubation. However, the MODS method entails some requirements that may be difficult to achieve in limited-resource settings, including acquiring and storing labile ingredients such as OADC. In addition, it requires the sophisticated facilities and equipment, including a biological safety cabinet, high-speed centrifuge, incubator, inverted microscope, etc., and safety practices of a biosafety level 3 laboratory.

Colorimetric Redox (Reduction/Oxidation) DST Methods
These methods using redox indicators for detection of growth may be performed using liquid or solid media. Use in liquid culture will usually provide the best time to result, comparable to that of the BACTEC MGIT 960 system (or the manual MGIT DST method). A colorimetric redox method may be a good alternative for first- and second-line DSTs in resource-poor settings that do not have the BACTEC MGIT 960 system or do not use the manual MGIT DST method. The media and reagents are nonproprietary, which may decrease costs (114–116).

Molecular Drug Susceptibility Testing Methods
Mutations in genes associated with resistance to antimycobacterial agents (Table 2) can be detected by a variety of methods. Real-time PCR coupled to fluorescence detection by molecular beacons or other probes has been used for detecting INH resistance in MTBC (107, 117). Various molecular methods, including pyrosequencing (118), Sanger sequencing, and next-generation sequencing, have also been developed for detecting resistance to INH, RIF, EMB, PZA, quinolones, and injectable drugs (32, 38, 107, 108, 110, 112, 119–127).

Commercial molecular testing products and well-validated laboratory-developed assays have made their way into many clinical and public health laboratories. Indeed, the use of those rapid molecular methods for detection of INH and RIF resistance has shortened the time to diagnosis of
MDR TB and enables patients with MDR TB to be started on appropriate therapy 40 to 50 days earlier than those who were diagnosed by conventional culture (128, 129).

Molecular tests may similarly become widely used for detection of second-line drug resistance and XDR TB. Examples are the MDRR service provided by CDC (http://www.cdc.gov/tb/topic/Laboratory/guide.htm) (120), laboratory-developed pyrosequencing assays (110, 121, 123), and Hain MTBDRs assays (106, 130, 131). Rapid identification of patients with XDR TB has been realized, although follow-up culture is recommended to achieve optimal accuracy and sensitivity. Use of a molecular technique allows XDR TB patients to be detected sooner and enables effective treatment to be initiated in a timely fashion to save lives, including those of patients who are immunocompromised.

Molecular methods can be divided into two major categories, which are probe-based methods and sequence-based methods. Cepheid’s GeneXpert MTB/RIF assay uses molecular beacon probes, and Hain’s MTBDRplus and MTBDRs assays using line probes are examples of probe-based methods. Sanger sequencing and pyrosequencing are examples of sequence-based methods. Probe-based methods detect the presence or absence of mutations, while sequence-based methods provide sequences of either wild-type organisms or mutants. Since mutations are not always associated with drug resistance (132), when a mutation is detected by probe-based methods without providing the identity of the mutation, confirmation by a sequence-based method is recommended (153). Revealing the identity of a mutation allows discerning the association of the mutation with drug resistance.

The GeneXpert MTB/RIF assay uses microfluidics with five molecular beacons in a simple-to-operate enclosed system for detection of MTBC and RIF resistance (133). It is FDA cleared for testing smear-positive and smear-negative sputa for diagnostic use. Detection of MTBC is established when there are at least two probes yielding valid positive signals, and detection of RIF resistance is determined when the absence of a mutation (or mutations) in the 81-bp RIF resistance-determining region of the rpoB gene is detected. When RIF resistance is detected, it should be confirmed by a sequencing-based method to prevent a false detection.

The Hain probe assays use reverse hybridization technology to detect mutations. These assays have not received FDA clearance for diagnostic use in the United States, but they have been widely used in many countries. Both MTBDRplus and MTBDRsl assays contain wild-type probes and several frequently encountered mutant probes. When a wild-type band is missing, it indicates the presence of a mutation. If at the same time, a mutant band is present, this informs the user of a specific mutation present in the specimen. Absence of a wild-type band without the presence of a mutant band indicates the presence of a mutation, but the mutation identity is not provided by the assay.

In contrast to probe-based methods, sequence-based methods not only detect the presence or absence of mutations but also provide sequence information. With the availability of sequence information and the knowledge of the association of a mutation with drug resistance or susceptibility, the user would be able to interpret the molecular result properly and prevent reporting false resistance for mutations that do not confer drug resistance. This is particularly important in regions with low prevalence of drug resistance, where the positive predictive value of detecting a mutation conferring resistance is likely to be low.

Furthermore, because the knowledge of mutations that contribute to drug resistance in MTBC is incomplete, molecular methods will likely not detect all drug resistance. For this reason, follow-up culture-based DST should be considered whenever resources permit. With this algorithm, the molecular testing is added to existing methods and increases the cost of TB laboratory work. Molecular detection of drug resistance may therefore be limited to cases in which drug resistance is suspected or a susceptible population has been exposed. It is also worth remembering that rapid detection of patients with drug-resistant disease can lead to improved patient therapy and reduced infectious periods (128). These can lead to cost savings.

NONTUBERCULOUS MYCOBACTERIA

Broth microdilution is the method recommended by the CLSI for susceptibility testing of NTM. The CLSI provides guidelines for testing MAC, M. kansasii, M. marinum, and the rapidly growing mycobacteria (11). These few mycobacteria, which are discussed in the following sections, were selected because sufficient data on which to base recommendations exist. For other slowly growing, nonfastidious NTM, CLSI suggests using the same method and drugs as those recommended for M. kansasii. However, there is little, if any, meaningful information concerning the correlation between susceptibility test results and clinical outcome. Therefore, clinicians who request that susceptibility testing be performed on NTM other than those listed above should be aware of the limitations of such testing and interpret results with caution.

Susceptibility testing of NTM should be performed only on clinically significant isolates, such as those from blood, other sterile body fluids, or tissues. Determining the clinical significance of isolates from the respiratory specimens, however, may be problematic. Because several NTM are found in the environment and may colonize the respiratory tract, their recovery from sputum, for example, does not necessarily indicate clinical disease. The American Thoracic Society (ATS) recommends the following microbiologic criteria as an aid for diagnosing NTM lung disease (9): (i) positive culture results from at least two separate expectorated sputum samples (a minimum of three sputum specimens should be collected for mycobacterial culture), or (ii) positive culture result from at least one bronchial wash or lavage specimen, or (iii) transbronchial or other lung biopsy specimen with histopathologic features consistent with a mycobacterial infection (granulomas or chronic inflammation with stain positive for acid-fast bacilli) and positive culture for NTM. One culture-positive, smear-negative sputum specimen is not likely to be clinically significant.

General recommendations regarding the broth microdilution method and QC that apply to all NTM are discussed in the following paragraphs. Specific details related to MAC, M. kansasii, M. marinum, and the rapidly growing mycobacteria are discussed in individual sections.

Test Method

The inoculum suspension may be prepared by sweeping the confluent portion of growth on a solid medium with a sterile cotton swab or directly from a broth culture. If colonies are used, growth on the swab is transferred to 4.5 ml of sterile water containing glass beads (e.g., 7 to 10 3-mm beads) until the turbidity matches the turbidity of a 0.5 McFarland standard by visual examination or by using a nephelometer. The suspension is mixed vigorously on a vortex mixer for 15 to 20 seconds and then allowed to sit so any remaining large clumps can settle; the supernatant is then used for the inoculum suspension.
If freeze-dried microtiter plates are used without the broth already added, the final inoculum (with an organism density of approximately $5 \times 10^4$ CFU/ml) is prepared by transferring 50 μl of the suspension to 10 ml of cation-adjusted Mueller-Hinton broth for rapidly growing mycobacteria or 10 ml of cation-adjusted Mueller-Hinton broth plus 5% OADC for slowly growing NTM. Tubes are inverted 8 to 10 times to mix the suspension thoroughly. Alternatively, if using prepared plates that contain antimicrobials in 100 μl of broth, it is necessary to calculate the volume of standardized suspension to be added to 36 ml of water diluent to obtain a final organism concentration of $1 \times 10^5$ to $5 \times 10^5$ CFU/ml ($1 \times 10^4$ to $5 \times 10^4$ CFU per well in a 0.1-ml volume). The volume depends on the delivery system that is being used.

Final inoculum suspensions are mixed well (by inverting the tube several times or vortexing) and poured into plastic troughs, after which 100 μl is transferred to each well of the microdilution tray. Each inoculated tray is covered with an adhesive seal and incubated in ambient air. Simultaneously inoculating a nutrient agar plate, such as 5% sheep blood or Trypticase soy agar, with a loopful of the final inoculum to check for purity is recommended. Incubation temperature and time are discussed for each species or group in the following sections.

**Quality Control**

QC testing should be performed on each new batch of test plates and once each week or each time testing is performed, if done less often than weekly (11). Strains recommended for MAC, M. kansasii, and the rapidly growing mycobacteria are listed in the sections in which these mycobacteria are discussed. Currently, interlaboratory proficiency testing available for testing NTM is limited. Therefore, laboratories are encouraged to submit isolates to reference laboratories with extensive experience in testing these mycobacteria for confirmatory tests in lieu of a formal proficiency test program.

**M. AVIUM COMPLEX**

MAC is among the most frequently encountered Mycobacterium species in many clinical laboratories. Isolation of MAC from blood is especially important in HIV-infected patients. Although the incidence of disseminated MAC in HIV-infected patients has dramatically decreased due to effective prophylaxis and the immune system restoration associated with highly active antiretroviral therapy, it still occurs in patients who develop resistance to antiretroviral treatment or who exhibit drug intolerance or poor compliance. In many of these patients, recovery of MAC represents a relapse of MAC disease rather than a new infection. MAC is also an important cause of chronic pulmonary lung disease (9, 10) and in the United States is the leading cause of lung disease due to an NTM (134). Patients with MAC lung disease generally may be placed in one of the following groups: those who have underlying lung disease with apical fibrocavitary lesions, postmenopausal women with bronchiectasis and nodular opacities, or patients with cystic fibrosis.

**Antimicrobial Agents**

Correlation between in vitro MAC susceptibility test results and clinical response has been demonstrated in a controlled clinical trial only with the macrolides clarithromycin and azithromycin (135). Because the mechanism of acquiring mutational resistance in isolates of MAC is the same for clarithromycin and azithromycin and because there are technical difficulties associated with testing azithromycin, current CLSI guidelines (document M24-A2) state that clarithromycin is the only primary drug to which susceptibility of MAC isolates should be evaluated (11). However, recent data have shown that AMK, either intravenous or inhaled (for pulmonary disease), also is useful clinically, supporting initial testing of AMK as well as clarithromycin (136).

Wild-type (untreated) MAC isolates typically have clarithromycin MICs of ≤8 μg/ml and are considered susceptible to macrolides. MAC isolates from patients who have relapsed after treatment, on the other hand, have clarithromycin MIC values of ≥32 μg/ml and no longer respond clinically to macrolide therapy. Virtually all such isolates have a mutation in the adenine at position 2058 or 2059 of the 23S rRNA gene, the presumed macrolide binding site on the ribosomal unit (52, 53).

Clarithromycin and azithromycin are approved by the FDA for the treatment of MAC disease, but because resistance develops quickly with macrolide monotherapy, single-drug therapy with either agent is contraindicated. A common regimen for MAC disease is shown in Table 1 (9). Very importantly, although EMB, RIF, RFB, and STR are useful clinically and broth dilution susceptibility testing of MAC to these agents may be performed, the results may not reliably predict clinical outcome. Because of the lack of data establishing a correlation between MIC values and clinical response, breakpoints separating susceptible from resistant strains have not been determined. Therefore, it is strongly recommended that susceptibility results for the above antituberculosis drugs not be reported for MAC. AMK, either intravenous or inhaled (for pulmonary disease), also is useful clinically, and Brown-Elliott and colleagues have suggested AMK breakpoints (shown in Table 5), based on data from 462 isolates (136). Most MAC isolates are intrinsically resistant to INH and PZA; these antimicrobial agents play no role in the treatment of MAC infection and should not be tested.

Treatment of macrolide-resistant MAC infections is problematic, and the role of susceptibility testing in guiding therapy for these patients is not clearly defined. Although data are limited, some experts believe that moxifloxacin and linezolid, which CLSI lists as secondary agents, may be clinically useful in select patients (9).

**Indications for Susceptibility Testing**

The ATS recommends that clarithromycin susceptibility testing be performed on all new, previously untreated clini-

cally significant MAC isolates and on MAC isolates from patients who relapse while on macrolide therapy or prophylaxis (9). Susceptibility testing should be repeated after 3 months for patients with disseminated disease and after 6 months for patients with chronic pulmonary disease if the patient does not improve clinically and remains culture positive.

Test Methods
As mentioned above, broth microdilution is recommended for susceptibility testing of all NTM. Aspergillus-based methods should not be used. The CLSI currently recommends cation-adjusted Mueller-Hinton broth with 5% OADC or OAD (pH 7.2 to 7.4) for broth microdilution testing, although some isolates grow poorly in this medium.

As previously mentioned, when broth microdilution is performed, the inoculum may be prepared directly from an agar plate or a broth culture and should be approximately $5 \times 10^5$ CFU/mL. Although it often is not practical, only transparent colony types should be tested, if possible, because this variant generally is more virulent and more resistant to antimicrobial agents than the opaque variant. Tween 80 or other surfactants should not be used to disperse clumps of bacilli because of the potential synergistic effect of the surfactant activity of Tween 80 and antimicrobial agents.

Incubation is at 35 to 37°C in ambient air. Trays are first examined at 7 days. If growth is insufficient, trays are reincubated and read again at days 10 to 14 of incubation. The endpoint for broth microdilution assay is visible turbidity.

Reporting Results
Both the MIC value and an interpretation should be reported (Table 5) (11). Because untreated wild-type strains of MAC rarely, if ever, are intermediate or resistant to clarithromycin, the CLSI subcommittee recommends that laboratories confirm such results by repeat testing (11). A confirmed intermediate result may indicate emerging resistance; therefore, patients with such an isolate should be carefully monitored, and susceptibility testing should be performed on subsequent MAC isolates. Based on data from a recent study, Brown-Elliott et al. (136) recommend testing MAC isolates against AMK in addition to clarithromycin; suggested breakpoints are shown in Table 5. Reporting secondary agents (i.e., moxifloxacin and linezolid) should be restricted to situations in which the clinician has extensive experience in the use of these drugs in the treatment of MAC disease or for research purposes.

Quality Control
M. avium ATCC 700898 is recommended for QC when testing clarithromycin and AMK. The range of acceptable results for clarithromycin is 0.5 to 2 μg/mL at pH 7.3 to 7.4 and 4 to 16 μg/mL for AMK (136). M. marinum ATCC 927 is an acceptable alternative QC organism for clarithromycin; the acceptable range is 0.25 to 1 μg/mL. When secondary drugs are tested, acceptable ranges for moxifloxacin and linezolid for M. avium ATCC 700898 are 0.25 to 2.0 μg/mL and 4 to 16 μg/mL, respectively. When testing M. marinum ATCC 927, acceptable ranges are 1 to 4 μg/mL for both drugs. Another option for QC of moxifloxacin or AMK is Pseudomonas aeruginosa ATCC 27853 (acceptable ranges can be found in the most recent CLSI M100 document (137)).

M. KANSASII
M. kansasii is the second most common cause of pulmonary disease due to NTM in the United States (9), second only to MAC. The therapeutic regimen currently recommended by the ATS for treatment of M. kansasii pulmonary disease consists of RIF, INH, and EMB (9), of which RIF is the component critical for treatment success. An alternative regimen that also is effective includes RIF, EMB, and clarithromycin (138). In patients with HIV infection receiving protease inhibitors, RFB is in place of RIF (9). Isolates of M. kansasii from previously untreated patients are predictably susceptible to RIF. However, resistance to RIF can develop during therapy, and a patient’s history of RIF therapy may be unknown or unclear. Therefore, CLSI recommends that all initial isolates of M. kansasii be tested for susceptibility to RIF only or, if short-course or intermittent therapy with RIF, EMB, and clarithromycin is planned, to both RIF and clarithromycin (11). Susceptibility testing should be repeated if cultures remain positive after 3 months of appropriate therapy.

Untreated wild-type strains of M. kansasii are susceptible to the critical concentrations of RIF and EMB used to test M. tuberculosis (discussed earlier in the chapter) but are resistant to the critical concentration of INH (0.2 μg/mL by agar proportion) and show variable susceptibility to the higher concentration (1.0 μg/mL). Although INH is used empirically, there currently are no laboratory or clinical data to support its use or nonuse. Therefore, routine susceptibility testing of M. kansasii to INH is not recommended and should be discouraged.

Susceptibility testing is done by broth microdilution using cation-adjusted Mueller-Hinton broth with 5% OADC or OAD and incubating at 35 to 37°C for 7 to 14 days in CO₂ or ambient air, although CO₂ should be avoided when testing macrolides. Acceptable QC strains and expected MIC results for RIF are as follows: M. kansasii ATCC 12478, ≤1 μg/mL; M. marinum ATCC 927, ≤0.25 to 1 μg/mL; and Enterococcus faecalis ATCC 29212, 0.5 to 4 μg/mL.

Isolates of M. kansasii that are resistant to RIF (MIC ≥1 μg/mL) should be tested for susceptibility to the following drugs: RFB, EMB, STR, INH (only if a provider insists), clarithromycin (unless initially tested as a primary drug), AMK, ciprofloxacin (as the class representative for the older fluoroquinolones, which are less active in vitro than moxifloxacin), trimethoprim-sulfamethoxazole, linezolid, and moxifloxacin. MIC values for resistance to these agents are shown in Table 6 (11). Although INH and STR may be useful clinically, breakpoints to establish susceptibility and resistance for NTM have not been established; therefore, only the MIC (with no interpretation) should be reported for these drugs.

M. MARINUM
M. marinum causes chronic granulomatous lesions of the skin and soft tissues (called “swimming pool granuloma” or “fish tank granuloma”) and occasionally bone. Routine susceptibility testing of M. marinum is not recommended and should be discouraged. Isolates are consistently susceptible to several clinically useful antimicrobial agents, including RIF, EMB, doxycycline (or minocycline), trimethoprim-sulfamethoxazole, and clarithromycin (11). Additionally, the risk of acquired mutational resistance to one or more of these agents is extremely low. Successful treatment may require surgical excision or debridement as well as antimicrobial
therapy. However, if a patient fails to respond clinically after several months of appropriate therapy and remains culture positive, susceptibility testing of *M. marinum* should be considered. As for MAC and *M. kansasii*, broth microdilution using cation-adjusted Mueller-Hinton broth supplemented with OADC or OAD is recommended. Incubation is at 28 to 30°C for 7 days. The drugs suggested by CLSI to test and the MIC values (in μg/ml) indicating resistance are as follows: Rif (>2), clarithromycin (>16, the class agent for newer macrolides), AMK (>32), doxycycline or minocycline (>4), ciprofloxacin (>2), moxifloxacin (>2), and trimethoprim-sulfamethoxazole (>2/38).^{4}

^a^Table and footnotes are adapted from reference 11.

^b^Ciprofloxacin and levofloxacin are interchangeable, but both are less active in vitro than moxifloxacin.

Clarithromycin is considered a primary drug in patients with *M. kansasii* infection receiving the short-course and/or intermittent therapeutic regimens consisting of rifampin, ethambutol, and clarithromycin. For patients with *M. kansasii* infection receiving the classic regimen of rifampin, ethambutol, and isoniazid, clarithromycin is a secondary agent. Clarithromycin is the class representative for the "newer" macrolides (clarithromycin, azithromycin, roxithromycin).

Breakpoints to establish susceptibility and resistance for NTM have not been established. Testing susceptibility of *M. kansasii* to isoniazid should be discouraged because in vitro results do not correlate with clinical outcome. If testing is performed at the provider's insistence, report the MIC value only, with no interpretation.

**OTHER SLOWLY GROWING NTM**

Many other slowly growing NTM may cause human disease, and susceptibility testing of these species may be requested. Although data are limited, CLSI suggests broth dilution using cation-adjusted Mueller-Hinton broth with OADC for nonfastidious species (11). The same primary and secondary agents listed for *M. kansasii* should be tested and reported with the same interpretive criteria (31). In general, testing *M. gordonae* is inappropriate because isolates almost always represent contaminants and only rarely are the cause of actual disease. For fastidious species, such as *Mycobacterium haemophilum*, susceptibility testing has been performed (139); however, there is insufficient information to recommend a standard method of testing.

**RAPIDLY GROWING MYCOBACTERIA**

Over 30 species of rapidly growing mycobacteria have been identified, but most human disease is due to *M. abscessus* subsp. *abscessus*, *M. chelonae*, and *M. fortuitum* group, which are important causes of skin and soft tissue infections, especially following penetrating trauma with possible soil or water contamination (140). CLSI recommendations for susceptibility testing of rapidly growing mycobacteria are based predominantly on results of studies involving these three species/groups, but they apply to other clinically significant rapid growers as well. For some drugs (e.g., clarithromycin, imipenem, and tobramycin), susceptibility test results apply to certain species or groups of rapidly growing mycobacteria; therefore, identification of isolates to the species level is important. If cultures (from any site except respiratory) are positive after 6 months of appropriate antimicrobial therapy, susceptibility testing should be repeated, and the species identity should be confirmed.

**Test Method**

As for all NTM, broth microdilution is recommended for susceptibility testing of the rapidly growing mycobacteria (11, 141). Antimicrobial agents that should be tested are AMK, cefoxitin (up to 256 μg/ml), ciprofloxacin, clarithromycin, doxycycline (or minocycline), imipenem, linezolid, moxifloxacin, trimethoprim-sulfamethoxazole, and tobramycin. Tobramycin is used predominantly for treatment of *M. chelonae* infections and should not be used to treat infections due to other rapid growers, because MIC values generally are in the resistant range.

The inoculum is prepared as described above, and trays are incubated at 28 to 30°C in air and examined at 72 h. If growth in the growth control well is sufficient (at least 2+ or definite turbidity and "clumpy" growth [11]) at that time, the MIC can be recorded. If not, trays are reincubated and read again on days 4 and, if needed, 5. Day 5 is the final reading for all drugs except clarithromycin, which should be read at 7 to 10 days and, if the isolate is susceptible at that reading, again at 14 days (11). The final day 14 reading is recommended to ensure detection of inducible macrolide resistance; however, if clarithromycin resistance (MIC, ≥8 μg/ml) is recognized at an earlier reading, the result can be finalized at that time. The MIC is the lowest concentration of antimicrobial agent that completely inhibits visible growth, with one exception. As with other types of bacteria, "trailing" is common when trimethoprim-sulfamethoxazole is tested, and the MIC values for this agent should be read at approximately 80% inhibition of growth. Trailing also is occasionally seen with isolates of *M. fortuitum* group and clarithromycin; when this occurs, the endpoint is read at the end of the trailing (i.e., complete inhibition).

**Reporting Results**

MIC values and an interpretation, based on the breakpoints for the rapidly growing mycobacteria listed in Table 7 (11), are reported for each drug. A few species/groups of rapidly growing mycobacteria are almost always susceptible to certain drugs. This is true for *M. abscessus* and AMK; for *M. fortuitum* group, *M. smegmatis* group, and *M. mucogenicum* and imipenem, and for *M. chelonae* and tobramycin. Therefore, if the MIC result for one of these isolate-drug combinations indicates resistance, susceptibility testing should be repeated, and the identification should be confirmed. If the repeat result indicates resistance, the isolate should be sent to a qualified reference laboratory for confirmation of the results if the drug in question is being considered for therapy.

<sup>a</sup>Table and footnotes are adapted from reference 11.
<sup>b</sup>Isolates of *M. abscessus* with an MIC of ≥64 μg/ml should be retested. If the repeat result is ≥64 μg/ml, the MIC should be reported with the following comment: “The MIC is greater than expected for this species; if the drug is being considered for therapy, the laboratory should be notified so the isolate can be sent to a reference laboratory for confirmation of resistance.”
<sup>c</sup>Ciprofloxacin and levofloxacin are interchangeable. Both are less active than the newer 8-methoxyfluoroquinolones.
<sup>d</sup>The final reading for nonpigmented rapidly growing mycobacteria should be at 14 days to ensure detection of inducible macrolide resistance, unless the isolate is resistant at an earlier reading. Clarithromycin is the class representative for newer macrolides (i.e., azithromycin and roxithromycin).
<sup>e</sup>If the MIC is ≥8 μg/ml for *M. fortuitum* group, *M. smegmatis* group, and *M. mucogenicum* group, the test should be repeated with an incubation period of no more than 3 days. If the result is ≥8 μg/ml, the MIC should be reported with the following comment: “The MIC is greater than expected for this species; if the drug is being considered for therapy, the laboratory should be notified so the isolate can be sent to a reference laboratory for confirmation of resistance. Imipenem results do not predict results for meropenem or ertapenem. Activity against rapidly growing mycobacteria is greater for imipenem than for meropenem or ertapenem.”
<sup>f</sup>Tobramycin is used predominantly for treatment of *M. chelonae* infections. If the MIC to tobramycin is >4 μg/ml for an isolate of *M. chelonae*, the test should be repeated. If the repeat result is ≤4 μg/ml, the MIC should be reported with the following comment: “The MIC is greater than expected for this species; if the drug is being considered for therapy, the laboratory should be notified so the isolate can be sent to a reference laboratory for confirmation of resistance.”

Actinomycetes

Clinical Significance

*Nocardia* spp. and other aerobic actinomycetes (*Actinomadura, Rhodococcus equi, Gordonia, Tsukamurella, and rarely Streptomyces spp.*) can cause serious disease in immunocompromised and occasionally even healthy hosts (142–149). In vitro susceptibility testing should be performed on all clinically significant isolates to serve as a guide for therapy and to monitor for resistance.

Testing Method

The recommended method for testing *Nocardia* and other aerobic actinomycetes is broth microdilution (11), although breakpoints for interpretation of MIC values have been established only for *Nocardia* species. Additionally, based on data from a recent multisite reproducibility study, use of a disk diffusion test for sulfisoxazole (250-μg disk) should be considered when testing *Nocardia* species as a check of the inoculum adequacy and to confirm sulfonamide MIC results (150). Because *Rhodococcus equi* grows within 24 h in most susceptibility panels for Gram-positive bacteria, it can be tested following the guidelines for staphylococci described in the most recent edition of CLSI documents M07, (151) and M100 (137).

The primary and secondary antimicrobial agents recommended for susceptibility testing are listed in Table 8. For *R. equi* only, there are two additional primary drugs: vancomycin and rifampin. Although broth dilution is preferred, for a few species-drug combinations, the accuracy of the results may be questionable. For example, ceftriaxone results may be falsely resistant when testing *Nocardia brasilienis*, and when testing *Nocardia farcinica*, imipenem results may be falsely resistant. In addition, there appears to be a problem with reproducibility of broth microdilution testing of ceftriaxone with *Nocardia cyriacigeorgica* and *Nocardia wallacei* and sulfonamides with *N. farcinica* and *N. wallacei* (150). Studies to further investigate these potential problems are needed.

Inoculum preparation is described in detail in CLSI document M24-A2 (11). First, a heavy suspension is prepared in

<sup>a</sup>Table and footnotes are adapted from reference 11.
<sup>b</sup>Ciprofloxacin and levofloxacin are interchangeable. Both are less active than the newer 8-methoxyfluoroquinolones.
<sup>c</sup>Class representative for newer macrolides.
cation-supplemented Mueller-Hinton broth or sterile, de-ionized water or saline, using colonies on a blood or Trypticase soy agar plate that was incubated at 35 ± 2°C in air until growth is sufficient (usually 3 to 7 days). Large clumps of organisms are broken up by using a micropestle or glass beads and mixing vigorously on a vortex mixer. The suspension is allowed to sit for approximately 15 minutes so that the clumps settle. Several drops of the supernatant are added to 2 ml of water or saline in a tube compatible with a nephelometer available in the laboratory. The turbidity of the suspension is adjusted to equal the density of a 0.5 McFarland standard.

Panels and Mueller-Hinton agar plates are inoculated with the appropriately prepared suspension. Panels are covered with an adhesive seal, placed in a plastic bag, and incubated at 35 ± 2°C in ambient air for 72 h. If growth in the growth control well is sufficient at that time, MIC values are recorded; if not, panels are reincubated and read daily until growth is adequate, for up to a total of 5 days. To assess the adequacy of the inoculum, the quantity of organism growth on the sulfisoxazole disk diffusion test should be evaluated after incubation in ambient air at 35 ± 2°C for 3 to 5 days. Growth should appear as obvious streak marks with clear areas between the streaks; it should not be confluent.

**Reporting of Results**

For broth microdilution, both an MIC value and an interpretation (as listed in Table 8) should be reported for *Nocardia* species. Sulfisoxazole disk diffusion is interpreted as follows: a zone of inhibition of ≥35 mm indicates susceptibility to sulfonamides, and a zone of ≤15 mm indicates resistance (150). A zone size of 16 to 34 mm is interpretable because currently there is insufficient data to determine intermediate susceptibility. If the results of broth dilution and disk diffusion testing are discrepant, testing should be repeated and/or sent to a reference laboratory. Because most isolates of Nocardia are susceptible to sulfonamides, a result of resistant should be confirmed before it is reported. For all other aerobic actinomycetes, including *R. equi*, an MIC value only should be reported, because breakpoints for these drugs have not been determined for genera other than Nocardia.

**Quality Control**

Recommended reference strains for QC are *S. aureus* ATCC 29213, *P. aeruginosa* ATCC 27853, and for amoxicillin-clavulanic acid only, *Escherichia coli* ATCC 35218. Acceptable ranges for these strains are found in the current edition of CLSI document M100 (137). In addition to these organisms, Conville and colleagues recommend including *Nocardia nova* ATCC BAA-2227 in the QC battery to show the attributes of Nocardia strains grown in the presence of antimicrobial agents (150).

Molecular Detection of Antibacterial Drug Resistance

APRIL N. ABBOTT AND FERRIC C. FANG

The detection of antibiotic resistance is one of the most important responsibilities of the clinical microbiology laboratory. This is traditionally achieved by phenotypic testing (chapters 71 to 73). However, a limitation of the phenotypic approach is that delays in appropriate therapy can adversely affect clinical outcomes (1-4). As most clinically important antibiotic resistance has a genetic basis, molecular methods to directly detect resistance are theoretically attractive because they are rapid and automated and do not require bacterial growth. However, the molecular detection of resistance determinants also poses significant challenges, perhaps foremost of which is the genetic complexity of antibiotic resistance. Resistance can arise due to the acquisition of resistance determinants (e.g., β-lactamase genes) but can also reflect changes in gene expression (e.g., efflux pumps, porins) or the acquisition of mutations (e.g., fluoroquinolone target mutations). The detection of a resistance gene may not necessarily imply phenotypic resistance if the gene is expressed at low levels or is nonfunctional. On the other hand, methods based on genotype may actually be superior to those based on phenotype in some instances, such as when heteroresistance is present or if a resistance phenotype is only weakly expressed under in vitro testing conditions (e.g., some methicillin-resistant Staphylococcus aureus [MRSA], Klebsiella pneumoniae carbapenemases [KPCs], or New Delhi metallo-β-lactamase-1 [NDM-1]). An ever-expanding diversity of resistance determinants is likely to result in continuing problems of sensitivity for molecular assays. The presence of PCR inhibitors, inefficient extraction of nucleic acids, and other technical issues may also interfere with detection, so it is essential for assays to include internal controls. Another limiting factor for most clinical laboratories potentially interested in using molecular assays to detect antibiotic resistance is the considerable cost. Therefore, at present, molecular methods to detect antibiotic resistance are limited to a few common and well-defined resistance mechanisms. A number of investigational approaches appear promising, and the application of molecular diagnostic tools to detect antibiotic resistance is likely to become more widespread in the future. This chapter provides an overview of current FDA-cleared molecular assays for the detection of antibiotic resistance. In addition, some commercial assays in development are briefly discussed. Analyte-specific reagents and “home-brew” assays continue to play an important research role but are impractical for the typical clinical laboratory; the interested reader is referred to other sources (5, 6).

TECHNOLOGY

Although the use of molecular assays in the clinical microbiology laboratory is not new, recent technological advances have made it possible for laboratories to implement user-friendly instrumentation that requires little to no training in advanced molecular techniques. Testing can be performed directly on clinical specimens (primarily for surveillance purposes) or on cultured isolates (e.g., positive blood cultures). Reference strains for assay validation may be readily obtained from sources such as the American Type Culture Collection (7). Current FDA-cleared molecular technologies for the detection of resistant determinants are based on two methods: PCR and solid-phase microarrays. When comparing these methods for molecular resistance detection, a key distinction should be recognized. Nucleic acid amplification in real-time PCR may allow an assay to be performed directly from a specimen but limits the number of fluorophores that can be used for simultaneous target detection. One solution is to perform independent target amplification and detection steps. In the FilmArray (BioFire) system, the initial targeted multiplex PCR is followed by distribution of the products into individual wells for a second round of PCR and detection. In contrast to PCR-based technologies, solid-phase or liquid arrays can simultaneously detect hundreds of targets, but they require a high target copy number, limiting their ability to be used for the direct analysis of clinical specimens in which low numbers of organisms are present. Unlike PCR, there are only a few instances in which direct-from-specimen microarray technologies have been applied to detect antimicrobial resistance in the clinical laboratory (8). However, combined amplification and array technologies are routinely found in research settings and are likely to become increasingly employed in clinical settings. One example is the FDA-cleared Verigene Respiratory Virus Plus assay (Nanosphere), which incorporates an amplification step prior to array-based detection. In a panel marketed outside the United States, this assay also detects oseltamivir resistance resulting from the H275Y mutation. It is likely that such combinations will find future clinical applications.

To our knowledge, seven manufacturers (some with multiple assays) have obtained FDA clearance for the molecular detection of antimicrobial resistance markers, as of July 2013. BD GeneOhm, bioMérieux NuclisSENS EasyQ, ELITech ELITe MGB, and Roche Lightcycler are PCR-based platforms with high-complexity CLIA (Clinical Laboratory Improvement Amendments of 1988) designations. Cepheid
GeneXpert is a self-contained, PCR-based system with a moderate-complexity designation. The moderate-complexity BioFire FilmArray blood culture identification (BCID) panel uses PCR to detect 20 Gram-positive or Gram-negative bacteria and yeasts, as well as the mecA, vanA, vanB, and KPC resistance determinants. Nanosphere Verigene is a moderate-complexity slide array assay that encompasses extraction, hybridization of target DNA to gold nanoparticle probes, and detection within a closed system.

Broad-range PCR with detection by electrospray ionization mass spectrometry (PCR/ESI-MS) has been used in a commercial system that combines organism identification with the detection of resistance determinants (PLEX-ID; Abbott) (9, 10), but the considerable cost of this system has limited its usefulness in most clinical settings. Matrix-associated laser desorption ionization—time of flight mass spectrometry (MALDI-TOF MS) has permitted rapid identification of microbial isolates in the clinical laboratory but lacks sufficient sensitivity to detect the proteins responsible for drug resistance (e.g., β-lactamases). Indirect methods that use MALDI-TOF MS to detect the products of antibiotic hydrolysis by carbapenemases have been developed (11–13), but the practical utility of these assays remains to be determined. Other technologies with possible future applicability to antimicrobial resistance detection include denaturing high-performance liquid chromatography (HPLC) (14, 15) and various deep-sequencing modalities (16, 17). A number of additional assays currently under development or in use outside the United States are mentioned in the corresponding resistance target section.

**COMMONLY USED RESISTANCE TARGETS**

**Methicillin-Resistant *Staphylococcus aureus***

*Staphylococcus aureus* is presently the most common cause of bacterial infections in industrialized countries (18). Particular effort has been exerted to develop assays for the rapid detection of MRSA, which carries an increased risk of symptomatic infection and has fewer effective treatment options (19, 20). However, methicillin-susceptible *S. aureus* (MSSA) also continues to be an important community-acquired pathogen and appears to be playing an increasingly important role in hospital infections as well (21). The rapid detection of MRSA is important for guiding infection control measures and antimicrobial treatment. MSSA detection is also clinically important because different antimicrobial agents are required for optimal MSSA treatment (3, 22–24). The rapid identification of MSSA/MRSA in blood cultures has been shown to result in decreased length of hospital stay and health care costs (25).

Molecular assays that recognize MRSA on the basis of a single target detect the junction between the SCCmec (staphylococcal cassette chromosome mec) cassette (which carries the mecA resistance determinant along with additional genes) and the flanking orfX gene (Fig. 1). It is important to note that such assays may yield false-negative results when MRSA strains carry SCCmec variants, as 11 types of SCCmec cassettes have now been described (26–28). SCCmec XI has been recently described in MRSA strains from bovine and human sources in Europe; this unusual SCCmec variant carries the mecC gene, which is only 70% identical to mecA and poses a new challenge to molecular diagnosis (26). It is advisable to validate a molecular MRSA assay using strains of local origin, as the prevalence of variant strains not detected by a molecular assay may be quite high at some geographic locations (29, 30). Another potential pitfall of single-target MRSA assays is the existence of MSSA strains that carry SCCmec remnants lacking an intact mecA gene, sometimes referred to as “empty cassettes” (31–35). Such strains are phenotypically methicillin susceptible but can be responsible for false-positive results when single-target MRSA assays are employed. A less common cause of a false-positive molecular MRSA assay is a
strain carrying a mutant mecA allele that is no longer functional (36). An alternative approach to the molecular detection of MRSA combines the mecA target and a second locus specific for \( S.\) aureus, such as saa424, nuc, femA-femB, spa, or ldd1 (37–42) (Fig. 1). This approach can be used to detect both MSSA and MRSA. However, mixed specimens may provide ambiguous results. In particular, the concomitant presence of MSSA and methicillin-resistant coagulase-negative staphylococci (CoNS) may be falsely interpreted as MRSA. In one study, colonization with methicillin-resistant CoNS and MSSA was found in 3.4% of specimens from anterior nares (43). Rare \( S.\) aureus strains lacking nuc or spa have been reported (44, 45).

Molecular assays for the detection of methicillin resistance in \( S.\) aureus are available for both surveillance testing and to assist in diagnosis of infection (Table 1). Assays approved for MRSA surveillance from nasal swabs include the BD GeneOhm MRSA ACP and BD MAX MRSA assays (Becton Dickinson), Xpert MRSA (Cepheid), LightCycler MRSA advanced test (Roche), and NucliSENS EasyQ MRSA test (bioMérieux) (32, 33, 46–48). Each of these tests is a PCR-based assay to detect the SCCmec- or mecJunction. The MRSA/SA ELITE MGB assay (Elitech) is designed for nasal swab specimens; discrimination between MRSA and a mixture of MSSA and methicillin-resistant CoNS is achieved by quantitative comparison of mecA and \( S.\) aureus target abundance.

Assays for the combined detection of MRSA and MSSA to assist in the diagnosis of infection include the BD GeneOhm StaphSR assay (Becton Dickinson), Xpert MRSA/SA BC and Xpert MRSA/SA SSTI (Cepheid), and the Verigene Gram-Positive blood culture test (Nanosphere). The BD GeneOhm Staph SR, Xpert MRSA/SA BC, and Verigene Gram-Positive blood culture tests are used to rapidly identify MRSA and MSSA once Gram-positive cocci are identified in blood cultures (48, 49). In addition, the Verigene assay also detects other Gram-positive pathogens (50) and has targets to differentiate \( S.\) aureus, \( S.\) epidermidis, and \( S.\) lugdunensis from other Staphylococcus species. For methicillin resistance to be reported, the assay must detect the presence of a particular staphylococcal species. In polymicrobial cultures, methicillin susceptibility cannot be inferred, as detection of mecA may be problematic (51). The Xpert MRSA/SA SSTI assay is performed on swabs obtained from infected skin or soft tissue lesions (49). Although any molecular assay may detect DNA from nonviable organisms, this feature may be particularly problematic for the MRSA/SA SSTI assay. Patients with severe soft tissue infections have frequently received antibiotics prior to the obtaining of diagnostic specimens. The false-positive rate (relative to culture) for patients receiving antibiotics within 3 weeks of testing is reported to be 13.8% and 9.5% for MSSA and MRSA, respectively (package insert). In addition, the MRSA/SA SSTI assay may yield false results in the presence of mixed staphylococcal infections.

Commercial multipathogen detection assays currently in development that can distinguish MRSA and MSSA include the FilmArray BCID Panel (BioFire), VYOO Pathogen Detection assay (AnalytiK Jena), Gram Positive 12 Easy-Plex PCR Panel (AusDiagnostics) (52), SepeT Test (Molym), and the next generation of the Plex-ID System (Abbott). The VYOO and SepeT Test assays are intriguing because they are able to detect pathogens in whole blood without requiring culture, but initial studies have shown poor concordance with conventional culture results (53, 54). In addition, PNA-FISH (AdvanDx), a rapid method for pathogen identification from blood culture, is evaluating a probe to target mecA mRNA (55).

Vancomycin-Resistant Enterococci

Enterococci are commensal residents of the gastrointestinal tract and female genital tract that account for approximately 10% of nosocomial infections (56, 57). The vast majority of enterococcal infections are caused by Enterococcus faecalis and Enterococcus faecium and predominately occur in patients requiring long-term care (e.g., intensive care unit, transplant, cancer, hemodialysis). The emergence of vancomycin-resistant enterococci (VRE) in the inpatient setting is of particular concern, given that vancomycin is commonly administered as empirical therapy for suspected bloodstream infections (58). Thus, infection with VRE is associated with increased morbidity and mortality, primarily due to the propensity of VRE to infect patients already at high risk from comorbidity (59).

In the United States, approximately 30% of enterococcal isolates are resistant to vancomycin (57). High-level vancomycin resistance occurs in enterococci via acquisition of mobile transposable genetic elements carrying the vanA or vanB resistance determinants. \( E.\) faecium is more frequently vancomycin resistant than \( E.\) faecalis, with vanA more commonly encountered than vanB. For this reason, currently marketed molecular assays identify VRE by the presence of vanA. Although the detection of vanA has been shown to be highly specific (aside from rare reports of vanA-carrying \( S.\) aureus and streptococcal species) (60, 61), the concomitant use of culture-based methods is required to definitively link the detection of the vanA gene to VRE carriage, to perform susceptibility testing, and to perform strain typing in an outbreak setting. Additionally, the regional prevalence of vanB-carrying VRE is an important consideration when deciding on a molecular assay, as not all commercial assays detect these strains.

As with MRSA, the rapid detection of VRE colonization to prevent health care-associated infections is widely recommended. Currently, two FDA-cleared assays are marketed in the United States for the detection of VRE from perianal and rectal swabs (Table 1). Both of these assays, GeneOhm VanR (BD) and Xpert VanA (Cepheid), target the vanA gene, the most prevalent vancomycin resistance determinant in enterococci in North America (62). In addition, the VanR assay also detects vanB. However, a number of studies have illustrated the presence of this gene in fecal or rectal specimens without culturable enterococci, questioning the specificity of this target. The vanB gene has been found in commensal nonenterococcal bacteria (e.g., Streptococcus mitis, Streptococcus gallolyticus, Eggerthella lenta, Clostridium spp., and Ruminococcus lactaris) (8, 63), necessitating culture confirmation of a vanB-positive result from a molecular assay.

The Verigene Gram-Positive blood culture nucleic acid test (Nanosphere) is a multiplexed nucleic acid test with the capability to identify 12 Gram-positive organisms as well as the presence of mecA, vanA, and vanB resistance determinants (Table 1). This assay is FDA cleared for use on positive blood cultures that have undergone a Gram stain assay to confirm the presence of Gram-positive organisms. With regard to enterococci, the test targets hsp60 for detection of \( E.\) faecalis and \( E.\) faecium, but not other Enterococcus species. This allows the accurate identification of most VRE responsible for bloodstream infections that carry either vanA or vanB (64).

**Abbreviations:** FDA, Food and Drug Administration; MSSA, methicillin-susceptible *S. aureus*; MRSA, methicillin-resistant *S. aureus*; VRE, vancomycin-resistant *Enterococcus*; LOD, limit of detection; min, minutes; CFU, colony forming unit; rxn, reaction; BCID, blood culture identification; BC-GP, Gram-positive blood culture.

*The approximate hands-on time is variable and would be scalable by the number of samples tested.

*Assays requiring substantial hands-on time and/or inclusion of external controls per run to validate results were considered best suited for batched processing.

*For assays with multiple targets, LOD differs depending upon target; ranges are given.

*Assay does not detect Enterococcus, only the resistance determinant.
Beta-Lactamases in Gram-Negative Bacteria

One of the greatest threats to the antimicrobial armamentarium has been the emergence of beta-lactamases in Gram-negative bacteria with the capability of hydrolyzing broad-spectrum penicillins, cephalosporins, and carbapenems. These enzymes include the extended-spectrum beta-lactamases (ESBLs), AmpCs, and carbapenemases (65–69). The accurate detection of broad-spectrum beta-lactamases is important for both infection control and treatment, and detection on the basis of the MIC or other phenotypic testing is imperfect (68, 70). A rapid and affordable molecular assay able to detect broad-spectrum beta-lactamasises would be clinically useful but at present represents an unmet need. The greatest challenge to molecular detection is the enormous diversity of beta-lactamasises, with more than 200 described ESBLs and numerous classes of carbapenemases, including the carbapenemases KPC (K. pneumoniae carbapenemase), NDM-1 (New Delhi metallo-beta-lactamase), VIM (Verona integron-encoded metallo-beta-lactamase), IMP (imipenem metallo-beta-lactamase), and OXA (oxacillinase). An additional consideration is that the detection of beta-lactamase genes does not provide information about copy number and expression, which are important determinants of phenotypic beta-lactam resistance.

A number of commercial assays for the molecular detection of broad-spectrum beta-lactamases are currently undergoing evaluation (Table 2). Check-Points (Wageningen, Netherlands) offers Check-MDR assays in both real-time PCR and microarray formats for the detection of ESBLs (TEM, SHV, CTX-M), AmpCs (CMY, ACC, DHA, ACT/MIR), and carbapenemases (KPC, NDM, VIM, IMP, OXA-48), in various configurations (71–73). The BD MAX platform (Becton-Dickinson) offers a CRE (carbapenem-resistant Enterobacteriaceae) assay for research use only (RUO) that detects KPC, NDM, and OXA-48 genes. The Hyplex (Amplex Diagnostics GmbH) system for detection of ESBLs (TEM, SHV, CTX-M) or carbapenemases (VIM, IMP, KPC, OXA-48, NDM) detects products from a multiplexed PCR using enzyme-linked immunosorbent assay (ELISA)-based principles (74). The NucliSENS EasyQ platform (bioMérieux) now offers a KPC assay (75), and the FilmArray (BioFire), PLEX-ID (Abbott), and VYOO (Analytik Jena) panels include a limited number of beta-lactamase targets. The Verigene Gram-Negative blood culture test (Nanosphere) is designed to identify common Gram-negative pathogens directly from positive blood cultures as well as to detect CTX-M, KPC, NDM, VIM, IMP, and OXA targets.

OTHER RESISTANCE TARGETS

At present, there appears to be limited interest in the commercial development of molecular assays for other resistance determinants. Some possible candidates might be considered.

Aminoglycosides

Resistance to aminoglycosides most often results from the actions of modifying enzymes: acetyltransferases (AAC), nucleotidyltransferases (ANT), phosphotransferases (APH), and 16S rRNA methylases. These genes may be detected by PCR, but sequence diversity among the resistance genes is considerable. Multiplex PCR assays to detect high-level aminoglycoside resistance in enterococci have been developed (76). Since aminoglycosides are principally used in combination with other agents, the need for rapid detection of aminoglycoside resistance genes may not be as great as with other agents.

Anaerobic Bacteria

The prevalence of resistance of anaerobic bacteria to antimicrobial agents appears to be increasing, including resistance to clindamycin (erm), metronidazole (nir), and carbapenems (cflA) (77). PCR assays to detect these determinants have been developed (78–82). However, the value of routine susceptibility testing of anaerobic bacteria is questionable (83).

Beta-Lactam-Resistant Pneumococci

Beta-lactam resistance in Streptococcus pneumoniae has become an increasing concern since first reported in 1967 (84). This resistance problem has posed a difficult challenge for molecular diagnosis. Beta-lactam resistance results from mosaic variants of low-affinity penicillin-binding proteins (PBPs1a, PBPs2b, and PBPs2x), which vary in their individual contributions to penicillin and cephalosporin resistance. PCR-based assays have been developed to detect some of the most common variants associated with resistance (85–87). As beta-lactam antibiotics can still be used to treat nonmeningeal infections with S. pneumoniae strains exhibiting intermediate levels of resistance (88), the utility of a rapid resistance assay may be limited, with the exception of the setting of meningitis.

Ceftriaxone-Resistant Neisseria gonorrhoeae

The emergence of ceftriaxone resistance in N. gonorrhoeae is of particular concern given the reliance on non-culture-based methods for gonococcal detection in the clinical setting. Incorporating resistance detection into currently available nucleic acid amplification tests would be highly desirable, but this is currently unavailable. One approach used in the research setting is the molecular detection of mosaic variants of penA, encoding penicillin-binding protein 2, that confer reduced beta-lactam susceptibility (89). The future development of molecular penA assays will need to account for the presence of mosaic PBPs2 in commensal Neisseria species, which is likely to be of particular importance in pharyngeal specimens (90). Combined detection of cephalosporin resistance and mutations conferring quinolone resistance (see “Fluoroquinolones”) would allow the use of a quinolone for isolates determined to be susceptible. However, at present, no molecular assay is commercially available to detect antimicrobial-resistant gonorrhea.

Fluoroquinolones

Fluoroquinolone agents are widely used in clinical medicine. Therefore, a rapid assay to detect resistance is theoretically attractive. However, resistance most frequently results from mutations in the gyrA and parC genes, encoding subunits of DNA gyrase and topoisomerase IV that are targeted by these antibiotics. Detection of these point mutations would require techniques such as sequencing, microarray, mismatch amplification mutation assay (MAMA), or allele-specific PCR (91–94). Alternatively, an assay might target Escherichia coli strain ST131, which appears to be responsible for more than one-half of the infections caused by fluoroquinolone-resistant E. coli at diverse geographic locations in the United States (95). Although alterations of the target site account for the predominance of high-level resistance, low-level resistance has been associated with additional mechanisms, making molecular detection of low-level resistance difficult.

**d**Other Check-MDR assays (CT101 and CT102) are configured to include fewer targets; MDR Carba and MDR ESBL assays are also available for beta-lactamase detection using real-time PCR instrumentation.
Linezolid

The oxazolidinone linezolid is an important last-line agent for the treatment of resistant Gram-positive cocci. Although resistance is infrequent, mutations that affect the linezolid-binding site have been described. In both staphylococci and enterococci, the most commonly reported mechanism of linezolid resistance is a G2576T mutation in domain V of 23S rRNA, making this region an attractive target for the molecular detection of resistance (96). A confounding issue in the development of an assay detecting the G2576T mutation is that the phenotypic level of resistance correlates with the number of rRNA operons carrying a mutation; strains that are phenotypically linezolid susceptible despite the presence of the G2576T mutation have been described. A number of additional mutations in 23S rRNA or the ribosomal proteins L3 and L4 have been described in linezolid-resistant strains, and the relationship between resistance and these mutations is currently under investigation. Linezolid resistance following acquisition of the cfr gene, encoding a 23S rRNA methyltransferase, has also been reported. This plasmid-borne mechanism of resistance has been implicated in outbreaks of infections caused by linezolid-resistant staphylococci and has recently been detected in a clinical isolate of *E. faecalis* (97–99). If linezolid resistance becomes more prevalent, a molecular assay to detect the 23S G2576T mutation and the presence of cfr may become useful.

Mupirocin

Mupirocin is an isoleucyl tRNA synthase inhibitor used for MRSA decolonization. Resistance to mupirocin is conferred by the *mupA* gene, which encodes a mupirocin-resistant isoleucyl tRNA synthase. Molecular assays for *mupA* detection have been developed (100) and may become increasingly useful if the prophylactic use of mupirocin becomes more widespread (101).

Mycobacteria

Assays for the rapid detection of mutations associated with resistance to isoniazid, rifampin, ethambutol, pyrazinamide, and streptomycin have been developed, and some are commercially available for research use. Additional information may be found in chapter 76.

Trimethoprim

Variant *dfr* genes, encoding dihydrofolate reductase, the target of trimethoprim, have been increasingly observed in *E. coli* isolates causing urinary infections, sometimes inserted into integrons (102). A rapid assay to identify the common *dfr* variants might help to identify patients unlikely to respond to empiric treatment with trimethoprim-sulfamethoxazole.

CONCLUSIONS

At present, FDA-cleared molecular assays for the detection of antibiotic-resistant pathogens are limited to those identifying MRSA and VRE, employing PCR and solid-phase array platforms. These assays must be employed with careful attention to the specific targets used for detection, as potential false-positive and false-negative results may be obtained. Selection of a specific assay must take specimen type, test volume, hands-on and turnaround time, on-demand capability, and cost into consideration. Although genetic diversity and cost pose significant obstacles, new assays for the detection of broad-spectrum beta-lactamases of Gram-negative bacteria appear promising. With a continuing urgent clinical need for the rapid detection of antimicrobial resistance, and with many novel technologies in development, the molecular diagnosis of antibacterial drug resistance is likely to see expanded application in coming years.

INTRODUCTION

Taxonomy

Taxonomy at its most basic level involves the classification and naming of objects. Living objects have been grouped for hundreds of years according to the Linnaean system (1), a classification scheme that places living things hierarchically into groups of species followed by groupings into higher-level taxa (from genera to families, orders, classes, phyla, kingdoms, and domains, including a number of now-recognized intervening ranks) dependent on common shared characteristics. Taxonomic assignments were originally based on visible structural similarities between organisms. Assignments now also include molecular and genetic information.

Taxonomy functions beyond mere categorization. By having information about, and an understanding of, a few of the organisms in a group of closely related taxa, it is often possible to extend that knowledge to other organisms in related taxa for which much less biological information may be available. For viruses, this process of comparative analysis plays a critical role in increasing our overall knowledge of the molecular biology, pathogenesis, epidemiology, and evolution of poorly understood or newly isolated viruses. This knowledge enhances our ability to respond to new threats by supporting the development of diagnostics, vaccines, and other antiviral therapies.

Viruses

Viruses are not easily placed on the evolutionary tree of life (2–4). They are not accurately represented by side branches sprouting off from the main branches or by their own single branch growing out from the base of the tree. In fact, it is likely that viruses have multiple independent evolutionary origins (5, 6) that cannot be easily or completely separated from the evolution of their hosts, as they cannot reproduce or evolve separately from their hosts (7, 8). Indeed, the host represents one of the most important characteristics of a virus that must be considered when making taxonomic assignments. Therefore, viruses might be better represented as individual twigs arising from branches spread throughout the rest of the tree.

In addition to distinct evolutionary histories, viruses differ from other domains of life in the variety of possible coding molecules they utilize to store their genetic programs (9, 10). Every other domain of life has, as the basic reservoir of its genetic program, double-stranded DNA (dsDNA). Virus genomes may be composed of dsDNA, single-stranded DNA (ssDNA), dsRNA, or ssRNA (which may be positive or negative sense with respect to the mRNA coding strand). In addition, reverse transcription may be a part of their molecular programs. Genome topology (linear, circular, single segment, or multiple segments) also varies among different viruses. All of these unique features, as well as numerous other criteria, are taken into account when classifying viruses and making taxonomic assignments.

VIRAL TAXONOMY: ICTV CLASSIFICATION OF VIRUSES

The process of making taxonomic assignments is the responsibility of a number of different organizations that have the internationally recognized authority to oversee or contribute to the process by defining the rules, methods, and nomenclature to be used in making assignments for particular domains or subdomains of life (11–13). For viruses, the Virology Division of the International Union of Microbiological Societies has charged the International Committee on Taxonomy of Viruses (ICTV) with the task of developing, refining, and maintaining a universal viral taxonomy (14, 15).

The ICTV currently recognizes five hierarchical ranks that are used to define the universal viral taxonomy: the order, family, subfamily, genus, and species. The 2013 ICTV viral taxonomy (16) comprises 7 orders, 103 families, 22 subfamilies, 455 genera, and 2,827 species. The official viral taxonomy is published on the ICTV website (http://www.ictvonline.org) and in the ICTV reports (14) (although the ICTV ninth report, compiled in 2010 and 2011, contains the 2009 ICTV taxonomy [17] and therefore lags behind the most recently published ICTV taxonomy published in 2014 [16]). The first report of the ICTV was based on deliberations made at and after the 1968 (Helsinki) International Congress of Virology (18). Subsequent reports have been published at regular intervals, authored by numerous and collaborating virologists, with the most recent report, the ninth, published in 2012. These reports provide a history of the efforts and the logic used in forming taxa, term definitions, the official taxonomy, and a description of higher-level taxa.

doi:10.1128/9781555817381.ch78
Initially, the ICTV only recognized and made assignments to ranks at the genus level and above. In 1991, the rank of species was added (19). A virus species is defined as "the lowest taxonomic level in the hierarchy approved by the ICTV. A species is a monophyletic group of viruses whose properties can be distinguished from those of other species by multiple criteria." This represents the new definition as redefined by the ICTV in 2013 (20). Note that, in general, every species is a member of a genus, which in turn is a member of a family. A few families are also members of one of the seven orders that are currently recognized, but the majority of viral families do not belong to an order. Some species are not yet assigned to a genus (but may be assigned to a family), and a few genera are not yet assigned to a family; additional biological information must become available before these assignments can be made. Subfamily and order assignments are optional and therefore not necessary to complete a taxonomic hierarchy.

The ICTV is governed by a series of statutes and follows rules and definitions provided by the International Code of Virus Classification and Nomenclature (20, 21) to make taxonomic assignments and name virus taxa. Any modifications or additions to the official ICTV taxonomic classification and names, as well as changes to the statutes or code, must be approved by the voting membership of the ICTV. Any individual can submit proposals to the ICTV for the modification of existing taxa or the creation of new taxa.

In addition to defining the process and rules for virus classification, the ICTV Code also defines the rules to be followed for name assignment. Higher-level taxon names are composed of a single word ending with a suffix that is dependent on taxon rank. The suffix “-virus” identifies an order. Families are identified by the suffix “-viridae”; subfamilies are identified by the suffix “-virinae”; and genera are identified by the suffix “-virus.” Species names should be as concise as possible but normally comprise two or more words. It is common for a species name to end with the word “virus” or have “-virus” as a suffix, but this is not required. When written, names of taxa are italicized, and the first letter of the name is capitalized. (As a part of a species name, the first letter of any proper noun, such as a geographic location, is also capitalized.) It is often difficult to determine in a particular context if a species name should be written in the formal italicized manner, since species names often coincide with the common names used to refer to a virus. Taxa are abstract concepts that do not physically exist. As an example, when referring to the species Variola virus that belongs to the genus Orthopoxvirus and the family Poxviridae, all names refer to abstract taxa and are therefore written in the formal italicized manner. However, when referring to variola virus, the physical entity that causes smallpox, the name is neither capitalized nor italicized.

It is important to note that the ICTV is only concerned with making taxonomic assignments at the species level and higher, although many viral isolates assigned to one particular species can be further subdivided into categories based on sequence phylogeny, immune reactivity, or other properties. In many cases, these subspecies-level assignments are made on an ad hoc basis by an individual investigator and reported in a journal article. In other instances, a more organized effort may have been made to subdivide a species into a series of “types” based on a defined set of demarcation criteria. Examples of viruses for which subspecies-level assignments have been made include hepatitis C virus (22), dengue virus (23), and HIV (24).

CRITERIA FOR TAXONOMIC CLASSIFICATION

Character-Based Descriptors

Taxonomic classification is accomplished by comparing and contrasting sets of characters that can be used to define the properties of any particular taxon. Any aspect of viral biology can be defined by a set of characters. These characters may have values represented by quantitative measures, such as the triangulation (T) number used to categorize icosahedral virion capsid structure, or they may be purely qualitative descriptors, such as the presence or absence of a host-derived lipid envelope.

Viruses are described by choosing a set of appropriate characters and then assigning values to these characters as necessary. The ICTVdb species and isolate database in the past provided one example of a comprehensive character list for describing viruses (25, 26). This list is summarized in Table 1. More than 2,500 different characters are avail-

able for use, and many of these have multiple values that might be associated with any one viral taxon or isolate. For example, a particular isolate may be described by the location and date of its isolation, each of which would be associated with the appropriate value (e.g., country and year). Characters describing a particular species may include its host range and a list of diseases associated with viruses belonging to that species. More than 40,000 different descriptors or values can be associated with the character set of the ICTVdb.

There is no one master character list utilized by the ICTV for classifying viruses. This is because every taxon is unique and characters useful for describing one taxon may be entirely inappropriate for describing another. The ICTVdb character list may be useful in providing a list of potential characters that might be used for any particular classification, but significant research still needs to be performed to determine the most appropriate set of choices. Character selection and character value assignment can only be performed by investigators with relevant expertise. Therefore, the research scientists who comprise the ICTV study groups are responsible for making taxonomic assignments for each viral family set the rules of classification for the viruses that fall under their areas of expertise (14, 27, 28).

The rules for taxonomic classification are defined by a set of demarcation criteria specific to each rank of every taxonomic hierarchy. These demarcation criteria can then be used by research scientists either to determine that a newly isolated virus belongs to an existing species (and therefore there is no need for it to be further classified) or to submit a proposal to the appropriate study group for the creation of a new species (or higher-level taxon) if the isolate, based on the demarcation criteria, is sufficiently different from other viruses that it warrants the creation of a new taxon. Demarcation criteria are provided in each chapter of the ICTV reports describing any particular taxon. Table 2 provides examples of some of the specific criteria utilized to define a species and its upper-level taxa for the species Human enterovirus C (polioviruses were recently reclassified as belonging to this species) (14, 28). Different sets of characters are utilized at each level in the taxonomic hierarchy to describe the viruses that would be assigned to that level and below. The order-, family-, and genus-level characters are universal and must be present in all viruses assigned to that taxon, while the species-level characters do not necessarily need to be present in all members of the species but are frequently shared by the viruses belonging to the species.

**Sequence-Based Characters**

Characters that describe virus morphology and structure have always been important classification criteria. With the advent of genome sequencing, sequence-based comparison has assumed an increasingly important role in classification. Table 2 provides a number of different sequence-based criteria at each rank that are used to define the important characteristics of that rank. There are conserved functional amino acid domains present in all members of the order Poxvirales. Conserved protease and polymerase protein sequences help define the family. A specific level of amino acid conservation across the whole polyprotein is required to place a virus within the Enterovirus genus. An even higher level of sequence identity is required for members of a particular species. Classification based on sequence comparison is now one of the major defining characteristics of all viral taxa. How these comparisons are made, how the relationships are measured, and the extent to which they are included in the taxonomic demarcation criteria vary significantly from taxon to taxon. This is understandable given the inherent differences in mutability between viruses, especially between viruses of different genomic composition. For example, viruses with dsDNA genomes show much less variability at the sequence level than RNA viruses. This difference is a direct consequence of the error rates of their DNA and RNA polymerases (5). Therefore, the measures used (as defined by each ICTV study group) to define specific sequence-based demarcation criteria will also vary from one taxon to another.

Sequence-based comparisons can be measured using a variety of different techniques. The most basic involve pairwise comparisons in which two sequences are aligned and the number of nucleotide or amino acid differences between each aligned position is counted. When comparing multiple sequences, a table of distances is compiled that provides the percent similarity between every possible pairwise comparison in the set. Depending on the particular taxon and hierarchical rank under study, nucleotide or amino acid sequences can be compared and alignments of complete viral genomes, a portion of the genome, or individual genes can be utilized. By examining these sequence distance tables, a study group can set specific similarity levels that define the demarcation criteria for classification of viruses into different taxa.

More-sophisticated analyses based on pairwise sequence comparisons can be utilized to provide alternative methods for visualizing differences, choosing cutoffs, and making assignments. One method used in recent years is the pairwise analysis of sequence conservation (PASC) (29). PASC utilizes pairwise sequence alignments of either whole genomic nucleotide sequences or individual gene nucleotide or amino acid sequences. A pairwise alignment is constructed between every possible pair of available sequences. Once all pairwise alignments have been constructed, the percent identity is calculated for each aligned pair and then plotted versus the number of aligned pairs producing similar identities. Figure 1A provides an example of a PASC plot using amino acid alignments of the DNA polymerase gene of all viruses isolated that belong to the family Poxviridae (30). As can be seen, several distinct peaks are produced, each of which corresponds to comparisons between viruses classified into particular ranks of the Poxviridae taxonomic hierarchy. The lowest percent identity (20 to 30%) corresponds to comparisons between viruses from different subfamilies. Genus-level comparisons produce multiple peaks from 45 to 75% identity. Peaks for interspecies comparisons vary between 80 and 98% identity, with the most prominent interspecies peaks occurring at 97 and 98% identity. Intraspecies comparisons (comparisons between strains of the same species) show very high levels of identity (99% and greater). Figure 1B shows how these taxa are arrayed on the Poxviridae phylogenetic tree. By utilizing PASC, a new virus isolate can be compared to all existing isolates, and by plotting its similarity to isolates already assigned to a known taxon, a determination can be made as to whether the new isolate can be assigned to an existing taxon or if a proposal for creation of a new taxon should be considered. It is interesting that, from a biological point of view, the distinct patterns of conservation that are exhibited by the peaks present in the PASC graph suggest that the evolutionary history of the protein being analyzed (in this case, poxvirus DNA polymerase) has selected for protein sequences that exhibit distinct peaks of fitness. PASC is now utilized by a number
### TABLE 2  Criteria for taxonomic classification

**Order: Picornavirales**

**Virion**
- Nonenveloped, icosahedral particles, ∼30 nm in diameter
- Capsid proteins composed of three distantly related jelly roll domains forming particles with pseudo-T=3 symmetry

**Genome**
- Positive-sense ssRNA
- One or two monocistronic genome segments
- 5′-bound VPg protein
- Genome serves as the mRNA
- Genome typically contains a 3′ poly(A) tail

**Protein**
- Primary polyprotein translation product proteolytically cleaved into mature proteins by one or more virus-encoded proteinases
- Functional domains include a superfamily III helicase (Hel); chymotrypsin-like proteinase (Pro); and superfamily I RNA-dependent RNA polymerase (Pol)
- Nonstructural proteins are arranged as Hel-VPg-Pro-Pol

**Family: Picornaviridae**

**Genome**
- Single monocistronic genome segment

**Protein**
- Conserved genome organization
- Conserved set of functional mature proteins
- Protein sequence conservation (protease-polymerase region)

**Genus: Enterovirus**

**Protein**
- At least 50% amino acid identity over the length of the polyprotein
- VPg sequence conservation
- Lacks an L protein
- Possesses a type 1 internal ribosomal entry site

**Host**
- Virus replication primarily in (but not limited to) the gastrointestinal tract

**Species: Human enterovirus C**

**Host**
- Share a limited range of host cell receptors
- Share a limited natural host range (e.g., human)

**Genome**
- Conserved genome map (organization of protein functional domains)
- Common polyprotein proteolytic processing program
- Share a significant degree of compatibility in proteolytic processing, replication, encapsidation, and genetic recombination

**Sequence similarity**
- Amino acid identity: 70% in the polyprotein
- Amino acid identity: 60% in the P1 structural proteins
- Amino acid identity: 70% in the 2C + 3CD nonstructural proteins
- Similar base G+C composition (within 2.5%)

**Phylogeny**
- Monophyletic

---

**FIGURE 1**  Taxonomic demarcation via sequence similarity. (A) PASC was carried out on the viral DNA-dependent DNA polymerase gene (the vaccinia virus E9L gene homolog) for every completely sequenced poxvirus genome. Each protein was aligned to every other protein, and the percent identity of each pairwise comparison was then included in a histogram plot of all possible comparisons. Peaks are identified across the top of the figure according to the taxa represented by particular pairwise sequence comparisons. (B) Phylogenetic reconstruction of the Poxviridae family of viruses based on their DNA polymerase protein sequences. Subfamily and genera demarcations are identified. Terminal nodes are labeled according to genus. Sequences belonging to one of the genera labeled either group A or B coincide with the A and B comparison peaks at the top of panel A. (C) Phylogenetic prediction based on the multiple nucleic acid sequence alignment of the core genomic region of each representative orthopoxvirus species or strain. of ICTV study groups for making taxonomic assignments (31, 32).

One final sequence-based analysis that is extensively utilized as a demarcation criterion for making taxonomic assignments is phylogenetic analysis (28, 33). Phylogenetic analysis utilizes a multiple-sequence alignment constructed from the nucleotide or amino acid sequence of a whole or partial genome or whole or partial protein sequence (with the exact parameters set for any particular taxon by the appropriate study group). This alignment is then used as the basis for phylogenetic reconstruction in which the evolutionary history of the virus isolates is inferred by applying one of a variety of possible phylogenetic prediction algorithms. The result is a phylogenetic tree showing branching patterns that reflect the evolutionary history of the individual isolates, with branch lengths that are proportional to the number of evolutionary changes that have occurred between each node (both internal and terminal) of the tree. Figure 1B displays a phylogenetic tree showing branching patterns that reflect the evolutionary history of the individual isolates, with branch lengths that are proportional to the number of evolutionary changes that have occurred between each node (both internal and terminal) of the tree. Figure 1B displays a tree that shows the branching topology and distances for subfamilies and genera of the family Poxviridae. At this level, it is not possible to discern the species topology for any of the genera, but species-level arrangements can be visualized if, for example, individual species for the genus Orthopoxvirus are compared separately (Fig. 1C) (30). The phylogenetic position of a newly described virus can be compared to that of any existing isolate on these trees to determine taxonomic assignment in a manner similar to PASC. Close inspection of Fig. 1C also reveals that the differentiation between species (e.g., Monkeypox virus and Ectromelia virus) is clearly distinguishable from the differentiation between isolates of the same species (e.g., the Congo and West African monkeypox virus clades).

TAXONOMY OF HUMAN PATHOGENS

As categorized according to the 2013 ICTV taxonomy (16), viruses that infect humans fall into four orders: the Herpesvirales, Mononegavirales, Nidovirales, and Picornavirales. (The other existing orders, the Caudovirales, Ligmenvirales, and Tymovirales, contain only bacteriophages, archaea viruses, and plant viruses, respectively.) Human pathogens are further subdivided into 25 families (not all of which belong to an order), 13 subfamilies, and 65 genera (with each genus usually comprising multiple species). Table 3 provides an overview of the taxa that contain human pathogens along with representative species for each genus. Table 4 provides a few of the structural features that define each viral family. Finally, Fig. 2 displays stylized representations of virion morphology for each family.

TAXONOMY DATABASES

The ICTV

The ICTV produces an extensive amount of information during the process of classifying and naming viruses that is published regularly in the ICTV reports. The ICTV website provides a database of the most recent officially approved viral taxonomy since publication of the last reports (which occurs, on average, every 4 to 5 years). Additional features of the website include a searchable hierarchical list of the current taxonomy; a downloadable spreadsheet, the “Master Species List,” that contains a listing of all taxa; access to past and present taxonomy proposals submitted for review to the ICTV Executive Committee; and a forum for discussion of ICTV-related issues. The ICTV also publicizes news and information regarding its efforts in the Virology Division News section of Archives of Virology (34). In addition, following approval of any updates to the taxonomy by the voting membership of the ICTV, an article that reviews all of the changes and additions is published in the Archives of Virology (16).

The NCBI

The National Center for Biotechnology Information (NCBI) provides access to a wide variety of databases containing various types of biological information (35). This includes GenBank, the primary repository of sequence data, including viral sequences (36). NCBI also provides RefSeq, a database of reference sequences derived from GenBank records (37). RefSeq contains one representative genomic sequence for each viral species. Viral RefSeq records have been extensively annotated by NCBI curators, and in many cases, they are also reviewed by investigators with expertise on individual viral species. Each viral sequence is linked to the NCBI taxonomic database using a taxonomy identification that is assigned to each taxon at every rank of the viral taxonomic hierarchy. The ICTV and NCBI taxonomies should be completely congruent; however, this has not always been the case. The ICTV and NCBI have therefore worked extensively in the past few years to update the NCBI viral taxonomy so that it reflects the official ICTV taxonomy, and this effort is mostly complete. Unfortunately, NCBI taxonomy is not automatically updated when new ICTV taxonomy is approved. A lag period of several months, therefore, exists before any officially approved ICTV taxonomy is fully represented in the NCBI taxonomy that is linked to GenBank and RefSeq sequence records.

FUTURE CHALLENGES

A number of challenges will affect viral taxonomic assignment now and in the future. These challenges include discovery of novel, previously unknown viruses (38, 39); consideration of the full complement of genetic mechanisms and machinery that viruses use to evolve, including recombination and horizontal gene transfer (40–43); management of vast increases in the amount of available information, such as data derived from metagenomic sequencing projects (44–46); determination of new data types (characters) for describing viruses; availability of only a limited set of characters for classification (such as solely sequence information) (47, 48); and creation of additional higher-level taxonomic ranks based on an increase in our knowledge of viral evolution (27, 28). Luckily, new analytical methods, new approaches to classification, and the dedication of virologists worldwide will allow us to handle these challenges and deal with future challenges as they arise.

Specimen Collection, Transport, and Processing: Virology*

JAMES J. DUNN

Given that laboratory data significantly influence medical diagnoses, it is critical that all phases of testing (pre-, intra-, and postanalytical) be approached systematically to ensure the accuracy of results and to detect and correct potential errors. The preanalytical phase is often the most vulnerable part of the testing process and accounts for the majority of errors in laboratory diagnostics (1). Preanalytical steps for viral diagnostics involving specimen selection, collection, transport, and processing are described in this chapter, as well as details for collection of specific sample types. While these recommendations are general guidelines, laboratories must also follow manufacturers’ instructions for testing of samples with commercially available kits and reagents.

Preanalytical variables should be controlled to maintain specimen integrity. Therefore, it is important for the laboratory to make available to all specimen-collecting areas within the institution, or other locations submitting samples, a comprehensive manual of tests available, indications for appropriate use, and methods of specimen collection. The manual should detail the appropriate (i) specimen types for specific clinical syndromes (Table 1); (ii) collection devices/containers and transport media, when indicated; (iii) collection techniques; (iv) volume of specimen required; (v) specimen labeling procedures; (vi) transport times and storage conditions; and (vii) clinical data, if available (2).

SPECIMEN COLLECTION

Viruses infecting humans cause a wide range of diseases. Signs and symptoms of infection largely influence which specimens are collected for virus testing. Additional factors to be considered are epidemiologic factors (e.g., travel, exposures, and season) and the patient’s immune status. It is important to recognize that viruses differ in their pathogenic mechanisms, their ability to disseminate from the primary site of infection, and which organ systems they infect. Generally, specimen selection is guided by the test best suited to establish a particular diagnosis (synopsized in chapter 81). The diagnosis of certain illnesses requires a basic understanding of viral pathogenesis, organ involvement, and viral epidemiology to determine the appropriate specimen(s) and tests. Specimen selection based on suspicion of a particular virus may be complicated by the fact that similar clinical syndromes can be caused by many different viruses (Table 1). By collecting only specimens needed to detect a specific virus, other important etiologies may be missed.

Depending on the anatomic site and means of collection, specimens are either nonsterile (i.e., contaminated with bacteria and/or fungi) or sterile. This determines the extent of specimen processing that occurs prior to viral culture, since bacteria and fungi grow rapidly in nutrient-rich cell culture systems. Non-culture-based test methods are less affected by this distinction. Sterile specimens are obtained from sites that are free of microorganisms in the absence of infection (e.g., blood, cerebrospinal fluid [CSF], and tissue) and avoid contact with nonsterile sites during the collection process. Identification of a virus in these sites is associated with a high likelihood of causality for disease. Nonsterile specimens are obtained from sites that contain normal biota (e.g., upper respiratory tract, skin, lower genital tract, and stool) or from sterile sites for which contact with nonsterile sites is unavoidable during specimen collection (e.g., sputum and voided urine).

SPECIMEN COLLECTION

Since no single diagnostic approach may be optimal for detecting every possible virus in a clinical situation, it may be necessary to utilize a combination of test methods to collect a number of different sample types and/or longitudinal samples for testing to yield the most medically useful information (2). Specimens should be collected as soon as possible after the onset of symptoms. For many viral infections in otherwise healthy and immunocompetent individuals, the likelihood of obtaining positive results is generally greatest within the first 3 days after onset of symptoms and diminishes rapidly as the course of infection proceeds (3). In cases of disseminated disease or in immunocompromised patients, viruses may be identified in clinical samples for prolonged periods (4). Generally, the level and duration of virus shedding depend on the virus, infected organ or organ system, and host factors such as age and immune status (5–7). Specimens with high concentrations of viral particles, viral antigens (Ags), or viral nucleic acids (NAs) improve the laboratory’s ability to make an accurate diagnosis. Specimen collection techniques can greatly affect specimen quality and, therefore, test results. Collecting an adequate specimen is straightforward when fluids (e.g., CSF, blood, or urine) are sampled, as standard collection procedures are used and are not subject to great variability. However,

*This chapter contains information presented by Michael S. Forman and Alexandra Valsamakis in chapter 76 of the 10th edition of this Manual.

*Refer to specific chapters for individual viruses; only common viral pathogens are listed. HAV, hepatitis A virus; HDV, hepatitis D virus; HEV, hepatitis E virus; HHV, human herpesvirus; HTLV-1, human T-cell lymphotropic virus 1; LCMV, lymphocytic choriomeningitis virus.

*bCommon specimens for viral diagnostics; refer to specific chapters for individual viruses. "Respiratory" includes throat and nasal swabs, nasal wash, nasopharyngeal aspirate, tracheal, and BAL specimens. "Eye" includes conjunctiva, cornea, and aqueous and vitreous fluids.

*cCommon detection methods used: EM, electron microscopy; IA, immunoassay such as immunofluorescence-antibody assay, enzyme-linked immunosorbent assay, or immunochromatographic test; NA, nucleic acid detection.

*dHemorrhagic fever viruses and smallpox virus processing in BSL4 facilities.

*eFIML, progressive multifocal leukoencephalopathy.

For serologic diagnosis, the timing of serum collection and type of antibody detected vary for specific viruses. An acute-phase serum specimen should be obtained early in the course of illness for virus-specific IgM testing. Convalescent-phase serum for IgG testing should be obtained 2 to 4 weeks after the acute-phase specimen or symptom resolution, and both acute- and convalescent-phase specimens should be tested concurrently to identify any significant changes in antibody concentration. However, due to the delay in collecting a convalescent-phase specimen, the final result will generally not affect patient treatment. For some viruses (e.g., severe acute respiratory syndrome coronavirus), timing of the collection of the convalescent-phase specimen may extend beyond 4 weeks after the onset of symptoms to reliably rule out infection (8). Additionally, in disease due to reactivation of latent or persistent viruses, there may or may not be a detectable rise in IgM and/or IgG levels. Generally, IgM is more sensitive to freezing and thawing than is IgG, so repetitive freeze-thaw cycles should be avoided.

For serologic diagnosis of HIV, since the newer generation of immunoassays can detect acute infection prior to collection of swab specimens is prone to variability, which can affect the amount of live virus, viral NA, or viral Ag present on the swab.
the detection of HIV-1/2-specific antibodies, a repeatedly reactive result should be confirmed by an HIV-1/HIV-2 antibody differentiation assay (e.g., Multispot HIV-1/HIV-2 Rapid Test; Bio-Rad Laboratories, Redmond, WA) and/or HIV-1 RNA assay (e.g., Apta HIV-1 RNA Qualitative Assay; Gen-Probe, San Diego, CA) (9, 10). Hepatitis C virus (HCV) antibody testing cannot distinguish between persons whose past HCV infection has resolved and those who are currently HCV infected. Therefore, persons with reactive results after HCV antibody testing should be evaluated for the presence of HCV RNA in their blood (11). To distinguish between true positivity and biologic false positivity for HCV antibody, a second assay that is different from the first may be performed. Biologic false positivity is unlikely to be exhibited by more than one test when multiple assays are used on a single specimen (12).

Health care workers who collect specimens from patients should wear personal protective equipment as appropriate for standard, contact, airborne, or droplet precautions (13, 14). The laboratory should always be notified in advance if rare agents representing a danger to laboratory workers (e.g., hemorrhagic fever viruses or novel influenza viruses) are suspected. Samples in which such viruses are suspected should not be manipulated in laboratories lacking the ability to undertake such handling under the appropriate biosafety level (BSL) conditions. Some specimens can be handled under enhanced BSL2 conditions, or BSL3 practices for certain viruses (e.g., severe acute respiratory syndrome coronavirus). Likewise, laboratories should provide instructions to those collecting and submitting specimens from individuals suspected of harboring a non-BSL2 pathogen. These should generally not be cultured in routine clinical laboratories, but rather referred to the Centers for Disease Control and Prevention (CDC; Atlanta, GA). Manipulation of these specimens and tissues, including sera obtained from convalescent patients, may pose a serious biohazard and should be minimized outside of a BSL4 laboratory. Use of vacuum tube collection systems is considered safer than use of syringes and needles, which must be disassembled before their contents are transferred to another tube. Procedures that generate aerosols should be minimized.NA extraction procedures, conducted in a biosafety cabinet, have the advantage of inactivating viruses prior to analysis.

**TRANSPORT MEDIUM**

Depending on the specimen source and type of testing requested, it may be appropriate to place the sample in viral transport medium (VTM). Liquid specimens such as amniotic fluid, blood, CSF, urine, and bronchoalveolar lavage (BAL) fluid do not generally require VTM (15). Specimens that are susceptible to drying (e.g., swabs and tissue) must be kept moist in VTM or other buffered solutions designed to maintain the titer of infectious virions for culture and the stability of viral Ags for direct Ag tests or viral NAs for NA tests (NATs). However, molecular testing can be an exception, as certain NAs have been found to be quite stable in a desiccated state. Dried samples for NATs have the advantages of (i) relatively long storage capability at room temperature; (ii) reduced biohazard risk to laboratory personnel, with no spill risk and reduced infectivity; and (iii) simple and inexpensive ambient temperature shipping of specimens where maintenance of a cold chain is limited. However, the versatility of a liquid specimen offers obvious advantages (i.e., it can be split and tested by multiple methods). When a complete microbiologic workup is requested on a specimen, including viral, bacterial, mycobacterial, and fungal testing, VTM should not be added to the specimen. Rather, samples should be collected independently or aliquoted into the appropriate transport media.

The most useful types of transport systems should allow for simultaneous detection of viruses by any number of methodologies, including culture, Ag detection, and NA testing. Although some common viral agents can withstand extended storage in suitable transport media at room temperature, it is generally the case that virus viability decreases over time, and at higher temperatures, this rate of decay is often accelerated. To stabilize the rate of decay, viral transport systems are usually kept on ice until they can be processed for testing. The optimal transport medium should further stabilize virus viability with minimal loss of virus titer as well as contain components to control potential microbial contamination, have a long shelf life, and be readily available at a reasonable cost (15, 16). Formulations of VTM typically consist of a buffered salt solution such as Hanks’ balanced salt solution buffered with HEPES to maintain a neutral pH, protein-stabilizing agents such as bovine serum albumin or gelatin, and antimicrobials to prevent bacterial and/or fungal overgrowth. Some laboratories have reported that media designed for collection and transport of bacteriology specimens are also acceptable for collection and transport of viral specimens. In infants with pneumonia, the sensitivity of NA testing for adenovirus, influenza viruses, and respiratory syncytial virus (RSV) in nasopharyngeal (NP) swabs stored and frozen in skim milk tryptone-glucose-glycerol media ranged from 65.2 to 100% compared to results with NP aspirates in VTM (17). Under experimental conditions, bacteriologic swab transport systems allowed for NA detection of influenza A, echovirus 30, herpes simplex virus 2 (HSV-2), and adenovirus up to 5 days after storage at 4°C or room temperature, albeit with lower sensitivity than swabs in VTM (18).

VTM can be prepared in the laboratory or purchased (Table 2). An advantage of commercially prepared media is that the burden of quality control is shifted from the laboratory to the manufacturer (19). Some transport media also sustain the viability of chlamydiae, mycoplasmas, and ureaplasmas. The inclusion of sucrose in the media serves as a cryoprotectant to maintain the integrity of viruses if specimens are frozen (-70°C or lower) for prolonged periods. Laboratories should validate the suitability of their selected media for their particular applications, as performances can vary (19, 20).

A sample collection and transport device that contains an absorbent matrix for drying of specimens, ViveST (ViveBio, Norcross, GA), has been used primarily for preservation of NA at ambient temperature, although some viruses remain viable for up to 7 days with the addition of fetal bovine serum (21, 22). Influenza RNA was detectable in clinical specimens after 3 weeks of room temperature storage in ViveST devices with minimal loss in RNA recovery compared with frozen samples (23). CyMol (Copan Italia, Brescia, Italy), an alcohol-based transport medium for collection and preservation of cells for cytologic and NA testing, compared favorably with VTM for maintenance of influenza A viral RNA for up to 14 days at 4°C or colder (24). However, direct fluorescent-antibody (DFA) testing from swabs in VTM was more sensitive than those in CyMol.

Manufacturers of commercial assays for NA testing or Ag detection either supply transport media or make recommendations for transport systems that are compatible with their test methods. The manufacturer’s package insert should therefore be consulted for information on appropriate
collection and transport systems. Most VTM products are compatible with NA and Ag detection tests (15, 25).

**TRANSPORT CONDITIONS**

Once a clinical specimen has been collected, it should be transported to the laboratory as soon as possible, since virus viability decreases with time (i.e., some clinically important viruses are more labile than others). The optimal time and temperature for transport, processing, and storage (discussed below) of specimens should be adhered to in order to generate accurate and meaningful results. Typically, specimens for viral culture should be transported to the laboratory promptly, ideally within 2 to 4 h of collection, since overall diagnostic yield improves when specimens are expeditiously processed for viral culture. The preferred transport temperature is 2 to 8°C, except for blood specimens, which can be transported at ambient temperature. Enzymes present in specimens and capable of inactivating viruses or degrading proteins and NAs are less active at refrigeration temperatures. For longer transport times or submission to reference laboratories, specimens should be stored and shipped under conditions that would preserve the integrity of the sample, preferably ≤70°C or lower. Viability is not a requirement for Ag or NA detection methods; therefore, transport time may be less significant, unless degradation of intact cells or viral NA is a consideration. However, for timely diagnosis, delay should be avoided during transport of these specimens to the laboratory.

**SPECIMEN STORAGE AND PROCESSING**

Accredited laboratories are required to specify rejection criteria for specimens that are collected, transported, or stored under improper conditions. Specimens that are unacceptable for testing include those that are (i) unlabeled or improperly labeled, (ii) received in improper or leaking containers, (iii) not appropriate for a particular test, (iv) transported under improper conditions, or (v) received beyond the acceptable transport time limit. At a minimum, the specimen container should be labeled with the patient’s full name, medical record number or unique identifier, date and time of collection, specific source, and the name of the collector. Each specimen should be accompanied by a requisition containing the same information as on the specimen container as well as the patient’s location, test(s) requested, source of specimen, requesting clinician with contact information, and suspected clinical diagnosis (26). Specimens that are deemed unacceptable but cannot be re-collected (e.g., tissue collected during surgery) may be processed and tested according to the laboratory’s clearly defined procedure allowing such exceptions.

Specimens submitted for virus isolation can be held at refrigeration temperature (2 to 8°C) for up to 2 days prior to

---

*Basal constituents: Hanks’ balanced salt solution, bovine serum albumin, l-glutamic acid, HEPES buffer (pH 7.3), phenol red, and amphotericin B.
inoculation onto cell culture. Many viruses lose infectivity at ambient or even refrigeration temperature. For example, 90% of RSV infectivity is lost after 4 days at 4°C and 24 h at 37°C (27). Freezing of specimens (−70°C or lower) is not recommended for virus isolation unless specimen processing will not occur within 2 days. The temperature in standard freezers (−20°C) is not low enough to maintain virus infectivity. Certain viruses may also lose infectivity with repeated freeze-thaw cycles, particularly enveloped viruses. Detailed specimen processing protocols for viral culture have been described (28, 29). Specimens should be processed using all appropriate biosafety guidelines (30), and a biosafety cabinet should be used when manipulating specimens suspected to contain virus(es) considered to be contagious by airborne routes.

Molecular assays are particularly sensitive to substandard preanalytical conditions. For RNA targets such as HIV or HCV, the Clinical and Laboratory Standards Institute recommends that EDTA whole-blood samples be centrifuged and the plasma removed to a secondary tube within 4 h of phlebotomy, a conservative time frame that may vary depending on the assay manufacturer’s requirements (31). However, studies have shown that for HIV-1 viral load testing, whole blood with EDTA and cell-free EDTA plasma can be stored at room temperature for up to 30 h, at 4°C for up to 14 days, and at −70°C for extended periods of time without significant decreases in viral load signal (32, 33), and HCV RNA is stable in EDTA whole blood for at least 24 h at room temperature (34). HIV proviral DNA can be detected in acid citrate dextrose (ACD)- or EDTA-treated whole blood for up to 10 days at both 4°C and ambient temperature (35). The preanalytical steps for selected Food and Drug Administration (FDA)-cleared/approved NATs are listed in Table 3.

Using RNAlater (Qiagen, Gaithersburg, MD), an RNA stabilization buffer, HCV and HIV viral loads were stable for up to 28 days at 37°C and HCV viral loads were essentially equivalent after 5 days when transported either frozen or in RNAlater at ambient temperature (36). Under experimental conditions, nonenveloped and enveloped viruses, including HIV-1, retained infectivity after more than 72 h of storage at room temperature in RNAlater (37). Arboviral RNA was stable for at least 35 days when virus-containing samples were stored at 4 or −20°C in AVL buffer (Qiagen), a lysis buffer for NA purification that contains guanidine isothiocyanate and RNase inhibitors (38). AVL buffer has the added property of inactivating viral infectivity. Enterovirus RNA was shown to be stable in CSF specimens stored at 4 and −80°C for up to 2 weeks, but the half-life when stored at room temperature was calculated to be 9 days. In NP wash specimens, there was a >65% reduction in influenza A RNA concentration when samples were maintained at room temperature, 4°C, or −80°C for 2 weeks (39). If no specific RNase inhibitors are used, long-term storage of diagnostic RNA samples should be done preferably at −70°C or lower to inhibit RNase activity, as RNase may limit the stability of RNA even in frozen samples at −20°C (40).

For DNA targets such as cytomegalovirus (CMV), the data on DNA quantification after storage are conflicting, with some studies reporting no decline in CMV DNA levels after 24 h (41), 72 h (42), and 2 weeks (43), while another

*Thaw specimens at 15−30 or 2−8°C; once thawed, specimen may be stored at 2−8°C for ≤6 h.*
showed increased levels in blood stored at room temperature or at 4 °C prior to plasma separation (44). The increased levels of CMV DNA in plasma separated beyond 2 h after collection may be falsely positive in latently infected patients due to the lysis of leukocytes and release of CMV into plasma during storage. In another study, CMV DNA in EDTA blood was stable for 2 weeks when stored at room temperature, 4 °C, and −80 °C, whereas CMV DNA in serum had a half-life of <1, 2, and 3 days when stored at room temperature, 4°C, and −80°C, respectively (39). At both 5 and 25°C storage conditions, there was a statistically significant decline in hepatitis B virus (HBV) DNA concentration in plasma for up to 28 days (33). For HSV, the quantity in oral and genital specimens stored in VTM for 16 months at −20°C was within 1 log of the original concentration for >90% of specimens (45). In CSF specimens, HSV DNA was detectable by PCR for up to 30 days after 4 months of storage at −70°C (46).

Human papillomavirus (HPV) DNA stored in two commercial, liquid-based cytology media at 2 to 8°C was stable for >2 years. However, the reproducibility of results after storage may be affected by the methods of NA extraction and detection (47). Generally, DNA in tissue is stable for up to 24 h at 4°C, for at least 2 weeks at −20°C, and for at least 2 years at −70°C or lower (31).

No exhaustive studies exist that evaluate the stability of NAs in stool specimens, although rotavirus RNA has been shown to be stable for up to 2.5 months at ambient temperature (48). Adenovirus DNA in fresh stool collected on SDS-EDTA-treated chromatography paper strips was detected after 4 months of storage at −20 to 37°C (49), and under experimental conditions, strips containing various concentrations of norovirus were stable for reverse transcription-PCR detection for up to 2 months at temperatures ranging from −80 to 37°C (50).

COLLECTION METHODS AND PROCESSING OF SELECTED SPECIMENS

For commercially available, FDA-cleared/approved assays, laboratories must follow manufacturers’ instructions for collection and processing of specimens. Assay performance must be verified by the individual laboratory prior to implementing any change in the preanalytical steps described in the manufacturer’s package insert (51, 52). For laboratory-developed tests, each test site must establish and validate appropriate processing and storage conditions, the extent of which may rely on studies performed by the laboratory or those in published sources.

Amniotic Fluid

Although rare, viral infections during pregnancy may be detrimental to the fetus or newborn. Testing amniotic fluid for viral pathogens is generally based on maternal history or ultrasound-guided indications. Fluid is collected by amniocentesis, and 2 to 5 ml should be submitted to the laboratory in a sterile container. NA detection methods are the most commonly used. NAs from samples should be extracted as soon as possible and stored at 2 to 8°C for up to 48 h or frozen at −70°C or lower if testing is delayed beyond 48 h (31). Virus can be isolated in culture, but sensitivity is generally lower than with NAT.

For the most accurate prenatal diagnosis of congenital CMV infection, amniotic fluid should be collected at between 21 and 23 weeks of fetal gestation (53, 54). If maternal varicella-zoster virus (VZV) infection occurs during the first or second trimester, VZV DNA may be detected in amniotic fluid, but its presence is not necessarily indicative of the development of congenital varicella syndrome. The presence of parvovirus B19 DNA in amniotic fluid should be correlated with other clinical and prenatal diagnostics since up to 25% of asymptomatic fetuses may have detectable virus (54).

Blood

Serum, plasma, purified peripheral blood leukocytes, and whole blood have all been used to detect and quantify viral pathogens. The most suitable blood compartment for testing depends on the virus targeted. Quantitative molecular methods performed on blood samples are useful in assessing patient prognosis, treatment response, and antiviral resistance. For viral load monitoring over time, it is particularly important that the sample matrix is not varied. Which blood compartment to test depends on the underlying condition of the patient and whether the viral target dictates that a cellular or cell-free portion be utilized (55–58).

Approximately 3 to 5 ml of blood should be collected in the appropriate anticoagulant vacuum tube. For pediatric specimens, smaller volumes are acceptable, but <1 or 2 ml may be inadequate for testing. The most commonly used anticoagulants are EDTA, heparin, and ACD. Anticoagulated blood may be fractionated to allow recovery of leukocytes (see below). EDTA and ACD are the preferred anticoagulants for obtaining plasma for NA testing, as heparin is inhibitory to many NA amplification chemistries (31). In addition, frozen EDTA plasma specimens have improved NA stability compared with heparin (32).

Whole blood used for NA amplification must be processed to remove inhibitors of DNA and RNA polymerases such as heme and metabolic precursors of heme. Many different extraction protocols are used in both commercial and laboratory-developed amplification tests to remove inhibitors and purify NAs (31). Plasma is obtained by centrifuging blood collected in tubes containing spray-dried anticoagulant (EDTA) at 1,500 × g for 20 min at 25°C. Plasma Preparation Tubes (PPTs; BD, Franklin Lakes, NJ) have spray-dried EDTA and a gel barrier that results in physical separation of plasma and cellular constituents, eliminating the need for decanting plasma. The use of PPTs for HIV-1 RNA quantitation have shown falsely elevated viral loads from centrifuged tubes that were stored frozen or for prolonged periods at 2 to 8°C (59–61), likely due to the presence of cells containing proviral DNA (62, 63). This limitation can be overcome by an additional centrifugation step prior to testing or use of an extraction method that recovers only RNA (64, 65). No decline in HCV RNA levels was observed in blood stored in PPT at 4°C for 72 h (66).

When serum is required for serologic or molecular testing, 4 to 8 ml of blood is collected in a serum separator tube (e.g., SST [BD Diagnostics], Corvac [Coviden, Dublin, Ireland], or Vacuette [Greiner Bio-One, Monroe, NC]) or a tube without anticoagulant. After allowing blood to coagulate for 30 min, tubes are centrifuged at 1,000 to 1,300 × g for 10 min. The serum fraction, removed to a sterile tube, can be stored at 2 to 8°C for up to 48 h or frozen at −20°C or lower for longer periods. Whole blood drawn for antibody determination should not be frozen.

For virus isolation, 5 to 10 ml of anticoagulated blood (EDTA or heparin) should be collected by venipuncture and transported to the laboratory at room temperature. Processing of the specimen for leukocyte fractionation should occur within 8 h. Whole blood should not be used to inoculate cell cultures because of toxicity caused by red blood cells. Theuffy coat fraction may also contain erythrocytes.
To adequately remove red blood cells and recover both polymorphonuclear and mononuclear cells for inoculation, density gradient methods should be used, a number of which are commercially available (28). Isolated leukocytes can be co-cultured with human diploid fibroblasts such as MRC-5 cells (tube or shell vial culture) or HS&V-Mix FreshCells (Diagnostic Hybrids, Athens, OH) (shell vial culture) (67), directly stained with fluorescence-labeled monoclonal antibodies (e.g., CMV pp65 antigenemia assay) (68), or extracted to detect viral genomes by molecular techniques. Quantifying leukocyte input is essential for optimizing assay performance (69, 70). For recovery of CMV in culture, the shell vial technique is more rapid and sensitive than conventional tube culture (71).

Bone Marrow

Bone marrow can be used to identify viral etiologies of hematologic disorders, including hemophagocytic lymphohistiocytosis, aplastic anemia, and chronic pure red cell aplasia (72, 73) (Table 1). At least 2 ml of bone marrow aspirate should be collected in the appropriate anticoagulant tube. The recommended anticoagulants for NA detection tests include EDTA and ACD (31). Although the diagnostic yield may be low, bone marrow aspirations for culture should be collected in a syringe or vacuum tube with heparin or EDTA and processed to fractionate the leukocytes as soon as possible after collection (74, 75). Bone marrow specimens should be stored at 2 to 8°C prior to NA extraction. Freezing and thawing of bone marrow lyses red cells, causing release of heme, a known inhibitor of PCR (76).

Cerebrospinal Fluid

CSF is an important specimen for diagnosis of viral central nervous system infections (Table 1). CSF is collected using sterile technique, by inserting a spinal needle into the L4-L5 interspace, located in the midline between the left and right iliac crest. Preferably, 2 to 5 ml should be collected in a sterile, leak-proof container. VTM is not added to sterile body fluids such as CSF, because they do not require antimicrobial treatment and dilution in transport media may cause false-negative results. Transport and store for up to 48 h at 2 to 8°C, and freeze at −70°C or lower for longer-term storage. NAs should typically be extracted prior to testing since CSF contains globulins, cell-derived proteins, and other uncharacterized substances that inhibit the activity of thermostable polymerases used in PCR (77, 78). However, some studies have demonstrated the suitability of simple methods such as exposure to high temperature or repetitive freeze-thawing to release NAs (79, 80). For virus isolation, specimens with visible blood may affect recovery of viruses since antibodies may be present in sufficient concentration to inhibit viral growth. No treatment of CSF is needed before inoculation of cell cultures.

Dried Blood Spots
